The increased incidence of *K. kingae* infection may be due to better methods of isolation. It has been demonstrated that inoculation of the material into a BACTEC culture bottle (Johnston Laboratories, Towson, MD) can dramatically increase the rate of recovery of *K. kingae* (100).

Like *H. influenzae*, *K. kingae* infections most often occur in children younger than 4 years of age. Most children are healthy before the onset of the infection. The organism affects joints most frequently. The clinical course and laboratory findings do not differ significantly from septic arthritis caused by other organisms. The bone infections are often insidious and frequently occur in the epiphysis.

K. kingae is sensitive to penicillin and many of the semisynthetic penicillins and cephalosporins that are used to treat bone and joint infections (101,102). It is possible that in the past many of the culture-negative cases of musculoskeletal sepsis resolved with these commonly used antibiotics, without *K. kingae* being identified. A second organism seen in septic arthritis in this age group is *Streptococcus pneumoniae*. Currently 30 to 50% of these organisms are relatively resistant to the semisynthetic penicillins and cephalosporins (103).

Today, ceftriaxone (Rocephin) is an excellent drug for initial treatment of bone and joint sepsis in children under the age of 4 years of age. The fact that it is effective against most of the common organisms seen in this age group; the fact that it can be administered once a day, significantly reducing costs; and the very high minimal inhibitory concentrations that are reached in the blood, all favor this antibiotic.

It is important to remember that despite the variety of organisms responsible for bone and joint sepsis in the younger child, *S. aureus* is still the most common causative organism in AHO after infancy, and particularly over the age of 5 years. The reported incidence ranges between 25 and 64%, depending largely on the age mix of the patients in the study (20,46,47,51). However, streptococcal organisms, including group A *Streptococcus* and *S. pneumoniae*, are also found in the child older than 5 years of age, with the reported incidence ranging from 4 to 21%. Infections with streptococcal organisms tend to occur in the younger age range (20,49,51,165), whereas *Staphylococcus aureus* becomes more common with increasing age. In this older age range in which *Staphylococcus* predominates, a semisynthetic penicillin, e.g., oxacillin or a cephalosporin, e.g., cefazolin (Ancef, Kefzol) or cefuroxime (Zinacef), are good initial choices.

Preferably, children between birth and 2 to 3 years of age are managed along with a pediatrician or pediatric specialist. One of the important reasons, other than the management of the antibiotics, is that these children more frequently have other sites of involvement, e.g., meningitis. They require a good clinical examination for meningitis and other problems which may not be commensurate with the best skills of the orthopaedist.

It needs to be understood that these are initial choices which are made before culture results are available. Once the organism is identified, the antibiotic choice is changed to one that is effective but narrower in its range of activity. The antibiotics most commonly used to treat bone and joint infections in children are listed in Table 13-3.

The selection of an oral antibiotic should be based on Gram stain and culture results. For the child younger than the age of 5 years, cefuroxime axetil (Ceftin) and cefprozil (Cefzil) are good choices. For the older child, cephalexin suspension or dicloxacillin capsules are a good choice (see Table 13-3).

Antibiotic Delivery

Giving an antibiotic to a patient who has an infection is not sufficient. The physician must ensure that the antibiotic both reaches all of the organisms and effectively kills them. This involves several issues. Does it matter whether the antibiotic is given intravenously or orally? How long should the antibiotic be given, and why? Where can the antibiotic be expected to penetrate? Can it kill the organism when it gets there? In this era of cost containment, and with the worthwhile goal of keeping children out of the hospital, the real questions are, how long does the patient have to remain in the hospital, and when can intravenous administration of antibiotic be switched to oral administration?

Route of Administration

Initial antibiotic therapy for bone or joint infections should always begin with intravenous administration. The question of how soon the intravenous route can be switched to the oral, in any particular case, is a question for which no data are available. Intravenous administration is more expensive than oral administration, however, and certainly less convenient for the patient (104). An advantage to intravenous administration is that high concentrations of antibiotic can be achieved quickly with certainty. These levels exceed those usually necessary, whereas the levels achieved with oral administration are usually adequate. The difficulty with oral administration is in ensuring that absorption from the gut is adequate, and that the patient is compliant. Despite these potential pitfalls, the efficacy of oral antibiotics in the treatment of bone and joint sepsis has been well documented (104,105,106 and 107), and represents an acceptable method of treatment following an initial course of intravenous antibiotics.

An additional troublesome problem with prolonged intravenous administration in small children, is maintaining vascular access. This usually requires that these children have a peripheral indwelling catheter (PIC line) placed. While lessening the problems, these lines are not without problems, e.g., clotting and becoming infected, as well as requiring a certain level of skill on the part of the home health agency that is managing the line. Thus, they are not a reason to give intravenous antibiotic longer than necessary.

The successful administration of oral therapy requires the same conditions as for intravenous therapy, i.e., that the antibiotic reach the organisms in sufficient concentration and be in the bone for a sufficient length of time to kill the organisms. Patients may generally be switched to oral antibiotics therapy when the course of the disease is resolving, abscess formation is not present or has been debrided, or the antibiotic is well-tolerated orally by the patient, and the parents are reliable.

In one series about 10% of the patients failed to achieve adequate serum concentrations of the antibiotic after oral administration (107). Reports such as this led to the recommendation that the peak serum level be measured to verify that adequate antibiotic was present. There is some evidence that it may actually be the trough level that is more significant (109,110). In practices in which measurement of bactericidal concentration of antibiotic has been measured as a routine in the past, it is

now used more often only for more difficult situations. This has evolved because, with adequate oral doses, it is very unusual to find insufficient levels of antibiotic or treatment failures that can be attributed to insufficient levels of antibiotic. Experience has taught that, to achieve adequate serum levels of antibiotic, larger oral doses (usually two times larger) are needed than those commonly recommended (Table 13-3).

Although it is decreasing as a routine practice, at times it will be necessary or advisable to measure the concentration of the antibiotic. Because the direct measurement in the blood of the level of commonly used antibiotics (e.g., semisynthetic penicillins, cephalosporins) is not feasible, it is measured indirectly by the serum bactericidal test. This test uses serial dilutions of patient serum to test against the bacteria, which is isolated to determine the minimal dilution that is bactericidal for the organism (111,112).

Blood is drawn after the administration of the oral antibiotic to determine the peak level. For antibiotic given in suspension, the blood is drawn 1 h after administration; for antibiotic administered in capsule or tablet, blood is drawn approximately 1.5 to 2 h after administration. If the trough level is to be measured, blood is drawn just before the next dose. Dilutions of the serum are prepared and tested against the isolated organism. If an organism is not isolated, a representative laboratory strain of the presumed organism is used. Although it is controversial regarding how much the peak serum level should exceed the bactericidal concentration, a 1:8 dilution is generally accepted as being effective. When adequate levels are not present, the dose may be increased: probenecid (Benemid) to inhibit renal excretion may be added, or intravenous therapy may be reinstituted.

The serum level of other antibiotics (e.g., gentamicin, vancomycin) can and should be monitored in all cases. These antibiotics can be measured directly in the blood. Not only does the blood level of these intravenous antibiotics vary significantly between individuals, but their toxic side effects are significant. Both the peak and trough levels need to be measured and monitored. For gentamicin, blood is drawn approximately 30 min after administration, and just before the next dose. The peak level should be between 5 and 10 µg/mL, and the trough should be 1.9 µg/mL or less. For vancomycin, blood is drawn 1 h after administration, and just before the next dose. The peak level should be between 20 and 40 µg/mL and the trough between 5 and 10 µg/mL.

Generally, blood levels of gentamicin or vancomycin should be measured every 3 to 4 days, in addition to those of blood urea nitrogen (BUN) and creatinine. For prolonged (longer than 3 weeks) or recurrent therapy with these drugs, it is wise to monitor the patient for ototoxicity also. Vancomycin should be infused over no less than 1 h to avoid the release of histamine by the drug (red man syndrome) or serious hypotension. If a rash occurs, it usually can be circumvented by administering the drug over 90 to 120 min, or by the use of intravenous diphenhydramine (Benadryl) 1 mg/kg (total dose not to exceed 50 mg) just before the infusion.

Penetration

After an adequate serum level of the antibiotic is achieved, it must reach all of the areas harboring bacteria. In evaluating data on antibiotic penetration, it is necessary to consider the antibiotic in addition to the methods used to measure its concentration (113). Methicillin, dicloxacillin, cephaloridine, and cefazolin all penetrate into pus and bone in children with osteomyelitis in concentrations several times greater than the mean inhibitory and mean bactericidal concentrations for *S. aureus* (114). The same is true for orally administered ampicillin, cephalexin, cloxacillin, dicloxacillin, and penicillin G in the synovial fluid of children with septic arthritis (115). There is no evidence that antibiotics penetrate into dead bone.

Efficacy of Antibiotic

The treatment of musculoskeletal sepsis presents a paradox. If the antibiotics kill the bacteria, and there is a sufficient serum concentration in the absence of dead bone, why is not antibiotic administration more rapidly and universally successful? The answer lies in understanding that there are several factors that may interfere with the antibiotic action. One factor that is poorly studied is the effect the local environment has on the ability of the antibiotic to kill bacteria. It is known that the interaction of purulent material from some Gram-negative organisms can interfere with the action of certain antibiotics (116,117).

With a large inoculum and the production of large amounts of b-lactamase, b-lactam antibiotics, such as semisynthetic penicillins and cephalosporins, are susceptible to breakdown, rendering them ineffective (118,119 and 120). In addition, the low pH at the site of infection is known to interfere with the action of some antibiotics. These factors suggest that the local environment is important to the effective action of the antibiotic, and that the site of infection may not be the ideal environment.

Duration of Administration

There are no good data that indicate how long antibiotics should be administered in any particular case. The old recommendation of 6 weeks of intravenous administration is often based on difficult and complicated referral cases from large tertiary medical centers, which do not represent the “usual” case (121). Conversely, there is no evidence, other than clinical experience, that a shorter duration can be effective. More important than rigid rules is an understanding of the pathophysiology of each case, so that the treatment can be based on the particulars of that case. The correct answer is that the antibiotic should be continued until all of the organisms have been killed.

To illustrate, consider two different cases. A 5-year-old boy presents with a history of increasing pain in the distal thigh for 3 days, and inability to walk on the day of presentation. His radiographs are normal, except for deep soft tissue swelling. Aspiration demonstrates pus, and he undergoes surgical debridement the same day. He is started on the correct antibiotic. Over the next 5 days, the pain, swelling, and fever subside, the CRP is falling, and he begins to walk. He can be safely treated with 5 days (perhaps less) of intravenous antibiotics, followed by oral antibiotics for an additional 3 or 4 weeks.

Another 5-year-old boy is seen 2 weeks after the onset of pain in the distal thigh. His physician had placed him on oral antibiotics after 3 days, but the pain and limp continued to worsen. His radiographs show extensive involvement of the distal femoral metaphysis, with radiolucent areas and periosteal new bone. He undergoes surgical debridement, but it is not deemed possible to debride all of the bone that is involved. At the end of 7 days, his fever is decreasing, the CRP has not fallen, and although his signs and symptoms are improving, he still has some swelling and tenderness. This patient should remain on intravenous antibiotics.

These two cases illustrate the factors to consider when deciding the duration of antibiotic therapy. How long has the infection been present, and how much bone is involved? Is there abscess formation? Has the patient had adequate surgical debridement to remove the pus and other materials that interfere with effective antibiotic action? Has all of the dead bone been removed to expose organisms to antibiotic? Is the patient getting better? These clinical observations can be aided to a limited extent by radiographic and laboratory studies, remembering that radiographic changes lag behind the actual bone changes, and that the ESR and, to a lesser degree, the CRP also lag behind resolving infection during the first week (51).

Current practice is a sequential course of intravenous antibiotic, followed by an oral course. Clinical parameters determine when oral antibiotics begin. In the typical case which resolves quickly with treatment, oral therapy starts after 5 days of intravenous antibiotic administration; in the case of osteomyelitis, it continues for 4 to 6 weeks and, in septic arthritis, for an additional 2 to 3 weeks.

Surgery

Destruction of tissue is the final result of infection. Although bone has the ability to repair itself, articular and epiphyseal cartilage do not. Therefore, one of the main goals of treatment is to stop tissue destruction. Killing the bacteria is the first part of the treatment, but not the only part. Tissue destruction is mainly the result of the complex process known as the “inflammatory reaction.” Although this reaction is initiated by bacteria, the presence of live bacteria is not necessary for its continuation. It is well recognized that the products liberated by bacteria, cell wall fragments of dead bacteria, products liberated from leukocytes, and products of tissue destruction are all capable of causing an inflammatory reaction, which results in tissue destruction (37,40,122,123 and 124).

With an understanding of the mechanisms of tissue destruction and the delivery of antibiotic to the bacteria in an environment where it can be effective, the basis for surgery becomes more meaningful. Surgery is for debridement. It removes the inflammatory products more rapidly than the host defense mechanisms. In so doing, it provides a more effective environment in which antibiotics can work. It reduces the size of the inoculum, ensuring more effective antibiotic action of many commonly used antibiotics. Lastly, it removes all of the dead and avascular bone or the thick fibrinous exudate from joints, thus exposing all of the organisms to antibiotic. This provides a more rapid end to tissue destruction, and requires a shorter course of antibiotic therapy.

The indications for surgical debridement of AHO remain controversial and in flux. Difficulty in evaluating published reports and recommending various points of view arise because of failure to identify the important characteristics of those who were treated with surgery and those who were not. Among those factors that are important to evaluate are the duration and severity of infection, the type of organism, appropriateness of antibiotic use, the duration of intravenous antibiotic versus

oral, and length of hospitalization.

The author has used the aspiration of pus, or failure of signs and symptoms to resolve within 36 to 48 h, as an indication for surgical debridement. This practice is based on the same principles used to treat infection in other parts of the body. Especially important is the age-old wisdom of draining an abscess, regardless of location. With these criteria, many cases avoid surgery, few require prolonged intravenous therapy, and recurrence is distinctly unusual. This is a mainstream opinion that is evolving in clinical practice, and that is supported by others (125,126).

Surgical debridement of a focus of hematogenous osteomyelitis requires an incision only large enough to expose the area of bone involved. Incision of the periosteum in the involved area is performed first, to drain the subperiosteal abscess. Stripping of the periosteum to expose additional periosteal abscess should be done sparingly, to avoid devascularization of the bone.Next, using a drill an entry hole is made into the bone. This can be enlarged with a rongeur to allow access with a curet, but this hole should not be any larger than necessary to curet the involved bone. The diseased area is easily distinguished from more normal bone by “feel” with the curet and the appearance of the material removed.

Specimens should be sent for both culture and routine histology. The importance of routine histologic examination of material from the bone is twofold. Some tumors have a tendency to become necrotic and, when surgically explored, may look similar to pus; the most common is metastatic neuroblastoma, followed by Ewing sarcoma. In addition, if positive identification of the organism is not obtained, it is reassuring to have a histologic diagnosis of osteomyelitis.

The indications for arthrotomy in the treatment of septic arthritis are perhaps even more controversial (except for the hip), although more sharply divided between the orthopaedic and pediatric literature. Experimental evidence supports lavage of the joint, but individual experiences constitute the evidence that drives clinical decisions.

In experimental staphylococcal septic arthritis in rabbits that were treated with antibiotic, the beneficial effect of surgical lavage was demonstrated (45). During the first arthrotomy at 4 days, all of the material in the knee could be washed out; at 7 days, it had to be removed manually. All cultures were negative at 7 days. Both the surgically treated and nonsurgically treated animals showed loss of glycosaminoglycan. There was no collagen degradation in those treated by surgical lavage, however. A similar study has shown that arthrotomy and irrigation may be more effective than repeated aspirations, as the above data suggest (127).

In the author's experience, there is no question that some joint infections can be cured with antibiotics alone. This seems to be especially true in the smaller joints, such as the wrist, and in younger children. Attempts to treat joints such as the knee without drainage have never been as prompt to resolve as those treated with a small arthrotomy and irrigation, followed by a brief period of splinting.

Effective drainage of most joints can be performed through a small incision. The incision should be large enough to permit a small retractor to be inserted into the joint. On the knee of a small child, this can be accomplished with an incision of no more than 2.5 cm. After suctioning the purulent material from the joint, a swab of the synovium is obtained for culture. A small biopsy of the synovium may also be sent for culture. Irrigation is then performed with saline through a small rubber catheter directed into all of the recesses of the joint. A drain (or irrigation system, if preferred) is inserted into the joint, and the wound is closed (128,129).

Repeated aspiration has been recommended, but suffers from two drawbacks: it is ineffective in draining the joint (Fig. 13-11), and it becomes a difficult trial for both the patient and the physician because it must be repeated at least daily for several days. Arthroscopy has also been recommended (130,131). Morbidity following arthroscopy does not seem to be any different than for open arthrotomy in septic joints, whereas the operative time and resources are more costly for arthroscopy.

FIGURE 13-11. This patient with 3 days of symptoms was diagnosed as having septic arthritis after aspiration of the joint. Within 2 h of aspiration, the knee joint was opened through a small arthrotomy, with the patient under general anesthesia. Before and after irrigation, large amounts of thick fibrinous pus were removed with a forceps, illustrating the inadequacy of aspiration as a method to debride the joint.

RESULTS

Most children who are seen for AHO or septic arthritis can expect to recover without sequelae. These disorders are curable. Untoward consequences are usually due to advanced disease at the time of presentation, or problems in the initial management. Other than these two factors, the literature sheds little light on other reasons for failure, because the reports cover decades during which organisms, antibiotics, and principles of management changed (20,60,120,126,132,133 and 134).

Most complications from musculoskeletal sepsis occur in the hip for reasons documented elsewhere in this chapter. Other than the hip, joint destruction is expected only in the late-presenting and neglected case. Chronic osteomyelitis remains distinctly unusual, probably because of the rapid bone turnover in children. Epiphyseal destruction with growth arrest is occasionally seen, but usually in cases in which appropriate treatment is delayed.

SPECIAL CONDITIONS

Spine

For decades, physicians have recognized hematogenous infections of both the disc space and the vertebral body. Descriptions of the disorder as “a benign form of osteomyelitis of the spine” provide a clue to its natural history (135), whereas the various descriptions in the literature of vertebral osteomyelitis and discitis, over the past several decades, reflect the uncertainty that these are indeed two separate conditions (136,137). Modern imaging modalities, such as scintigraphy, CT scanning, and MRI have resolved the confusion by demonstrating evidence of bone involvement in children with the clinical presentation of discitis (138,139). It thus appears that both vertebral osteomyelitis and discitis are the result of a hematogenous infection beginning in the bone adjacent to the cartilaginous vertebral end plate.

The vascular anatomy of the vertebral body and disc has been well studied (140,141,142 and 143). These studies demonstrate that the blood supply to the disc comes from the contiguous bone of the vertebral bodies. In the young child, vessels can be identified traversing the cartilaginous vertebral end plate and entering the annulus. By the age of 8 years, these vessels have largely disappeared, but a rich anastomotic network of vessels remains along the periphery of the disc that can persist until 30 years of age.

The etiology of the syndrome of discitis is most likely infectious. Occasionally, the question of traumatic injury to the vertebral end plate, similar to a Salter-Harris I fracture, is raised; however, substantial proof is lacking. The different presentations, the characteristic age range (average age, 7 years), and the isolation of bacteria from many cases also militates against this being a traumatic disorder. It is recognized, however, that this is an infection that behaves differently than most musculoskeletal infections.

The presentation of patients with discitis is variable and insidious, with fewer than one-half presenting with the characteristic symptoms of refusal to walk or back pain (144). In addition, signs of infection, such as fever, are usually minimal or absent. Despite this, three different patterns of clinical presentation have been described

(145,146). The first presentation is in the younger child, usually younger than 3 years of age, who has difficulty walking. In the very young child this may begin with a reluctance, then refusal to walk, and may be confused with more common causes, such as a septic hip. In the child who is attempting to walk, there is often a characteristic gait, with the child bending forward and hands on the thighs for support.

The second presentation, usually occurring in children 7 to 15 years of age, is abdominal pain. This can be vague and associated with a poor appetite and listlessness. Sometimes the pain radiates anteriorly and can be confused with an intraabdominal condition, although localized physical signs in the abdomen are lacking.

The final presentation is back pain. In the classic presentation, the patient complains of back pain, has loss of the normal lumbar lordosis, and is painful to percussion. In some children, this onset may be gradual, whereas in others who often have radiographic evidence of vertebral osteomyelitis, the onset may be rapid and may suggest infection. In most cases, fever is absent or low. It is also important to remember that these presentations may overlap greatly in age, symptoms, and findings.

The laboratory evaluation, as with most cases of skeletal sepsis, is not helpful unless the underlying disease is suspected and all of the correct tests are obtained. The leukocyte count may or may not be elevated or show a leftward shift. The ESR and CRP are usually elevated, and blood cultures may be positive, but not so reliably as in the usual infection involving a major bone or joint.

Radiographs at the initial presentation are often normal, and usually show no changes in the first 1 to 3 weeks of symptoms. One of the earliest findings, often seen only in retrospect, is an irregularity of the vertebral end plate. This is followed by narrowing of the disc space, then erosion of the vertebral end plate, as evidence of involvement of more than just the disc space (Fig. 13-12).

FIGURE 13-12. A: AP view of the pelvis of a 14-month-old child who stopped walking after several days of limping, falling, and irritability. This radiograph was ordered by the initial treating physician because of the suspicion of hip infection. Note the narrowing of the L4–L5 disc space. **B:** The lateral view was taken subsequently, when examination by the orthopaedic surgeon demonstrated pain on percussion of the lower spine. Again, note the narrowing of the L4–L5 disc space. **C:** Increased isotope uptake in the vertebral bodies of L4 and L5, which is typical of discitis, is demonstrated. **D:** At 10-month follow-up, the disc space has almost recovered its normal height. **E:** A fast spin-echo T2 MRI of a 22-month-old child with a similar story. Note the more significant changes in the disc than expected on the radiographs. The enhancement of the vertebral bodies demonstrates that the process is not confined to the disc as described in the past.

Bone scintigraphy is useful in suspected cases, demonstrating increased isotope uptake at the affected disc space. This usually occurs sooner than the radiographic changes, but the author has seen negative bone scans after 2 weeks of symptoms in patients with proved discitis. CT scanning is a useful technique to delineate the anatomic changes in the vertebral bodies. When performed on patients having classic disc space narrowing, it usually shows unsuspected areas of vertebral involvement. Although it is not often necessary, MRI is a useful tool in the case that is difficult to diagnose. In addition, it gives so much clear information that it is hard to resist using this as the first imaging test following the plain radiograph. MRI clearly demonstrates the involvement of the adjacent vertebrae (138,139).

Differential diagnosis between tumor and infection is usually not difficult on the plain radiographs. Collapse of the vertebral body, with preservation of the disc space, is seen in eosinophilic granuloma (vertebra plana) and, to a lesser extent, in leukemia. Neither of these conditions demonstrates increased isotope uptake on bone scan early in their course. Destruction of bone, with subsequent involvement of one or two disc spaces, suggests infection. A large amount of bone destruction, especially in adjacent vertebrae, suggests tuberculosis. Primary bone tumors of the spine are unusual in childhood, but must also be considered when bone destruction is present. MRI offers more detail about the extent of both bone and surrounding soft tissue involvement, and for that reason is a very useful test when a question arises as to the possibility of tumor (147).

In almost all other cases of musculoskeletal infection, aspiration or biopsy for culture is considered to be mandatory. With infections of the vertebrae and disc, however, difficulty, potential complications, morbidity, and cost are factors that usually lead to treatment without biopsy. This course is supported by the usually benign natural history of this condition, and by the excellent results that are achieved with empiric treatment in the absence of positive cultures. In those series in which biopsy has been performed, the yield of positive cultures is slightly less than 50%. Open biopsy is more likely to yield positive cultures than needle biopsy, and there is a trend toward better identification of organisms in more recent series. The results of the positive biopsies show a preponderance of *S. aureus* as the causative organism (144,145 and 146,148).

The treatment of disc space infections reflects both past observations and contemporary knowledge. Past observations of this disease demonstrated that it was largely self-limited, with occasional morbidity, and was successfully treated with rest, despite recognition of a likely infectious etiology (136,149). Current treatment consists of antistaphylococcic antibiotics (e.g., a semisynthetic penicillin or first-generation cephalosporin, as used in the initial treatment of AHO) (146). This has resulted in less morbidity (138). Antibiotic therapy is usually started intravenously, with hospitalization and bed rest. Careful observation for the onset of neurologic signs that would indicate epidural abscess formation is advisable until the patient shows resolution of symptoms. Immobilization may also be used, but the trend is to avoid it. If the patient's symptoms resolve, intravenous antibiotics are switched to oral antibiotics after 5 to 7 days. Oral antibiotics are continued for 3 to 5 weeks.

Resolution of symptoms usually occurs within the first 72 h. If this is not the case, the physician should begin to question the diagnosis or the specific bacterial etiology. Further imaging studies, such as CT scan or MRI, may be justified in such circumstances to search for tumor or abscess formation. Biopsy is indicated in a patient who fails to respond to antibiotics and bed rest, or has findings on imaging studies that suggest a diagnosis other than typical discitis.

Pelvis and Sacroiliac Joint

Infections of the pelvis and SI joint share two features with each other and with discitis: They present with a wide variety of symptoms, and are thus difficult to diagnose, and they can usually be treated successfully without surgery. However, unlike discitis, pelvic infections can occur in many locations within the pelvis, making diagnosis and localization more difficult. The debate over whether the process in the SI joint is an osteomyelitis or true septic arthritis is largely irrelevant to the clinician. Both are possible and probably occur, and both are treated in the same way.

The presentation is not always acute, as in most forms of septic arthritis and osteomyelitis. In one series, only one-third of the cases were acute, and the average time from onset to diagnosis was 3.9 weeks (150). Morgan and Yates (151) described four different presentations of osteomyelitis of the pelvis, depending on the initial area of pain: hip joint, abdominal, buttocks, and sciatic. In addition, they described a systemic presentation with malaise and fever. Beaupre and Carrol (152) described three presentations of SI joint osteomyelitis, which they termed gluteal, abdominal, and lumbar disc. The lumbar disc syndrome presents with pain in the lower back, hip, and thigh; the gluteal syndrome presents with pain, and possibly a mass in the buttocks; and the abdominal syndrome can mimic acute appendicitis.

The most important step in the diagnosis of pelvic osteomyelitis is to consider it as a possibility. Failure to perform an adequate examination for symptoms in the SI joint by compression and careful palpation of the other pelvic bones is a common cause of delay in diagnosis and confusion with other sites of infection. At the same time, it is important to remember that the pelvis and the SI joint are the site for many different pathologic processes, of which infection is only one (153).

Perhaps the most common diagnosis that is confused with SI joint sepsis is septic hip. SI joint infection is generally seen in older children, with the mean age being 10

years, whereas septic hip is more common in the younger child (150). Despite the complaint of pain around the hip, children with SI joint infection often remain ambulatory, and have relatively free internal rotation of the hip, in contrast to those with a septic hip. Conversely, patients with SI joint infection frequently experience greater pain on external rotation of the hip than internal rotation. If the FABER test (flexion, abduction, external rotation) is performed, it usually elicits pain in the presence of SI joint sepsis, as does compression of the pelvis (Gaenslen test). Tenderness almost always is found over the SI joint, if sought. Other areas (e.g., the ischium, pubis, ilium) should always be palpated for tenderness in children with gait disturbance or hip pain.

It is important to remember that osteomyelitis can occur in any location in any pelvic bone, and failure to elicit symptoms in the SI joint does not rule out pelvic osteomyelitis (154,155). Bony tenderness is usually present at the site of involvement, emphasizing the importance of suspicion, followed by a careful examination (155).

Osteomyelitis of the ischiopubic synchondrosis presents a confusing picture, despite tenderness being present. This synchondrosis, which fuses between 5 and 12 years of age, and occasionally later, shows a radiographic picture of expansion, and uneven mineralization before fusion. In addition, it is often asymmetric to the opposite side, which may have fused earlier, and radioisotope uptake is increased in many cases (156). Kloiber and colleagues report that, if the radioisotope activity at the ischiopubic synchondrosis is equal to or greater than that adjacent to the triradiate cartilage, or if the activity extends into the adjacent pubic ramus or ischium, it is indicative of a pathologic process (157).

Oblique radiographic views demonstrating the SI joint may be obtained, but their value today in making an early diagnosis with better imaging techniques is doubtful. In most cases of pelvic osteomyelitis, the initial radiographs are normal. This is especially true when symptoms have been present for fewer than 1 or 2 weeks. The earliest sign of infection on the radiograph is disappearance of the subchondral margins and erosion; however, this should be considered to be a late finding. If radiographic changes are present with less than 1 week of symptoms, careful consideration should be given to other disorders, such as tumor or chronic inflammatory SI disease. Until recently, the ^{99m}Tc bone-scanning was the most effective test in localizing a focus of pathology within the pelvic bones, but this may be changing, with further experience with MRI (158,159,160 and 161). Single photon emission computed tomography (SPECT) scanning should be utilized in the pelvis, as in the spine.

CT scans likewise can be helpful in several respects, but are not necessary in all cases (159,161,162). CT scans can better delineate the extent of bone involvement than can the radionuclide scan.

More recently, the value of MRI has become apparent in not only localizing the location and extent of bone involvment, but also in better delineating soft tissue changes, e.g., abcess formation (163) (Fig. 13-13).

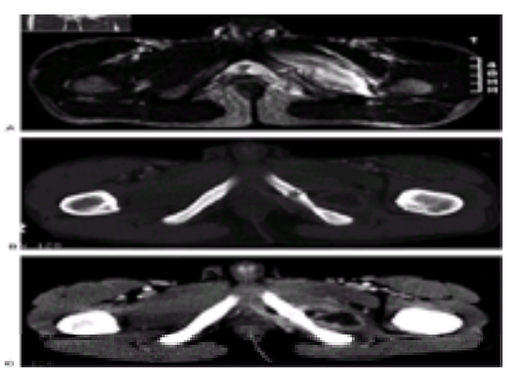

FIGURE 13-13.A: A T2 MR image of a 9-year-old boy with a history of increasing limp and hip pain for 1 week. The edema in the obturator muscle, the increased signal intensity around the ischiopubic synchondrosis, and the suggestion of abscess formation all suggest pelvic osteomyelitis. When the symptoms failed to resolve with intravenous antibiotics, CT-guided needle aspiration of the abscess was performed. **B:** Note the changes in the bone around the ischiopubic synchondrosis seen on the bone windows. **C:** Note the abscess seen on the soft tissue windows. Although MRI might still be the best choice for an initial imaging study in suspected pelvic osteomyelitis because of its ability to detect early changes within the bone, a great deal of information can be obtained from a good CT scan.

Schaad and colleagues reported that the bacterial etiology was established in 57% of the cases they studied from their own patients, and from a literature review (150). In most cases, *S. aureus* is the organism that is cultured from blood, direct aspiration, or biopsy (150,152,159,161,164). *Staphylococcus epidermidis* and *Streptococcus* species are also reported, but, in many cases, may be contaminants (159). An occasional *Salmonella* species may be isolated in patients who are not otherwise predisposed (150,161,165).

Laboratory findings in SI joint sepsis and pelvic osteomyelitis parallel other bone and joint infections, with the leukocytes often being normal and the ESR and CRP levels usually elevated. Blood cultures are positive in about 50% of cases; therefore, considering the difficulty in obtaining cultures from the SI joint and pelvis, they should always be obtained. *Salmonella* is always a possibility, even in those not predisposed to this organism, and, thus, stool cultures should be obtained. Joint aspirates are positive for the organism less often than in other cases of bone and joint sepsis (150,153,164). Although this is partly due to the difficulty in entering the joint, even biopsy specimens and pus seem to yield positive culture results less often than would be expected.

In the report by Reilly and colleagues (161), six of ten cultures from aspiration or biopsy of the SI joint were positive; the same yield as obtained from blood cultures. The technique for aspirating the SI joint has been described (166,167).

The author prefers to aspirate only those cases that do not respond promptly to antibiotics, or that exhibit atypical features, for the following reasons:

- Morbidity and expense associated with this procedure, which usually requires general anesthesia, are high
- Blood or stool culture can identify at least 60% of the organisms
- Most organisms are *S. aureus*
- The literature indicates that most of these patients respond to antistaphylococcic antibiotics.

Reports in the literature demonstrate that surgical debridement of pelvic osteomyelitis is usually not necessary (152,153,164). This contradicts reports in the older literature. The ability of this process to resolve with antibiotic therapy alone is probably due to a variety of factors: the large and diffuse blood supply to the bones, which makes sequestrum formation unlikely; the rigid ligament structure around the SI joint, which contains the spread of infection; and negligible long-term morbidity, even when the joint becomes ankylosed (164). Indications for surgery are those for biopsy in the case of suspected tumor, an unusual presentation, or failure to achieve resolution of the symptoms in a reasonable amount of time. Drainage of a large abscess may be necessary, especially in the presence of systemic symptoms.

Initial antibiotic therapy should be with an intravenous semisynthetic penicillin or first-generation cephalosporin, as used in the treatment of AHO (see Table 13-3). If symptoms resolve and the CRP begins to fall, the patient may be switched to oral antibiotics in 5 to 7 days, if adequate blood levels are obtained with oral administration. Initial and subsequent antibiotics should be adjusted to reflect information from blood and stool cultures, in addition to biopsy material, if that has been obtained. Failure of a response suggests that the antibiotic is not effective against the causative organism, a large abscess persists, or the etiology is not infectious.

The Neonate

Both AHO and septic arthritis can occur in the neonatal period. The classic definition of the neonatal period is the first 28 days of life. For the purposes of antibiotic selection in community-acquired infection, however, the physician is well advised to consider this period to extend to the first 8 weeks of life. The pathogenesis, diagnosis, and treatment of bone and joint sepsis differ significantly in the neonate.

The immune system in the neonate is immature. The factors are multiple, with some being specific and others nonspecific, and many of them are incompletely understood (168,169). There are two important effects of this lack of well-developed immunity. First, neonates are susceptible to a wide range of organisms that are

less virulent under normal circumstances. Second, because they lack a well-developed immune system, neonates do not have the usual inflammatory response that creates the signs and symptoms so important to early diagnosis.

In most circumstances, the organisms reach the bone or joint by the hematogenous route. In addition to their unusual susceptibility to many organisms that may be considered normal flora, neonates may be subjected to a wider range of organisms and to opportunities for these organisms to gain access to the circulation. This is particularly true of the neonate (especially the premature infant) who is sick and remains in the intensive care unit in the presence of nosocomial pathogens, coupled with invasive monitoring, intravenous feeding, drug administration, and blood sampling. Indwelling vascular catheters, particularly those in the umbilical vessels, have long been recognized as being one of the main sources of infection (170).

There appears to be two types of infection in the neonate: that recognized in the hospital in premature infants, and that which becomes apparent after discharge from the nursery in otherwise healthy, full-term neonates. The type manifest in the hospital usually occurs in premature infants undergoing invasive monitoring. These infants are more likely to have infection caused by *S. aureus* or Gram-negative organisms, to have multiple sites of involvement, and to be systemically ill. More than 40% of affected infants have more than one site of involvement (171, 172). The other type is usually manifest between 2 and 4 weeks of life (sometimes as late as 8 weeks), in infants who are not systemically ill, and are developing and feeding normally. These infections are more likely to be due to group B *Streptococcus,* and involve a single site.

Most cases of bone and joint sepsis in the neonate are caused by *S. aureus*, with group B *Streptococcus* being the next most common. Gram-negative organisms probably comprise 10 to 15% of the infections (171 and 172). *Candida albicans* is not uncommon, but usually occurs along with or after other infection, often in patients on prolonged antibiotic therapy or hyperalimentation (179). It is characterized by an even greater lack of the usual symptoms (e.g., increased warmth, tenderness).

A unique feature of neonatal bone and joint sepsis is the frequent association of contiguous bone and joint involvement and high morbidity due to the subsequent destruction of the growth plate or joint. This association, which has been reported to be as high as 76% (171, 172), leads to another important difference between the neonate and the older child, regarding the changing anatomy with growth and maturation. Trueta (31, 180) described the changing vascular anatomy of the physis, and particularly the femoral head, during growth. Ogden (181) extensively studied the role that this unique vascular anatomy plays in neonatal osteomyelitis, and Chung (182) beautifully demonstrated this changing anatomy with injected human specimens.

The changing anatomy of the blood supply within the physis has been addressed previously in this chapter. Its importance in neonatal osteomyelitis is that the vascular channels penetrating the physis and the chondroepiphysis (cartilaginous anlage of the epiphysis) permit an early destruction of both, with consequent disturbance of growth and joint congruity. This probably occurs both by lysis of the cartilage, through the direct action of the organisms, and by destruction of the blood vessels (and the consequent avascular changes) by the inflammatory process (181, 183).

Ogden's studies led him to conclude that the frequent association of bone and joint involvement was the result of primary bone infection, and was mainly due to the vascular canals traversing the physeal plate and the chondroepiphysis, allowing early abscess formation in the chondroepiphysis, which could rupture into the joint. An additional factor is that the metaphysis in neonates may lie within the capsule of the joint, thus creating septic arthritis when the pus penetrates the metaphysis and elevates the periosteum (181, 183). The lesson for the physician is that, when a septic joint is diagnosed in the neonate, a thorough search for osteomyelitis in an adjacent metaphysis or epiphysis is mandatory.

The diagnosis of bone and joint sepsis in the neonate is not easy, largely because of the absence of signs and symptoms secondary to the immature immune system. In one report on the value of bone scintigraphy in detection of neonatal osteomyelitis, the sensitivity for diagnosing focal disease by clinical findings was 20%, radiography 65%, and bone scintigraphy 90%. This illustrates the need for a high index of suspicion and reliance on tests other than examination, for the localization of the disease (184).

The most common presenting findings are swelling, followed by pseudoparalysis and tenderness. The large amount of fat surrounding the limbs of the neonate often makes detection of swelling difficult, whereas the lack of apparent illness often leads the unsuspecting physician to ascribe the lack of motion or apparent pain to some other cause. The diagnosis in the septic premature neonate is often delayed while other causes, such as meningitis or pneumonia, are sought.

Because early diagnosis is so important, the evaluation of the septic infant for osteomyelitis or septic arthritis should be serial, and not sequential. Any neonate with sepsis should be suspected of musculoskeletal sepsis. Any infant who exhibits disuse, discomfort of a joint with motion, or tenderness of a limb should be suspected of having bone or joint sepsis.

Other than possible soft tissue swelling, radiographic changes do not accompany an early diagnosis. The ^{99m}Tc bone scan is useful because it can survey the entire skeleton and detect changes before they are radiographically apparent. Ash and Gilday (185), however, found that only 32% of proved sites of osteomyelitis in 10 neonates were positive on the bone scan. This lack of ability to detect osteomyelitis may be partly due to the lack of inflammatory response to the infection, or because the infectious focus lies adjacent to the active growth plate, and is thus obscured by the uptake of the isotope in the growth plate. Subsequently, Bressler and colleagues (186) reported a more favorable experience, detecting all 25 sites of proved osteomyelitis in 15 affected infants. The improved results appear to be due to higher-resolution equipment and magnification views of all suspected areas.

Routine laboratory evaluation is of little value. The leukocyte count and differential leukocyte count are not reliably elevated. The sedimentation rate is usually elevated, but is a nonspecific finding. The blood cultures are positive in about 50% of patients with proven infection.

Once the area of involvement is identified, aspiration is mandatory. This permits confirmation, either through obtaining pus, a positive Gram-stain, or a positive culture. The author strongly believes that in any neonate with known osteomyelitis or septic arthritis, both hip joints should be aspirated because:

- Multiple sites of involvement are common
- The proximal femur and hip joint are frequently involved
- Symptoms and signs are often subtle or lacking
- The hip is the most difficult joint to examine
- The window of opportunity for effective treatment is small
- The hip joint is the most frequent site of permanent sequelae.

The antibiotic management of the neonate is difficult, and should be undertaken in conjunction with a physician having such experience. The selection of the antibiotic is guided by the probable causative organisms, and modified by positive Gram-staining and culture. The dosage varies, depending on the degree of prematurity and the status of hepatic or renal function. Because penicillinase-resistant forms of *S. aureus*, in addition to Gram-negative enteric organisms, are possible, initial antibiotic selection should cover these organisms, as well as group B *Streptococcus*. Choices may include oxacillin, along with gentamicin or a third-generation cephalosporin such as cefotaxime or ceftazidime. Ceftriaxone (Rocephin) may also be used if there is no jaundice. If methicillin-resistant *S. aureus* is suspected, vancomycin should be considered in the initial therapy.

Some authors have implied that surgical drainage may worsen the result (172), and others have implied success without surgical drainage (174). Such studies suffer from treatment of only the most severe cases with surgery, acceptance of a high incidence of complications, and inadequate follow-up to detect the magnitude of growth alteration. It would seem to be even more imperative to treat the neonate with surgical debridement because adequate immune mechanisms are lacking. Therefore, when pus is found its removal is advised. This cannot be adequately accomplished with repeated aspiration, and therefore this form of therapy is not recommended.

Sickle Cell Disease

Sickle cell disease is the result of an autosomal recessive gene that produces abnormal hemoglobin, with numerous effects. Marrow hyperplasia, as a mechanism to compensate for the reduced oxygen-carrying capacity of the erythrocytes, resorbs both trabeculae and cortex, whereas reactive bone formation thickens the existing trabeculae. Susceptibility to infections other than osteomyelitis (e.g., sepsis, pneumonia) is increased, growth and sexual development are retarded, and infarction of bone and other organs is common. This section discusses only those factors relating to bone and joint infection.

The gene responsible for production of the abnormal hemoglobin (hemoglobin S gene) occurs predominantly in those of African descent, but is also present in whites in Greece, Turkey, Italy, and India. It is estimated that between 8 and 30% of African-Americans carry the hemoglobin S gene. About 2.5% of African-Americans are estimated to be homozygous for the gene that produces the clinical picture of sickle cell anemia. Although patients who are homozygous for the sickle cell gene are those most likely to be affected with bone infarction and infection, those who have hemoglobin SC disease, or hemoglobin *S. thalassemia,* are also predisposed. The pathophysiologic effects of the abnormal hemoglobin molecule are discussed in Chapter 11.

Although the orthopaedist is most familiar with the bone manifestations of this disease, it is important to remember that the most serious, common, and important infections result from the *Pneumococcus* organism. This is because those children who are homozygous for the sickle gene have defects in the alternate complement pathway, defects in opsonic activity, and impaired splenic function, which renders them susceptible to infection from pneumococci (187). In addition, these children may have an increased susceptibility to *H. influenzae*. Neither of these organisms play a large role in the bone and joint sepsis seen by the orthopaedist.

The incidence of osteomyelitis in patients with sickle cell anemia is low (particularly in the United States), despite the attention it receives in the literature. In 1971, Specht (188) found only 82 cases in the literature, whereas the few cases reported over several years in other large centers attest to the infrequent occurrence (189,190). This low incidence is even more important to the orthopaedist, when considered relative to the number of admissions for sickle cell crisis, a clinically similar presentation (190).

The presentation of osteomyelitis or sickle cell crisis in patients with sickle cell disease does not differ significantly. Because infection is thought to follow bone infarction, both conditions may coexist. The patient with known sickle cell disease in crisis presents as an uncomfortable child with pain in one or more joints or bones. Mild swelling is often present, joint effusions are not uncommon, and bone tenderness is usual. A late but differentiating feature is that with proper management the pain of infarction is usually markedly diminished by 3 to 5 days, whereas that of infection is not, unless antibiotics are also administered.

The leukocyte count and differential are not helpful in distinguishing infection from infarction. The ESR must be interpreted with caution, because it is elevated in both infarction and infection. In addition, the ESR tends to be falsely low in patients with sickle cell disease. The ESR is more likely to be above 20 mm/h in those with infection (191,192), and significant elevations should raise the suspicion of sepsis.

The initial radiologic manifestations of osteomyelitis in sickle cell disease are indistinguishable from those of bone infarction, and consist of periosteal new bone along the diaphysis. As the infection proceeds, however, a diffuse moth-eaten appearance of the bone occurs, with longitudinal fissuring and increasing periosteal bone formation. This results in the typical radiographic findings of a chronic diaphyseal bone infection with involucrum and sequestrum. Frequently, the other changes of sickle cell disease are seen also—the result of marrow hyperplasia and previous bone infarction (Fig. 13-14).

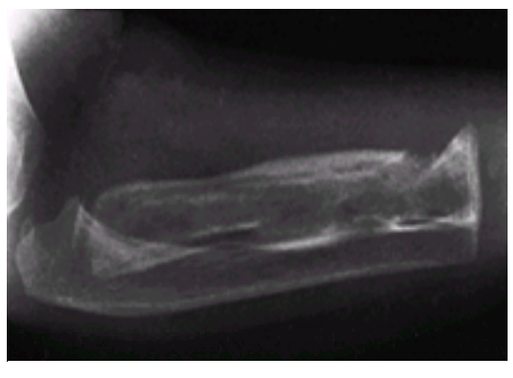

FIGURE 13-14. Lateral radiograph of the forearm in this infant demonstrate the typical changes of sickle cell osteomyelitis: longitudinal fissuring, diaphyseal location of the infection, and developing involucrum. These changes would be expected in any chronic infection of bone, and are not unique to sickle cell osteomyelitis.

The role of bone scintigraphy to differentiate marrow infarction from infection has been controversial (190,193,194). An understanding of the local pathophysiology in both conditions explains the problem and the potential usefulness of this modality. Bone infarction initially produces an area of decreased vascularity, and thus decreased isotope uptake. Once the inflammatory reaction to the infarction is established, however, the vascularity around the infarction results in increased isotope uptake. This probably occurs between 3 and 7 days after the infarction. Once it occurs, the scintigraphic appearance is the same as that of infection, which also produces increased vascularity and increased isotope uptake.

Therefore, if bone scintigraphy is to be useful, it must be performed early, preferably within 72 h of the onset of symptoms. Two different scans must be used: a ^{99m}Tc bone scan, followed by a bone marrow scan with a different isotope. Increased uptake on the ^{99m}Tc scan, with decreased uptake on the marrow scan, suggests infection (190,195). Although gallium 67 citrate scanning after ^{99m}Tc scanning has been recommended, it has not been found useful by others (190), and its high radiation dose to the child is an additional factor to consider.

The use of MRI has not proven to be of great value. This is in part because the findings of marrow infarction, as well as those in the soft tissues, are not reliably distinguished from sepsis (196). At the same time, other reports value ultrasonography in the differentiation of osteomyelitis from vasoocclusive crisis by demonstrating subperiosteal fluid and thickening of the periosteum (197,198). The answer as to why ultrasonography was successful when MRI failed lies in the details of these reports. In the reports of ultrasound diagnosis, many other parameters were actually used to arrive at the diagnosis.

A unique manifestation of this disorder is a condition known as sickle cell dactylitis, or hand–foot syndrome (24,199). The condition occurs in infants and young children, usually those younger than 4 years of age. No case of a child older than 7 years of age has been reported. It may precede the diagnosis of sickle cell disease. The actual incidence is probably between 10 and 20% of children with sickle cell disease, and it seems to be more common in Africa. Although it is logical to assume that it is due to infarction, there is also evidence that it may be secondary to acute marrow hyperplasia, because it is not seen once the hands and feet are no longer the site of active hematopoietic production.

Patients present with acute symmetric or asymmetric painful swelling of the hands and feet. Although considered to be a benign condition, obviating further evaluation (199), *Salmonella* osteomyelitis has been associated with this condition (200,201). Laboratory tests do not help in the differential diagnosis. Radiographic findings in the hand–foot syndrome at first demonstrate only soft tissue swelling, followed in 7 to 14 days by the formation of subperiosteal new bone. This is followed by medullary resorption and the appearance of irregular densities, in addition to cortical thinning. The changes revert to normal in weeks to months. Thus, radiographs do not help in the differential diagnosis.

With so few objective findings and tests to help in the differential diagnosis of bone infarction and osteomyelitis, how should the orthopaedist approach the patient in a clinical situation, wherein the diagnosis could be either? Awareness, repeated examination, and blood cultures are basic and important. High fever, an elevated ESR, and a sequential bone scan early in the course of the disease may raise the suspicion of osteomyelitis. Aspiration of the suspected bone, with Gram-staining and culturing of all material, should not be postponed when the orthopaedist or another caring for the child suspects infection. This is the only test that confirms the diagnosis, and allows appropriate early treatment.

In the literature, recommendations for or against surgical debridement are variable: Some believe it to be the best treatment (202), some believe that patients do well without surgery (191,192,203), and others report surgery without specific indications (191,192). A close look at the outcomes and complications of this disease lead the modern orthopaedist to question the treatment of osteomyelitis without surgical drainage. Although in children the diaphyseal infections eventually heal, the contemporary standard of care seeks to avoid the diaphyseal destruction commonly seen, and the morbidity of prolonged hospitalization, intravenous antibiotic administration, and late sequelae. In other words, early diagnosis (not common in reports in the literature) and prompt drainage of an abscess, especially in an area of infarction, may result in outcomes comparable with normal children having the usual course of pyogenic osteomyelitis.

The question of using a tourniquet in patients with sickle cell disease who are undergoing extremity surgery is frequently raised because of the possibility that the

ischemia may provoke thrombosis. This does not seem to be a problem; when the patient is properly prepared for surgery, no complications from the use of a tourniquet should result (204,205).

Which organism is the most common cause of osteomyelitis in sickle cell disease: *S. aureus* or *Salmonella?* This is a frequent test question, although it has little relevance in practice because both are so common that antibiotics must be given against both organisms until cultures establish the etiology. In addition, the literature is contradictory on which organism is the most common (191,203,205). A recent article reviewing the world literature since 1959 found *Salmonella* to be the most common (207).

Initial antibiotic choices are cefotaxime (Claforan) or ceftriaxone (Rocephin), each of which covers both *S. aureus* and *Salmonella* species, including those *Salmonella* resistant to ampicillin, chloramphenicol, or trimethoprim-sulfamethoxazole (Bactrim) (Table 13-3).

Arthritis may be seen in various forms in patients with sickle cell disease (208). The most common is an aseptic arthritis, most likely due to the sickle cell disease. It may be seen during crisis, but is more often a transient synovitis, usually involving the knee, which resolves within 5 days (209,210). A second form of aseptic arthritis is that associated with a remote *Salmonella* infection. This may be seen with other organisms, and the exact mechanism is not clear. Finally, the patient with sickle cell disease may have a septic arthritis. When this is the case, *Salmonella* is not the most likely organism. *Salmonella* is a rare organism in septic arthritis (210); when it occurs, it is most often in patients without sickle cell disease. When *Salmonella* septic arthritis occurs in sickle cell patients, it is most often from contiguous spread of osteomyelitis. More likely organisms in septic arthritis are *Staphylococcus* species (202,212). As with osteomyelitis, there is a difference of opinion on the advisability of arthrotomy for drainage (202,212).

Chronic Recurrent Multifocal Osteomyelitis

In 1972, a condition described as “subacute and chronic symmetrical osteomyelitis” was reported in the radiology literature (213). Since then, more than 50 cases of this disorder, which has come to be known as “chronic recurrent multifocal osteomyelitis” (CRMO) have been described. Females are affected in about 70% of the cases (214). This entity is distinct from pyogenic osteomyelitis, and is associated with a variety of other curious disorders of bone and skin. These associations include chronic sclerosing osteomyelitis of Garré, condensing osteitis of the clavicle, sternocostoclavicular hyperostosis, and palmoplantar pustulosis.

The clinical picture is characterized by the insidious onset of pain, often with swelling and occasionally erythema, suggesting infection of the bone. In a retrospective review of 14 patients with CRMO, 86% presented with a single tender swollen periarticular site (215). Patients usually remain ambulatory. Although more often multifocal, the initial presentation may be unifocal, progressing to multifocal. Although arthritis is more common in adults, it may be seen in adolescents (216). This and subsequent attacks are usually associated with symptoms of malaise and occasionally low-grade fever.

A curious, associated condition is palmoplantar pustulosis, a descriptive term for vesicles that may appear on the hands or feet. The association of these lesions with a variety of bone lesions is common, and all of these various conditions, previously described as being associated with palmoplantar pustulosis, are probably the same disease (217). These lesions do not occur in all cases, but seem to recur with recurrence of the bone symptoms. The bone lesions and the clinical course do not seem to differ between patients with and without these skin manifestations.

The subsequent course of resolution, then recurrence months later, is characteristic of this disease. Subsequent flare-ups are associated with the same findings and symptoms of the initial attack. The same or different bones may be involved. Generally, the symptoms recur over a period of 2 years; however, symptoms may recur as many as 5 years later. Growth arrest has been both absent (216) and present (218) in different series.

Laboratory findings are distinct from the usual findings in pyogenic osteomyelitis because the leukocyte count remains normal. The sedimentation rate is elevated, and cultures of bone and blood are negative. It has been noted that the chemotactic activity of the polymorphonuclear cells is increased, whereas in the presence of bacterial infection, this activity is decreased(214).

The descriptions of the pathology in the bony lesions vary in the literature (214,217,218). This variation probably results from sampling differences and the stage of the lesion at the time of the biopsy. It seems that early lesions consist of infiltration predominantly with neutrophils. This is followed by infiltration with fibrovascular tissue and inflammatory cells (predominantly lymphocytes and plasma cells). Osteoblasts and trabecular thickening follow.

At the time of presentation, the characteristic metaphyseal lesions are usually well developed. These lesions consist of poorly delimited eccentric metaphyseal lucencies along the physeal border. These lesions have been shown to cross into the epiphysis (216,221). The most common sites for these lesions are the distal and proximal metaphyses of the tibia and femur. Other affected sites are the distal radius and ulna, the distal fibula, and the metatarsals (Fig. 13-15). From a review of the literature, it seems that almost every bone has been reported as being involved, including the pelvis.

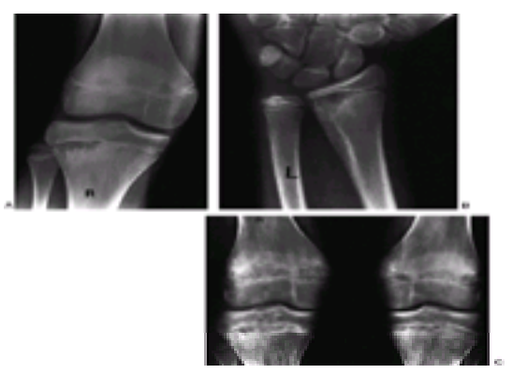

FIGURE 13-15.A 12-year-old girl presented with recurrent limp over a period of 18 months. She complained of pain in the right knee. Examination demonstrated tenderness about the right knee, but no other signs of inflammation. **A:** Radiograph of the right knee showed metaphyseal irregularity of the proximal tibia. **B:** Skeletal survey demonstrated additional similar lesions in the opposite knee, distal tibia, and radius. These lesions were asymptomatic. **C:** Radiographs 1 year later show diffuse metaphyseal changes of the distal femur and proximal tibia of both legs. No antibiotics were administered, and the symptoms resolved over the next several months.

As healing occurs, sclerosis surrounds the lesion. When the lesion extends into the cortex, periosteal reaction may occur. This is more likely to be seen early in the course in the small tubular and flat bones. This picture can be confused with bony neoplasm, such as leukemia, Ewing sarcoma, or eosinophilic granuloma.

The clavicle is frequently involved, presenting as a chronic sclerosing osteomyelitis (220). When present, this starts in the medial end of the clavicle and may present with both lucencies and an onionskin periosteal reaction.

Bone scintigraphy shows increased uptake in radiographically apparent lesions, and also helps to identify lesions that are not apparent on plain radiographs. In one report, bilateral lesions were found in 64% of the patients, and bone scintigraphy was very useful in finding the asymptomatic lesions (215).

It is doubtful that every case needs to undergo biopsy. If the picture is characteristic, little is to be gained. There may well be circumstances wherein the diagnosis is in doubt, in which case biopsy is necessary to rule out a malignancy, or to obtain culture from a lesion suspected of being pyogenic or tuberculous.

The most likely confusion is between subacute osteomyelitis and chronic recurrent multifocal osteomyelitis. Gamble and Rinsky (222) compared groups of patients with each other. From their data, the only helpful initial finding is the presence of multiple bone lesions in patients with chronic recurrent multifocal osteomyelitis. The age, symptoms, and laboratory findings were similar in both groups. Occasionally the periosteal reaction can indicate a more serious bone lesion, such as Ewing sarcoma, when it is the only lesion.

There is no specific treatment for this disorder, and the symptoms resolve without treatment. In most cases, nonsteroidal antiinflammatory medications ameliorate the pain. Antibiotics have not been demonstrated to have any effect on the course of the disorder, and are not indicated.

Subacute Osteomyelitis

In 1965, Harris and Kirkaldy-Willis (223) called attention to a subacute form of pyogenic osteomyelitis in which there had been no acute symptoms and the patient had received no antibiotics. Four years later, King and Mayo (224) reported a similar group of patients. The characteristic presenting features were no previous acute attack to suggest evolution of an acute osteomyelitis to a chronic form, insidious onset of pain, absence of systemic signs, and radiographic presence of a bone lesion at the time of presentation. They found these lesions in both the epiphysis and diaphysis, and described the various radiographic presentations.

Regardless of the location within the bone, the presentation is usually the same: weeks to months of worsening pain that started insidiously, and limp and tenderness with swelling visible, depending on the location. In addition, the laboratory findings are similar in most cases, and are distinct from AHO. The leukocyte count is usually normal or only slightly elevated. The ESR is usually elevated, although usually not as high as in AHO. Blood cultures are usually negative, although curettings from the lesions are frequently culture-positive, usually for *S. aureus*. Histology is compatible with acute and chronic inflammation.

Radiographic lesions are usually seen at the time of presentation. Far from being uniform, these lesions can present in many different locations and with a plethora of radiographic features. This highlights the main problem that faces the treating physician: the differential diagnosis of the lesion. Gledhill's classification (225) was further expanded by Roberts and colleagues (226) (Fig. 13-16). Differentiating some of these lesions from tumor is the most difficult part of the diagnosis (227).

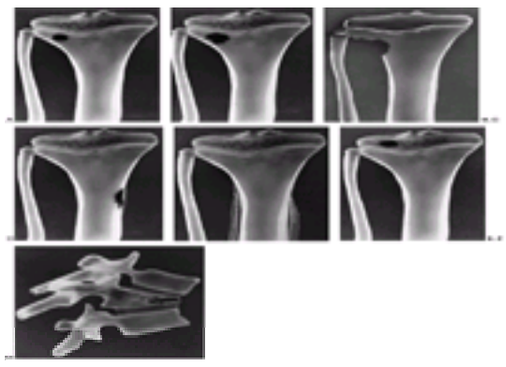

FIGURE 13-16. The variety of presentations of subacute hematogenous osteomyelitis in the classification of Roberts and colleagues (226). **A:** Type 1A is a punched-out metaphyseal lesion resembling an eosinophilic granuloma. **B:** Type 1B is similar to type 1A, but has a sclerotic cortex. **C:** Type 2 lesions erode the metaphyseal bone, often including the cortex, and appear as aggressive lesions. **D:** Type 3 lesions are localized cortical and periosteal reactions, simulating osteoid osteoma. **E:** Type 4 lesions produce onion-skin–like periosteal reactions in the diaphysis, and resemble Ewing sarcoma. **F:** Type 5 lesions are epiphyseal erosions. **G:** Type 6 lesions involve the vertebral bodies.

The most common type of subacute osteomyelitis in the pediatric age group is the metaphyseal lesion (types IA and IB) (228). This represents a true Brodie abscess, a localized abscess of bone without previous acute illness. The lesion is located eccentrically in the metaphysis, frequently with visible extension into the epiphysis (Fig. 13-17). The lesion may have a sclerotic border, or may be irregular and ill-defined. The second most common type is the epiphyseal lesion (type V) (229,230 and 231). The radiographic appearance is similar to the lesion in the metaphysis; it also may extend across the plate into the metaphysis. The other lesions— erosion of the metaphyseal cortex (type II); localized conical and periosteal reaction (type III); onionskin cortical reaction in the diaphysis (type IV); and those involving the vertebral body (type VI)—are seen less commonly.

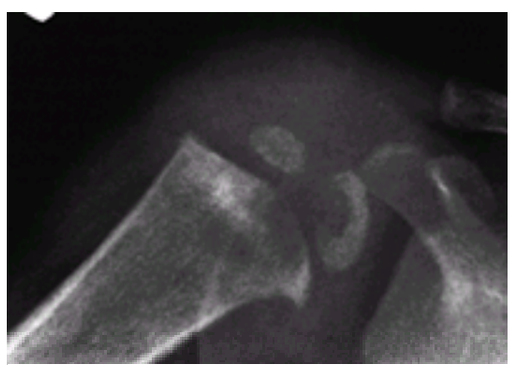

FIGURE 13-17. A 13-month-old girl presented for examination when her mother noted the child experienced discomfort when lifting her arms while her mother changed the child's clothes. *Haemophilus influenzae* was cultured from the lesion. The epiphyseal lesion communicates with the metaphyseal lesion.

Increasingly seen in patients presenting with a limp is the presence of these lesions in the tarsal bones (232). The lesions most often are lytic in the talus and calcaneus, and sclerotic in the other bones.

As mentioned, the differential diagnosis of these lesions is the most important step in correct treatment, and is often the most difficult. In a series of 71 children with subacute osteomyelitis, Ross and Cole (233) divided the lesions into two categories: aggressive lesions (26) and cavities in the region of the metaphysis and epiphysis (45). All of the lesions in the aggressive group that were in the diaphysis or metaphysis demonstrated onionskin periosteal new bone. Two lesions were in the spine. The other lesions were all in the metaphysis or epiphysis, and had the typical radiologic features of type I and V lesions described above. The differential diagnoses of a type V lesion in the epiphysis include chondroblastoma and osteoid osteoma (and osteoblastoma), with eosinophilic granuloma, enchondroma, and chondromyxoid fibroma being less common. Of these, only chondroblastoma produces a periosteal response. The differential diagnoses of the typical type I lesion include eosinophilic granuloma, and perhaps giant cell tumor. Computerized tomography can be useful in the questionable case. The type III metaphyseal lesion, with erosion of the cortex, can be confused with osteosarcoma. A recent report of a characteristic finding on T1-weighted MR images may prove helpful in some cases. While not pathognomonic, the finding of a rim of tissue, which is hyperintense relative to the main cavity, called the “penumbra sign,” suggests infection as opposed to tumor (234).

The appearance of the typical lesion of a bone abscess in the epiphysis or metaphysis is so characteristic that Ross and Cole believed that it was diagnostic, and could be treated without biopsy or curettage. For these patients, they recommended 48 h of intravenous semisynthetic penicillin or first-generation cephalosporin, followed by 6 weeks of oral antibiotic. Eighty-seven percent of 37 children were healed with one course of antibiotics. Failure increased with the age of the child, and led to curettage and a further course of antibiotic. The authors do not mention the dosage of oral antibiotic, nor whether adequate serum levels of antibiotic, were verified in these patients. This 13% failure rate may be improved with a longer course of intravenous antibiotic, without resort to surgical treatment. All of the cases of aggressive lesions underwent biopsy and curettage. Hamdy et al. have subsequently reviewed 24 cases treated with antibiotics only, and 20 with surgical debridement and antibiotics, and concluded that there was no difference in the results (235).

Puncture Wounds of the Foot

Since Johanson's 1968 report (236), orthopaedic surgeons have become increasingly aware of the association between puncture wounds of the foot and

Pseudomonas aeruginosa as the causative organism of deep infections that follow. It was subsequently demonstrated that *Pseudomonas* can be recovered from the inner spongy sole of well-worn tennis shoes (237). *P. aeruginosa* is a Gram-negative aerobic organism with anaerobic tolerance, which is found widely in soil, water, and on the skin. As a human pathogen seen in orthopaedic conditions, it seems to have an affinity for cartilage.

However, despite the common isolation of *Pseudomonas* from puncture wound of the foot, it is important to remember that *S. aureus* is the most common soft tissue infection following puncture wound. In addition, *Aeromonas hydrophilia* is common when puncture wounds or lacerations occur in fresh water, e.g., ponds (238). Gentamicin or Bactrim are effective against this organism.

Fitzgerald and Cowan (239) identified puncture wounds of the foot as the reason for an emergency room visit in 0.8% of children younger than the age of 15 years. Of the total number with puncture wounds, 8.4% who were seen within the first 24 h after the injury, either had cellulitis at the time of presentation or returned within the first 4 days with cellulitis. Of those presenting 1 to 7 days after the injury, cellulitis was present in 57%. Only 0.6% of those who were not referred to the emergency room for an established infection subsequently developed osteomyelitis. Of 132 patients seen with soft tissue infection after puncture wound of the foot, 112 had a prompt response to soaks, rest, elevation, and antibiotics.

The importance of these data is that most infections after puncture wounds of the foot do not develop osteomyelitis or septic arthritis. This has been confirmed by a more recent report, which found osteomyelitis in only 16% of 44 children admitted to the hospital with puncture wounds of the foot (240). The cases of cellulitis that do not develop osteomyelitis or septic arthritis after puncture wounds of the foot represent the denominator usually not seen by the orthopaedist. Most of these infections respond to nonoperative therapy, such as rest, elevation, and oral antibiotics.

A major dilemma is the initial management of the puncture wound. Suggestions for “debridement and irrigation with loose closure over small irrigation tubes” are impractical, given the number of puncture wounds occurring annually in the United States, and the infrequency of serious infection (236). Similarly, the recommendation that “any deep wounds should be surgically debrided” seems impractical, because the treating physician would not know how deep the puncture wound is without anesthesia and surgical exploration (241).

Given the data on the development of cellulitis and osteomyelitis after puncture wounds, it appears that subsequent development of osteomyelitis and septic arthritis is mostly determined by whether the nail punctures the bone or joint. It is usually impossible for the initial treating physician to know this, although there should be a high degree of suspicion if the wound is over the metatarsal heads, the lateral border of the foot, or the heel—areas where the bone is in close approximation to the skin of the sole of the foot.

A reasonable approach to the initial management of a puncture wound of the foot includes superficial debridement of the skin and inspection for a foreign body, because a foreign body is found in almost 3% of cases (239). Tetanus prophylaxis is important. Because of the possibility of cellulitis developing in the first several days, patients should be advised to return at the first sign of infection. There does not seem to be any solid evidence either for or against the routine use of antibiotics in the initial management. They can be used effectively in the management of cellulitis, and there is no effective oral antibiotic for *Pseudomonas* osteomyelitis or septic arthritis in the pediatric age group.

The typical course of osteomyelitis or septic arthritis is the onset of pain and swelling 2 to 5 days after the puncture, when the initial symptoms should be gone. At this time, soaks, elevation, and an oral antistaphylococcic antibiotic are prescribed. If the patient has cellulitis, this regimen usually results in a cure. When osteomyelitis or septic arthritis is present the symptoms may improve, but do not disappear. This is probably due to the mixed flora in these infections. Finally, either continued pain and swelling or radiographic changes prompt the correct diagnosis. Good treatment includes close follow-up of those puncture wounds having signs of infection, and appropriate treatment if signs and symptoms of cellulitis do not resolve promptly on oral antibiotic treatment.

Initially, the signs and symptoms of cellulitis and osteomyelitis or septic arthritis can be difficult to differentiate. Pain on motion of a specific metatarsophalangeal joint is usually indicative of a septic arthritis in that joint. Dorsal swelling on the forefoot, or swelling laterally and medially around the heel, is often an additional sign of a serious deep infection (Fig. 13-18). Aspiration is helpful, not only in locating pus, but in obtaining material for culture. If no pus is obtained, bone scintigraphy may help in the early differentiation of cellulitis from osteomyelitis or septic arthritis. More recently, it has been suggested that MRI may be a more cost-effective way of diagnosing early osteomyelitis in the foot, following puncture wounds (242).

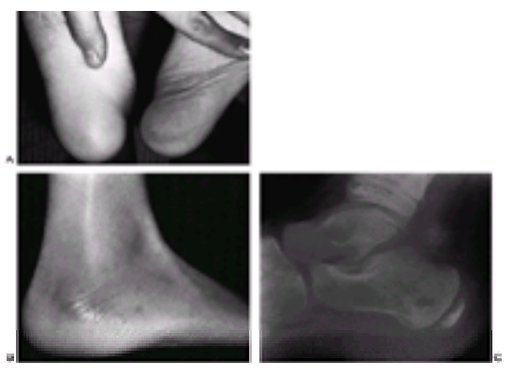

FIGURE 13-18. This patient was seen with pain 2 weeks after a puncture wound of the heel. He returned to the emergency department 3 days after the puncture wound because of increasing pain and swelling. Therapy was begun with a first-generation cephalosporin antibiotic. He experienced temporary improvement, but later the pain became worse. **A:** Note the swelling of the affected heel, when compared with the opposite contralateral heel side. **B:** Because of the dense septated tissue in the heel, osteomyelitis of the calcaneus usually is seen laterally. The swelling and erythema on the lateral side of the heel indicates deep infection. **C:** A radiograph demonstrates a lytic lesion of the heel, in addition to the soft tissue swelling. *Pseudomonas aeruginosa* was cultured from the infected site.

Pseudomonas infection of a bone or joint is a surgical disease; the failure of antibiotics alone to resolve these infections has been adequately demonstrated (243). The surgical approach may be either dorsal or volar, but must give adequate access to both the bones and joints in the region of the puncture, because *P. aeruginosa* is a cartilage-seeking organism. Some surgeons believe that the volar approach leaves a potentially painful scar. When properly placed, however, this should not be the case. This approach has the advantage of directly exposing the puncture track, which is an essential part of the surgery, because of the high incidence of foreign material found at surgical debridement (239,244). The dorsal approach allows direct access to the joints and bones through a more anatomic and easier-to-extend approach, which is not limited by the considerations of placement on the sole of the foot. This can be combined with a limited debridement of the volar puncture wound. Except in the most extensive cases of destruction of the calcaneus, in which the “cloven hoof” incision can be used, this bone should be approached from a medial or lateral incision, or from both.

Infections due to puncture wounds have two characteristics: They are caused by multiple organisms, and *P. aeruginosa* is usually one of them. For this reason, it makes sense to begin antibiotic therapy with a combination of antibiotics effective against both Gram-positive organisms and Gram-negative organisms, including *P. aeruginosa*. An initial choice may be ceftazidime (Fortaz) and gentamicin or oxacillin and gentamicin (Table 13-3). Jacobs and coworkers (243,244) suggest that 7 days of intravenous antibiotics after adequate surgical debridement are sufficient, although others recommend longer treatment (e.g., 10 days to 2 weeks).

Ciprofloxacin is another antibiotic that is effective against *Pseudomonas*. However, its use in children has been limited by reports of interfering with the growth plate in animal studies. Despite this, it has been used in cystic fibrosis and other serious infections in children, without reports of ill effects on cartilage or growth.

In cases that fail to respond to the above treatment, the fast-growing mycobacteria (e.g., *Mycobacterium chelonae* and *Mycobacterium fortuitum*) should be considered as possible pathogens.

Gonococcal Arthritis

Gonococcal arthritis is usually a sexually transmitted disease caused by the Gram-negative diplococcus, *Neisseria gonorrhoeae*. In the newborn, the disease is

contracted from the mother during passage through the birth canal, and results most commonly in conjunctivitis and scalp abscesses. When the disease is noted after the newborn period, before puberty, and in sexually inactive adolescents, sexual abuse should be suspected. Gonococcal infection is most common in women in the second and third decade, and therefore is seen frequently in the adolescent age group. Although gonococcal infection can take many forms, the orthopaedist is most likely to encounter this infection as septic arthritis in the disseminated form of the disease.

In the adolescent, the infection most often results from dissemination of a genitourinary infection, which is frequently asymptomatic. The delay between the genitourinary infection and the arthritis is variable, ranging from a few days to several weeks. In adolescence, the disseminated form of the disease is associated with pregnancy and menstruation, periods of low progesterone activity (245).

The orthopaedist needs to be especially aware of the possibility of sexual abuse in patients with gonococcal arthritis. Sexual abuse may occur in as many as 10% of all abuse cases, and it is estimated that between 5 and 20% of sexually abused children have a sexually transmitted disease, most commonly gonococcal infection (246,247). Children who are identified with or suspected of having a gonococcal infection should have cultures of all mucous membranes, including pharynx, vagina, and rectum, before the administration of antibiotics. These cultures should be handled in a manner that permits them to be used as evidence in court. In addition, reporting of suspected cases is mandated by the Child Abuse Reporting Law. For all of these reasons, the orthopaedist should involve a knowledgeable pediatrician in the evaluation of these patients.

The classic presentation is rash, tenosynovitis, and migratory polyarthralgia. Only about one-third of the cases develop a distinctive, but not pathognomonic rash, which is a result of gonococcal septicemia. The initial lesion is a small erythematous macule. This may disappear or develop a small vesicle, followed by a necrotic center that may form a pustule. The tenosynovitis, when seen, often affects the dorsal surface of the wrist and hand. This finding, like the skin rash, is nonspecific and can be caused by other organisms.

The clinical presentation of the disseminated disease with septic arthritis begins with chills and fever in about three-fourths of the patients. Joint involvement is polyarticular in 80% of cases. The knee is most often affected, but it is important to remember that any joint, large or small, can be involved. The size of the effusion may vary widely, and may even be absent. The involved joints are usually painful. The nature of the arthritis does not appear to have changed over the past several decades, although treatment with antibiotics has resulted in the virtual elimination of joint destruction (248,249,250,251 and 252). Osteomyelitis still may be seen as an occasional complication (221).

The leukocyte count is elevated in two-thirds of the patients. Culture is the only way to confirm the diagnosis. Culture and Gram-staining of joint fluid, and of the cervix of postpubertal girls and the vagina of prepubertal girls, should be performed. Any urethral or prostatic discharge in the male should also be cultured and examined by Gram-staining. Blood cultures should be routine. The organism may occasionally be isolated from skin lesions, but Gram-staining gives a higher yield.

N. gonorrhoeae is a difficult organism to grow, and special care is needed in the handling of the material for culture. Because the organism is sensitive to cold, material for culture should be plated directly onto a warm medium, whenever possible. Special culture tubes for transport of gonococcal cultures are available, and should be used, in addition to prompt delivery of specimens to the bacteriology laboratory, when direct-plating is not feasible. Cultures from sterile sites (e.g., blood, synovial fluid) are plated on chocolate blood agar. Cultures from nonsterile sites (e.g., the vagina, skin lesions) should be plated on selective media (e.g., Thayer-Martin agar) that contains antibiotics to inhibit the growth of other organisms. Cultures are grown in a 5 to 10% CO_2 atmosphere.

The increasing resistance of *N. gonorrhoeae* to penicillin and tetracycline makes parenteral administration of a third-generation cephalosporin (e.g., ceftriaxone, 50 mg/kg/day, intramuscularly or intravenously, once daily) the initial drug of choice (Table 13-3). If the organism is demonstrated to be sensitive to penicillin, it can be used. Recommendation for drainage of the joints remains variable. In the hip joint, there is no controversy; surgical drainage, as for pyogenic septic arthritis caused by any organism, is required. In other large joints with large amounts of purulent fluid, surgical drainage may be preferable to repeated needle aspiration. If surgical drainage is used, it is wise to leave a closed suction drain in the joint, because the tendency to reaccumulate fluid is greater than with other forms of septic arthritis.

Tuberculosis

Fewer cases of tuberculosis were reported in the United States in 1985 since reporting began in 1953. Between 1985 and 1991, the incidence rose sharply, only to slightly decrease in both 1992 and 1993 for all age groups except those younger than 15 years of age. During this period, the largest increase was reported for patients born outside of the United States and its territories. In 1993, these patients comprised almost 30% of the reported cases. California, New York, and Texas saw the largest increases. The increased incidence has been accompanied by human immunodeficiency virus infection and multi-drug–resistant organisms.

Because extrapulmonary tuberculosis is more common among children, particularly those younger than 5 years of age, the orthopaedic surgeon must again become aware of this possibility when evaluating chronic joint inflammation or chronic bone lesions.

Patients who are exposed to tuberculosis may or may not become infected, and those who are infected may or may not become diseased. There is a time lag between infection and diagnosis of the extrapulmonary disease of about 1 year.

Most patients are infected by human contact because bovine tuberculosis has been eliminated in this country by the pasteurization of milk. The lungs are the most common site of initial infection in children; the kidneys are not. The tubercle bacilli may disseminate to bones or joints during the lymphatic and hematogenous spread of the initial infection. If the initial lung infection remains untreated, involvement of the bones and/or joints occurs in 5 to 10% of children (253). The development of the lesions in bone is time- and location-related. Dactylitis may occur within a few months in younger children. Long-bone involvement may occur in 1 to 3 years.

The initial focus in the bone is usually the epiphysis or metaphysis, and rarely the diaphysis. As the osteomyelitis develops, it enlarges the area of bone destruction in a centrifugal fashion, producing a characteristic round cystic lesion with ill-defined margins. These lesions are filled with an inflammatory granulation tissue, creating a reactive hyperemia, which produces a wide area of osteopenia surrounding the lesion. This process is almost purely destructive or lytic, with little or no bone reaction (Fig. 13-19)—thus, the lack of sclerotic margins and a periosteal response. Because of the chronicity and hyperemia, widening and accelerated growth of the epiphysis may be seen. The physeal plate offers little resistance to the spread of the infection, as it does in other pyogenic infections. Before extraosseous abscess formation the bone lesions may mimic pyogenic infection or tumors such as eosinophilic granuloma.

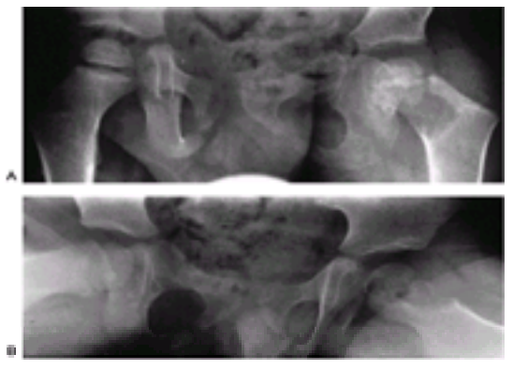

FIGURE 13-19.A and **B:** Radiographs of a 3-year-old boy who recently moved to the United States from Mexico. The child had complaints of increasing limp on the left, pain that worsened at night, and no significant limitation of activity. Examination demonstrated limited motion with irritability. Laboratory studies showed a normal complete blood count, erythrocyte sedimentation rate of 25 mm/h, and a positive purified protein derivative test. Open biopsy confirmed the diagnosis of tuberculosis by histology and culture. (Courtesy of Hugh Watts, M.D.)

Most skeletal tuberculosis affects the spine. The infection almost always begins in the vertebral body, usually the anterior one-third. The most frequent site of involvement in the spine is the lower thoracic and upper lumbar spine. Paravertebral abscess formation is characteristic, and calcification developing within the abscess is almost diagnostic of a tuberculous abscess. The discs become involved when two adjacent vertebral bodies are affected. The bone lesions in the vertebral

bodies are mainly destructive (Fig. 13-20).

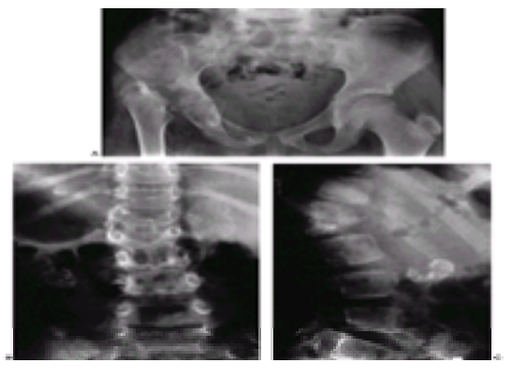

FIGURE 13-20.A: Anteroposterior (AP) radiograph of a 10-year-old girl from Mexico who had a past history of several operations on the right hip for tuberculosis presented with increasing back pain and kyphosis. **B** and **C:** AP and lateral views of the spine show bony destruction of the vertebral body, with relative preservation of the intervertebral disc and the calcified node; both are features of tuberculosis. Open biopsy confirmed the diagnosis of tuberculosis. (Courtesy of Hugh Watts, M.D.)

Skeletal tuberculosis outside of the axial skeleton usually affects the major joints, particularly the hip and knee. Isolated joint infections, unusual in childhood, are initially characterized by effusion, in addition to synovial proliferation and thickening. In the early stages there are no radio- graphic characteristics that separate tuberculous arthritis from any chronic inflammation of the joint. As with the bone lesions, the hyperemia causes widespread osteopenia, and may cause overgrowth of the epiphyses. The infection proceeds both by pannus formation over the articular cartilage and by erosion of the subchondral bone, beginning at the synovial margins (254). The result is joint space narrowing and subchondral cystic erosion. Early in the process, the clinical and radiologic findings may closely resemble those of JRA or pigmented villonodular synovitis. Laboratory studies, however, should easily separate these entities.

As the infection continues untreated, large amounts of caseous material and pus accumulate and dissect along normal tissue planes. Eventually, a sinus track to the surface is formed—a hallmark of a long-standing neglected case. The abscess formed by tuberculous infection is called a “cold abscess,” because of the lack of any signs of acute inflammation.

Two other presentations occur in childhood. The first, tuberculous dactylitis, may resemble sickle cell dactylitis, with swelling of the phalanges, metacarpals, and metatarsals. Tuberculous dactylitis is usually not very painful, however, and onset is usually consecutive, rather than simultaneous. Before the availability of radiographs, this was called *spina* (Latin for “a short bone”) *ventosa* (meaning “inflated with air”). The radiographs show a cyst-like expansion of the tubular bones, with thinning of the cortex (255). A second presentation is with multifocal cystic involvement of the bone. This is characterized by areas of simultaneous destruction in the shafts of long bones and in flat bones, with a strong tendency to symmetry (256).

The first and most important step in the diagnosis of tuberculous infection of the bone or joint is to consider it as a possibility. In addition, when tuberculosis is diagnosed, underlying HIV infection must also be considered. Tuberculosis should be considered whenever a chronic-appearing bone lesion is encountered. Early diagnosis is important to prevent spread to a contiguous joint. The clinical picture is variable, depending on the location and the stage of the disease. It is characterized by its insidious onset; lack of characteristic inflammatory features, such as erythema; and bone destruction or joint involvement greater than the symptoms would suggest.

Laboratory studies usually show a normal leukocyte count and an elevated ESR. The purified protein derivative skin test usually is positive. Radiographic changes are usually present at the time of presentation. The diagnosis depends on the identification of the organism, *Mycobacterium tuberculosis*. Positive cultures are obtained in 85.5% of patients who have both pulmonary and extrapulmonary disease, in 83.5% of those with only pulmonary disease, and in 76.5% of those who have only extrapulmonary disease (257).

Tuberculosis produces a widespread inflammatory response which may mislead the surgeon in obtaining biopsy material, especially if the synovium is to undergo biopsy. In cases with bone lesions, the granulation tissue filling the cystic bone lesion is the best material for biopsy. In tuberculosis arthritis without bone involvement, the biopsy should be taken from the peripheral junction of the synovium with the bone, or preferably from the junction of the synovium with a cyst (258).

The treatment of skeletal tuberculosis is medical. Surgical debridement of the bone lesions is not necessary for a cure, although drainage of large abscesses often improves the patient's overall constitutional symptoms (256,258,259). In addition, open surgical biopsy is often necessary. Because of the effectiveness of drug therapy, there is little chance that surgical biopsy will lead to sinus formation. It is important to always be aware that superinfection with pyogenic organisms can occur, and this may be a reason for apparent treatment failure with antitubercular drugs. This is particularly true when a sinus has formed (259).

Several studies on tuberculous spondylitis demonstrate that surgery is necessary primarily to treat the kyphosis and not the tuberculosis; many cases do well with only medical management (260,261 and 262). Indications for surgery remain relative, and include neurologic involvement, spinal instability, and failure of medical treatment. Although patients with neurologic involvement can recover with medical management, they seem to do so faster with surgical management (260). Surgical treatment of the kyphosis produces a higher rate of union and less deformity than regimens without surgical stabilization (261,262). Thus, it appears that with contemporary surgical and anesthetic techniques tuberculous kyphosis is best treated early with anterior surgery for debridement and strut grafting. The treatment of spinal instability, especially that spanning more than two disc spaces, is difficult and probably requires both anterior arthrodesis with strut-grafting and posterior arthrodesis with instrumentation (263).

Although the effectiveness of ambulatory drug treatment has been demonstrated (261,262), there is evidence of an increasing incidence of resistant strains, due most likely to inadequate treatment of the initial infection (257). This emphasizes both the need for constant surveillance for drug resistance and the importance of careful supervision of outpatient oral therapy, to be certain that compliance is optimal.

Initial antimicrobial agent selection depends on the likelihood of drug-resistant organisms, whereas long-term selection should be guided by susceptibility testing. In those who are not at high risk for drug-resistant organisms, various regimens of isoniazid, rifampin, and pyrazinamide are recommended (264). In children who come from areas where antibiotics are sold over the counter, where high rates of drug-resistant tuberculosis occur, and when incomplete treatment may have resulted in multidrug-resistant strains, ethambutol or streptomycin should be added to the standard three-drug regimen. Treatment of bone and joint tuberculosis in children should be continued for 1 year.

CHAPTER 14

BONE AND SOFT TISSUE TUMORS

DEMPSEY S. SPRINGFIELD
MARK C. GEBHARDT

D. S. Springfield: Leni and Peter W. May Department of Orthopaedics, Mount Sinai School of Medicine; Department of Orthopaedics, Mount Sinai Hospital, New York, New York 10029.
M. C. Gebhardt: Department of Orthopaedic Surgery, Harvard Medical School, Boston, Massachusetts 02115; Orthopaedic Service, Massachusetts General Hospital, Boston, Massachusetts 02114.

Primary bone and soft tissue tumors in the pediatric age group are uncommon and when they occur, usually benign. There are two primary malignant tumors of bone, osteosarcoma and Ewing sarcoma/peripheral (or primitive) neuroectodermal tumor (PNET), and one soft tissue sarcoma, rhabdomyosarcoma, which occur predominantly in the pediatric patient. The orthopaedist must remain alert because the malignant tumor is an unexpected event, and its infrequency can result in improper or delayed initial management. The orthopaedist who sees pediatric patients, but is not prepared to manage a malignant or aggressive benign musculoskeletal tumor, must be comfortable with evaluating patients with musculoskeletal tumors, and know whom to refer and whom to manage. This chapter reviews the common bone and soft tissue tumors of childhood; it discusses how the patients present, what physical findings to expect, and how the plain radiographs should look; and it suggests additional diagnostic and staging evaluations and treatment. This chapter is not intended to be a definitive text of musculoskeletal pathology, and includes only the more common tumors of childhood.

MOLECULAR BIOLOGY OF TUMORS

Dramatic improvements in the survival of children with previously lethal sarcomas have occurred in the last 30 years from the use of adjuvant chemotherapy. One of the intriguing aspects about childhood sarcomas is that despite similar histologies, stages, and prognostic factors, some patients respond well to treatment, whereas others seem to be resistant to chemotherapy. To date, patients with good prognoses cannot be distinguished from those with poor prognoses except by crude clinical characteristics, such as the presence of metastatic disease at diagnosis. Recent molecular findings in sarcomas may shed light on the biologic behavior of sarcomas and their response to chemotherapy.

One method of seeking genetic alterations in tumors is to examine the chromosomes by karyotype analysis. The identification of recurrent chromosomal abnormalities provides clues regarding sites of potential gene mutations. Normally, there are 23 pairs of chromosomes in the human cell nucleus. Osteosarcomas in general have multiple, bizarre karyotypic abnormalities: Some chromosomes are missing, some are duplicated, and some are grossly altered. All high-grade osteosarcomas studied to date have complex karyotypes and nonclonal chromosome aberrations superimposed on complex clonal events (1,2). Low-grade parosteal osteosarcoma, on the other hand, is characterized by the presence of a ring chromosome, accompanied by no or few other abnormalities. Although it is usually possible to distinguish high-grade from low-grade osteosarcoma by standard histology, in other tumors the karyotype information can be diagnostically useful. In addition to possibly providing prognostic information, the specific chromosomal aberrations provide clues that assist molecular biologists looking for gene mutations (2).

In contrast to osteosarcoma, Ewing sarcomas, PNETs, and alveolar rhabdomyosarcomas have single chromosomal translocations characteristic of their respective histologies. In these tumors, part of one chromosome is transposed to part of another chromosome through a breakpoint. In these tumors, a novel gene and gene protein product are created that presumably give the cell a growth advantage. The most common translocations for these tumors are listed in Table 14-1.

Tumor	Translocation	Genes
Ewing sarcoma/peripheral (or primitive) neuroectodermal tumor	t(11;22)(q24;q12)	*EWS-FLI-1*
	t(21;22)(q22;q12)	*EWS-ERG*
Alveolar rhabdomyosarcoma	t(2;13)(q35;q14)	*PAX3-FKHR*
		PAX7-FKHR

(From ref. 3, with permission.)

TABLE 14-1. CYTOGENETIC FINDINGS IN EWING SARCOMA/PERIPHERAL (OR PRIMITIVE) NEUROECTODERMAL TUMOR AND ALVEOLAR RHABDOMYOSARCOMA

The demonstration of translocations has been useful in the differential diagnosis of round cell tumors. Under the light microscope, there is little to distinguish one of these tumor types from the other, and although immunohistochemistry helps to an extent, it is at times difficult to be sure of the diagnosis. Demonstration of these characteristic karyotypic findings makes pathologists more secure in their diagnosis, and has helped with the classification of these tumors. To perform a karyotype analysis, short-term cultures and metaphase spreads are necessary, but these are labor-intensive and require fresh tissue (4). More recent techniques, with fluorescent *in situ* hybridization and reverse transcriptase-polymerase chain reaction, allow rapid analysis for the presence of translocations, and these techniques can be performed on frozen and sometimes paraffin-embedded tissue (5,6).

These translocations have import beyond establishing the diagnosis. For several years, the distinction between Ewing sarcoma and PNET was difficult, and clinicians were not sure whether to treat them differently. The observation that both Ewing sarcoma, a poorly differentiated mesenchymal tumor of uncertain cell lineage, and PNET, a tumor believed to be of neural crest origin, shared the same chromosomal translocation led pathologists to believe that both were related neuroectodermal tumors (7,8). There is debate regarding whether one or the other has a better prognosis, but the treatment strategies used today are the same for both tumors (9,10

and 11).

More recently, these markers have been used in staging and follow-up of high-risk patients (12). Using reverse transcriptase-polymerase chain reaction technology, one can detect small numbers of tumor cells in a bone marrow or peripheral blood cell population. This makes the interpretation of bone marrow aspirates more precise, and may provide a means of earlier detection of relapses after treatment. It is hoped that the gene products of these translocations can also be used in treatment strategies. Because the novel genes formed from the translocation make a novel protein that normal cells do not make, antibodies or targeted T cells can be generated to specifically kill tumor cells. This is being tried in early-phase trials of relapsed patients with rhabdomyosarcoma and Ewing sarcoma/PNET, and if it works, it may be a way of treating patients who fail standard drug therapy.

Genetic alterations in the DNA of sarcomas have been well demonstrated. Mutations in genes, called “oncogenes,” give some evidence relative to the pathogenesis of these tumors, and may have some prognostic and therapeutic import (13,14). Oncogenes are normal cellular genes (*protooncogenes*) that are necessary for the normal development and function of the organism (15). When they are mutated, they may produce a protein capable of inducing the neoplastic state. Oncogenes act through a variety of mechanisms to deregulate cell growth. This is obviously a very complex process and may involve more than one genetic event.

There are two categories of oncogenes: *dominant oncogenes* and *tumor-suppressor genes* (15). The dominant oncogenes encode proteins that are involved in signal transduction, i.e., transmitting an external stimulus from outside the cell to the machinery controlling replication in the cell nucleus. Mutant cellular signal transduction genes keep the cell permanently “turned on.” The protein products of oncogenes also function as aberrant growth factors, growth factor receptors, or nuclear transcription factors. These types of genes seem to have a lesser role in osteosarcomas.

A second class of genes, the tumor suppressor genes, are genes that encode proteins whose normal role is to restrict cell proliferation (16,17,18,19 and 20). They act as brakes rather than accelerators of growth. Their normal role is to regulate the cell cycle and keep it in check.

The retinoblastoma gene (*RB1*) was the first gene recognized in this class (21,22). Osteosarcomas are very frequent in patients with hereditary retinoblastoma, both in the orbit and in the extremities, unrelated to irradiation. It was subsequently learned that osteosarcomas in these patients as well as spontaneous osteosarcomas carry mutations or deletions of the *RB1* gene. It was one of the first clues that osteosarcomas had a genetic cause. It is estimated that approximately 60 to 75% of sporadic osteosarcomas have an abnormality of the *RB1* gene, or do not express a functional RB1 product (14). The retinoblastoma gene is located on the long arm of chromosome 13 (13q14), and is 200 kilobases in length. Its product is a 105- to 110-kilodalton nuclear phosphoprotein (pRB) that appears to have a cell cycle regulatory role. The retinoblastoma protein acts as a signal protein to connect the cell cycle with the transcription of genes that mediate the cell cycle. Deactivation of the *RB1* gene or absence of pRB allows cells to enter the cell cycle in an unregulated fashion, a condition that imparts a growth advantage to the affected cell. It should be noted that one copy of the gene is sufficient for a normal phenotype. A child born with a normal and a mutant or absent allele will not manifest retinoblastoma until some event occurs in retinoblasts to alter the normal allele. If both copies thus become deranged, the normal check on the cell cycle disappears and the conditions for the neoplastic state are met.

The second tumor suppressor gene to be identified was the *p53* gene (23,24 and 25). Located on the short arm of chromosome 17 (17p), its product is a nuclear phosphoprotein that has a cell cycle regulatory role similar to that of the Rb protein. Like RB, inactivation of p53 gives the cell a growth advantage, probably as a result of loss of cell cycle regulation. p53 may be inactivated by a variety of mutations, including a single base change (point mutation) that increases the half-life of the protein, allelic loss, rearrangements, and deletions of the *p53* gene. Each of these mechanisms can result in tumor formation by loss of growth control. It is estimated that about 25% of osteosarcomas have detectable mutations of the *p53* gene (26).

The *p53 protein* is a transcription factor, meaning that it binds to regions of other genes (DNA), and controls the expression of genes responsible for cell cycle control (cell growth), apoptosis (programmed cell death), and other metabolic functions, such as control of repair of DNA damage. p53 acts in concert with Rb, and a variety of other proteins, to regulate the cell cycle by a complex cascade of enzymes, of which Rb probably has the central role. Apoptosis has recently become recognized as an important mechanism by which chemotherapy and radiotherapy kill cancer cells. p53 is involved in this process, and appears to arrest cell division after sublethal damage (e.g., by radiation), to give the cell time to repair DNA defects before the next division (27,28 and 29). If repair does not take place, the cell undergoes apoptosis and dies. If p53 is not functional, the cell may survive and accumulate genetic defects, leading to malignant transformation. Osteosarcomas have been shown to have a variety of mutations of the *p53* gene (30,31,32,33,34,35,36,37,38 and 39). Preliminary evidence suggests that overexpression of mutant p53 protein, detected by immunohistochemistry or loss of heterozygosity of the *p53* gene, is related to outcome in human osteosarcoma (40,41).

In sarcomas, genetic defects other than p53 and Rb have been detected. One example is a gene called *mdm-2*, which is a zinc finger protein amplified in some sarcomas (23,42,43 and 44). It inactivates p53 protein by binding to p53, and prevents its transcription factor activity. Cordon-Cardo et al. (45) studied 211 adult soft tissue sarcomas by immunohistochemistry, using monoclonal antibodies to mdm-2 and p53, and demonstrated a correlation between overexpression of mdm-2/p53 and poor survival. Patients without mutations in either gene (mdm-2/p53–) had the best survival, those with one mutation (either mdm-2+/p53– or mdm-2–/p53+) had intermediate survival, and those with mutations in both genes (mdm-2+/p53+) had the worst survival.

Not only are genetic mutations found in the tumors of patients with sarcomas, but mutations may also be present in all somatic cells (*germline mutations*) in patients with heritable cancer (46,47,48,49,50,51,52 and 53). Although such defects do not appear to be common in the general population, germline p53 mutations are present in patients who are part of a familial cancer syndrome. These families have a variety of cancers, often at an early age, and osteosarcomas and soft tissue sarcomas are a fairly common occurrence in these kindreds. Identification of patients with p53 germline mutations can be useful in determining which patients in an affected family are at risk for developing cancers, but much more work is needed in genetic counseling to determine how best to use this information. A recent study showed that germline mutations were present in approximately 3 to 4% of children with osteosarcoma, and that the detection of these mutations was more accurate than family history in predicting family cancer susceptibility (54).

How is this information useful for treatment? One possibility is that p53 mutations may be a potential biologic marker of prognosis and response to treatment (chemotherapy). There is some preliminary evidence that p53 mutations in the tumor may portend a worse prognosis in osteosarcoma. More recently, the association of p53 and apoptosis has suggested possible strategies for chemotherapy, based on the status of the p53 pathway (28,29). Gene therapy (replacing the missing or mutated gene by transfection with viral carriers) is often discussed, but there are major technical hurdles to overcome before this technology can be used to treat cancers in humans. However, it might be possible to make tumor cells more antigenic, or to make them more sensitive to antineoplastic drugs, by gene transfer. Another strategy would be to alter normal cells to make them less sensitive to damage by chemotherapeutic agents. Currently, these techniques pose technical challenges, but they offer realistic promise for the near future.

Another exciting area in the molecular biology of sarcomas is multidrug resistance (MDR). MDR probably explains why some patients respond to chemotherapy and others do not. Drug resistance may be intrinsic (present at diagnosis) or acquired (appearing after treatment of a tumor) (55,56). At least four basic mechanisms of drug resistance are now recognized under the category of the MDR phenotype. They are (a) changes in glutathione metabolism, (b) alterations in topoisomerase II, (c) non–P-glycoprotein (P-gp)-mediated mechanisms, and (d) P-gp-mediated mechanisms (1,2). Recent evidence has suggested that P-gp may be of particular relevance to osteosarcoma.

P-gp is a glycoprotein encoded by the MDR-1 gene on the long arm of chromosome 7 in humans (55,57,58). MDR-1 is one member of the aneurysmal bone cyst (ABC) superfamily of genes that encode membrane transport proteins, which function as unidirectional membrane pumps using adenosine triphosphate hydrolysis to work against a concentration gradient. P-gp is a 170-kilodalton protein located in the cell membrane that functions as an energy (adenosine triphosphate)–requiring pump that excludes certain classes (amphipathic compounds) of drugs from the cell. This physiologic mechanism is believed to be important in certain organ systems, such as the blood–brain barrier, placenta, liver, kidney, and colon for ridding the cell of unwanted toxins, but it is also responsible for actively excluding chemotherapeutic agents, such as *Vinca* alkaloids, anthracyclines, colchicine, etoposides, and taxol (many of which are active in osteosarcoma protocols) from the cancer cell. Another feature of the P-gp mechanism which may have some relevance to therapeutic strategies is that some classes of drugs can reverse the MDR phenotype by blocking the action of the pump. These drugs include verapamil, cyclosporin A, tamoxifen, and others.

Several studies have demonstrated that some (25 to 69%) sarcomas display the MDR phenotype at diagnosis, and that relapsed sarcomas show higher incidence and intensity of MDR expression (59,60,61,62,63 and 64). These studies suffer from small numbers of patients and a variety of methods by which MDR was tested, so comparisons of studies and accurate determination of the incidence of MDR expression are difficult to accomplish. In addition, the age of the patient and the sarcoma type appear to be related to the incidence of detectable P-gp at diagnosis. One study showed that osteosarcomas have a higher incidence of MDR than other types of adult sarcomas (65). Serra et al. (61) demonstrated that overexpression of P-gp protein was evident in 23% of primary and 50% of metastatic osteosarcomas.

Recently, Baldini et al. (66) reported on 92 patients with nonmetastatic extremity osteosarcoma treated with chemotherapy and surgery, and related immunohistochemically determined P-gp expression to event-free survival. They found that P-gp expression predicted a decreased probability of remaining event-free, and was more predictive than histologic response to preoperative chemotherapy.

Findings such as these are important in planning future protocols in human osteosarcoma. The drug-resistant tumor is becoming better identified as one that has a poor histologic response to preoperative chemotherapy and that expresses P-gp. Undoubtedly, it is more complex than this, and other mechanisms will pertain. Several caveats exist. One is the complexity of defining the resistant tumor. Preoperative chemotherapy requires 10 to 12 weeks to provide an estimate of histologic necrosis unless ways can be found to accurately predict percentage of necrosis by positron emission tomographic scans, thallium scans, and/or gadolinium-enhanced magnetic resonance imaging. Detection of P-gp at diagnosis is difficult, and no one method has proven superior. It is probably not sufficient to demonstrate the presence of P-gp; also important is whether the pump is functioning to exclude cytotoxic agents from the tumor cell. Ideally, one would like to reverse the action of the P-gp mechanism, but just as there are not new agents to rescue patients who have poor histologic response, the agents currently available to reverse MDR are of limited benefit. They are potentially problematic in that they make the normal cell less tolerant to chemotherapy, and thereby increase toxicity, and in other tumors their use has not proven to be effective (56,58). The future probably lies in developing more effective reversing agents, and in defining other drug-resistant mechanisms.

EVALUATION

The differential diagnosis for patients who present with a bone or soft tissue mass includes neoplasia, infection, and trauma. Infection and trauma are more common than neoplasia, and one of these is usually the explanation of a mass or abnormality seen on a radiograph. Neoplasia should not be forgotten. The consequences of the mismanagement of a patient with a musculoskeletal tumor can be grave (Fig. 14-1).

FIGURE 14-1. Anteroposterior radiograph of the knee of a young man who complained of it “giving way.” The orthopaedist who saw the patient suspected a derangement, and the patient eventually had arthroscopic surgery. A radiolucent lesion can easily be seen in the lateral aspect of the proximal tibial metaphysis and epiphysis. This giant cell tumor of bone was missed because the physician did not consider this diagnosis when he was examining the patient or the radiograph. By the time the tumor was recognized, it had grown so large that resection and allograft reconstruction were required. Had it been treated when this radiograph was taken, a curettage and bone graft packing, or polymethyl methacrylate packing probably would have been done.

Chief Complaint

Pain is the most common presenting complaint of a patient with a musculoskeletal tumor. The characteristics of the pain can help determine the diagnosis. Ask the patient: Where is the pain? How did it begin? Is it sharp, dull, radiating, or constant? Is it associated with activity? Is there a particular activity that makes the pain worse? What makes the pain better? Does it wake you at night? Is the intensity of the pain increasing, staying the same, or diminishing?

Patients who have active benign tumors (e.g., ABCs, chondroblastoma, and chondromyxofibroma) usually have a mild, dull, slowly progressive pain that is worse at night and aggravated by activity. Patients with malignant musculoskeletal tumors complain of a more rapidly progressive symptom complex, not specifically related to activity, which often awakens them at night. Occasionally, the pain pattern is diagnostic. The pain of an osteoid osteoma is so typical that the diagnosis should be strongly suspected from the history. This pain is a constant intense pain that is worse at night, and it is almost always relieved by aspirin or nonsteroidal antiinflammatory drugs (NSAIDs). The pain caused by a Brodie abscess is similar to that of an osteoid osteoma, but the Brodie abscess pain is rarely relieved by aspirin.

Most children and parents date the onset of symptoms to a traumatic event. The specific nature of the trauma and the relation of the trauma to the current symptoms must be evaluated thoroughly. Trauma without a definitive fracture can be the explanation for an abnormal radiograph but should not be used as the explanation, even for a periosteal reaction, unless the history is perfectly consistent. With the increased level of organized sports for children, there has been an increased incidence of fatigue fractures, and these fractures can be confused with neoplasias. Be cautious about ascribing a lesion to trauma.

The child presenting with a fracture should be questioned about the specifics of the injury that produced the fracture. Most lesions that lead to a pathologic fracture are easily recognized on a plain radiograph, but occasionally they may not be obvious. When the traumatic event seems insignificant, a pathologic fracture should be suspected. The patient should be asked about symptoms, no matter how minimal, before the fracture. Most aggressive benign tumors and malignant tumors produce pain before the bone is weakened enough to fracture. Inactive benign tumors are almost always asymptomatic until the bone breaks.

Medical History

Most children have no significant past medical history, but inquiries should be made. Has the child had a previous fracture? Has the child had other illnesses? Have radiographs been taken previously? Do not assume that the patient or the family will volunteer significant past medical history. Ask specific questions.

Review of Systems

Ask specifically about systemic symptoms of fever, decreased appetite, irritability, and decreased activity. Most patients with musculoskeletal tumors do not have systemic symptoms, and the presence of a systemic illness should alert the physician to the possibility of an underlying generalized disorder or osteomyelitis. Patients with Ewing sarcoma may have elevated temperature, weight loss, and malaise, but this is the exception rather than the rule. Even children with large primary malignant musculoskeletal tumors usually appear healthy. Patients with cancer do not always present with obvious signs of the underlying malignancy.

Most children with a soft tissue mass do not have symptoms. If the patient is younger than 5 years of age, the mass usually is noted first by a parent. The parent is convinced that the mass appeared overnight, but this is rarely the case. Teenagers may report the presence of a mass, but often only after a few weeks or months of waiting for it to resolve spontaneously. Painful soft tissue masses are most often abscesses. The majority of even malignant soft tissue tumors do not produce significant symptoms until they are large. Although most of the soft tissue masses seen in children prove to be benign, all soft tissue masses, even those in children, should be considered malignant tumors until proven otherwise. The consequences of mistaking a malignant soft tissue tumor for a benign tumor can be devastating, whereas the consequences of approaching a benign tumor as if it were a malignancy are minimal.

Physical Examination

All patients with musculoskeletal complaints, especially those in the pediatric age group, should have a complete physical examination. Not only can important information be gained about the specific disorder being evaluated, but other significant abnormalities may be found. Cafeé-au-lait lesions of the skin are a clue that the patient has fibrous dysplasia or neurofibromatosis. Numerous hard, nontender, fixed masses near the ends of long bones are diagnostic of multiple

osteochondroma. Exophthalmos and otitis media indicate that the patient has Hand-Schüller-Christian disease.

The affected extremity should be examined carefully. The gait pattern should be recorded, muscular atrophy measured, and abnormalities in the vascular supply and motor and sensory innervation noted. The range of motion of the adjacent joint should be measured. If there is a mass present it should be measured, and the presence of erythema, tenderness, pulsations, bruit, or increased temperature should be noted.

Soft, movable, nontender masses, especially those in the subcutaneous tissues, usually are benign. These can be felt best when lubricant is applied on the overlying skin. Firm-to-hard, fixed or tethered, tender masses, especially those deep to the superficial fascia, are more likely to be malignant, but neurofibroma, deep lipoma, and cyst usually are firm to the touch. Transilluminate the mass; if light is transmitted more easily through the mass than through the surrounding tissue, the mass is a fluid-filled cyst.

Plain Radiograph Examination

Patients with musculoskeletal complaints should have at least anteroposterior and lateral plain radiographs. Good-quality plain radiographs (at least two views, preferably at 90 degrees) are necessary. The entire lesion must be observed. The radiograph should be reviewed systematically. Look at the bone, all of it, and every bone on the radiograph. Ask yourself these questions: Is there an area of increased or decreased density? Is there endosteal or periosteal reaction, and if there is, what are the characteristics of the reaction? Is there cortical destruction? Is it localized or are there multiple defects? Is the margin in the tumor well defined or poorly defined? Is there a reactive rim of bone surrounding the lesion? Are there densities within a radiolucent lesion? Is the bone of normal, increased, or decreased overall density? Is the joint normal? Is there loss of articular cartilage? Is the subchondral bone normal, thick, or thin? Are there abnormalities in the bone on both sides of the joint? Are there intraarticular densities? Is there a soft tissue mass? Are there calcifications or ossifications in the soft tissue? By looking specifically for abnormalities, it is unlikely that an abnormality will be missed. The pelvis and the scapula are exceptions to this rule. Large tumors involving the pelvis or the scapula, even those with marked destruction of bone, can be extremely difficult or impossible to see on a plain radiograph. If there is a suggestion that the patient has a pelvic or a scapular tumor, bone scanning and computed axial tomography (CT) or magnetic resonance imaging (MRI) are recommended.

Enneking (67) teaches that four sets of questions should be asked when looking at plain radiographs of a possible bone tumor.

1. Where is the tumor? This refers to the lesion's anatomic location: long bone or flat bone; epiphyseal, metaphyseal, or diaphyseal; and medullary canal, intracortical, or surface.
2. What is the tumor doing to the bone? Is there erosion of the bone, and if so, what is the pattern?
3. What is the bone doing to the tumor? Is there periosteal or endosteal reaction? Is it well-developed? Is it sharply defined?
4. Are there intrinsic characteristics within the tumor that indicate its histology? Is there bone formation by the tumor? Is there calcification? Is the lesion completely radiolucent?

The examination of a radiograph should not be a casual glance, but a detailed study of all tissue present. Do not forget to specifically examine the soft tissues visible on the radiograph.

Most bone tumors can be diagnosed correctly after obtaining the history, performing a physical examination, and examining the plain radiograph. When the specific diagnosis is made from these examinations, additional studies are requested only if they are necessary for treatment. Specific treatment often can be planned from only the history, physical examination, and plain radiographs. For example, a 16-year-old boy with a hard, fixed mass in the distal femur that has not increased in size for more than 1 year, and has been present for 9 years, complains of pain after direct trauma to this mass. Plain anteroposterior and lateral radiographs confirm the clinically suspected diagnosis of osteochondroma. Further evaluation to make the diagnosis is not necessary, but if surgical resection is elected as the treatment, CT or MRI may be useful in planning the operative procedure.

When the specific diagnosis cannot be made, it should be possible to limit the differential to three or four diagnoses, and appropriate additional evaluations can be requested. CT, MRI, nuclear bone scanning (technetium, gallium, thallium, and indium), and positron emission tomography may reveal findings that are diagnostic, or that provide needed information with which to plan a subsequent biopsy. For example, a 10-year-old boy complains of mild knee pain that has been present for 3 months, has loss of knee flexion, and on the lateral radiograph of the distal femur there is a bone density lesion attached to the posterior femoral cortex. From this information, the lesion is recognized as either a parosteal osteosarcoma or an osteocartilaginous exostosis. A technetium bone scan, with increased activity in the area of the lesion does not distinguish between these two, but both CT and MRI allow one to distinguish between a parosteal osteosarcoma and an osteocartilaginous exostosis. A parosteal osteosarcoma is attached to the cortex of the bone, whereas an osteocartilaginous exostosis arises from the cortex, and has a medullary canal continuous with the medullary canal of the bone. CT or MRI is critical in the evaluation of a patient in this clinical setting.

Additional Diagnostic Studies

Laboratory Examinations

Urine and serum laboratory values in musculoskeletal neoplasia are usually normal. Only a few musculoskeletal disorders are associated with abnormal laboratory values. The erythrocyte sedimentation rate (ESR), or sedimentation rate, is nonspecific but sensitive. Patients with infections or malignant tumors usually have an elevated ESR, but patients with benign disease should have a normal value. A normal ESR value can be used to increase the physician's confidence that a suspected benign, inactive lesion is just that. A markedly elevated value (>180 mm/h) supports a diagnosis of infection, and may be just what is needed to justify an early aspiration of a bone or soft tissue lesion. Patients with active benign or malignant musculoskeletal tumors, particularly those with Ewing sarcoma, often have an elevated ESR, but it is rarely greater than 80 mm/h. C-reactive protein is another serum value that indicates systemic inflammation. It increases and returns to normal more quickly that ESR.

Serum alkaline phosphatase is present in most tissues in body, but the bone and the hepatobiliary system are the predominant sources. In the pediatric age group conventional high-grade osteosarcoma is associated with elevated serum alkaline phosphatase (68). Not all patients with osteosarcoma have elevated serum alkaline phosphatase, and therefore, a normal value does not exclude osteosarcoma from the diagnosis. A minimal elevation can be observed with numerous processes, even a healing fracture. Adults with elevated serum alkaline phosphatase secondary to bone disease are most likely to have Paget disease of bone or diffuse metastatic carcinoma. Patients with a primary liver disorder have elevated serum alkaline phosphatase as well, but they also have elevated serum 5-nucleotidase, elevated leucine aminopeptidase, and glutamyl transpeptidase deficiency. These are not elevated in primary bone tumors.

Serum and urine calcium and phosphorus should be measured, especially if a metabolic bone disorder is suspected. Serum lactic dehydrogenase (LDH) is elevated in some patients with osteosarcoma, and Ewing sarcoma patients with elevated levels have a worse prognosis (69,70 and 71). Elevated LDH may also indicate relapse in a patient who has been treated for these tumors. Patients entering chemotherapy treatment protocols will need to have LDH levels determined to stratify them on the protocol. Other laboratory determinations are not helpful, and are not recommended.

Radionuclide Scans

Technetium bone scanning is readily available, safe, and an excellent method to evaluate the activity of the primary lesion (Fig. 14-2). In addition, bone scanning is the most practical method to survey the entire skeleton. Technetium 99 attached to a polyphosphate is injected intravenously, and after a delay of 2 to 4 h the polyphosphate, with its attached technetium, concentrates in the skeleton proportional to the production of new bone. A disorder that is associated with an increase in bone production increases the local concentration of technetium 99 and produces a “hot spot” on the scan. The technetium bone scan can be used to evaluate the activity of a primary lesion, to search for other bone lesions, and to indicate extension of a lesion beyond what is seen on the plain radiograph. The polyphosphate–technetium 99 compound also concentrates in areas of increased blood flow, and soft tissue tumors usually have increased activity compared with normal soft tissues. The technetium scan can be used to evaluate blood flow if images are obtained during the early phases immediately after injection of the technetium. The polyphosphate–technetium 99 is cleared and excreted by the kidneys, so the kidneys and the bladder have more activity than other organs. The technetium scan is sensitive but nonspecific. The principal value of a radionuclide scan is as a means of surveying the entire skeleton for clinically unsuspected lesions. In approximately 25% of cases of Langerhans cell histiocytosis and plasmocytoma, the bone scan is normal, or there is decreased activity at the site of the lesion (72,73 and 74).

FIGURE 14-2. This is an anterior view of a whole body technetium 99 bone scan. This patient has an osteoid osteoma of her talus, and there is increased activity in the talus. There is also increased activity in the distal tibia, which is thought to be a reaction to the local increased blood flow. Technetium 99 bone scanning is an efficient means of evaluating the entire skeleton of a patient with a bone lesion. It is important to have the entire skeleton scanned, rather than limit the scan to a small part of the skeleton.

Gallium 67 imaging is another radionuclide study to evaluate both bone and soft tissue tumors (75). This examination takes longer to perform (24 to 72 h) than technetium 99 scanning (2 h), but it is believed to be useful in the evaluation of musculoskeletal tumors (76) because it can help differentiate a musculoskeletal infection from a neoplasia. Gallium scans are most useful when evaluating a patient suspected of having an occult infection. Scanning should be performed before a surgical procedure, because the operative site has increased uptake on the radionuclide scan.

Thallium scans have been used to evaluate a tumor's response to therapy before resection (77,78). Because thallium uptake correlates well with the vascular supply of a tumor, decreased thallium uptake after therapy is a reflection of tumor necrosis, which is the best evidence that the chemotherapy is working. Unfortunately, to date the accuracy of thallium scanning is not sufficient for it to be completely reliable.

Positron emission tomography (PET) is being used more frequently in the evaluation of musculoskeletal tumors (79). Fluoro-2-deoxy-D-glucose (FDG) PET is the type of PET used most frequently in the musculoskeletal system. Because there is a differential uptake of FDG between neoplastic tissue and normal tissue (neoplastic tissue has greater uptake), it is possible to identify neoplastic tissue on a PET scan. The role of PET in the evaluation and monitoring of patients with musculoskeletal neoplasia is under investigation.

Computed Axial Tomography

When introduced in the late 1970s, CT dramatically improved the evaluation of bone and soft tissue tumors. Anatomic location and extent could be determined accurately. This improved the accuracy of anatomic localization, so that less radical surgery can be performed safely. Often, a specific diagnosis can be made or a suspected diagnosis can be confirmed after seeing the CT scan. Smaller nodules are seen on whole-lung CT scans than are seen with plain chest radiographs or whole-lung linear tomographs. With CT the abdomen can be evaluated thoroughly without surgical exploration.

The most common error made when requesting CT is not asking specific questions of the radiologist. Radiologists do not know what specific information the orthopaedist wants; only if specific questions are asked is the maximum value of CT realized. A specific differential diagnosis should be made from the presentation and plain radiographs. Only then can a decision be made regarding whether to request CT, MRI, both, or neither. Ask the radiologist to determine the lesion's location and its density and vascularity, and to search for intralesional characteristics that may provide a diagnostic clue. Have the radiologist include the contralateral normal extremity on the CT scan for comparisons.

The density of a bone or soft tissue mass on a CT scan is called its “attenuation coefficient” and is measured in Hounsfield units (HU) (Fig. 14-3). The density of water is 0 HU; tissues more dense than water have a positive value, and tissues less dense than water have a negative value. The vascularity of a lesion can be evaluated by measuring the increase in the attenuation coefficient of a lesion after intravenous infusion of contrast, and comparing this increase to that in an adjacent muscle. Normal muscle has an attenuation coefficient of approximately 60 HU, and increases 5 to 10 HU with a bolus of intravenous contrast. Fat has an attenuation coefficient of approximately –60 HU, and cortical bone usually has a value of more than 1,000 HU.

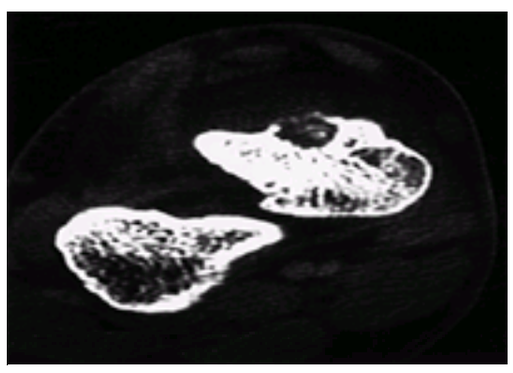

FIGURE 14-3. The density of a lesion can be measured on a computed tomography scan. This cortical bone lesion is an osteoid osteoma. The radiologist can measure the actual density of the lesion and provide information regarding the type of tissue. The measurements are made in Hounsfield units, after a developer of computed tomography. Zero Hounsfield units is the density of water. Negative units are less dense than water (fat measures approximately –70 Hounsfield units), and positive units are more dense than water (cortical bone measures greater than 1,000 Hounsfield units).

CT can be performed quickly with the newer “spiral” scanners and is less anxiety-producing, so sedation is less likely to be needed compared with MRI. CT remains most useful in the evaluation of small lesions in or immediately adjacent to the cortex (e.g., osteoid osteoma on the surface) and lesions with fine mineralization or calcifications (e.g., chondroblastoma). Percutaneous biopsies of musculoskeletal lesions can be performed with the assistance of localization obtained with CT. For all other situations, MRI has replaced CT.

Magnetic Resonance Imaging

MRI does not expose the patient to radiation, and has proved to be the most useful tool in the evaluation of musculoskeletal lesions. MRI produces images of the body in all three planes (axial, sagittal, and coronal) as easily as in a single plane, and possesses no known hazards to the patient.

The images are produced by a computer program that converts the reactions of tissue hydrogen ions in a strong magnetic field excited by radio waves. By adjusting excitation variables, images that are T1- and T2-weighted are obtained. A variety of techniques have been used to produce images of improved quality compared with routine T1- and T2-weighted images. The use of gadolinium as an intravascular contrast agent allows one to judge the vascularity of a lesion, providing even more information about the tumor. Fat suppression images with gadolinium enhancement often are especially useful to demonstrate a soft tissue neoplasia. As with CT, it is important for the orthopaedist requesting MRI to discuss the case with the radiologist. The radiologist can then determine the optimal setting to see the lesion.

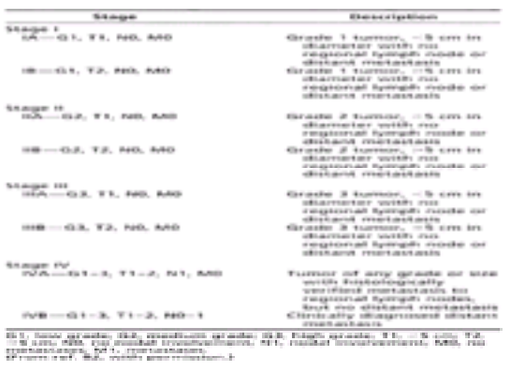
MRI is the single most important diagnostic test after physical examination and plain radiography for evaluating a musculoskeletal lesion. The ability to view the lesion in three planes, determine its intraosseous extent, see the soft tissue component clearly, and have an idea of the tissue type from one diagnostic test makes MRI a powerful tool (80). Unfortunately, variations in technique mean that it is important that the examination be planned carefully if the most information possible is to be

obtained (see Chapter 3). The radiologist must understand what questions need to be answered from the MRI. As a rule, it is important that the image be reviewed while it is being made, to ensure that the entire lesion is examined. Image the entire bone. T1-weighted (with and without gadolinium), T2-weighted, and fat-suppression techniques are the minimal images needed.

Staging

Patients with neoplasia can be separated into groups based on the extent of their tumor and its potential for metastasis. These groups are called stages. Grouping patients by their stage helps the physician predict a patient's risk of local recurrence and metastasis. This facilitates making treatment decisions about individual patients and helps in the comparison of treatment protocols. Staging systems are based on the histologic grade of the tumor, the tumor's size and location, and the presence of regional or distant metastasis. The presence of a metastasis at the time of presentation is a bad prognostic sign, and, regardless of other findings, puts the patient in the highest-risk stage. For patients without metastasis at presentation, the histologic grade of the tumor is the principle prognostic predictor. Size is next in importance. Higher histologic grade and larger tumors are associated with the worst prognosis.

There are two common staging systems used for musculoskeletal tumors. The task force on malignant bone tumors of the American Joint Commission on Staging and End Result Studies published a staging system for soft tissue tumors in 1977 (81). This system was revised in 1987 (82,83). This staging system is based on the histologic grade (G), local extent or size (T), whether or not there is involvement of nodes (N), and metastases (M). The tumors are separated into three histologic grades (G1, low grade; G2, medium grade; G3, high grade) and two sizes (T1 for less than 5 cm, T2 for equal to or greater than 5 cm). Patients with nodal involvement are designated N1, and those without nodal involvement are designated N0. Patients with metastatic disease are designated M1, and those without metastatic disease are designated M0. There are four stages, with subclasses in each stage. The patient with stage 1 has the best prognosis, and the patient with stage 4 has the worst prognosis (Table 14-2).



Stage	Description
Stage I	
IA—G1, T1, N0, M0	Grade 1 tumor, <5 cm in diameter with no regional lymph node or distant metastasis
IB—G1, T2, N0, M0	Grade 1 tumor, >5 cm in diameter with no regional lymph node or distant metastasis
Stage II	
IIA—G2, T1, N0, M0	Grade 2 tumor, <5 cm in diameter with no regional lymph node or distant metastasis
IIB—G2, T2, N0, M0	Grade 2 tumor, >5 cm in diameter with no regional lymph node or distant metastasis
Stage III	
IIIA—G3, T1, N0, M0	Grade 3 tumor, <5 cm in diameter with no regional lymph node or distant metastasis
IIIB—G3, T2, N0, M0	Grade 3 tumor, >5 cm in diameter with no regional lymph node or distant metastasis
Stage IV	
IVA—G1–3, T1–2, N1, M0	Tumor of any grade or size with histologically verified metastasis to regional lymph nodes, but no distant metastasis
IVB—G1–3, T1–2, N0–1	Clinically diagnosed distant metastasis

G1, low grade; G2, medium grade; G3, high grade; T1, <5 cm; T2, >5 cm; N0, no nodal involvement; N1, nodal involvement; M0, no metastases; M1, metastases.

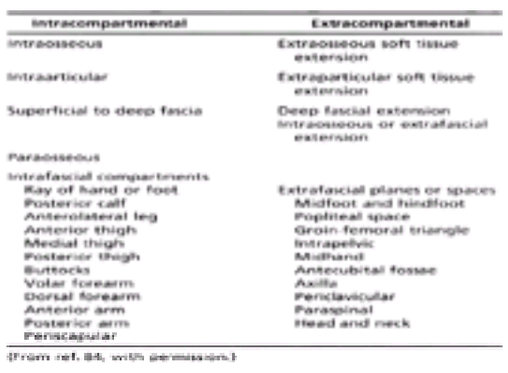
TABLE 14-2. REVISED AMERICAN JOINT COMMISSION STAGING SYSTEM FOR SOFT TISSUE SARCOMA

Enneking and colleagues (84) also proposed a musculoskeletal staging system. This system is used more often by orthopaedists involved in the management of patients with musculoskeletal tumors. It was designed to be simple, straightforward, and clinically practical. The tumors are separated into only two histologic grades (I, low grade; II, high grade) and two anatomic extents (A, intracompartmental; B, extracompartmental). Patients with metastatic disease in either a regional lymph node or a distant site are grouped together as stage III. Each bone is defined as its own separate anatomic compartment. The soft tissue anatomic compartments are defined as muscle groups separated by fascial boundaries (Table 14-3). There are five stages in this system (Table 14-4).



Intracompartmental	Extracompartmental
Intraosseous	Extraosseous soft tissue extension
Intraarticular	Extraarticular soft tissue extension
Superficial to deep fascia	Deep fascial extension Intraosseous or extrafascial extension
Paraosseous	
Intrafascial compartments	
Ray of hand or foot	Extrafascial planes or spaces
Posterior calf	Midfoot and hindfoot
Anterolateral leg	Popliteal space
Anterior thigh	Groin femoral triangle
Medial thigh	Intrapelvic
Posterior thigh	Midhand
Buttocks	Antecubital fossae
Volar forearm	Axilla
Dorsal forearm	Periclavicular
Anterior arm	Paraspinal
Posterior arm	Head and neck
Periscapular	

(From ref. 84, with permission.)

TABLE 14-3. SURGICAL SITES

Stage	Grade	Site and Size
IA	Low	Intracompartmental (T1)
IB	Low	Extracompartmental (T2)
IIA	High	Intracompartmental (T1)
IIB	High	Extracompartmental (T2)
III	Any grade; regional or distant metastasis	Any site or size

T1, <5 cm; T2, ≥5 cm.
(From ref. 84, with permission.)

TABLE 14-4. SURGICAL STAGES

Enneking and colleagues (84) also introduced four terms to indicate the surgical margin of a tumor resection. These terms are commonly used, and provide a means of describing the relation between the histologic extent of the tumor and the resection margin. The surgical margins are defined as intralesional, marginal, wide, and radical. An intralesional margin is the surgical margin achieved when a tumor's pseudocapsule is violated and gross tumor is removed from within the pseudocapsule. An incisional biopsy and a curettage are two common examples of an intralesional margin. A marginal surgical margin is achieved when a tumor is removed by dissecting between the normal tissue and the tumor's pseudocapsule. This is a surgical margin obtained when a tumor is “shelled out.” A wide surgical margin is achieved when the tumor is removed with a surrounding cuff of normal, uninvolved tissue. This is often referred to as *en bloc* resection. A radical surgical margin is achieved when the tumor and the entire compartment (or compartments) are removed together. This usually is accomplished only with an amputation that is proximal to the joint just proximal to the lesion (e.g., an above-knee amputation for a tibial tumor). As a rule, benign lesions can be managed with an intralesional or marginal surgical margin, but malignant tumors require a wide surgical margin. Radical surgical margins are reserved for recurrent tumors and the most infiltrative malignancies.

Biopsy

Biopsy should be the last step in the evaluation of a patient with a bone or soft tissue tumor, and it should be performed only after careful planning (85,86 and 87).

Often, biopsy proves unnecessary after the patient has been thoroughly evaluated, the diagnosis having been made by the clinical setting and radiographic findings. When a biopsy is required, the prebiopsy evaluation improves the chance that adequate and representative tissue will be obtained, the least amount of normal tissue will be contaminated, and the pathologist will make an accurate diagnosis. Biopsies performed without an adequate prebiopsy evaluation are more likely to produce unsatisfactory results.

The purpose of the biopsy is to confirm the diagnosis suspected by the physician after the evaluation, or to determine which diagnosis, among a limited differential diagnosis, is correct. In addition to providing confirmation for a specific diagnosis, the tissue obtained must be sufficient for histologic grading. It must be representative of the tumor, and because many musculoskeletal tumors are heterogeneous, the specific site from which the tissue is taken is important. The surgeon who is willing to assume the surgical management of the patient, regardless of the diagnosis, should biopsy the patient's tumor. The biopsy incision and the tissue exposed during the biopsy must be excised with the tumor, if a wide surgical margin resection proves to be necessary. If the surgeon who performs the resection has planned and performed the biopsy, the patient has a better chance of limb salvage and less risk of local recurrence (86). The surgeon should consult with the radiologist and the pathologist before performing the biopsy to get their suggestions of the best tissue to obtain. Discussing the case with the pathologist the day before the biopsy also allows the pathologist to be better prepared when he or she is expected to make a diagnosis from a frozen section.

Needle biopsy and fine-needle aspirate biopsy often are suggested (88,89,90 and 91). Usually, they can be performed without general anesthesia and hospital admission, saving money and the need for general anesthesia. The needle track can be seeded with tumor, and should be excised at the time of the definitive resection. Needle biopsy and fine-needle aspirate biopsy must be planned just as open biopsy is planned, and the responsible surgeon should decide how the biopsy is to be performed. Needle biopsy and fine-needle aspirate biopsy are most useful for lesions whose clinical presentations are diagnostic, and when treatment is either nonsurgical or requires presurgical therapy. Although an experienced pathologist usually can make the correct diagnosis from a well-done needle biopsy or a fine-needle aspirate biopsy, more mistakes are made with these techniques than with open biopsy, and histologic grading can be difficult or impossible without open biopsy (88,89,91).

Plan the biopsy carefully. Think about possible future treatment, especially limb-salvage resection. The skin incision and deep dissection should be made so that they can be resected with the tumor at the time of definitive limb-salvage operation. Longitudinal skin incisions are better than transverse skin incisions. The dissection should be as limited as possible, flaps should not be raised, and neurovascular bundles should not be exposed. The dissection should be through a muscle, not between muscles. The tumor's pseudocapsule and a portion of the tumor should be excised as a block and sent to the pathologist. A frozen section analysis should be done, even when there are no plans for immediate additional surgery. The pathologist should be certain that adequate and diagnostic tissue is available. Only when dense bone is biopsied is it impossible to obtain a frozen section analysis. The pathologist should set aside tissue for subsequent examination with an electron microscope. Some tissue should be kept frozen in the event that immunohistochemistry is required.

A tourniquet can be used during the biopsy, but deflate the tourniquet before closure. The tumor should be manipulated as little as possible, and do not use a compressive bandage to exsanguinate the extremity, but rather elevate the extremity for 3 to 5 min before inflating the tourniquet.

Extra care should be taken to achieve hemostasis before closing the wound. The hematoma from the biopsy may contain tumor cells, and will require resection if surgery is the treatment. The wound can be drained, but the exit site of the drain must be in line with the incision and close to it. The drain track is resected with the tumor and the biopsy incision.

Occasionally an excisional biopsy, rather than an incisional biopsy, is indicated. An excisional biopsy is appropriate when the lesion is small, and can be excised with a cuff of normal tissue. An excisional biopsy may be appropriate even when a major resection is required. If the preoperative evaluation strongly supports the diagnosis of a malignancy, particularly one for which a frozen section analysis will be difficult to do, an excisional biopsy should be considered. The choice between an incisional biopsy and an excisional biopsy usually is easy to make. A clinically obvious exostosis on the proximal tibia should have an excisional biopsy, if it is biopsied at all. A surface osteosarcoma, diagnosed based on the results of plain radiography and CT or MRI, can be excisionally biopsied with a resection. A large aggressive lesion within the distal femur and invading the adjacent soft tissues should be biopsied incisionally. This decision is more difficult when the evaluation reveals a small, active, possibly low-grade malignancy on the proximal humerus or the distal radius. An incisional biopsy exposes uncontaminated tissues to the tumor, and if the tumor proves to be a malignancy, the definitive resection is more complicated. If the lesion can be treated with curettage or a marginal excision, the incisional biopsy leads to the least functional loss. The final decision is made for each patient based not only on the tumor's characteristics, but also on the patient's desires. Some patients want to take the least chances, and are willing to accept the possibility of slight overtreatment, whereas others choose to take one step at a time. It is the surgeon's responsibility to inform the patient so that an informed decision can be made.

An added advantage of the excisional biopsy is that the pathologist is able to examine the entire lesion, improving the accuracy of the pathologic examination. Musculoskeletal tumors often are heterogeneous, and the amount of tissue obtained with an incisional biopsy always is limited. It can be particularly difficult to distinguish active benign cartilage tumors from low-grade chondrosarcomas. When the entire lesion, especially its connection with the adjacent bone and soft tissue, is seen the distinction is made more easily.

A final note of caution is offered with regard to the biopsy: Osteomyelitis is more common than bone tumors, especially in children, and osteomyelitis often mimics neoplasia. The reverse also is true; whenever performing a biopsy, even when the diagnosis seems obvious, culture the tumor and biopsy the infection.

SPECIFIC BONE TUMORS

This text is not designed to be a definitive musculoskeletal pathology text, and only those tumors that are common are discussed. The authors have tried to confine the discussion to pertinent information regarding the tumors, their evaluation, and their treatment.

Bone-forming Tumors

Osteoid Osteoma

Jaffe (92) is credited with the initial description of osteoid osteoma, distinguishing it from a sterile abscess called a Brodie abscess, and from Garré osteomyelitis. It is a benign tumor and accounts for 11% of the benign bone tumors in Dahlin's series from the Mayo Clinic (93). The patient is usually a young boy (males are affected more commonly than females, at a ratio of 3:1; 80% are between 5 and 24 years of age at the time of their initial symptoms) complaining of an intense pain at the site of the lesion.

The pain is an unrelenting, sharp, boring pain, worse at night and, almost without exception, completely relieved by aspirin or NSAIDs. The pain is not related to activity. The pain is thought to be attributable to prostaglandins produced by the nidus. The relief obtained with aspirin and NSAIDs is most likely the result of their ability to block prostaglandin's action. If a patient has the typical pain of an osteoid osteoma, but is not relieved by aspirin, the diagnosis of an osteoid osteoma should be doubted. The patient may have pain before any abnormality appears on the plain radiograph, and often the patient has had an electromyogram, a myelogram, or an arthrogram, before the typical plain radiographic changes are seen. Some patients are suspected of having a psychosomatic disorder before the osteoid osteoma is found.

Osteoid osteomas may arise in any bone, but one-half of them are found in the femur or the tibia, whereas the other half are distributed throughout the rest of the skeleton (Fig. 14-4). The proximal femur is a common site. It is also a site at which it may be difficult to find the lesion. Young patients with persistent pain in the groin, the middle thigh, or the knee should be suspected of having an osteoid osteoma. The other common location of an occult osteoid osteoma is the spine. When osteoid osteoma arises in the spine, usually it is located in the posterior elements (Fig. 14-5). The osteoid osteoma in the spine does not elicit a significant bony reaction, and is very difficult to see on plain radiographs. The patient presents most commonly with a painful scoliosis (94,95). When a patient with scoliosis complains of back pain, osteoid osteoma should be considered. A technetium bone scan is particularly useful when the clinical presentation suggests an osteoid osteoma but the lesion cannot be found on the plain radiograph. It reveals an area of increased uptake, supporting a diagnosis of osteoid osteoma, and shows the lesion's location.

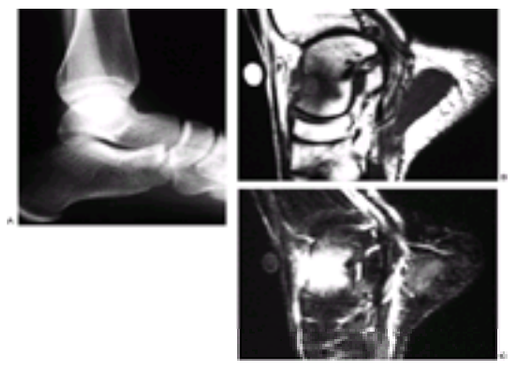


FIGURE 14-4. A: This plain radiograph is a lateral view of an 18-year-old woman's ankle. She complained of severe pain for 6 months, which was totally relieved by aspirin. There is a small erosion in the anterior neck of her talus. (Her computed tomography scan is seen in Fig. 14-3.) **B:** The sagittal view of a T1-weighted magnetic resonance image shows the lesion in her anterior talus. **C:** The T2-weighted magnetic resonance image reveals the extensive edema that is characteristic of osteoid osteoma.

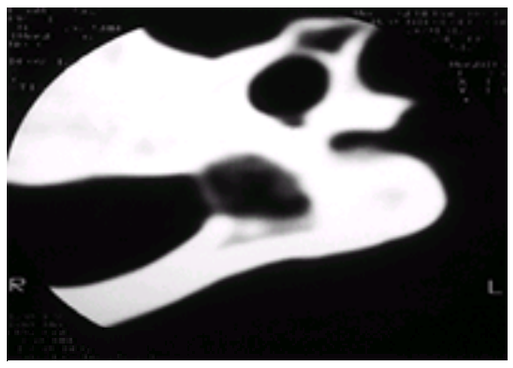

FIGURE 14-5. This is a computed tomography scan cut through a lesion in the pedicle of a teenager with neck pain. The lesion has all of the characteristics of osteoid osteoma. It could not be seen clearly on the plain radiograph, but there was a discrete focus of increased uptake on a technetium 99 bone scan.

Patients with osteoid osteoma show few abnormalities on physical examination, with the exception of scoliosis in patients with osteoid osteoma of the spine. The child may walk with a limp and have atrophy of the involved extremity. If the bone with the osteoid osteoma can be palpated directly, it will be tender. Local erythema or increased temperature are not seen, and joint motion is normal. Serum and urine laboratory values are normal.

The plain radiographic appearance of an osteoid osteoma is of dense reactive bone, and usually is diagnostic. The lesion itself (the nidus, less than 15 mm in diameter) is radiolucent, but often is not seen on the plain radiograph, because of the density of the intense bone reaction that surrounds it. The nidus may be on the surface of the bone, within the cortex, or on the endosteal surface. Lesions on the endosteal surface have less reaction than lesions within or on the cortex. The lesion and the reaction are associated with increased uptake on the radionuclide study (technetium bone scan) (96). The nidus is best demonstrated by CT (97). The distance between the CT scan sections should be small (1 to 2 mm), so that the nidus is not missed. The window settings of the CT scanner should be adjusted so that the dense reaction around the lesion does not obscure the small, low-density nidus. When the nidus is found, it helps to have the distance from a bony landmark to the nidus measured on the scan, so that the nidus can be found at the time of surgical removal. MRI has been used to examine osteoid osteoma, and the diagnosis may be suspected, but the associated edema and reaction make the diagnosis less specific than with CT.

On gross inspection, the nidus of an osteoid osteoma is red and surrounded by dense white bone. The nidus is small, usually not more than 5 to 10 mm in diameter. A lesion that is identical histologically to the nidus of an osteoid osteoma, but larger than 2 cm, is called an osteoblastoma. The nidus is composed of numerous vascular channels, osteoblasts, and thin, lace-like osteoid seams (Fig. 14-6). Multinucleated giant cells can be seen, but are not common.

FIGURE 14-6. Histologic appearance of an osteoid osteoma. The bone tissue on the **left** is reactive trabeculae surrounding the nidus (**right**). The nidus is composed of osteoid, multinucleated giant cells, osteoblasts, and vessels. A thorough curettage of the nidus was done, and the patient's pain resolved completely. (Original magnification ×10.)

The pain of an osteoid osteoma can resolve spontaneously (98). Kneisl and Simon (99) treated 24 patients with osteoid osteoma. Thirteen were operated on immediately, and all had complete relief of pain. Nine were treated with NSAIDs. Three subsequently elected to have surgery, but six eventually became free of pain (an average of 33 months). It is believed that osteoid osteoma is a spontaneously healing lesion that eventually involutes over a period of years, and the nidus completely ossifies. Occasionally, a patient uses aspirin or NSAIDs to control the symptoms until the pain disappears, but most often the intensity of pain, the time it takes for the lesion to heal spontaneously, and the amount of medication required is not tolerable, and the patient elects to have surgery. Complete removal of the nidus relieves the patient's pain. Partial removal may provide temporary relief, but the pain usually returns (100). Only the nidus needs to be excised, whereas the reactive bone around the nidus does not need to be removed.

There are two surgical methods of removing the nidus. The conventional method is a block resection of the nidus and most of the surrounding reactive bone. The other is a curettage of the nidus. The advantage of the block resection is the greater assurance that all of the nidus is removed, but this technique requires removal of a segment of the cortex, and produces a marked reduction in the strength of the bone. The defect created by the excision may need to be bone-grafted, and the patient's extremity may need to be protected for an extended period of time. The advantage of the curettage technique is that the bone is not weakened significantly, and bone grafting is not required. However, with curettage it is more difficult to be certain that all of the nidus is removed.

If curettage is the excision technique used, the nidus must be accurately localized preoperatively, and seen intraoperatively. When the nidus cannot be localized accurately preoperatively, or seen intraoperatively, block excision is preferred. Intraoperative radionuclide scanning and intra operative tetracycline-fluorescence demonstration have been reported as methods of finding the nidus in the operating room and assuring the surgeon of its complete removal (101,102,103 and 104). The authors have not found these techniques necessary. Preoperative planning and careful localization of the nidus is the most important means of ensuring that the

nidus can be found during the operation.

Radiofrequency ablation has become an accepted means of treating osteoid osteoma (105,106 and 107). The procedure is performed under general anesthesia, but usually can be done without hospitalization. Using CT to control placement, a needle biopsy is performed to confirm the diagnosis. Then, through the same needle track a radiofrequency electrode with an internal thermistor is placed in the nidus. The patients were not protected, nor were their activities limited after the heat ablation, and there have been no complications. Other closed methods of treatment have been reported (108).

Osteoblastoma

Osteoblastoma is sometimes called “giant osteoid osteoma” because it is histologically identical to osteoid osteoma, but larger. Unlike osteoid osteoma, osteoblastoma is not surrounded by dense reactive bone. Cementoblastoma of the jaw is histologically identical to osteoblastoma. Osteoblastoma is less common than osteoid osteoma, accounting for less than 1% of the primary bone tumors in Dahlin's series (93).

The typical patient is a boy in the second decade of life (50% of the patients are between 10 and 20 years of age, although the age range is from 5 to 35 years of age) complaining of back pain (approximately 50% of the lesions are in the spine). The pain of an osteoblastoma is not as severe as the pain of an osteoid osteoma, and aspirin or NSAIDs do not have such a dramatic effect. There are no physical findings characteristic of osteoblastoma. When the tumor is in the spine, the patient has decreased motion of the spine in the involved area. Osteoblastomas are tender, and direct palpation often localizes a lesion, even when it cannot be seen on a plain radiograph.

Extremity lesions are usually diaphyseal; the patient often has a limp and mild atrophy, and complains of pain directly over the lesion. Blood and urine laboratory examinations are normal. The appearance of osteoblastoma on a radiograph is variable. It is usually a mixed radiolucent, radiodense lesion, more lucent than dense. There is minimal reaction in the surrounding bone. Lesions in the spine may be difficult or impossible to see when initially examining the plain radiograph, but when located by other studies, the subtle abnormality on the plain radiograph can usually be appreciated.

Clues to look for on the plain radiograph to indicate the location of an osteoblastoma are an irregular cortex, loss of pedicle definition, and enlargement of the spinous process. As with osteoid osteoma, CT is the best method of localization. On the CT scan, the lesion usually “expands the bone” and has intralesional stippled ossifications and a high attenuation coefficient (100 HU or more). Osteoblastoma on the radionuclide scan has increased uptake, and technetium bone scanning is an excellent method of initially screening a patient suspected of having an osteoblastoma. The bone scan localizes the lesion, but it is not specific enough to plan a surgical resection for lesions in the spine.

Osteoblastomas should be excised surgically. They continue to enlarge and damage the bone and adjacent structures if left untreated. A wide surgical resection is preferred when practical, but an extended curettage is sufficient for most cases. As much of the surrounding bone should be removed as possible. Most osteoblastomas are controlled by the extended curettage, but recurrence is not uncommon, and some can be locally aggressive. It is difficult to give a percentage risk of local recurrence, but in the authors' experience, it is less than 10% of cases. Although irradiation has been used in the management of these patients, there is little evidence that it is of benefit.

The histology of an osteoblastoma is identical to the nidus of an osteoid osteoma. There should not be abnormal mitoses, although mitotic activity can be observed. There are osteoblasts, multinucleated giant cells, seams of osteoid, and a rich vascular bed. Schajowicz and Lemos (109) suggested that a subset of osteoblastoma be termed malignant osteoblastoma. They believe that this subset has histologic features that are worse than those of the usual osteoblastoma, is more aggressive locally, and is more likely to recur after limited surgery. A rare osteoblastoma metasta-sizes but still meets the histologic definitions of a benign tumor, although it probably should be classified as low-grade osteosarcoma.

Osteosarcoma

Osteosarcoma is defined as a tumor in which malignant spindle cells produce bone. There are two major variants that have significantly different clinical presentations and prognoses. The more common osteosarcoma is classic high-grade or conventional, and the other is juxtacortical. Some authors separate juxtacortical osteosarcomas into parosteal and periosteal. Less common variants of osteosarcoma (e.g., intracortical, soft tissue, radiation-induced, Paget) are not discussed in this text.

Classic High-grade Osteosarcoma. The patient is usually a teenager (about 50% of the patients present during the second decade of life; more than 75% are between 8 and 25 years of age) complaining of pain and a mass around the knee (Fig. 14-7 and Fig. 14-8). Half of the lesions are located in the distal femur or the proximal tibia. The proximal humerus, proximal femur, and pelvis are the next most common sites. The pain precedes the appreciation of the mass by a few weeks to 2 or 3 months. Boys and girls are affected with equal frequency. The patient does not have systemic symptoms, and usually feels well. The mass is slightly tender, firm-to-hard, and fixed to the bone but not inflamed. The adjacent joint usually has restricted motion.

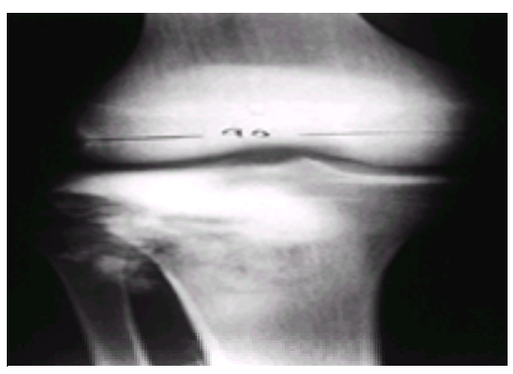

FIGURE 14-7. This is an anteroposterior plain radiograph of an 18-year-old man with an osteosarcoma of his proximal tibia. There is increased density in the proximal tibia associated with cortical destruction and extraosseous bone formation. Biopsy was confirmatory.

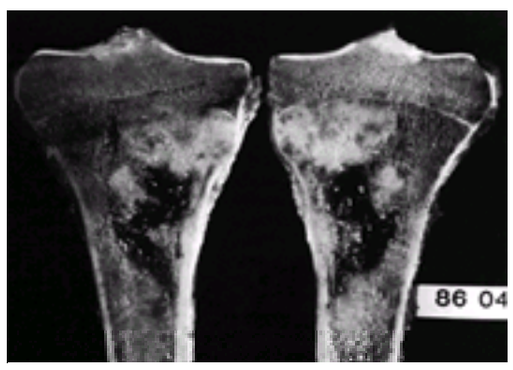

FIGURE 14-8. Classic high-grade osteosarcoma of the proximal tibia. The tibia was bisected for examination. The tumor is composed of an osteoblastic component in the metaphysis, which is up to, and just through, the epiphyseal plate; there also is a more distal cystic component. The tumor has penetrated the cortex, and has a small extracortical component. The patient had not received preoperative chemotherapy, but was treated successfully with limb salvage resection and knee arthrodesis. The patient received postoperative adjuvant chemotherapy, and has been continuously free of disease for 4 years.

The remainder of the physical examination is normal, except in the rare (less than 1%) patient who presents with metastases or multiple focal osteosarcoma. One-half of all patients have elevated serum alkaline phosphatase (extremely high serum alkaline phosphatase values indicate a worse prognosis), and approximately one-fourth of all patients have elevated serum LDH (an elevated LDH also is associated with a worse prognosis). The remainder of the blood and urine laboratory values are normal.

The plain radiograph of an osteosarcoma is usually diagnostic. The typical lesion is located in the metaphysis, involves the medullary canal, is both lytic (radiolucent) and blastic (radiodense), and has an extraosseous component and a periosteal reaction suggestive of a rapid growth (Codman triangle or sunburst pattern). Many osteosarcomas have a soft tissue component, with a fluffy density suggestive of neoplastic bone, adjacent to the more obvious bone lesion. Those osteosarcomas that consist primarily of cartilage or fibrous tissue are almost purely radiolucent. Telangiectatic osteosarcoma, a histologic variant of classic high-grade osteosarcoma, may be mistaken on a radiograph for an ABC or a giant cell tumor. This will not be a clinical problem for the pathologist if adequate clinical information is provided by the surgeon.

MRI is the method of choice for evaluating suspected osteosarcoma. The lesion's extent is more clearly defined by MRI, especially the intraosseous component. The lesion can be seen in all three planes, and its soft tissue extension is easily appreciated. It is critical that the entire bone be included on at least one plane (usually the coronal view). The tumor should be viewed with a minimum of T1-weighted (with and without gadolinium), T2-weighted, and fat-suppressed images.

Osteosarcomas should be resected with at least a wide surgical margin, and the anatomic extent of the tumor is the principal determinant of what operation will be required. MRI is the best method to determine the anatomic extent of an osteosarcoma. The relation of osteosarcoma to the major neurovascular bundle must be determined. The muscles invaded by the soft tissue component must be identified. Involvement of the adjacent joint must be looked for, the intraosseous extent measured, and the presence of metastasis noted. Talking to the radiologist before MRI is performed helps to ensure that all this information is obtained.

Chest radiography and whole lung CT are performed because of the relatively high incidence of patients presenting with pulmonary metastasis (approximately 10%).

The technetium bone scan shows increased uptake in the area of the tumor. Occasionally it is useful in determining the intraosseous extent, although MRI is more accurate. More importantly, technetium scanning is an excellent screen of the entire skeleton for occult bone lesions. On rare occasions a lung metastasis is seen on the bone scan, but usually a hot spot in the chest on the bone scan is secondary to involvement of a rib.

There are five major histologic types of conventional osteosarcoma, and each is graded for the degree of malignancy. The histologic type is determined by the predominant cell type of the tumor. Although initially it was thought that the different types had distinct prognoses, it is now recognized that if matched for size and histologic grade, all types have the same prognosis. Even telangiectatic osteosarcoma, which was originally described as having a particularly poor prognosis, is thought to have the same prognosis as the other classic high-grade osteosarcomas.

The five types are osteoblastic, chondroblastic, fibroblastic, mixed, and telangiectatic osteosarcomas. These tumors are graded on a scale of either 1 to 3 or 1 to 4. The higher the histologic grade, the worse the prognosis. Most osteosarcomas are grade 3 or 4, and of the mixed type. The tumor is composed of a mixture of neoplastic cells, but must have malignant spindle cells making osteoid. Atypical mitoses are common, and small areas of necrosis are usually seen (Fig. 14-9).

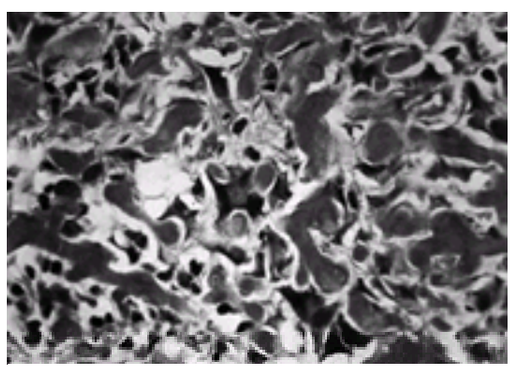

FIGURE 14-9. Histologic appearance of classic high-grade osteosarcoma. The malignant spindle cells are recognized by their abnormal variation in size and shape. No mitotic figures are seen in this photomicrograph, but abnormal mitoses usually are seen in high-grade conventional osteosarcoma. (Original magnification ×40.)

Treatment of classic high-grade osteosarcoma includes adjuvant chemotherapy and surgical resection. The standard protocol consists of chemotherapy (neoadjuvant; usually three or four courses of a multidrug regimen), then surgical resection, and finally additional chemotherapy (Fig. 14-10). The entire treatment takes almost 1 year. The surgical resection can almost always be done without an amputation of the extremity, and less radical surgery is being performed now compared with only a few years ago. Recently, Picci and associates suggested that patients whose tumors have more than 90% necrosis after preoperative chemotherapy do not require as wide a surgical margin as patients with less necrosis (110,111). The use of neoadjuvant chemotherapy has not produced increased survival compared with postoperative adjuvant chemotherapy, but it does seem to make surgery easier, and gives the pediatric oncologist a predictor of survival.

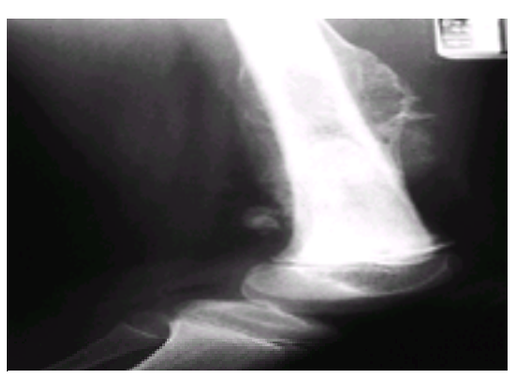

FIGURE 14-10. This plain radiograph is a lateral view of the distal femur of a patient who has had standard preoperative chemotherapy. The original lesion had a large extraosseous component that has been reduced in size, and there has been “maturing” of the periosteal reaction. The patient's pain diminished, and the range of motion in her knee returned to normal.

The three most important drugs used for osteosarcoma are doxorubicin (Adriamycin), high-dose methotrexate, and cisplatin. The majority of chemotherapy protocols include these three drugs in various dosage schedules, in addition to one or more other drugs. The development of granulocyte-stimulating factor to counteract bone marrow suppression, has allowed increased intensification of the treatment with fewer complications; granulocyte-stimulating factor is now used routinely. Overall survival has increased to more than 60%, with even better survival for those patients with greater than 90% necrosis after chemotherapy (112,113,114,115,116,117,118,119,120,121 and 122).

Limb-salvage surgery is being performed for all but the largest of osteosarcomas. Amputation is done in less than 20% of cases (122,123,124,125 and 126). The accepted incidence of local recurrence is between 5 and 10%, which does not seem to increase the incidence of death (125). This is an area of concern, however, because it appears that the vast majority of patients with local recurrence die of their disease (123,125). One explanation is that local recurrence is a sign of a more aggressive tumor, not solely the consequence of poor surgery. That being said, however, the insistence on wide margins is paramount. The tumor with a small amount

of surrounding normal tissue is resected. This usually means 1 or 2 cm of normal bone proximal and/or distal to the extent of the tumor and a small cuff of muscle directly on the tumor and bone. It is uncommon to perform extraarticular resection unless there is gross extension of tumor into a joint, and increasingly close bone margins are accepted in an attempt to save a young child's growth plate or a patient's articular cartilage.

The management of patients with pathologic fractures is controversial. There is an increased incidence of local recurrence if limb-salvage resection is performed, but this increased incidence of local recurrence does not seem to increase the risk of death (123,127,128,129 and 130). The usual management of a patient with a pathologic fracture and osteosarcoma is to treat the fracture closed, give neoadjuvant chemotherapy, and perform limb salvage if negative surgical margins can be obtained.

The patient younger than 10 or 11 years, whose tumor resection requires the removal of a major growth plate (distal femur, proximal tibia, or proximal humerus), presents a special problem (131,132,133,134 and 135). Older patients with limb-length inequality can be managed with a combination of initial lengthening, opposite-side growth arrest, and heel lifts. A variety of techniques have been developed to manage the patient who has so much growth left in his or her extremity that these simple methods are insufficient. Some patients will have a conventional amputation, and this remains an excellent method for many patients. There have been advances in prosthetic design during the past decade, and patients with amputations do not require additional operations (as patients with limb salvage do), and remain the most physically active patients. Variations on a conventional amputation (either a rotationplasty or a tibial turn-up) can be done, particularly for the young patient with an osteosarcoma in the femur, to improve function, compared with conventional amputation (136,137,138,139,140,141,142,143,144,145,146,147,148,149,150,151,152,153,154,155 and 156). Limb salvage for the patient younger than 10 years is particularly difficult. All methods require repeated operations, and their long-term success has yet to be completely documented. The most common method currently used involves a “growing” endoprosthesis (131,133,157,158,159,160,161,162,163,164 and 165). There are a number of methods to make the endoprosthesis grow, but they all require a repeat operation every 8 to 12 months. In addition, as the child grows in length, the bone grows in diameter, and fixation is problematic.

Juxtacortical Osteosarcoma. Osteosarcomas that arise from or are adjacent to the external surface of the bone behave differently than those that arise from within the medullary canal. They are less aggressive locally, have less potential for distant metastasis, and are less common than conventional osteosarcoma. There seem to be two distinct juxtacortical osteosarcomas, parosteal and periosteal, but neither is common, and how distinct they are from one another remains a topic of debate. Parosteal osteosarcoma is most commonly located in the posterior aspect of the distal femur, and is composed of bone and low-grade malignant fibrous tissue. Periosteal osteosarcoma is more often located in the diaphysis, and is composed of bone and cartilage with malignant spindle cells.

Geschickter and Copeland (166) were the first to describe osteosarcoma. They thought that there were two distinct lesions, a benign parosteal bone-forming tumor and a malignant bone-forming tumor, but all osteosarcomas are defined as malignant, and have the potential to metastasize. The patient's age at presentation varies over a greater range (10 to 45 years) than in classic high-grade osteosarcoma, and the median age of presentation tends to be slightly older (167,168,169,170 and 171). The patient usually complains of a painless mass that blocks motion in the adjacent joint. This is most often knee flexion, because the posterior distal femur is the most common site of a juxtacortical osteosarcoma (93). Occasionally the patient complains of a mild, dull ache in the area of the tumor, but symptoms are minimal. The mass is fixed, hard, and nontender. The adjacent joint may have limited passive and active motion as a result of the mechanical block from the tumor. Inflammation is not observed. The patient's laboratory values are normal.

The plain radiograph is almost always diagnostic, but the findings may be mistaken for osteocartilaginous exostosis (Fig. 14-11). The lesion arises from the cortex, which may be normal or thickened. The juxtacortical osteosarcoma often wraps around the bone, with the periosteum between the tumor and the underlying cortex. This growth pattern (wrapping around the bone) produces the “string sign” on the plain radiograph, with a thin radiolucent line between the lesion and the cortex of the bone. The lesion itself is dense, and has the pattern of bone. There is increased uptake on the technetium bone scan. The appearance of the lesion on a CT scan is characteristic, and distinguishes a juxtacortical osteosarcoma from an exostosis. Juxtacortical osteosarcoma is attached to the cortex growing out into the soft tissue and may invade the cortex, but the normal cortex is intact (167,168,171). An exostosis arises from the cortex, and the cortex of the normal bone becomes the cortex of the exostosis, with the medullary canal of the bone communicating with the medullary canal of the exostosis. Intraosseous extension of the tumor is seen more easily with MRI than with CT.

FIGURE 14-11. A: Lateral radiograph of the distal femur and knee of a patient with a parosteal osteosarcoma. The posterior distal femoral cortex is thickened and slightly irregular. The radiodensity adjacent to the posterior cortex is the central portion of the parosteal osteosarcoma. Surrounding this bony mass is a nonossified component of the tumor, composed primarily of fibrous tissue, but with some cartilage. This patient was treated with limb-salvage wide resection of the distal femur, and underwent reconstruction with an osteoarticular allograft. No chemotherapy was used, and the patient has remained free of disease for 5 years. **B:** The parosteal osteosarcoma is larger than it appears on the plain radiograph. The cap of fibrous tissue and cartilage can be seen covering the bony center. The tumor is attached to the cortex, but does not extend through it. This gross relation is similar to that of an exostosis, and may lead to a mistaken histologic diagnosis. The gross difference between an exostosis, and a parosteal osteosarcoma is that the stalk of an exostosis is cortical bone that blends with the cortex of the host bone, and the medullary canal of the stalk and host bone are connected (see Fig. 14-13**B**). The parosteal osteosarcoma, conversely, is attached to the cortex, but the cortex of host bone is intact, and the medullary canal does not communicate with the parosteal osteosarcoma.

FIGURE 14-13. A: Anteroposterior radiograph of the distal femur with a typical pedunculated exostosis. The cortex of the lesion blends into the cortex of the femur. The exostosis has an irregular proximal end that is covered by a cartilaginous cap. The pathologic material is the cartilage, but what is seen on the radiograph is the bone formed by enchondral ossification of the cartilage. This patient repeatedly hit the mass while playing football, and it was marginally excised. A small rim of the cortex of the femur was removed along with the exostosis because occasionally any residual cartilage that lies at the base of the stalk can lead to a recurrence. **B:** Gross bisected specimen from the same patient. The femoral attachment is inferior, and the cortex of the femur can be seen blending with the cortex of the exostosis. The medullary canal of the femur is filled with hematopoietic marrow, and appears dark. The hematopoietic marrow extends into the base of the exostosis, but most of the marrow of the exostosis is fatty. There is a thin, cartilaginous cap. In a child, a cartilaginous cap more than 1 cm thick is of no concern, but in an adult a cartilaginous cap of more than 1 cm is considered to indicate early malignant degeneration to secondary chondrosarcoma.

An incisional biopsy of a juxtacortical osteosarcoma can be difficult to interpret, and based on histology alone, the lesion can be mistaken for an exostosis. This is particularly true when juxtacortical osteosarcoma is not suspected by the clinician, or when the pathologist does not examine the radiograph. This lesion, more than most, is diagnosed by its clinical and radiographic presentation, and is confirmed by histology. An excisional biopsy is recommended in most cases. The lesion is composed of regularly arranged bone, with a background of usually bland spindle cells and fibrous tissue. A cartilage cap is often present. Parosteal osteosarcomas are graded histologically on a scale of 1 to 3 (170). Higher-grade lesions, especially those with medullary involvement, have a greater risk of metastasizing (usually to the lung) than those of lower grade without medullary extension (169,173,174,175,176 and 177).

When the diagnosis can be relatively certain from the preoperative studies, a wide excisional biopsy is recommended. The cortical margin should be generous and the tumor pseudocapsule not disturbed. When a lesion from the posterior distal femur is resected, the neurovascular bundle usually can be freed from the lesion without dissecting the pseudocapsule, but the posterior capsule of the knee and the posterior aspect of the femoral condyle usually must be resected with the tumor. Those lesions that wrap around the bone and have gross invasion of the medullary canal may require a resection that includes the entire end of the bone.

The initial resection is the best opportunity to control the lesion without an amputation. Most patients do not need adjuvant chemotherapy because the cure with surgery alone is approximately 80% (167,168,170,171,178,179). Patients with histologic grade 3 lesions probably should receive adjuvant chemotherapy, especially if the medullary canal has been invaded, although the data are limited (170).

The periosteal osteosarcoma is another type of juxtacortical osteosarcoma (93,180,181). It is most common in the anterior proximal tibia, and it tends to be diaphyseal in location. It has a sunburst appearance on the plain radiograph, and is composed of malignant cartilage and bone (182). A wide surgical resection is recommended (169,180,181,183). The place of adjuvant chemotherapy is controversial; as with parosteal osteosarcoma, probably only patients with grade 3 lesions should receive it.

Local Control of Extremity Sarcomas. The “gold standard” for achieving local control in patients with bone and soft tissue sarcomas in the extremities is amputation. However, no one wants to lose a limb if it can be prevented, and the authors have learned that sarcomas can be safely resected as long as a cuff of normal tissue can be kept surrounding the resected specimen. This is called “achieving a wide margin of resection.” Usually adjuvant therapies such as chemotherapy are used either before or after these resections.

There is a fairly wide experience with limb salvage in adults. Children have the added problems of growth, small size, and (it is hoped) more longevity, which make reconstruction more challenging. The options for limb salvage include osteoarticular and intercalary allografts, metallic prostheses, and vascularized and nonvascularized autograft transplants. All of these are used at various times by the tumor surgeon. Rotationplasty is another option somewhere between limb salvage and amputation; it is occasionally useful in very young patients.

The child must first be a limb-salvage candidate. This means that the tumor is located such that the major nerves and vessels can be preserved, and enough muscle will remain to make the limb functional. MRI is the best imaging test to aid in the decision (80). It shows the extent of the tumor within the medullary cavity, the extent of the soft tissue mass, and the relationship of the mass to the joint, nerves, and vessels. Most of the time the adjacent joint is not involved, but the epiphysis is frequently involved with tumor (184,185). This must be carefully assessed. Usually, the patient will have received chemotherapy preoperatively, which makes the resection easier in tumors without a matrix, such as Ewing sarcoma/PNET, because the mass becomes smaller.

In some locations, such as the fibula and clavicle, no bony reconstruction is necessary. Very young children with bone tumors of the foot and ankle are usually best treated by ray, Syme, or below-knee amputation. Soft tissue sarcomas at these sites may be resectable without amputation, if it is possible to achieve wide margins with or without adjuvant irradiation. A method of using a metatarsal head in the tibial stump to prevent stump overgrowth has been described, and seems to be useful (186,187).

For tumors of the distal femur or proximal tibia, the resection will almost certainly include an epiphyseal center. In children near skeletal maturity, this will not lead to a major limb-length inequality. An allograft or prosthesis 1 to 2 cm longer than the length of bone that is resected can be used, and a contralateral epiphysiodesis can be performed at a later date, if necessary. As long as the predicted discrepancy is less than 2 cm, no special reconstruction is necessary. In younger children, limb length is more of a concern. One option is to reconstruct with an osteoarticular allograft, and treat the limb-length discrepancy using standard methods of epiphysiodesis, closed femoral shortening, or limb lengthening. The allograft has the advantage of not disturbing the adjacent growth plate. Growth arrest of the adjacent growth plate may occur by placing a prosthetic stem across it. One difficulty with this approach is obtaining a graft of appropriate size. For children older than 10 years, it is usually possible to use a small adult bone. Use of grafts with open growth plates is not advised because they will fracture through the allograft physis. Use of an osteoarticular allograft for the proximal tibia has the advantage of providing a site of attachment for the patellar ligament. The results of allografts for limb salvage in osteosarcoma are reasonable, but the patient should not expect normal limb function (131,188,189,190,191,192,193 and 194). A good or excellent result, based on a functional evaluation system devised by Mankin et al. (195), can be expected in about 65 to 70% of patients. It should be noted that there are no ideal measures of function after limb salvage (although several have been developed), and this remains an area of investigation. In general, if patients can return to normal walking activities without supports or braces, it is considered to be a good result. Seldom can they return to contact sports or running activities (196). Complications include infection, nonunion, fracture, and joint instability (195,197,198). If the patient survives, he or she may need joint arthroplasty at some time in the future, but by then the patient should be old enough that growth is no longer a consideration. Growth equalization can be achieved by contralateral epiphysiodesis, limb shortening, or ipsilateral lengthening (132,134). The experience with limb lengthening in these patients is limited because limb length is seldom a major issue.

Another option is the use of a metallic prosthesis. Modular prostheses are now available that allow the surgeon to construct an implant of suitable length in the operating room (133,199). Custom implants are seldom necessary. Some prostheses have the ability to be expanded as the child grows (131,133,157,159,160,162,163,164 and 165). There are a variety of types, but perhaps the best is the modular prosthesis that can be lengthened by removing one of the body segments and replacing it with another segment 1 to 2 cm longer (133). This is not a simple operation because the soft tissues form a dense fibrous layer around the implant, which must be resected or released to achieve lengthening. The neurovascular structures are difficult to identify in these lengthening procedures, and are at risk for direct and stretching injury. Usually it is possible to achieve at least 2 cm of length per procedure. In very young patients, this must be repeated every 6 months until maturity, at which point revision to an adult prosthesis may be necessary. There are few data on these prostheses, but at least one report shows that it is possible to gain 2 to 18 cm in length, and to have equal limb lengths at skeletal maturity (162). The issues of prosthetic failure, loosening, wear of polyethylene, and infection remain unresolved. The choice of implant or reconstructive method is up to the surgeon and the family. Prostheses are more functional initially, but their longevity is unknown. Expandable prostheses have a high failure rate (133). More than 80% of these will require revision by 5 years, and the revision rate appears to be higher in uncemented prostheses. Many of these patients will have knee stiffness and the infection rate, especially in the tibia, may be as high as 38%, although this can be improved with the liberal use of gastrocnemius flaps (133). The modular prosthesis has been reported to have a 5-year revision-free and amputation-free survival rate of 75%, presumably because it is mechanically stronger and less complex (133). Function appears better in children who are older than 8 years at the time of the reconstruction. Allografts require more difficult rehabilitation, but they hold the promise of superior longevity. It is very important to tell the patient in either case that the function will not be normal, and that neither reconstruction is meant to return the patient to sports activities. For lower-extremity sarcomas about the knee or hip, it is the authors' feeling that patients older than 8 to 10 years with open growth plates, are best treated with allografts to preserve the adjacent growth center, but that skeletally mature patients may be better served by prostheses because of the easier recovery and rehabilitation. In either case, subsequent revisions or eventual amputation may be necessary.

For diaphyseal lesions, an intercalary resection can be performed that spares the adjacent joints and occasionally the epiphyseal plates. These patients can be reconstructed with intercalary allografts and/or vascularized fibulae (191,192,200). Recently, a method of using an allograft to provide initial stability, augmented by a vascularized fibular graft to achieve quicker union and long-term healing potential, was described (201,202 and 203). This technique is especially helpful when only a small segment of the epiphysis remains after the resection.

For lesions of the proximal humerus, intraarticular or extraarticular resection is usually performed (204,205,206 and 207). If the rotator cuff and part of the deltoid can be preserved, reconstruction with an osteoarticular allograft yields good results (208,209). Some surgeons prefer to use an endoprosthesis with the allograft to prevent late joint collapse and fracture (188,210). In either case, the allograft position allows attachment of the rotator cuff, which is an advantage over the use of a prosthesis. For extraarticular resections when both the deltoid and the rotator cuff are sacrificed, arthrodesis, using allograft, vascularized fibula, or both, is indicated (211). It is difficult to achieve an arthrodesis, but when it works, it is very functional. When a formal Tikhoff-Linberg resection, which includes the scapula, is necessary, the reconstruction is more difficult; leaving a flail upper extremity may be the only option (204,207,212,213).

For very young patients with tumors of the distal femur, or older patients who want to be athletically active, rotationplasty is an option (136,137,138,139,140,143,145,146 and 147,150,151,156). In these patients, above-knee amputation would lead to a very short stump with a poor lever arm (214).

Rotationplasty, by taking advantage of the tibia and foot, provides a longer lever arm and an active “knee” joint. It also avoids resection of the major nerves, so that phantom pain is not an issue. The physical appearance without the prosthesis is disturbing to some patients, but with a prosthesis they look similar to other amputees and function much better than above-knee amputees (139,142,144,145,152,215). The technical details are well described elsewhere (143), and the technique has been described for lesions of the proximal tibia and the proximal femur (141,149,153); more recently, similar procedures have been described for the upper extremity (216). It is very important to have frank discussions with the patient and his or her family about the appearance and expected outcome of this reconstruction. Having the patient meet another patient who has undergone rotationplasty, or at least viewing a video and meeting with an experienced physical therapist and prosthetist, can be very helpful. Interestingly, young patients do not view this as an amputation, because the foot is still present, and the long-term psychological outcomes of these patients has been very good.

CHEMOTHERAPY FOR MUSCULOSKELETAL TUMORS

It was not until the 1970s that chemotherapy was believed to be effective for malignant tumors of the musculoskeletal system. The extremely high incidence of metastatic disease in patients with osteosarcoma (more than 80%) and Ewing sarcoma (more than 85%), and some promising results in patients with metastatic sarcoma, prompted the use of adjuvant chemotherapy in patients who did not have documented disease but in whom the risk of having subclinical metastases was high (217). The early results were exciting, and even the use of what was considered minimal amounts of less-than-optimal drugs improved survival. These early studies led to the acceptance of adjuvant chemotherapy for Ewing sarcoma, osteosarcoma, and rhabdomyosarcoma (218,219,220,221,222,223,224,225,226,227,228,229 and 230). There are no chemotherapeutic agents believed to be effective for chondrosarcoma (231), and the use of chemotherapy for soft tissue sarcomas (except rhabdomyosarcoma) remains controversial (232,233 and 234).

In the 1980s, preoperative chemotherapy was introduced, and preoperative administration is now standard for the initial chemotherapy for patients with Ewing sarcoma, osteosarcoma, and rhabdomyosarcoma (26,115,116,119,217,235,236,237,238,239,240,241,242,243,244,245,246,247 and 248). “Neoadjuvant chemotherapy” is a term used to indicate that the patient receives chemotherapy before the definitive treatment of the primary lesion. This was initially used as a means of treating patients with osteosarcoma who were waiting for the production of a custom prosthesis. The effect of chemotherapy on the tumor was significant and of prognostic significance, leading to the routine use of preoperative chemotherapy.

There are numerous chemotherapeutic protocols for the three skeletal malignancies for which chemotherapy is used (Ewing sarcoma, osteosarcoma, and rhabdomyosarcoma). All use more than one drug, and usually three to five. Most protocols are between 9 and 12 months long. Approximately one-third of the chemotherapy is given preoperatively, and the remainder is given after surgery.

The drugs used for musculoskeletal tumors include:

Doxorubicin (Adriamycin), a cytotoxic anthracycline antibiotic that passively enters the cell to diffuse into the nucleus, where it binds nucleic acids and prohibits DNA synthesis (217). It is cardiotoxic, myelosuppressive, and produces alopecia. It is given intravenously in divided doses over 6 months, with 450 mg/m ^{2} recommended as the maximum dose.

Methotrexate is an antimetabolite that inhibits dihydrofolic acid reductase. This interferes with DNA synthesis and repair, and alters cellular replication. When administered in high doses (12 mg/m^2 intravenously), leucovorin or citrovorum factor is given to the patient to rescue the normal cells. Leucovorin is a chemically reduced derivative of folic acid and is used by the cells to complete normal cell functions without the need for dihydrofolic acid reductase. Tumor cells seem less able to use leucovorin than normal cells, and this difference allows methotrexate to be effective against malignant tumors. The primary side effects of methotrexate are gastrointestinal, including nausea, vomiting, and loss of appetite.

Cisplatin is a heavy metal that is thought to cause intrastrand cross-links in DNA, and therefore interference with the DNA. It is given intravenously in doses of 75 to 100 mg/m^2 repeatedly over the course of the treatment. The principal side effect of cisplatin is nephrotoxicity.

Cyclophosphamide (Cytoxan) is a synthetic drug chemically related to nitrogen mustard. It cross-links DNA and interferes with DNA functions. It is given intravenously at a dose of 40 to 50 mg/kg in divided doses over 4 to 5 days. The major side effects of cyclophosphamide are gastrointestinal disorders and myelosuppression.

Ifosfamide is a synthetic analog of cyclophosphamide, with similar actions. It is given intravenously at 1.2 g/m ^{2}/day for 5 days.

Vincristine is an alkaloid from the periwinkle plant. It is thought to arrest dividing cells in the metaphase state by inhibiting microtubule formation in the mitotic spindle. It is given intravenously at weekly intervals at doses of 1.4 mg/m^2 in adults and 2.0 mg/m^2 in children. The major side effect of vincristine is peripheral neuropathy.

Bleomycin is a cytotoxic glycopeptide antibiotic from a strain of *Streptomyces verticillus* that inhibits DNA synthesis. It also probably inhibits RNA and protein synthesis. It is given intravenously at 0.25 to 0.50 U/kg once or twice per week. The most serious side effect of bleomycin is a 10% incidence of severe pulmonary fibrosis.

Actinomycin D (dactinomycin) is one of a number of actinomycin antibiotics from *Streptomyces*. It binds to DNA by intercalation with the phenoxazone ring. This inhibits the DNA from being a template for RNA and synthesizing itself. It is given intravenously at 0.5 mg/day for 5 days. Dactinomycin produces nausea and vomiting, and is myelosuppressive.

These drugs are given in various combinations and doses, depending on the specific diagnosis, the protocol, the response of the patient, and the aggressiveness of the medical oncologist.

Cartilaginous Tumors

Cartilaginous tumors include enchondroma, exostosis (osteocartilaginous exostosis, osteochondroma), chondromyxofibroma, periosteal chondroma, chondroblastoma, and chondrosarcoma. The benign tumors are common, especially enchondroma and exostosis, whereas chondrosarcoma is extremely rare in the pediatric age group (93,249,250).

Enchondroma

The origin of enchondroma is debatable, and it probably is not a true neoplasia. It may be the result of epiphyseal growth cartilage that does not remodel and persists in the metaphysis, or it may result from persistence of the original cartilaginous anlage of the bone (251). Both possibilities have been suggested as explanations of the cause of this common benign tumor. The majority of patients with a solitary enchondroma present with either a pathologic fracture through a lesion in the phalanx, which is the most common location (251) (the proximal humerus and the distal femur are the other common locations for enchondroma), or the history that the lesion was an incidental finding on a radiograph taken for another reason (Fig. 14-12). Enchondromas are common lesions that account for 11% of benign bone tumors (93,253). They do not need to be removed. The problem they present is diagnostic. Usually, the diagnosis can be made from the clinical setting and the plain radiograph. Forty percent of enchondromas are found in the bones of the hand or feet—usually a phalanx. An enchondroma should not produce symptoms unless there is a pathologic fracture. There are no associated blood or urine abnormalities. The femur and proximal humerus are the next most common sites. Enchondromas are located in the metaphysis and are central lesions in the medullary canal. The bone may be wider than normal, but this is caused by the lack of remodeling in the metaphysis rather than by expansion of the bone by the tumor. The cortex may be thin or normal; the lesion is radiolucent in the pediatric age group, but later has intralesional calcifications. There should be no periosteal reaction. In the pediatric patient, unicameral bone cysts have a similar radiographic appearance, but they are most common in the proximal femur and the proximal humerus. The appearance of an enchondroma on MRI is typical. The cartilage matrix has an intermediate signal intensity on the T1-weighted image and a high signal intensity on the T2-weighted image (80,254,255,256,257 and 258). It should have a sharp margin with the adjacent bone without peripheral edema.

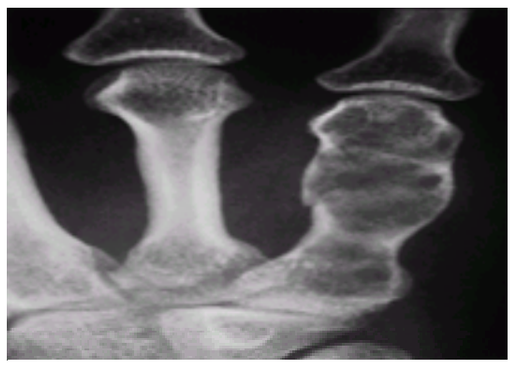

FIGURE 14-12. This enchondroma of the fifth metacarpal is typical. The shaft is enlarged, and the lesion is radiolucent. This patient had been aware of this lesion since she was 10 years of age. She had sustained numerous pathologic fractures, and decided to have it curetted. The curettage was done after the fracture had healed.

When the findings are typical for an enchondroma, no biopsy is necessary. Repeat plain radiography and physical examination should be performed in approximately 6 weeks, then every 3 to 6 months for 2 years. Although there are reports of solitary enchondromas differentiating into chondrosarcomas, usually late in adult life, this does not occur frequently enough to justify the removal of all enchondromas. The patient should be advised that after age 30 years if the lesion becomes painful or enlarges, it should be considered a low-grade chondrosarcoma and be surgically re-sected.

Incisional biopsy usually is contraindicated. Pathologists have difficulty distinguishing between active enchondroma (most pediatric-age patients have active lesions) and low-grade chondrosarcoma. The clinical course is the best measure of the lesion's significance, and an incisional biopsy alters the status of the lesion and makes subsequent evaluation difficult. If the patient or the patient's parents insist on biopsy, it is best that the entire lesion be removed.

Patients with multiple enchondroma (Ollier disease) are much less common than those with solitary enchondromas. Multiple enchondroma was originally described in the late 1800s by Ollier (259). Most patients with Ollier disease have bilateral involvement, but with unilateral predominance. These patients have growth deformities, both angular and in length. Their extremity deformities should be managed surgically to maintain the function of the limbs without specific regard to the enchondroma. Patients with Ollier disease have an increased risk of developing secondary chondrosarcoma later in life, and should be so advised (260,261 and 262). The incidence of secondary chondrosarcoma in patients with Ollier disease is not known, but may be as high as 25%. The pelvis and shoulder girdle are the most common locations of secondary chondrosarcoma.

Maffucci disease consists of multiple enchondroma and soft tissue hemangioma (263). Patients with this disorder have an even greater risk of developing malignant cartilage tumors than patients with Ollier disease; more importantly, they have a great risk of developing carcinoma of an internal organ (264).

Exostosis

The terms “osteochondroma,” “osteocartilaginous exostosis,” and “exostosis” are used interchangeably. This lesion was first described in the early 1800s. It is common. Although the pathogenesis of this lesion is not known, an abnormality or injury to the periphery of the growth plate has been suggested as the cause (251). It has been shown in an experimental animal study that the periphery of the growth plate can be traumatized and a typical exostosis produced.

The patient with a solitary exostosis usually is brought in by a parent who has just noticed a mass adjacent to a joint. The patient usually has no symptoms. An occasional patient has loss of motion in the adjacent joint, attributable to the size of the mass. The patient often has been aware of the mass for months to years, and reports that it has been slowly enlarging. Some patients have pain resulting from irritation of an overlying muscle, repeated trauma, pressure on an adjacent neurovascular bundle, or inflammation in an overlying bursa. On physical examination, the mass is nontender, hard, and fixed to the bone. The rest of the physical examination is normal.

Exostoses are so characteristic on a plain radiograph that they should be diagnosed from their radiographic appearance alone (Fig. 14-13). The mass is a combination of a radiolucent cartilaginous cap with varying amounts of ossification and calcification. The amount of calcification and bone formation increases with age. The base may be broad (sessile exostosis) or narrow (pedunculated exostosis). In both types, the cortex of the underlying bone opens to join the cortex of the exostosis, so that the medullary canal of the bone is in continuity. This usually can be appreciated on the plain radiograph, but if not, CT or MRI establishes this finding and confirms the diagnosis.

In the pediatric age group exostoses should be expected to grow. They may continue to grow well into the third decade of life. This is not a sign of malignancy. Only after 30 years of age should growth of an exostosis be thought to indicate malignant degeneration. The growth rate is not steady, and occasionally a lesion grows more rapidly than expected. Removal of the lesion in a child is indicated only for those patients who have symptoms attributable to pressure on a neurovascular bundle or irritation of the overlying muscle. Removal in a young child may result in damage to the growth plate and recurrence of the lesion. Malignant degeneration is extremely rare in children and uncommon in adults. Malignant degeneration is more common in lesions of the scapula, the pelvis, and the proximal femur. Although it is often stated that the risk of malignant degeneration is as high as 20%, the real incidence is not known. It is probably less than 5%.

Gross examination of an exostosis reveals a lesion that looks like a cauliflower. It has an irregular surface covered with cartilage. The cartilage is usually less than 1 cm thick, except in the young child, in which it may be 2 or 3 cm thick. In an adult, when the cartilaginous cap is thicker than 1 cm a secondary chondrosarcoma should be suspected (253,257,265,266,267,268 and 269). Deep in the cartilaginous cap there is a variable amount of calcification, enchondral ossification, and normal bone with a cortex and cancellous marrow cavity. The microscopic appearance of the cartilaginous cap typically is benign hyaline cartilage.

Some patients have multiple exostoses (270,271 and 272). A patient may have three or four lesions, but more often there are 10 to 15. Usually, the patient has exostoses of all shapes and sizes. They are concentrated in the metaphysis of the long bones, but may be in the spine, the ribs, the pelvis, and the scapula. On physical examination, they are hard, fixed masses adjacent to joints. Patients with multiple exostoses usually are shorter than average but not below the normal range. They have loss of motion in the affected joints, especially forearm rotation, elbow extension, hip abduction and adduction, and ankle inversion and eversion.

Multiple heritable exostosis is transmitted by an autosomal dominant gene with a variable penetrance, and usually half of the children of an affected parent have clinical manifestations (270,273,274). An extensively involved parent may have a child with minimal involvement, or vice versa. In the majority of patients with multiple heritable exostoses, the radiographic appearance of the proximal femur is diagnostic. The femoral neck is short and broad with multiple bony excrescences.

After the age of 30 years, patients with multiple heritable exostoses have an increased risk of developing secondary chondrosarcoma (266,267,273,275,276,277,278,279,280 and 281). Secondary chondrosarcoma in the pediatric age group is extremely rare (282,283). Occasionally, one or more of the exostoses are removed to relieve the pain related to repeated local trauma, or to improve the motion of the adjacent joint. Those lesions in the pelvis and the spine should be observed closely because they have the greatest risk of undergoing malignant degeneration. The authors do not recommend removing these lesions simply because they are present.

The authors advise patients with exostosis, whether single or multiple, to be examined and to undergo radiography at least yearly. Patients are told to report symptoms or increasing size immediately. Patients older than 30 years of age with an enlarging exostosis should have it removed as if it were a secondary chondrosarcoma, because this usually is the case (284).

Chondromyxofibroma

Chondromyxofibroma is a rare tumor. The patient is usually a male (males are more frequently affected than females at a ratio of 2 to 1) in the second or third decade of life (93,285). The patient complains of a dull, steady pain that is usually worse at night. The only positive physical finding is tenderness over the involved area, and occasionally a deep mass can be appreciated. Approximately one-third of chondromyxoid fibromas occur in the tibia, usually proximally. It is a radiolucent lesion that

involves the medullary canal, but is eccentric and erodes the cortex (253,286) (Fig. 14-14). It may be covered by only periosteum, and is often mistaken for the more common ABC. The solid nature of chondromyxofibroma versus the cystic nature of an ABC, as seen on MRI, is a means of differentiating between these two lesions. The natural history is not known because of infrequency and the fact that surgical treatment is nearly universal. Thorough curettage and bone grafting are recommended.

FIGURE 14-14. Anteroposterior radiograph of a chondromyxofibroma of the proximal lateral tibia. The lesion is typically an eccentric, radiolucent abnormality that usually destroys the cortex but is contained by the periosteum. As in this case, the radiographic appearance of chondromyxofibroma is often similar to that of an aneurysmal bone cyst.

Chondroblastoma

Chondroblastoma, or Codman tumor, initially was thought to be a variant of giant cell tumor of bone. Codman's detailed description in 1931 was of an “epiphyseal chondromatous giant cell tumor” (287). Jaffe and Lichtenstein in 1942 (288) suggested that it be called “benign chondroblastoma,” and separated it from giant cell tumor of bone. Codman was particularly interested in the shoulder, and he thought that this lesion was found principally in the proximal humerus (Fig. 14-15). It has since become clear that chondroblastoma is found in many bones, but the proximal humerus is the most common site (approximately 20%) (93,289,290 and 291).

FIGURE 14-15. Radiograph of a chondroblastoma in the proximal humeral epiphysis. This is a typical Codman tumor. The lesion is both epiphyseal and metaphyseal, has an irregular reactive border, and has intralesional calcifications, although these are difficult to see on plain radiographs. Giant cell tumor of bone is similar to chondroblastoma, except that there are no intralesional calcifications. This patient was treated with curettage and bone grafting.

Chondroblastoma accounts for 1% of bone tumors (93). The patient with a chondroblastoma is usually in the second decade of life, with an open growth plate, but it occurs in older patients as well. The initial symptoms are of pain in the joint adjacent to the lesion, and the patient usually presents with joint complaints. The findings on physical examination also may suggest an intraarticular disorder because most patients have an effusion and diminished motion in the adjacent joint. Frequently the patient is believed to have chronic synovitis; he or she does not have other symptoms or abnormal physical findings. The patient's laboratory data are normal.

The lesion arises in the secondary ossification center. In children, it is the most common neoplastic lesion of the secondary ossification center (292), and in adults, only giant cell tumor of bone involves the secondary ossification center more often. (Osteomyelitis is the most common diagnosis in adults to produce a lesion in the secondary ossification center.) On the plain radiograph, the lesion is radiolucent, usually with small foci of calcification (293). The calcification is best seen on a CT scan. There is usually a reactive rim of bone surrounding the lesion, and sometimes metaphyseal periosteal reaction. The edema associated with chondroblastoma can be appreciated on MRI (Fig. 14-16). There is increased uptake on a technetium bone scan. Chest radiography or CT should be performed, because chondroblastoma is one of the benign bone tumors that can have lung implants and still be considered benign (294). Chondroblastoma and osteochondritis dissecans can have a similar appearance on plain radiographs, but they should not be confused with one another. Osteochondritis dissecans produces an abnormality in the subchondral bone, but with chondroblastoma the subchondral bone is almost always normal. Patients with chondroblastoma have more of an effusion than patients with osteochondritis dissecans, and their pain is constant and not related to activity as it is in patients with osteochondritis dissecans.

FIGURE 14-16. A: This is an anterior view of a 14-year-old girl's ankle. She complained of pain and swelling, and had limited range of motion in the joint. There is a radiolucent lesion in the talus that is close to the subchondral bone. There are central calcifications. **B:** The sagittal T1-weighted magnetic resonance image reveals the lesion and an associated edema. This lesion is a chondroblastoma, and was treated with curettage.

The histologic appearance of chondroblastoma is typical, and this disorder is rarely confused with other diagnoses. It consists of small cuboidal cells (chondroblasts) closely packed together to give the appearance of a cobblestone street (288,289,290 and 291). In addition, there are areas with varying amounts of amorphous matrix that often contains streaks of calcification, and usually there are numerous multinucleated giant cells. Chondroblastoma is not as vascular as osteoblastoma, and there are few, if any, mitoses, and no abnormal mitoses (Fig. 14-17).

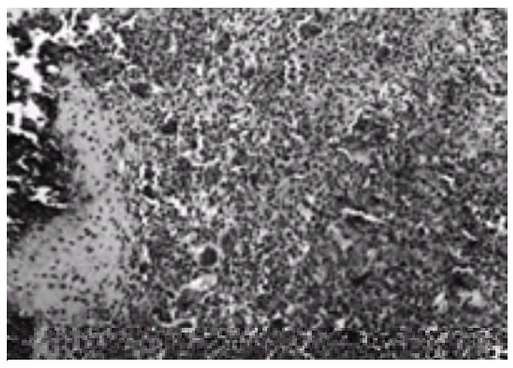

FIGURE 14-17. Histologic appearance of a chondroblastoma. The tumor consists of cuboidal cells (i.e., chondroblasts), varying amounts of amorphous matrix (some of which is calcified), and multinucleated giant cells. Calcification is seen (**left**). The cuboidal cells fit together in such a manner that they have the appearance of cobblestones. (Original magnification ×10.)

Chondroblastomas progress and invade the joint. They should be treated when found. Curettage is the treatment of choice, but it must be a thorough curettage and extend beyond the reactive rim (291). The lesion should be seen adequately at the time of the curettage, which usually means that the joint must be opened. Iatrogenic seeding of a joint is not a significant risk, and intraarticular surgical exposure is recommended if this facilitates visualization. The majority of recurrences are cured with a second curettage, but a rare lesion can be locally aggressive, and requires a wide resection (290). Chondroblastoma of the pelvis frequently behaves more aggressively than that in long bones, and an initial wide excision is recommended.

Most patients are close to skeletal maturity when the diagnosis is made, and the risk of growth disturbance from the tumor or its treatment is minimal. When the patient is younger than 10 years old care should be taken not to damage the growth plate.

Periosteal Chondroma

This is an uncommon lesion that arises from the surface of the cortex, deep in the periosteum (295,296 and 297). The patient usually complains of pain at the site of the lesion. More than half of these lesions are found in the proximal humerus, and the others are evenly dispersed through the long bones. The lesion often can be palpated. It is a nontender, hard mass that is fixed to the bone. The plain radiograph is typical (Fig. 14-18). Periosteal chondroma is a scalloped defect on the outer surface of the cortex, occasionally with intralesional calcifications and minimal periosteal reaction. Microscopically, periosteal chondroma is benign cartilage, but it appears more active than enchondroma. It has been mistaken for chondrosarcoma. Because local recurrence is a risk, a wide excision, including the underlying cortex, is the treatment of choice.

FIGURE 14-18. Radiograph of the shoulder of a 12-year-old boy. The large periosteal chondroma involves the medial aspect of the metaphysis. Most such tumors are smaller. This patient had no symptoms; the lesion was found by the boy's pediatrician on routine physical examination, and an incisional biopsy confirmed the diagnosis. The lesion was only partially removed. The tumor did not change appreciably during 2 years of follow-up.

Lesions of Fibrous Origin

Nonossifying Fibroma

Nonossifying fibroma, which is also known as fibroma of bone, nonosteogenic fibroma, metaphyseal fibrous defect, and fibrous cortical defect, is probably the most common lesion of bone (298,299,300,301 and 302). Up to 40% of children have this lesion, which is found most often between the ages of 4 and 8 years (303). Ninety percent are in the distal femur. These are asymptomatic lesions that are found only if a radiograph is taken for another reason or when the patient has a pathologic fracture. The patient has no abnormal physical findings, and the serum and urine chemistries are normal.

Nonossifying fibroma should be recognized based on the clinical presentation and plain radiographic findings (298). Biopsy for diagnosis is rarely necessary. Two radiographic appearances are seen. The more common fibroma is a small (less than 0.5 cm) radiolucent lesion within the cortex, with a sharply defined border. Most authors call this lesion a “fibrous cortical defect” (93). There is little or no increased uptake on the technetium bone scan.

The other appearance is that of a metaphyseal lesion eccentrically located (Fig. 14-19). This lesion probably started out as a fibrous cortical defect, but continued to enlarge. It appears to have arisen from within the cortex, expanding into the medullary cavity and raising the periosteum. The lesion is surrounded by a well-defined thin rim of reactive bone. There should be no acute periosteal reaction unless there has been a fracture. There may be slightly increased uptake on the technetium bone scan. Multiple nonossifying fibromas occur in approximately 20% of patients. Usually they are found in the lower extremities, so investigators suggest obtaining plain radiographs of both lower extremities, whenever a nonossifying fibroma is found.

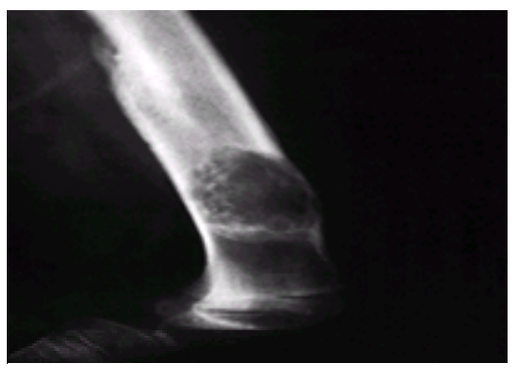

FIGURE 14-19. Lateral radiograph of the distal femur with a large nonossifying fibroma (NOF). The patient had sustained a pathologic fracture that had healed, but the lesion persisted. NOF is usually a metaphyseal, radiolucent, irregular lesion surrounded by a reactive rim of bone. As is often the case, the cortex surrounding a large NOF is thin and appears to be expanded. Although this lesion eventually heals spontaneously, its large size and persistence after pathologic fracture indicated that curettage and bone grafting were necessary. NOFs that replace more than half of the bone should be curetted and grafted.

Both lesions consist of benign, spindle, fibroblastic cells arranged in a storiform pattern (298,299) (Fig. 14-20). Multinucleated giant cells are common, and areas of large, lipid-laden macrophages often can be seen. Hemosiderin within the fibroblastic stromal cells and multinucleated giant cells is usual. There is no bone formation within the lesion, and mitoses are not seen.

FIGURE 14-20. Low-power histologic view of a typical nonossifying fibroma. The fibroma is composed of benign fibrous tissue and multinucleated giant cells. Hemosiderin is often present. The nonossifying fibroma is invading cortical bone (**right**). (Original magnification ×10.)

The small cortical lesion (fibrous cortical defect) needs no treatment, but should be observed. Repeat radiographs at 3- to 6-month intervals for 1 to 2 years are suggested. These lesions should heal spontaneously. Nonossifying fibroma may need surgery. Nonossifying fibromas that are less than 50% of the diameter of the bone can be merely observed, but curettage and packing with bone graft should be considered if they enlarge (304,305 and 306). Patients who present with nonossifying fibromas that are more than 50% of the diameter of the bone should consider having the lesions curetted and packed with bone graft. According to Arata and colleagues (306), these patients have an increased risk of developing pathologic fractures. Many patients with these large nonossifying fibromas elect not to have surgery, and reduce their activity instead. This is an alternative treatment.

Patients who present with pathologic fractures should have the fractures treated nonoperatively if possible. The fracture should heal without difficulty in a normal length of time. There is no evidence that the healing of the fracture increases the chances of spontaneous healing of a nonossifying fibroma, or of any other benign lesion. Nonossifying fibroma usually heals spontaneously, which may happen after the fracture, but usually the fracture callus obscures the radiolucent lesion and the physician is fooled into thinking that the lesion is healing. When the callus has remodeled and the cortices become distinct on the radiograph, the lesion can be seen again. Patients with pathologic fractures must be followed until the callus has remodeled sufficiently so that a final determination can be made about the status of the underlying nonossifying fibroma. If it persists after the fracture has healed, curettage and bone grafting are suggested.

Fibrous Dysplasia

Fibrous dysplasia may not be a true neoplasia, but a developmental abnormality caused by a somatic mutation with a defect in the formation of bone (see Chapter 7). It is a common disorder that produces a variety of complaints and physical findings. The majority of patients (approximately 85%) have a single skeletal lesion (monostotic fibrous dysplasia), whereas the remainder have numerous lesions (polyostotic fibrous dysplasia). The patients with polyostotic fibrous dysplasia may have only two or three small areas of involvement, or may have extensive skeletal abnormalities with grossly deformed bones.

The patient with monostotic fibrous dysplasia usually presents without symptoms, and the lesion is found when a radiograph is taken for unrelated reasons (307,308,309 and 310). Occasionally the child presents with a pathologic fracture or angular deformity. A rib is the most common location of monostotic fibrous dysplasia, but any bone can be involved. There are no physical findings associated with monostotic fibrous dysplasia, and the cafeé-au-lait lesions and endocrine abnormalities sometimes found in patients with polyostotic fibrous dysplasia, do not occur in patients with the monostotic variant. Serum and urine chemistries are normal in patients with fibrous dysplasia.

The plain radiograph is often diagnostic, although the radiographic appearance of fibrous dysplasia is variable (Fig. 14-21A). It is a medullary process that typically produces a ground-glass appearance on the radiograph. The lesion is usually diaphyseal. The diaphysis is larger than normal, and the ground-glass appearance of the medullary canal blends into the thinned cortex so that it is difficult to define the border between the medullary canal and the cortex. When typical-appearing lesions are seen in a single bone or in a single limb, the diagnosis is almost certain. There may be an angular deformity in the bone, especially when the lesion is large. The lesions may mature with age and become radiodense or cystic. Fibrous dysplasia shows excessive uptake on a technetium bone scan out of proportion to what one might predict from the plain radiographic appearance.

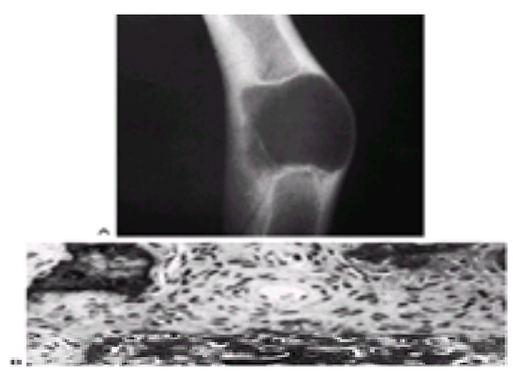

FIGURE 14-21. A: Radiograph of a fibrous dysplasia in the diaphysis of a long bone. The ground-glass appearance, the thin cortex, and the angular deformity of the bone are all typical features of fibrous dysplasia. Because this lesion was large and the patient had an angular deformity, a cortical bone graft was placed within the cortex to increase the strength of the bone. Curettage of the lesion probably does not increase local control, but should be performed if it can be carried out easily. Fibrous dysplastic bone is structurally weak, and cortical grafts are more likely to improve the strength of the bone and not be resorbed by the host. **B:** Histologic appearance of fibrous dysplasia. The tumor is mostly fibrous tissue composed of collagen and fibroblast. Small bits of bone and osteoid, often having a “C” or an “O” shape, seem to have been sprinkled on the fibrous tissue. Osteoblasts are not seen, and the bone seems to be produced by the fibroblastic cells. (Original magnification ×40.)

The patient with polyostotic fibrous dysplasia usually presents around the age of 10 years, complaining of an angular deformity of a bone (307,311,312,313 and 314). The most common deformity is varus of the proximal femur, or shepherd's crook deformity. The light brown skin lesions with irregular borders are called “coast of Maine” cafeé-au-lait spots. The lesions with smooth borders associated with neurofibromatosis are called “coast of California” cafeé-au-lait spots.

Hyperthyroidism and diabetes mellitus have been reported as associated endocrinopathies, and vascular tumors have been seen in association with fibrous dysplasia (313,315,316,317 and 318). Albright syndrome is a triad of fibrous dysplasia, café-au-lait spots, and precocious puberty (315). The lesions in polyostotic fibrous dysplasia tend to be more unilateral than bilateral. The radiographic appearance of the lesion is the same as in patients with monostotic disease. The structural strength of bones with fibrous dysplasia is reduced as a result of the poorly organized trabecular pattern and the thinned cortex. The weakness of the bones leads to

the deformities that are usually present.

Microscopically, fibrous dysplasia, both the monostotic and polyostotic forms, is composed of fibrous tissue with normal-appearing nuclei and irregularly shaped strands of osteoid and bone (Fig. 14-21B). There are few if any osteoblasts present, and the osteoid and bone seem to arise directly from the background fibrous stoma. The bone is irregularly organized, and often has a “C” or an “O” shape. Multinucleated giant cells are rare in fibrous dysplasia, and there should be few mitoses, and none of these cells should be abnormal. Nodules of cartilage may be present in typical fibrous dysplasia.

Monostotic fibrous dysplasia usually does not need surgical treatment. Occasionally, a solitary lesion will be painful and curettage with grafting is required. Small lesions can be packed with cortical cancellous bone graft (autogenous or allogenic), whereas large lesions are probably better treated with cortical bone grafts. A special circumstance is a lesion in the femoral neck. These lesions seem to have a risk of developing fatigue fractures, and cortical bone grafting is recommended (319). Resorption of the bone graft with recurrence of fibrous dysplasia can occur, and the patient should be seen in follow-up for up to 5 years. Occasionally it is necessary to augment the bone with long-term or permanent internal fixation to prevent repeated fractures and relieve pain. Progressive bone deformity is unusual in patients with monostotic fibrous dysplasia. Patients with polyostotic fibrous dysplasia are more often in need of surgical therapy. Bone deformity is the most common indication. The proximal femur is the most challenging bone to manage. Once a varus deformity develops, it is important not only to bone graft (preferably cortical bone), but to correct the angular deformity with a valgus osteotomy. Rigid internal fixation is recommended (307,320,321,322,323,324,325,326,327 and 328).

Osteofibrous Dysplasia

Kempson (329) described the osteofibrous dysplasia lesion, which is found in the mandible and the anterior cortex of the tibia of children. It is benign, but may be locally aggressive. It is *not* a healing nonossifying fibroma. The patients usually do not have symptoms, and usually are brought to the physician's attention by a parent who has noticed an anterior bowing or mass in the tibia. The lesion is almost always located within the anterior cortex of the tibia, and is best seen on the lateral radiograph (Fig. 14-22). There are usually numerous radiolucent lesions with a rim of reactive bone. There is increased uptake on the technetium bone scan in the area of the lesion.

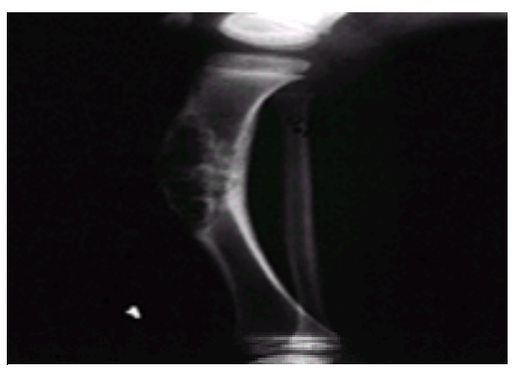

FIGURE 14-22. Lateral radiograph of the leg of a patient with osteofibrous dysplasia. Found almost exclusively in the tibia, this lesion involves the anterior cortex, and can extend into the medullary canal. The tibia commonly has an anterior bow.

Although Kempson (329) suggested the name “ossifying fibroma,” the more commonly used term is “osteofibrous dysplasia” (330,331,332,333 and 334). Some authors believe that osteofibrous dysplasia is a type of fibrous dysplasia, but this is controversial. Fibrous dysplasia has numerous characteristics that osteofibrous dysplasia does not have. Fibrous dysplasia arises from the medullary canal, and rarely produces bowing of the tibia. It rarely recurs after curettage, and is not an aggressive lesion unless the patient has polyostotic disease. Osteofibrous dysplasia, on the other hand, arises from the cortex and involves the medullary canal late in the disease process. It usually is associated with a bowed tibia, and quickly recurs if curetted. Usually it requires a resection for control. There have been few studies of patients with osteofibrous dysplasia with adequate follow-up, but many of these lesions slowly progress, and are eventually resected.

The authors recommend observation of the lesion when it is found in a patient younger than 10 years of age. Incisional biopsy is not necessary in most cases, because the clinical presentation is diagnostic. In addition, the biopsy reveals only a small portion of the lesion, and does not change the initial management. Bracing may not prevent progressive bowing, but can be tried if there is an angular deformity. If the lesion progresses before closure of the growth plate, biopsy and resection are suggested. If the patient presents after closure of the growth plate, especially if the lesion is large (more than 3 or 4 cm in diameter) or has aggressive features on plain radiographs, a biopsy is suggested. If an adamantinoma is found a wide resection is recommended. If the biopsy reveals osteofibrous dysplasia, it is best to excise the entire lesion for a complete histologic examination to rule out the possibility of there being a focus of adamantinoma. If the lesion is small (less than approximately 3 cm) and the patient has no symptoms, continued observation is suggested.

Adamantinoma has a clinical presentation similar to osteofibrous dysplasia. In adamantinoma, however, usually the patient is older (third decade of life), and the lesion appears more aggressive on the radiographs (e.g., soft tissue extension, acute periosteal reaction, large size, involvement of the medullary canal), but this is not always the case. It has been suggested that there is another type of adamantinoma that looks extremely similar to osteofibrous dysplasia, even with histologic examination. One must be suspicious of the diagnosis of osteofibrous dysplasia, especially in a progressive lesion in a patient older than 10 years of age (335,336).

If a lesion suspected of being an osteofibrous dysplasia is going to be observed, the patient should undergo radiography at least every 6 months until the lesion heals or is resected. Typical adamantinoma has a risk of metastasizing, but it is not known if the adamantinoma that looks like osteofibrous dysplasia can metastasize (333).

Miscellaneous Lesions

Langerhans Cell Histiocytosis

“Langerhans cell histiocytosis” is the name selected to refer to what we once called “histiocytosis X,” and includes the syndromes eosinophilic granuloma, Hand-Schüller-Christian disease, and Letterer-Siwe disease (337,338). In 1941 Farber suggested that eosinophilic granuloma, Hand-Schüller-Christian disease, and Letterer-Siwe disease were related (339). Later, Lichtenstein published an article agreeing with Farber, and suggested the term “histiocytosis X” (340). This is a disorder of the Langerhans histiocytes, and although eosinophils are a common component of the lesion, they are not necessary for the diagnosis (Fig. 14-23).

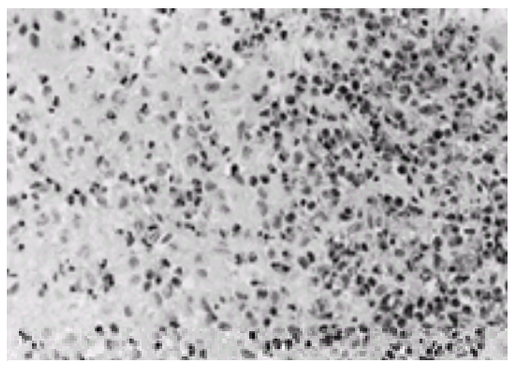

FIGURE 14-23. Low-power view of an eosinophilic granuloma (Langerhans granuloma). The eosinophils are numerous, but it is the presence of histiocytes that defines this tumor. The histiocytes are large cells with a clear, folded nucleus and a prominent nucleolus. (Original magnification ×10.)

Eosinophilic granuloma usually occurs in patients between the ages of 5 and 15 years. The skull is the most commonly involved site (341) (Fig. 14-24). Many of the skull lesions probably are not diagnosed because the only abnormality is a painless, small, spontaneously resolving lump in the scalp. The vertebral bodies and the ilium are the next most common sites of involvement (342,343 and 344). Those lesions in long bones may weaken the bone sufficiently that the patient presents with activity-related pain suggestive of a fatigue fracture, or with a pathologic fracture. The lesion is a radiolucent abnormality with sharp borders of transition and often no reaction by the host bone. An apparent central sequestrum of bone may be seen. Eosinophilic granuloma usually results in increased uptake on a technetium bone scan, but as many as 25% of lesions will not be associated with abnormal bone scans (72,73,345,346,347,348,349 and 350) (Fig. 14-25).

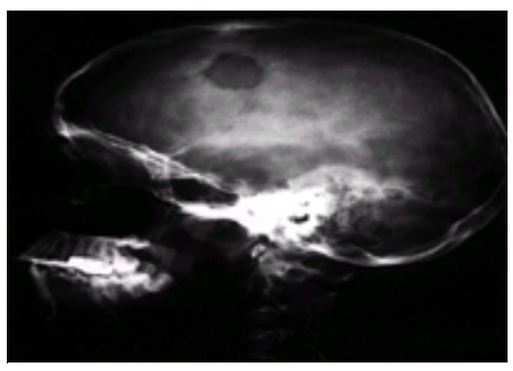

FIGURE 14-24. This is a lateral plain radiograph of the skull of a patient with a solitary Langerhans cell histiocytosis (eosinophilic granuloma). The skull is the single most common site of involvement for eosinophilic granuloma. Plain radiographs of the skull are recommended when eosinophilic granuloma is suspected. These lesions rarely require treatment.

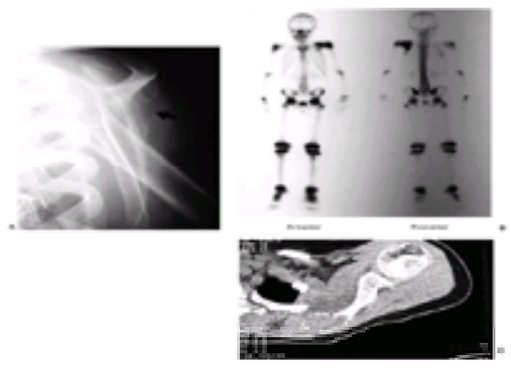

FIGURE 14-25. A: This plain radiograph is an oblique view of an 8-year-old girl's scapula. The *arrow* points to a subtle area of cortical erosion. The patient complained of pain, and there was a tender mass over the scapula. **B:** On the anterior view of the same patient's technetium 99 bone scan, the increased uptake in the scapula is easily seen. This patient has a solitary Langerhans cell histiocytosis (eosinophilic granuloma), but her lesion is associated with increased uptake. This is true in the majority of cases. **C:** On the computed tomography scan, a lesion is seen in the medial border of the scapula. After biopsy, curettage without graft was curative.

Patients with eosinophilic granuloma do not progress to Hand-Schüller-Christian disease, but should be evaluated on presentation to exclude the presence of that syndrome. Obtaining a lateral skull film to observe the size of the sella turcica, and a first voided urine specimen after overnight fluid restriction to prove that the patient can concentrate his or her urine, is the easiest way to evaluate the patient for diabetes insipidus. Liver enzymes should be determined. A skeletal survey also should be done to look for other lesions. Multiple lesions can be seen in eosinophilic granuloma. If any of these parameters are abnormal, the patient should be referred to a pediatric hematologist. The authors routinely seek a consultation from a pediatric hematologist for all patients with Langerhans cell histiocytosis.

It was believed that eosinophilic granuloma needed to be treated, and many children underwent irradiation, curettage, or excision. At present, it is believed that the majority of these lesions are self-healing, and that no specific treatment is necessary (338). Intralesional injection of corticosteroids has been recommended by some physicians (351,352 and 353).

Hand-Schüller-Christian disease is a combination of bone lesion, exophthalmos, and diabetes insipidus. Patients with this disorder should be treated with systemic corticosteroids or chemotherapy (354,355,356 and 357).

Letterer-Siwe disease is a malignant form of Langerhans cell histiocytosis. Most patients present before 3 years of age with skin, visceral, and brain lesions, and they may or may not have bone lesions. They require aggressive chemotherapy (341,358,359 and 360).

Unicameral Bone Cysts

Unicameral bone cysts are not always unicameral. They also are called “simple bone cysts,” but they may not be simple to treat. These common lesions usually are found when the patient sustains a pathologic fracture. Their radiographic appearance is so typical that most can be diagnosed without a biopsy (Fig. 14-26). The proximal humerus and the proximal femur account for 90% of unicameral bone cysts (361,362,363,364 and 365). The cysts seem to arise from the epiphyseal plate, and are immediately adjacent to the plate extending into the metaphysis (366,367,368 and 369). The metaphyseal bone does not remodel and the metaphysis is broader than normal, but not broader than the width of the epiphyseal plate. A thin rim of bone borders the unicameral bone cyst. The surrounding bone is not reactive, and there is no acute periosteal reaction. When the cyst becomes mature (latent), usually after the patient reaches the age of 10 years, the epiphysis grows away from the lesion. The unicameral bone cyst eventually heals spontaneously and fills in with bone. No evidence of its previous existence is seen.

FIGURE 14-26. Anteroposterior radiograph of a proximal femoral unicameral bone cyst (UBC). UBCs are radiolucent lesions immediately adjacent to the growth plate that extend into the metaphysis. This UBC is considered active because it is immediately adjacent to the growth plate and the patient is younger than 10 years old. Large lesions in the proximal femur should be treated because of the risk of pathologic fracture. Initial treatment should be a corticosteroid injection.

Treatment is to prevent a pathologic fracture. Some lesions remain small and do not present a significant risk to the patient. Other lesions are large (e.g., proximal humeral lesions), are in high-stress anatomic sites (e.g., the femoral neck), or persist after the patient has become a young adult, and in these cases treatment is indicated. Only those patients who have unicameral bone cysts that are at risk for pathologic fracture should be treated (370,371,372,373,374 and 375). Injection is recommended rather than an operative procedure because the results of injection are equal to those of curettage and bone grafting, whereas the risk, recovery, and cost are less. Intracystic injection of corticosteroids is the treatment of choice as an initial means of stimulating the cyst to heal (376,377). Before the common use of corticosteroid injections, curettage and autogenous bone grafting had been the most common treatment. Operative treatment with curettage and autogenous bone grafting is reserved for those lesions that do not respond to repeated injections of corticosteroid (361,376,378,379 and 380). The number of injections that should be tried before deciding to operate is not agreed upon. The authors give at least three injections approximately 1 month apart before resorting to an open operative procedure. The injection of autogenous bone marrow is a technique advocated by some (381). In a study of ten patients whose unicameral bone cysts were treated with autogenous marrow, all were free of pain within 2 weeks of the injection, and all healed completely within 1 year.

The injection of corticosteroid was introduced by Scaglietti and colleagues (377,382). It has been used extensively and is an established method of treatment of a unicameral bone cyst. It should be performed with anesthesia (usually general anesthesia), and with the aid of fluoroscopic visualization. An 18- or 20-gauge spinal needle is passed percutaneously into the cyst. The wall of the cyst is penetrated easily by an 18-gauge needle with the stylet in place. Rotating the needle as it is pushed through the bone often helps it penetrate the cortex. Clear yellow or slightly bloody fluid should be obtained. If no fluid is aspirated, the diagnosis of unicameral bone cyst should be questioned and the lesion biopsied.

Once the fluid has been withdrawn a second needle is introduced into the cyst as far from the first as possible. A radiopaque dye (usually Renografin 60) is injected into the cyst to confirm that it is unicameral, and that all parts fill with dye. Frequently the draining veins are seen shortly after the cyst is injected. If the cyst has more than one cavity, each one should be injected.

It is not known if the type of corticosteroid used is important, but methylprednisolone acetate (Depo-Medrol) is probably the most commonly used steroid. There is no standard amount of corticosteroid. Usually, 80 mg is sufficient for a small cyst, and up to 160 mg may be used for large cysts. There are two techniques for corticosteroid injection. One is to inject the corticosteroid under pressure, with the second needle occluded, to rupture the cyst wall. The other is to inject the corticosteroid without pressure, using the second needle as a vent. It is unclear which method is better. A repeat radiograph is taken in 1 month, and if there is no evidence of early healing (e.g., increased thickness of the reactive wall), a repeat injection is done. Repeated injections are often needed, but more than three to five probably are not beneficial.

The rare unicameral bone cyst that requires operative treatment should be curetted and packed with bone graft. When the cyst is adjacent to the growth plate, care should be taken not to damage the epiphyseal cartilage during curettage (383). Autogenous bone or allograft cortical cancellous bone can be used to pack the cavity (361,378,384,385). Freeze-dried cortical cancellous allograft is particularly advantageous because it is associated with an excellent healing rate and little, if any, incidence of complications, and no secondary incision is required to obtain the autogenous bone graft. Calcium sulfate tablets are an alternative material that can be used to fill the cavity (386,387).

Aneurysmal Bone Cysts

An ABC is a controversial lesion (361,363,388,389,390 and 391). Some investigators believe that this lesion occurs only in association with another bone tumor, whereas others recognize ABCs as a primary diagnosis (389,392,393). ABCs often occur in association with a number of benign tumors (e.g., giant cell tumor, chondroblastoma, osteoblastoma), or with osteosarcoma (389). When it is a secondary lesion, the primary lesion usually is obvious, and the ABC component is limited to only a small portion of the tumor. Secondary ABCs are classified with their underlying diagnosis. The presence of a secondary ABC does not change the therapy or prognosis of the underlying primary tumor.

A primary ABC occurs most commonly in teenagers (80%). More than 50% of these cysts arise in large tubular bones, and almost 30% occur in the spine. The patient usually complains of a mild, dull pain, and only rarely is there a clinically apparent pathologic fracture. The patient's physical examination is usually normal, and there are no abnormal laboratory findings associated with ABC.

On the plain radiograph an ABC is a radiolucent lesion arising eccentrically within the medullary canal of the metaphysis (Fig. 14-27). It resorbs the cortex and elevates the periosteum, generally making the bone wider than the epiphyseal plate. Usually, there is a thin shell of reactive periosteal bone, but occasionally this bone cannot be seen. When ABC arises in a long bone, it is metaphyseal. When it arises in the spine, it originates in the posterior elements but it may extend into the body, and not uncommonly will extend to an adjacent vertebral body or rib. Giant cell tumor of the bone and telangiectatic osteosarcoma may have identical radiographic appearances as an ABC (379,389). The periosteal reaction has an aggressive appearance, and the lesion may be mistaken for an aggressive or malignant tumor (363). ABCs may arise in the cortex and elevate the periosteum with or without involving the medullary canal.

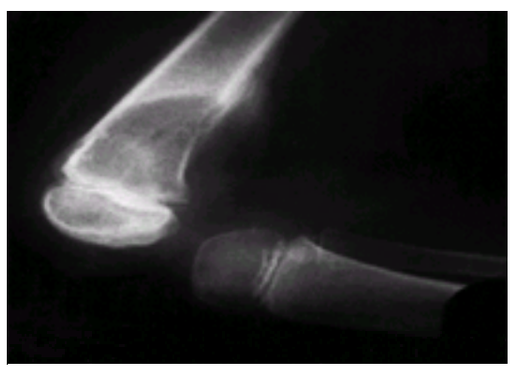

FIGURE 14-27. Radiograph of a distal femur with an aneurysmal bone cyst involving the distal metaphysis, and extending through the posterior cortex. As in this patient, an aneurysmal bone cyst may have the appearance of an aggressive tumor. When the cyst erodes through the cortex it usually is contained by the periosteum, which reacts and produces bone. The differential diagnosis should include aneurysmal bone cyst, osteosarcoma (telangiectatic variant), Ewing sarcoma, and osteomyelitis. This patient was successfully treated with curettage and bone grafting.

The CT scan is helpful in making the diagnosis of ABC. The lesion should have a density of approximately 20 HU, and this does not increase with intravenous contrast injection. When the patient lies still for 20 to 30 min, the cells in the fluid within the cyst cavity settle, and a fluid/fluid level can be seen (394). Similar findings can be seen on MRI. Fluid/fluid level was originally described in ABC but has subsequently been seen in a number of other lesions. It cannot be considered diagnostic of ABC. An ABC has an increased uptake of technetium on the bone scan, but often the scan has a central area of decreased uptake (395).

ABCs should be biopsied to establish the diagnosis, then curetted and packed with bone graft. The pathologist should be advised in advance, and the possibility of a telangiectatic osteosarcoma should be discussed. It is uncommon for the histologic appearance of an ABC to be confused with that of a telangiectatic osteosarcoma, although the radiographic and gross appearances can be identical. On gross inspection, an ABC is a cavitary lesion with a villous lining. Microscopic examination reveals the lining to be composed of hemosiderin-laden macrophages, multinucleated giant cells, a fibrous stroma, and usually small amounts of woven bone (Fig. 14-28). The microscopic appearance of the lining of the ABC is similar to that of a giant cell tumor of bone.

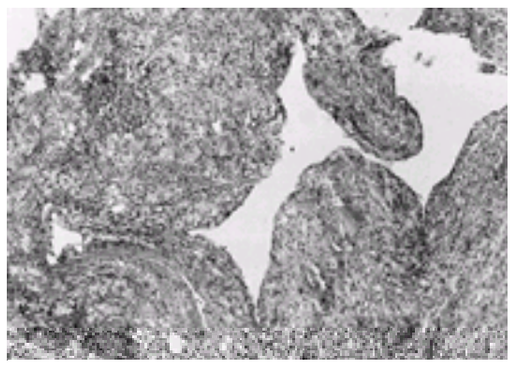

FIGURE 14-28. Low-power view of the tissue lining an aneurysmal bone cyst. The lining is composed of fibrous tissue with multinucleated giant cells, foamy histiocytes, hemosiderin, and, often, spicules of immature bone (not seen). The fronds and spaces are typical. (Original magnification ×10.)

The majority of ABCs are treated successfully with curettage and packing of bone graft. The first recurrence can be recuretted and grafted. Embolization has been used to decrease blood loss during surgery, and has been associated with fewer recurrences (396,397). Whether embolization is necessary or of help is debatable. Cryosurgery has also been reported (361,388,398). Cryosurgery has associated complications, and it is not considered necessary in most cases. It may play a role in the treatment of recurrent lesions. Definitive resection can be performed when the consequences of the resection are minimal, but it is absolutely necessary only when the lesion has a particularly aggressive clinical growth pattern.

An ABC of the spine (approximately 30% of cases) can present a particularly challenging problem. The lesion always involves the posterior elements, but can also involve the vertebral body. The patients complain initially of pain at the site of the lesion, but the ABC often is not found until the patient has nerve root or cord compression. Radiotherapy has been used in the management of patients with ABC of the spine, but surgery is recommended for all patients as the initial means of treatment. Most cases are controlled with simple curettage. Usually the posterior elements are resected, and involvement of the pedicles or the body is curetted. If complete laminectomy is performed, a short posterior fusion is advised. Radiotherapy can be used in the postoperative period, but usually this is reserved for the rare case of rapid recurrence with soft tissue infiltration. Postoperative MRI or CT is recommended as a baseline study with which to compare any later scans.

Ewing Sarcoma/Peripheral Neuroectodermal Tumor

Ewing sarcoma and peripheral (or primitive) neuroectodermal tumor (EWS/PNET) are discussed together because they are closely related (247,399). Both have the same chromosomal translocation between chromosomes 11 and 22, similar presentations, identical treatments, and almost identical histologic characteristics. PNET is also called Askin tumor, and was originally identified from tumors classified as Ewing sarcoma. EWS/PNETs are thought to arise from the neural crest. At least 90% have a characteristic chromosomal translocation [t(11:22)(q24:q12)]. This translocation leads to a novel fusion protein called EWS-FLI1 (400,401).

EWS/PNET was the most lethal of all primary bone tumors before the routine use of adjuvant chemotherapy, with a 5-year survival of approximately 15% (402). Before the use of adjuvant chemotherapy, most patients were treated with irradiation alone. With improved survival associated with adjuvant chemotherapy the role of surgery has been reevaluated, and there is evidence, albeit only from retrospective studies, that surgical resection combined with chemotherapy produces improved survival compared with survival after irradiation and chemotherapy (239,402,403,404,405,406,407,408,409,410,411,412 and 413).

The patient with EWS/PNET initially complains of pain. Some have generalized symptoms of fever, weight loss, and malaise, but this is not the usual presentation. Males are affected at a 3:2 ratio over females, and most patients are between the ages of 5 and 30 years. Any bone may be affected. The femur is the most common site of origin (20%); the pelvis and the humerus are also common sites. There is usually a soft tissue mass associated with the bone lesion, and on physical examination this mass often can be palpated. The mass is warm, firm, and tender, and it may be pulsatile. There are no specific abnormal laboratory values diagnostic of EWS/PNET, but the sedimentation rate often is increased. Elevated LDH is a poor prognostic sign (247,399).

The typical plain radiograph of a EWS/PNET reveals diffuse destruction of the bone, extension of the tumor through the cortex, a soft tissue component, and a periosteal reaction (414) (Fig. 14-29). The periosteal reaction may produce a Codman triangle, an “onionskin” appearance, or a sunburst appearance. These suggest an aggressive lesion that has rapidly penetrated the cortex and elevated the periosteum. The extraosseous soft tissue mass and medullary canal involvement can be seen on CT and MRI scans, and usually are more extensive than what was expected from the plain radiograph (80,415,416).

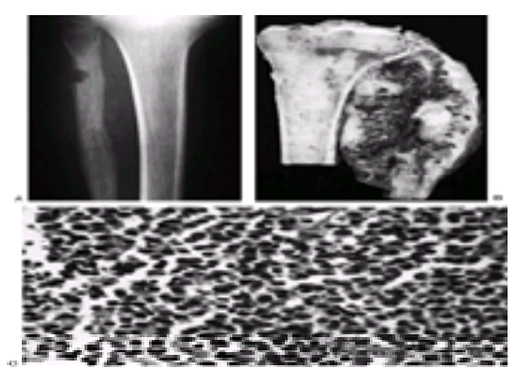

FIGURE 14-29. A: Anteroposterior radiograph of the proximal tibia and fibula of a patient with Ewing sarcoma involving the proximal fibula. The fibular cortical detail is lost, and erosion of the medial surface, soft tissue mass, and periosteal reaction—all typical findings of Ewing sarcoma—are present. The combination of these findings is indicative of an aggressive process. Acute osteomyelitis may have this appearance, but the patient usually has other signs of infection. The defect in the lateral aspect of the fibula is attributable to an incisional biopsy of the bone. The bone should not be biopsied if there is sufficient soft tissue extension. This will lessen the chance of pathologic fracture. In addition, the extraosseous tumor is usually more easily cut, and the histologic appearance is better. **B:** Gross specimen of Ewing sarcoma of the proximal fibula, similar to the case in **A**. The tumor has replaced the proximal fibula, and there is a large soft tissue mass, with invasion of surrounding muscles and no involvement of the tibia. This patient chose to have an immediate amputation, although this is not standard treatment. **C:** Histologic appearance of Ewing sarcoma. The nuclei are easily seen, and there are nucleoli within each nucleus. The cells are small and round, with very little variation in nuclear appearance. Mitoses are rare. The cytoplasm is faint and difficult to see, and the cytoplasmic borders are poorly defined. (Original magnification ×10.)

MRI has proved to be more accurate in determining the intramedullary extent of EWS than CT. The inflammation around the tumor is seen with MRI more easily than with other studies, and its extent is often more than expected from the other tests. The technetium bone scan is most useful in finding occult bone metastasis. Approximately 5% of these patients present with pulmonary metastasis.

The histologic appearance of EWS/PNET is that of a small, round, cell tumor. The EWS/PNET cell has a distinct nucleus with minimal cytoplasm and an indistinct cytoplasmic border (7,417,418 and 419). The cells are similar and mitoses are uncommon. Necrotic areas usually are seen. There are glycogen granules in the cytoplasm, and these produce the positive periodic acid Schiff (PAS) stain on routine histologic examination. The intracellular glycogen granules are diastase positive (i.e., exposure to diastase will break the glycogen down, eliminating PAS staining). The glycogen can be seen as dense cytoplasmic granules with the electron microscope. Increasingly, genetic analysis is being done for EWS/PNET to identify the 11:22 translocation as a means of establishing the diagnosis.

Treatment of EWS/PNET is a combination of chemotherapy and either irradiation or surgery (245,412,420,421,422,423,424,425,426,427,428,429,430,431 and 432). The drugs commonly used include vincristine, doxorubicin, cyclophosphamide, ifosfamide, and etoposide. Actinomycin D, a drug used previously, is currently used less often. Most protocols begin with two to four courses of chemotherapy before deciding how to manage the primary tumor. This usually results in a significant

reduction in the size of the primary tumor. Surgical resection is recommended if the functional consequences of the resection are acceptable (406,407,408,433,434 and 435). If the margins are close and viable tumor is present in the resected specimen, postoperative irradiation is recommended. If the primary tumor cannot be resected without undue morbidity, irradiation alone can be used (223,224,423,436,437,438,439,440,441,442,443,444 and 445). The total dosage should be kept as low as possible, usually around 50 gray (Gy), and certainly less than 60 Gy, because dosages of more than 60 Gy are associated with an unacceptable incidence of later irradiation-associated sarcomas (446,447,448,449,450,451,452 and 453).

Current survival statistics for patients presenting without metastasis reveal a 5-year disease-free survival of greater than 65% (444). Patients who present with metastasis have less chance of being cured but should be treated aggressively because some will survive.

Soft Tissue Tumors

The majority of soft tissue tumors in children are benign (454). Only rhabdomyosarcoma in the younger age group and synovial cell sarcoma in teenagers and older patients occur with any frequency, and they are both rare tumors (455). Hemangioma, the fibromatoses, neurilemoma, and neurofibroma are more common. The physician must be aware of the possibility of malignant soft tissue tumor in the child and evaluate any lump carefully (456).

Hemangioma

Hemangioma may be a true neoplasia, a hamartoma, or an arteriovenous malformation. Its origin is controversial. It is important that the abnormality be recognized as a benign lesion that in certain circumstances regresses spontaneously, and in others infiltrates the muscle and occasionally bone. Hemangiomas are the most common tumors in infancy and childhood, and account for 7% of benign soft tissue tumors in all age groups. They are most common in the head and neck regions, but also may be found in internal organs, especially the liver. Often an intrahepatic hemangioma can be seen on a CT scan of the abdomen taken for another reason, and its existence is of little concern.

Enzinger and Weiss (457) provide a classification of vascular tumors of soft tissue. The borderline malignant and malignant vascular tumors are not pertinent to this discussion; therefore, only the benign tumors are included:

- localized hemangioma
- capillary hemangioma (including juvenile type)
- cavernous hemangioma
- venous hemangioma
- arteriovenous hemangioma (racemose hemangioma)
- epithelioid hemangioma (angiolymphoid hyperplasia, Kimura disease)
- hemangioma of granulation tissue type (pyogenic granuloma)
- miscellaneous hemangiomas of deep soft tissue (synovial, intramuscular, neural)
- angiomatosis (diffuse hemangioma)

Capillary hemangioma constitutes the largest group of benign vascular tumors. The juvenile hemangioma variant of capillary hemangioma occurs in 1 of every 200 live births. They may be cutaneous or deep, and usually are seen within the first few weeks of life, often enlarging for the first 6 months but then regressing and becoming 75 to 95% involute by the age of 7 years. Capillary hemangiomas do not require treatment.

Cavernous hemangiomas are not as common as the capillary type, but do not spontaneously regress and may require treatment. They most commonly arise within muscle, and invade tissue planes extensively. The patient often presents with complaints of swelling, tenderness, and inflammation secondary to thrombophlebitis within the hemangioma. This inflammation resolves within a few days, and can be treated with local heat and oral aspirin. The noninflamed hemangioma is soft and ill defined. The patient may have no symptoms or the sensation of heaviness or a tight feeling in the extremity. On the plain radiograph there are often small, smooth, round calcifications called “phleboliths.” The appearance of hemangiomas on MRI is virtually diagnostic, because they are composed of smooth, regular blood vessels and normal fat.

The cavernous hemangiomas have an indirect communication with the major vascular tree, and are not easily filled with contrast for angiography or venography; they are better visualized with MRI. Occasionally a tourniquet proximal to the hemangioma permits filling of the tumor veins at the time of venography or angiography (Fig. 14-30). If an intravenous injection does not demonstrate the hemangioma, the dye can be injected directly into the hemangioma. CT, particularly if performed with intravenous contrast, is almost always diagnostic. The hemangioma has varying densities with multiple dye-filled areas. Biopsy is performed only to confirm the diagnosis, and resection is not necessary unless the patient has repeated bouts of inflammation or complaints of discomfort (usually a full or tight feeling), or the parents are anxious about the mass.

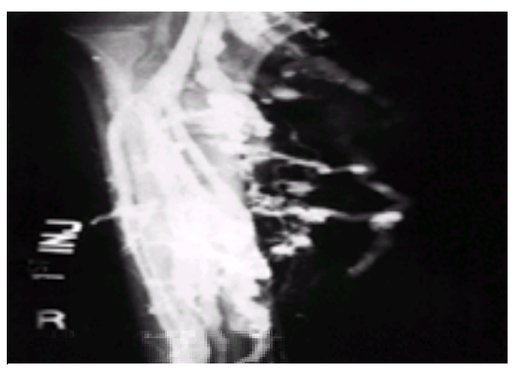

FIGURE 14-30. Venogram of a patient with hemangioma of the calf. The hemangioma communicated with the deep venous system and was easily filled when normal veins were injected with contrast; this is not always the case. This patient had two pulmonary emboli, and the hemangioma was confined to the gastrocnemius muscle. Therefore, the entire gastrocnemius muscle was resected.

Surgical excision usually is not required. When surgery is performed the hemangioma often recurs unless the entire muscle (or muscles) involved is resected. These lesions are probably best considered congenital abnormalities that involve most of the veins in the extremity. When the grossly involved veins are resected the surrounding vessels dilate, resulting in clinical recurrence. Hemangiomas do not undergo malignant degeneration, and although they can produce significant abnormalities in the extremity surgical resection is rarely curative, although it may reduce the symptoms. Irradiation has been used with varying benefit. Embolization also has been used for patients who have severe pain. Direct injections have been used, but there are few data regarding the results, and published reports of this management have not been found.

Hemangioma of bone, either solitary or diffuse, is a hamartoma, and not a true neoplasia. The solitary lesions are more frequent, especially in the vertebral bodies where they are most often found (Fig. 14-31). Solitary lesions may occur in any bone, but the skull is the second most common site. These lesions do not produce symptoms, and usually are found when a radiograph is taken for another reason. The radiograph and CT scan are diagnostic. The bone has a honeycomb appearance, with increased trabecular markings around radiolucencies.

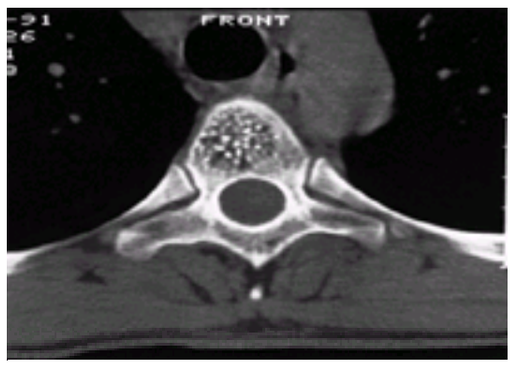

FIGURE 14-31. Computed tomography scan of a typical hemangioma of the vertebral body. The small foci of increased density are thickened trabeculae of bone, and the low-density areas are filled with the hemangiomatous tissue.

Patients with multiple lesions are more likely to present during the first or second decade of life, with either mild discomfort or pathologic fracture. These patients can have involvement of their viscera and skin. When multiple sites are involved they are usually the long bones of the extremities and the short bones of the hands and feet. Treatment should be symptomatic, with curettage and bone grafting for lesions that weaken the bone. Lesions that do not produce symptoms, or that are not at risk for fracture should be observed. They should resolve with time.

Fibromatoses

Benign fibrous lesions in children are relatively common and rarely malignant. Extraabdominal desmoid, or aggressive fibromatosis, is the most common benign fibrous lesion seen in children (458). The less common lesions are not discussed in this text. Enzinger and Weiss (457) discuss these elsewhere.

Extraabdominal desmoid or aggressive fibromatosis is the most common benign fibrous tumor seen in patients older than 10 years of age (459). The patient presents with mild pain and a slowly enlarging mass. The mass is deep, firm, and slightly tender, but it is not inflamed. The adjacent joint is normal. A soft tissue mass can be seen on a plain radiograph, but there are no distinguishing features. Calcifications within the mass are not expected.

There is usually increased activity in the lesion on the technetium bone scan, although some large masses will not display increased uptake. Often, even when the lesion is immediately adjacent to the bone, there is no increased uptake of technetium. The mass has a density similar to that of muscle on the CT scan, but usually it is more vascular and can be distinguished best from the surrounding tissue by performing CT while the patient is infused with intravenous contrast. The classic collagen bundles produce a relative signal void (dark on T1- and T2-weighted images) on MRI, but because the cellularity varies, fibromatoses may have an appearance on MRI similar to any soft tissue neoplasia (460,461).

Histologically, fibromatosis has the appearance of scar tissue (457,462). It is composed of dense bundles of collagen with evenly dispersed benign cells (Fig. 14-32). The cell of origin is believed to be the myofibroblast. The histologic appearance and cell of origin of fibromatosis are identical to those of plantar fibromatosis and Dupuytren contracture, but the latter conditions are not as clinically aggressive as fibromatosis. Although they recur, they do not extend proximally out of the feet or hands as seen in aggressive fibromatosis.

FIGURE 14-32. Histologic appearance of fibromatosis. The lesion infiltrates a muscle, and is more cellular than the typical fibromatosis. A wide resection was attempted, but this patient had a microscopically positive margin. One year later, the patient had not had a recurrence. (Original magnification ×10.)

Aggressive fibromatosis is an infiltrative lesion, and local excision rarely removes the entire tumor. Often what in the operating room appears to be the extent of the tumor is found to have microscopic tumor when examined by the pathologist. Fortunately, the presence of a positive margin at the initial resection does not always lead to a local recurrence, and it is recommended to observe the patient for a local recurrence. Approximately half of the patients will develop recurrent disease regardless of the histologic margin. Those patients whose lesions recur must be widely excised if local control is to be expected. Patients younger than 10 years of age have a greater risk of developing a local recurrence than older patients. When a wide surgical margin is accomplished with the resection of the recurrence, local control is usually achieved. When the second surgical margin is microscopically positive, irradiation is recommended (459). The majority of a patient's lesions will be controlled with this combination. Low-dose methotrexate and vinblastine (355,463) have been used to treat some patients with aggressive fibromatosis, and the initial reports have been encouraging, but the effect of this treatment is unpredictable. Fibromatosis has a variable clinical course, and the treatment needs to be individualized for each patient.

Benign Tumors of Nerve Origin

There are two common benign tumors that arise from nerves: neurilemoma and neurofibroma (457,462). Neurilemomas, or schwannomas, arise from the nerve sheath. They occur most often in early adulthood, and usually are solitary and slow-growing. The patient usually presents with a painless mass, and has a Tinel sign when the mass is tapped. The mass may be from any nerve, but it is often in the superficial tissue arising from a small sensory nerve. When arising from a spinal nerve root, the foramen may be enlarged because of the pressure of the tumor on the bone. Nerve dysfunction is uncommon, and is seen only when the nerve is compressed between the tumor and an adjacent rigid structure. Patients with superficial nerve lesions usually present early with small tumors, but deep-seated lesions may be large before they are discovered (Fig. 14-33). Neurilemoma rarely is seen in patients with von Recklinghausen disease because neurofibroma is the common type in these patients. Neurilemomas are nodular masses with a distinct capsule, and are easily separated from the nerve of origin. Their microscopic appearance is a combination of a cellular area (Antoni A) and a myxoid area (Antoni B). The Antoni A area is composed of benign spindle cells that tend to have their nuclei stacked with intervening cytoplasm (Fig. 14-34). The nuclear stacking is called a “palisaded appearance,” and the arrangement of alternating nuclei and cytoplasm is called a “Verocay body.” The Antoni B area is composed of myxomatous tissue with less cellularity than the Antoni A area. Neurilemomas are treated by marginal excision without sacrificing the affected nerve. Neurilemomas should not recur.

FIGURE 14-33. This is a sagittal view of a T1-weighted magnetic resonance image. The round, well-circumscribed mass posterior to the femur is within the peroneal nerve. It proved to be a schwannoma. Schwannomas have a typical appearance on magnetic resonance images. If they arise from a major nerve, as is the case in this patient, the nerve can usually be traced into the lesion. The schwannoma is smooth, slightly oblong, and has both bright and intermediate signals.

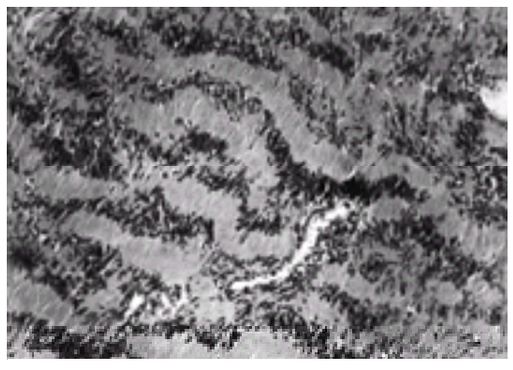

FIGURE 14-34. Histologic appearance of a neurilemoma (Antoni A area). The nuclei are stacked, giving the lesion a palisaded appearance. (Original magnification ×10.)

Neurofibromas may arise as a solitary lesion or multiple lesions. The majority, maybe as many as 90%, are solitary and are not characteristic of von Recklinghausen disease. They may arise in the skin or be associated with a recognizable peripheral nerve. Like neurilemomas, they usually present as a painless mass with a Tinel sign. Unlike neurilemomas, they tend to be intimately associated with the nerve fibers. Fortunately, most arise from small cutaneous nerves and can be removed without loss of nerve function. Histologically, neurofibromas are not encapsulated and invade the nerve fibers and, rarely, the adjacent soft tissue. The cells are elongated, wavy, and have dark-staining nuclei. There is a collagen matrix composed of stringy-appearing fibers. Neurites usually are seen within the lesion. Surgical resection is recommended for those lesions that are solitary and not associated with a major nerve. Lesions arising from a major nerve can be resected, but the nerve fascicles must be split and the neurofibroma removed from between them. Neither solitary neurilemoma nor neurofibroma has a significant incidence of malignant degeneration, although patients with neurofibromatosis have a small risk of developing neurofibrosarcoma.

Rhabdomyosarcoma

Rhabdomyosarcoma is a malignant tumor of muscle (3,246,464,465 and 466). It was once thought to occur in adults and children with almost equal frequency, but, since the middle 1970s, most of the adult tumors once called rhabdomyosarcoma have been reclassified as malignant fibrous histiocytoma. Rhabdomyosarcoma is believed to be extremely rare in adults, but it is the most common malignant soft tissue tumor in patients younger than 15 years of age. It accounts for approximately 3.5% of children's malignancies, and there are approximately 350 new cases per year in the United States (246,467). There are four histologic patterns: embryonal, botryoid-type, alveolar, and pleomorphic (468,469 and 470).

Botryoid-type rhabdomyosarcoma is histologically identical to the embryonal pattern, but is considered a separate entity because of its gross appearance. A botryoid rhabdomyosarcoma is an embryonal cell type that involves a hollow viscus. Pleomorphic rhabdomyosarcoma is a histologic type seen in adults, and is the least common. Embryonal rhabdomyosarcoma is the most common type, and usually arises in the head, the neck, the genitourinary tract, and the retroperitoneum. It is rare in the extremities. Botryoid rhabdomyosarcoma tends to occur in the first decade of life. The current treatment is a combination of chemotherapy, surgery, and, if not totally excised, irradiation. When chemotherapy is given preoperatively, the surgery required is less radical, and adequate surgical margins are more easily achieved.

Alveolar rhabdomyosarcoma is more common in the extremities than in the trunk, and is seen in older children and young adults usually between 10 and 25 years of age (227,246,471,472,473,474,475 and 476). The patient presents with a rapidly growing, painless mass deep within the muscle. This occurs with equal frequency in the upper and lower extremities. There are no clinical or laboratory findings that distinguish rhabdomyosarcoma from other soft tissue tumors.

Characteristic chromosomal abnormalities have been identified in the alveolar subtype (5,477,478 and 479). Approximately 70% of the tumors will have a translocation between chromosome 13 and chromosome 2, whereas another 30% will have the translocation between chromosome 13 and chromosome 1. Prognostic variables include histologic subtype, size of the tumor, site of the tumor, and age of the patient (480,481,482 and 483). Alveolar subtype, larger tumors, patients older than 10 years of age, and extremity location are associated with a poor prognosis. Therefore, the patients that the orthopaedist treats tend to do worse than those treated by the urologist and the otolaryngologist. Alveolar rhabdomyosarcoma, like the other subtypes, is treated with a combination of chemotherapy and surgery (226,227,246,484,485,486,487 and 488). Irradiation can be used if total surgical resection cannot be achieved without excessive morbidity. If the lesion is small it should be totally resected initially. Unlike in rhabdomyosarcoma at other sites, preoperative chemotherapy should be considered, because this often makes total resection of an extremity lesion possible when it was not possible before chemotherapy. A wide surgical margin is recommended (230,487,489,490 and 491). Unless the patient has palpable regional lymph node enlargement, biopsy of the lymph nodes is not necessary. Preoperative irradiation is reserved for lesions that would require an amputation to obtain a wide margin. Postoperative irradiation is used when no preoperative irradiation was given and the surgical margins are positive for tumor (486,492,493 and 494). Survival is related to stage, but the overall survival for a patient with extremity rhabdomyosarcoma is approximately 60% (3,464,481,485,486,495,496).

The histologic appearance of embryonal rhabdomyosarcoma can vary (473,475). This lesion consists of poorly differentiated rhabdomyoblasts with limited collagen matrix. The rhabdomyoblasts are small, round-to-oval cells with dark-staining nuclei and limited amounts of eosinophilic cytoplasm. Cross-striations are not seen regularly. Alveolar rhabdomyosarcoma is composed of small, round-to-oval tumor cells loosely arranged together in groups by dense collagen bundles. This arrangement of cells in groups produces an alveolar appearance; hence the name.

The Intergroup Rhabdomyosarcoma Committee, with representation from both the Pediatric Oncology Group and the Children's Cancer Study Group, has been the dominant group treating rhabdomyosarcoma in the United States. Their management and cooperative efforts have resulted in major advances in the management of this malignancy (230). Their staging system for patients with rhabdomyosarcoma is currently in use (474,476,483,497) (Table 14-5).

Stage	Site	Size	Nodes	Metastases
1	Orbit Head and neck Genitourinary (not bladder or prostate)	Any	Any	None
2	Bladder and prostate	<5 cm	None or unknown	None
	Extremity Cranial parameningeal Other			
3	Bladder and prostate	<5 cm	Clinically involved	None
	Extremity Cranial parameningeal Other	≥5 cm	Any	None
4	All	Any	Any	Present

TABLE 14-5. INTERGROUP RHABDOMYOSARCOMA STAGING SYSTEM

Synovial Cell Sarcoma

Synovial cell sarcoma is a malignant tumor of soft tissue whose cellular characteristics suggest that the tumor arises from primitive synovial cells, but it rarely occurs within a joint (233,457). Unlike other soft tissue sarcomas, synovial cell sarcomas occur frequently in the hand and foot (498). They usually are in the deep soft tissues near a joint. These tumors account for 10% of all soft tissue sarcomas (457). Most patients are between 15 and 35 years of age, and males predominate slightly. Patients with synovial cell sarcoma often complain of pain before they have palpable masses, and many patients give a history of having complained of pain for 2 to 4 years before the lesion was found. Synovial cell sarcoma, although rare, may be the explanation for persistent pain in a young patient (454,499,500,501 and 502).

The usual physical finding is the firm, slightly tender mass. Up to 25% of these patients have metastasis to regional lymph nodes, and the lymph nodes should be examined carefully (503). The patient's blood and urine laboratory values are normal.

The lesion occurs in all parts of the body. The head, the neck, and the trunk account for approximately 15% of the lesions, whereas the upper and lower extremities account for more than 50% of them. Almost 10% of the lesions arise in the hands or feet.

Synovial cell sarcomas may have calcifications or ossifications within the tumor, and these often are seen on plain radiographs. The radiodensities are usually very small. Small, irregular calcific foci, or irregular ossification within a soft tissue tumor should suggest the diagnosis of synovial cell sarcoma. The CT scan demonstrates a soft tissue mass, with these calcified densities deep within the tumor. Although the small foci of calcification or mineralization are not seen as well with MRI as with CT, MRI is preferred over CT as the staging test (504). This is true for all soft tissue masses. Neurofibrosarcoma and fibrosarcoma also can have intralesional calcification, but synovial cell sarcoma is the most common tumor with intralesional densities.

The characteristic histologic findings are of a biphasic tumor with areas of epithelioid or glandular appearance mixed with areas having spindle cell appearance (457). Usually the spindle cell component predominates (Fig. 14-35). Some synovial cell sarcomas have only the spindle cell component and are called monophasic synovial cell sarcomas. There seem to be no clinically significant differences between the two types. Mitoses are usually present, but the tumor is more difficult to grade histologically than other soft tissue sarcomas. Synovial cell sarcoma is almost always a high-grade soft tissue sarcoma.

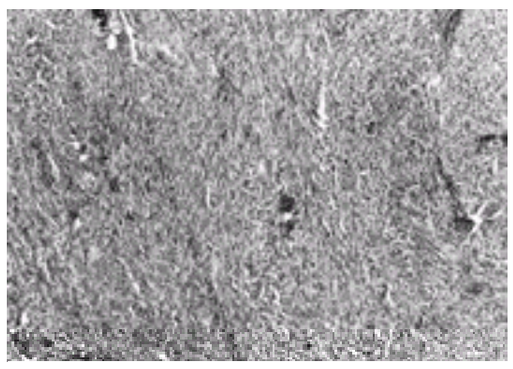

FIGURE 14-35. Low-power view of the spindle component of a synovial cell sarcoma. This lesion is composed of malignant spindle cells with a minimal amount of matrix. At a higher power, mitotic figures are seen. Other areas of this tumor have a glandular appearance, which is the reason that this synovial cell sarcoma is a biphasic tumor. (Original magnification ×10.)

Surgical resection is, and has been, the principal treatment of synovial cell sarcoma (499,500,501,502,505,506,507,508,509 and 510). Adjuvant chemotherapy is used, but the data regarding the efficacy in synovial cell sarcoma are equivocal at best (500,509,511,512). In adults and older children with synovial cell sarcoma, as in those with other soft tissue sarcomas, preoperative radiotherapy is used in conjunction with nonradical surgery in an attempt to salvage more extremities. Approximately 15% of synovial sarcomas occur in the feet (498). It was believed that the scarring from irradiation precluded its use in the feet and hands, but with modern techniques adjuvant irradiation and marginal resection can be performed in the majority of sarcomas of the feet or hands with preservation of a functioning extremity. Preoperative irradiation and surgery are recommended for most soft tissue sarcomas of the feet. This has been successful in saving extremities and controlling the disease locally, but the incidence of metastatic disease remains high, at slightly more than 50% (233,455,500,501,505,508,512,513).

Benign Synovial Tumors

There are only two neoplasias that arise from the synovial lining of a joint. Synovial cell sarcoma has been reported to have arisen from within a joint, but this is decidedly rare, and the majority of synovial sarcomas arise within periarticular soft tissues and do not invade joints. Synovial chondromatosis and pigmented villonodular synovitis arise from synovial tissue and are found in joints, bursa, and tendon sheaths. They are the only two neoplasias that commonly occur in the joint.

Synovial Chondromatosis. Synovial chondromatosis is a disorder of the synovial tissues (457). It is most common in the knee but can arise in any joint, tendon sheath, or bursa. Its cause is unknown, and it has no recognized familial pattern of occurrence. The subliminal lining of the joint produces small nodules of hyaline-appearing cartilage that are extruded from the synovial lining to become loose bodies within the joint (Fig. 14-36). The cartilage may become necrotic if they become large, or they may undergo enchondral ossification if they have a blood supply. In both cases, they can be seen on plain radiographs. Without the calcification or the ossification, the cartilage is radiolucent and not visible on routine radiographs.

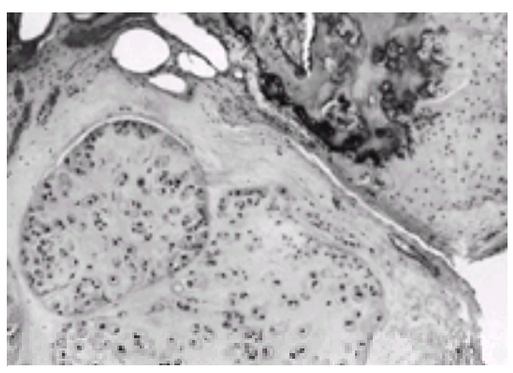

FIGURE 14-36. Low-power view of synovial chondromatosis. The nodules of cartilage are formed within the synovial lining and extruded into the joint to produce loose bodies. The nodules can undergo enchondral ossification if they have a blood supply (**top right**).

The disease is rare in children, and presents most commonly between the ages of 20 and 50 years. The most common joint involved is the knee, with the elbow next in frequency, and the hip third. The patient usually presents with mild discomfort, minimal loss of motion, and a joint effusion. There may be a history of locking. The knee may appear normal on examination, but usually there is a moderate-to-large effusion, limited motion, and a boggy synovium. The plain radiographs show nothing abnormal or small intraarticular calcified bodies. The arthrogram is diagnostic with an irregular synovial surface and normal-to-thinned synovial fluid. The MRI scan is usually diagnostic.

Most patients have sufficient symptoms and require removal of loose bodies. Usually synovectomy is performed, but recurrence is common as the synovial lining is regenerated (514). The process seems to have a limited natural history, and the production of new loose bodies ceases after 1 or 2 years.

Pigmented Villonodular Synovitis. Pigmented villonodular synovitis (PVNS) is a rare disorder of the synovial tissues that may be a true neoplasia, although it has been suggested that it is caused by an infectious process (457,515). The synovial lining becomes proliferative and hypertrophic. It can involve a joint (most commonly the knee) or a tendon sheath. When tendon sheaths are involved, PVNS usually occurs in the hand or the foot. The patient presents with a swollen joint that is usually painless. The synovial tissue is boggy on examination. The joint fluid has old, dark blood in it, and it is common for the diagnosis to be suspected first when the joint is aspirated just before the injection of contrast material for arthrography. The arthrogram or MRI scan is diagnostic, with a thickened shaggy lining and demonstration of dark pigment signal on MRI (516).

The majority of the patients with PVNS are between 20 and 40 years of age (515). The plain radiograph is usually normal except for the soft tissue swelling, but occasionally the proliferative synovial tissues invade the bones adjacent to the joint. This happens most frequently when the hip joint is involved. MRI is the best radiographic method to evaluate the extent of the lesion. Bone invasion can be appreciated, as can the extent of enlargement of the synovial cavity. Synovectomy is the treatment of choice, but there is a high incidence of recurrence (approximately 50%) (515). Intraarticular injection of radioactive materials (dysprosium or yttrium) has been used successfully as a means of controlling recurrent disease. Some patients have minimal symptoms with their recurrence and accept the chronic swelling. As long as the bones remain uninvolved, there is no absolute indication for surgical removal. Patients are followed with clinical examination and plain radiography. For patients with diffuse involvement, recurrence is common (more than 75%), but most have no or little progression or symptoms and do not need treatment.

CHAPTER 15

CEREBRAL PALSY

THOMAS S. RENSHAW

T. S. Renshaw: Department of Orthopaedic Surgery, Yale University, New Haven, Connecticut 06520; Department of Orthopaedic Surgery, Yale–New Haven Hospital, New Haven, Connecticut 06510.

Cerebral palsy is a generic term used to describe certain clinical syndromes whose common feature is the abnormal control of motor function by the brain. The abnormal control results in a nonprogressive disorder of movement and/or posture, but the manifestations can change with growth, development, and maturation. Often, sensory and other brain functions are involved.

The etiologic agents of cerebral palsy afflict the immature brain to produce neuropathologic lesions that do not worsen. Although some parts of brain development continue throughout childhood, Gage has defined the “immature brain” as being younger than age 2 years. Accepting this definition, one may classify and code a brain lesion occurring thereafter as producing static encephalopathy, with a specific cause, instead of cerebral palsy, which may be coded without a known causative agent (1). In general, this differentiation does not affect the prognosis, and most clinicians refer to both as cerebral palsy.

BASIC BRAIN DEVELOPMENT

An excellent overview of brain development has been provided by Goldberg (2). During the first trimester of embryonic life, the brain differentiates into a grossly recognizable cerebrum, cerebellum, and other structures. An insult during this period usually produces a structural lesion that is detectable by magnetic resonance imaging (MRI).

Neurons begin to develop early in the second trimester, originating in the periventricular regions and migrating toward the surface of the cerebral cortex. By the fifteenth week of gestation fetal reflex movements can be detected. At the end of the second trimester all neurons have been formed and any damage or loss cannot be replaced.

Synaptic connections begin to be established early in the third trimester and intensify after birth. Glialization, which begins in the second trimester, occurs at least until age 2 years (3). Myelination in the brain does not begin until late in the third trimester, but continues into adolescence in a well-defined pattern. As more pathways become myelinated, primative reflexes drop out, mostly during the first 6 months of life, and normal postural reflexes appear. As myelination continues pathology in the brain becomes apparent. Brain morphologic maturation, as detectable by MRI, has been reported to continue through at least age 10 years (4).

As Goldberg points out, only after the neuronal pathways from brain lesions have become myelinated and can be tested and found to be abnormal can such lesions be detected. Because different pathways are myelinated at different times, spastic diplegia usually is not detected until at least 8 to 10 months of age, hemiplegia usually at about 20 to 24 months, and athetosis usually after 24 months (2).

ETIOLOGY

In most cases of cerebral palsy only risk factors can be identified, and not specific causes. The etiology is not necessarily the result of a brain insult that occurred in the prenatal or perinatal period. Only approximately 10 to 15% of patients in one large group had documented perinatal hypoxia or other problems (5). Cerebral palsy is not solely the result of prematurity because 60 to 65% of afflicted children were born at full term (1). Although only approximately 10% of cerebral palsy patients weigh less than 1,500 grams at birth, in this low birth weight group the risk of having cerebral palsy is 90 per 1,000, compared with 3 per 1,000 if weighing more than 2,500 grams and appropriate for gestational age (1,5,6). Low birth weight for gestational age and prematurity are commonly associated with the development of spastic diplegia (6).

Maternal risk factors in the prenatal period include infection, drug or alcohol abuse, epilepsy, mental retardation, hyperthyroidism, severe toxemia, an incompetent cervix, and third-trimester bleeding (4). Genetic abnormalities, teratologic agents, or congenital malformations of the child's brain may play a causative role, and in some patients, there may be multiple contributing agents (7,8 and 9).

Risk factors in the perinatal period include trauma; kernicterus; vaginal bleeding at the time of admission; placental complications such as abruptio, premature rupture of membranes, and chorionitis; and hypoxia or anoxia. It has been suggested that four questions must have positive answers in order to establish birth asphyxia as the probable cause of cerebral palsy (10):

1. Was there evidence of marked and prolonged intrapartum asphyxia?
2. Did the newborn exhibit signs of moderate or severe hypoxic-ischemic encephalopathy?
3. Is the neurologic condition one that intrapartum asphyxia could explain?
4. Has the clinical evaluation been extensive enough to exclude other conditions?

Oxytocin augmentation, cord prolapse, and breech presentation also have been associated with increased risk for cerebral palsy, but only if accompanied by low apgar scores (1).

Postnatally, an insult can come from head trauma (11); vascular accidents in the brain; central nervous system infections; kernicterus; hypoxia or anoxia from such causes as near drowning, suffocation, and cardiac arrest; and other problems. The long-term manifestations of cerebral palsy, caused by different specific agents,

have not been extensively studied, but there is evidence that postnatal infectious causes commonly produce more severe orthopaedic deformities than do many other agents (12).

The brain lesion is permanent and nonprogressive, but the natural history of cerebral palsy is not static. Growth and maturation of not only the central nervous system but other systems as well often result in changing musculoskeletal problems in the child.

PREVALENCE

Cerebral palsy is found in from 1 to 7 per 1,000 children throughout most of the world, theoretically being more common in geographic regions where prenatal maternal and perinatal infant care are poor (3,13). In regions where sophisticated neonatal intensive care units exist, the risk of brain damage may be reduced by early treatment of certain problems, but also the lives of very premature infants and those with other life-threatening problems are often saved. In this latter group, the incidence of cerebral palsy is higher than in the general population. The result is that the incidence of cerebral palsy is only slightly reduced by preventing some cases, while saving others who have cerebral palsy who would not have survived (3). Twin pregnancies result in a child with cerebral palsy about 12 times more commonly than do single pregnancies. This is largely related to low birth weight (14). The prevalence of the neuropathic types and anatomic patterns of cerebral palsy varies greatly in many reports because of the widely differing populations studied. For example, a study containing the residents of state institutions shows many more severely involved individuals than does a study derived from a large private medical practice.

CLASSIFICATION

Cerebral palsy is classified by the neuropathic type of motor dysfunction and by the anatomic region of involvement.

Neuropathic Types

Spastic

This is the most common type of motor dysfunction. In cerebral palsy spasticity is an upper motor neuron syndrome caused by a lesion of the pyramidal system of the brain. The manifestations are a velocity-dependent increase in muscle tone and hyperexcitable tonic stretch reflexes. Spasticity is usually accompanied by weakness, loss of muscle control or dexterity, interference with balance, fatigability, and often the simultaneous contracting of antagonistic muscles (15). Severe spasticity is often referred to as rigidity. Joint contractures are common in spastic cerebral palsy.

Athetoid

Athetosis is a type of dyskinesia (abnormal movement) caused by an extrapyramidal brain lesion. It is characterized by purposeless writhing movements which become intensified when the child is frightened or excited. With pure athetosis, joint contractures are uncommon and muscle tone may not be increased. Tendon lengthenings in children with athetosis are often unpredictable, and may result in the creation of an opposite deformity that is more difficult to treat. Decades ago athetosis comprised about 25% of the cases of cerebral palsy because a major cause, Rh incompatibility with resulting kernicterus, was not so easily detected and prevented as is now the case. Dystonia, a phenomenon of increased general muscle tone, distorted postures, and abnormal positions that are induced by voluntary movements can occur together with athetosis.

Ataxic

Ataxic cerebral palsy is uncommon. It is a disturbance of coordinated movement, most noticed when walking, and is usually the result of cerebellar dysfunction. A mild intention tremor may be present, contractures are rare, and except for the treatment of scoliosis and hip dysplasia, surgery is rarely necessary.

Mixed

Children with mixed cerebral palsy have both pyramidal and extrapyramidal motor control abnormalities. Variable amounts of spasticity, athetosis, and/or ataxia occur together in this form. Sometimes the athetoid component is barely detectable, but it may nevertheless make surgical treatment less predictable.

Hypotonic

Generalized hypotonia may last for 2 or 3 years, and is most often a stage through which an infant passes before developing overt spasticity or ataxia. The brain lesion is present but masked by lack of myelination of the pathways that will carry its abnormal messages. Occasionally, mentally retarded children are erroneously referred to as having hypotonic cerebral palsy.

Anatomic Patterns

Quadriplegia

Quadriplegia, also known as tetraplegia, implies involvement of all four limbs. Many of these children have global involvement with mental retardation; bulbar dysfunction, manifested by drooling, dysarthria, and dysphagia; and seizures. The usual cause is severe hypoxia. After initially presenting as a floppy baby, the child shows delayed developmental milestones. The spectrum of severity is variable, from having no sitting ability or head control to being able to walk independently.

Diplegia

With diplegia, both lower extremities are always involved to a greater extent than the upper extremities, which are affected to some degree. A substantial percentage of diplegia results from prematurity. There has often been associated periventricular hemorrhage in and/or around the third ventricle, producing the characteristic lesion of diplegia (periventricular leukomalacia) in the motor fibers to the lower extremities before they enter the internal capsule (1). Intelligence is usually normal.

Hemiplegia

In hemiplegia, one side of the body is involved, the upper limb being more affected than the lower. The diagnosis is not often made until after walking has begun or fine motor hand control is noted to be deficient. A focal traumatic, vascular, or asymmetric infectious lesion is likely to be the cause of hemiplegia.

Seizure disorders are most frequently seen in this type of involvement, probably because of the focal brain lesion (4). The seizures usually begin in the first 2 years of life (16). Children with hemiplegia are also more likely to have homonymous hemianopsia and stereognostic deficits than are those with other types of involvement (4). Asymmetry of upper and lower limb growth, with the involved side being smaller, is also a common finding and probably is related to the trophic factor of sensory loss (17).

Other Types

Anatomic patterns of involvement are not always clear-cut, and some patients do not fit these common types. Blair and Stanley found only 55% intraobserver agreement in a cerebral palsy classification study (18).

Double hemiplegia refers to bilateral, usually symmetric involvement, with the upper extremities being more afflicted than the lower extremities. Triplegia implies difficulty with any three limbs, usually both lower and one upper. Monoplegia means only one limb is affected.

Paraplegia is used to describe involvement of the lower extremities only. This is a rare occurrence as the result of a brain injury, and such a pattern of motor

dysfunction should alert the physician to the possibility of pathology in the spinal cord or canal.

ASSOCIATED PROBLEMS IN OTHER SYSTEMS

Central Nervous System

Other central nervous system problems occur as the result of global brain involvement, but the spinal cord usually is spared. Seizures afflict about 30% of children with cerebral palsy, and are most often seen with patients who have hemiplegia and quadriplegia, with mental retardation, or in postnatally acquired syndromes (19).

Mental retardation, defined as IQ less than 50, occurs in 30 to 65% of children with cerebral palsy (19). It is most prevalent in those with spastic quadriplegia. Other problems include behavioral and emotional difficulties; perceptual disorders; learning disorders; bulbar involvement with drooling, difficulty swallowing, and speech impairment; sensory deafness (which is most often seen in those with extrapyramidal involvement); and visual difficulties, such as perceptual problems, strabismus, nystagmus, and cortical blindness. Visual problems affect about 50% of children with cerebral palsy (1), so visual screening examinations are important for young children.

Gastrointestinal System

Problems with this system are particularly common in more severely involved children. Constipation and fecal impaction are common problems in children with global involvement. Impaired swallowing, vomiting, esophageal reflux, and hiatal hernia can cause aspiration and the risk of severe pneumonia, epigastric pain, profound feeding problems, and poor nutrition (20). Children with cerebral palsy who are malnourished have soft tissue wasting and interference with growth (21,22). When they undergo surgery they are at higher risk for postoperative infections (23).

Assessment of nutrition includes composition of the diet, especially regarding calorie and protein intake, and the feeding history. Can the child feed him- or herself, and if not, who is the feeder? Is the swallowing competent or does frequent aspiration occur? A radiologic contrast study of swallowing and to rule out gastroesophageal reflux may be helpful. Nutritional status can be poor despite obesity, and therefore studies such as total serum proteins and albumin; iron, iron-binding capacity, and transferrin levels; hemoglobin and erythrocyte mean corpuscular volume; and total lymphocyte count may be helpful to assess nutritional status (24,25). This is routinely done preoperatively with patients who will undergo extensive spinal surgery, but is not necessary for all preoperative workups. Keep in mind, however, that no single study is an absolute indicator of malnutrition.

Correction of malnutrition is best accomplished by enteric feeding augmentation, if possible. If swallowing is impaired, a tube-feeding program should be considered. When oral or tube-feeding supplementation is not feasible, the child should be referred to an appropriate surgeon for consideration for a feeding gastrostomy or jejunostomy. Gastroesophageal reflux sometimes can be managed successfully by medical means, but may require surgical fundoplication.

Genitourinary System

Bladder dysfunction and urinary incontinence are common in severely afflicted children. They also have a higher incidence of urinary tract infections than the normal population. This may relate to bladder dysfunction and retrograde colonization from frequent diaper soiling, or to urolithiasis, probably caused by dehydration and urinary stasis.

McNeal and colleagues, in a study of cerebral palsy patients, noted that 28% complained of enuresis, 26% had stress incontinence, 18% had urgency, and 36% had more than one symptom (26).

DIAGNOSIS

The diagnosis usually is established by a pediatrician or a neurologist before the child has had occasion to visit the orthopaedic surgeon. In some instances, however, an unexplained abnormal posturing, limp, toe walking, limb asymmetry, joint tightness, developmental delay, or other finding enables the orthopaedist to make the diagnosis of cerebral palsy.

History

Except for familial spastic paraparesis and congenital ataxia which are inherited conditions, cerebral palsy is not a genetic disease. The medical history begins with a search for possible causes and risk factors, including environmental agents, abnormal events during the pregnancy, the details of the birth, and assessment of the neonatal and infantile periods. Next, it is important to assess some benchmark physical developmental milestones, such as sitting, crawling, cruising, and walking (Table 15-1). These may be normal with hemiplegia. The review of systems should be thorough to detect any of the commonly related problems. A history of previous treatment, including surgery, is essential.

Milestone	Average Age Achieved (mo)	95th Percentile
Head control	3	6
Independent sitting	6	9
Crawling	8	Some never do
Pull up to stand	8	12
Independent walking	12	17

(From ref. 3, with permission.)

TABLE 15-1. SIMPLE DEVELOPMENTAL MILESTONES

Physical Examination

The main goals of the physical examination are:

- to determine the grades of muscle strength and selective control;
- to evaluate the muscle tone and determine whether it is normal, hypotonic, spastic, athetoid, or mixed;
- to assess reflexes and sensory function;
- to evaluate the degree of deformity or muscle contracture at each of the major joints;
- to assess linear, angular, and torsional deformation of the spine and long bones, and fixed hand or foot deformities;
- to appraise balance, equilibrium, and standing or walking postures.

Physical assessment begins with observation of the child while taking the history. Next, as a dynamic examination evaluate the head control, sitting balance, the ability to crawl, the ability to pull up to stand, standing posture and balance, and the ability to walk. Observational gait assessment is imperative in those who can walk. The remainder of the examination is performed on the examining table, or, better yet, on the parent's lap, if the child is age 4 or 5 years or younger. The primitive neurologic reflexes, tendon reflexes, sensation, muscle strength, muscle tone, joint range of motion, contractures, torsional abnormalities, and spine should be assessed (1,27,28). Remember that motor dysfunction in the extremities can also be a manifestation of a brain or spinal cord tumor, infection, or other problem.

At the end of the initial history and physical examination formulate a functional assessment of the patient for documentation at that time and for communicating with other health care professionals. The following is an example of such an assessment: “The patient is a 5-year-old boy with spastic quadriplegic cerebral palsy. He is the product of a 32-week uncomplicated pregnancy, and was delivered by emergency cesarean section because of uncontrolled uterine bleeding. He has fair head control, poor sitting balance, and has never pulled to stand, or walked. He is able to communicate discomfort only, and does not participate in any activities of daily living.”

Other Tests

Specialized gait analysis, valuable in the management of certain patients with cerebral palsy, is rarely necessary for diagnostic purposes. It may be useful in differentiating between idiopathic toe walking and mild spastic diplegia (29,30 and 31).

The diagnosis of conditions such as dysmorphic syndromes or congenital metabolic, neurologic, and muscular diseases, usually can be differentiated from global involvement with cerebral palsy, by clinincal examination, and, if necessary, chromosomal analysis. Special imaging techniques, including MRI, positron emission tomography (PET), and computed tomography (CT), are useful in the evaluation of intracranial pathology.

Plain radiographs may be important. If there is any sign of a spinal deformity, radiographs in the coronal or sagittal planes, or both, document the degree, and sometimes the cause (e.g., a congenital vertebral anomaly), of the deformity. It can be argued that a periodic (every 12 months) coronal plane radiograph of the pelvis is necessary for the early detection of hip pathology, such as acetabular dysplasia or subluxation, in children with spastic diplegia or quadriplegia who are not walking (Fig. 15-1). These problems may not be clinically detectable, and are more easily managed and have better outcomes if treated early. Weight-bearing radiographs of the feet and ankles in the anteroposterior and maximally dorsiflexed lateral projections document the status of foot deformities when surgical intervention is being considered.

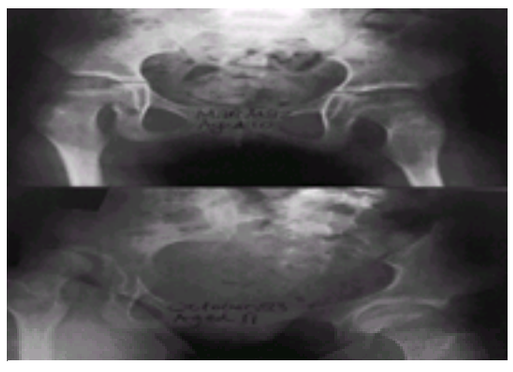

FIGURE 15-1. Radiographs showing substantial changes in the right hip, including dislocation, which developed over a few months at age 10 years. Annual hip evaluations, including radiographs, are important in detecting such problems.

COMMON TYPES OF CEREBRAL PALSY AND THEIR MANAGEMENT

The remainder of this chapter uses the formats of spastic quadriplegia, diplegia, and hemiplegia; athetoid cerebral palsy; and the upper extremity, to discuss the principles and techniques of management of common problems.

Many centers have developed cerebral palsy management programs conducted by teams of knowledgeable specialists. Team members usually include a pediatrician, orthopaedic surgeon, neurologist, consultant neurosurgeon, clinical nurse specialist, physical therapist, occupational therapist, speech–language specialist, social worker, educator, and psychologist (4). It is especially important for the team members to frequently communicate and confirm that they are in agreement, at least substantially, so that the family does not receive mixed or conflicting messages about their child's problems or care. The family is the most important member of the team.

Assessment of Treatment Results. Unfortunately, most treatment methods in cerebral palsy are not grounded in databased research, but rather are based on empiricism, opinions, and experience, as the best that can be done. Fortunately, physicians now recognize that treatment must be measured in terms of technical outcomes, functional health assessments, and patient satisfaction (2). Many measurement instruments now have been developed and validated (32). These include gait analysis, the Gross Motor Function Measure, the Pediatric Orthopaedic Society of North America's Health Status Questionnaire (33), the Gillette Children's Specialty Healthcare Normalcy Index and Functional Assessment Questionnaire, and the WeeFIM. In time, these and others should provide the needed data to base clinical care on reliable critical pathways.

Spastic Quadriplegia

An example for spastic quadriplegia is a patient with global involvement who is unable to walk and who requires nearly total care. Of paramount importance are the priorities of such a person which are, in order of importance:

- communication with others;
- the ability to take care of activities of daily living, especially personal hygiene;
- mobility in the environment; and
- walking (29).

Only about 20% of children with spastic quadriplegia will eventually walk. Realistic goals for nonambulatory orthopaedic care are directed toward maintaining balanced, comfortable sitting. The specific objectives are achievement and maintenance of:

- a straight spine and a level pelvis;
- located, mobile, painless hips that flex to at least 90 degrees for comfortable sitting, and extend to at least 30 degrees of flexion, to accomplish pivot transfers;
- mobile knees that flex for sitting, and can extend enough (to <20 degrees or less of flexion) to be controlled by orthoses for transfers;
- plantigrade feet for wearing shoes and for comfort on the footplates of wheelchairs;
- an appropriate wheelchair;
- management of problems in the other systems.

It is important to understand that it is in the wheelchair that the patient with spastic quadriplegia will spend most waking hours. The chair should be considered a total body orthosis, to be fitted and maintained by an expert (Fig. 15-2). The ability to independently transfer in and out of a wheelchair greatly facilitates the ability to live in a group-home setting for an adult with spastic quadriplegia. It is beneficial for all concerned to have a physical therapist experienced with patients in wheelchairs collaborate in developing the wheelchair prescription. The following should be considered in wheelchair design:

FIGURE 15-2. An appropriately fitted wheelchair provides proper body positioning, including head control.

Foot rests:
should be long enough for the shoes,
either should support the entire foot in a plantigrade position or be removed to allow free dangling of fixed deformities, such as severe equinus, to avoid increased pressure over a small area of contact,
should be able to swing out of the way for entering and exiting the chair, and
should accommodate foot restraint straps if needed.
Seat:
height must allow the feet to correctly contact the foot rests,
depth should entirely support each of the thighs, which may not be of equal lengths, but not compress the popliteal area,
width should not compress the trochanters, but also should not allow lateral shifting or excessive tilting of the pelvis,
firmness should be as much as tolerated by the patient to provide maximum pelvic stability without creating excessive skin pressure over bony prominences,
contour should be incorporated, if necessary, for comfort.
Chairback:
height should support the patient's trunk from the pelvis to the midscapular region,
width should accommodate the trunk and any needed thoracic support pads,
firmness should be as firm as is comfortable to aid in preventing collapsing kyphosis,
contouring should be incorporated, if necessary, to accommodate scoliosis,
reclining may be a necessary feature.
Restraint components:
may be necessary for foot, leg, pelvic, trunk, arm, or head control.
Portability:
is necessary if transportation in the community is desired.
Propulsion method:
the patient's arms,
an attendant,
motorization.

Because the child's waking activities are performed while sitting, the spine and hips are of prime importance, and are often the site of major problems in spastic quadriplegia. Other lower extremity problems specific to the ambulatory patient with spastic quadriplegia are addressed in the section on spastic diplegia.

Hyperlordosis

Increased lordosis in the lumbar spine is almost never a primary deformity in cerebral palsy. It is usually secondary to hip flexion contractures, and it responds to appropriate correction of those contractures by such means as stretching exercises or surgical lengthening of the psoas tendon. Hyperlordosis can also be a compensatory deformity below a rigid thoracic hyperkyphosis, and it usually responds to correction of the primary problem. When surgical spinal fusion is necessary to correct severe scoliosis, it is essential to consider the sagittal plane spinal balance and to preserve adequate lumbar lordosis by avoiding overdistraction across the lumbar spine.

Hyperkyphosis

Hyperkyphosis is most commonly seen in the young child with cerebral palsy who has weak spinal extensor musculature and a resultant long, C-shaped kyphotic posturing of the entire spine. This is almost always flexible, correcting fully on prone lying. It is best controlled by proper seating adaptation such as restraint straps on the wheelchair, slight reclining of the back, or, less often, by a thoracolumbosacral orthosis to provide sitting support. There is debate regarding whether increasing sitting support inhibits the function in the spinal extensor muscles and weakens them further, and whether physical therapy or muscle stimulation is helpful in maintaining or enhancing spinal extensor muscle strength.

Kyphosis occasionally occurs in the lumbar spine as the result of overly tight hamstring muscles. This kyphosis disappears with proximal lengthening of the hamstrings.

Children with cerebral palsy are not immune to the spinal deformities that afflict other children, so thoracic hyperkyphosis as the result of the Scheuermann condition, or postural juvenile kyphosis may also occur. Indications for orthotic treatment in these kyphotic conditions are similar to those in other children, but spinal orthotics are not likely to be as well tolerated.

Scoliosis

Scoliosis is more prevalent in all types of cerebral palsy compared with the general population, and varies directly with the severity of motor involvement. With patients who have mild hemiplegia, scoliosis occurs in fewer than 5%; with patients with severe spastic quadriplegia, its occurrence is much greater; in all cerebral palsy patients, it is about 25%. Specific increased risk factors for curve progression are quadriplegia, younger age, poor sitting balance, pelvic obliquity, and the presence of multiple curves.

Scoliosis in cerebral palsy is different from idiopathic scoliosis. It develops earlier; is more likely to be progressive; progresses beyond skeletal maturity, especially when the curve exceeds 40 degrees; is markedly less responsive to orthotic control; and is more likely to require surgical treatment.

As with idiopathic or other types of scoliosis, there are only three appropriate options for management. These are observation with documentation, orthotic treatment, or surgical stabilization. Observation alone is indicated for a curve that is of insufficient magnitude to require treatment (25–30 degrees), or is present in a patient whose best interests may not be served by active surgical intervention. The latter category is difficult to define: It would include the most severely involved individuals who are unable to perceive or interact with their environment in any meaningful fashion, based on severe and global compromise of their cognitive and sensory perceptual abilities. Only careful study by members of the cerebral palsy team and the patient's family can lead to this assessment. In such cases, the overall management goals are the patient's safety and comfort.

The orthotic treatment of scoliosis in quadriplegic cerebral palsy was based mostly on hope and empiricism until two studies showed that it rarely succeeds in controlling a curve (34,35). Most quadriplegic patients from each center did not experience any meaningful curve control from orthotic treatment. In some cases, however, an orthosis may slow curve progression, particularly in curves of 30 to 60 degrees, allowing beneficial growth in an immature spine before definitive surgical stabilization. At best no more than 15% of brace-treated curves stop progressing, and this may simply reflect the natural history of some cases of scoliosis in cerebral palsy (35). Ambulatory patients with spastic diplegia may develop idiopathic-type scoliotic curves. In these milder cases of cerebral palsy, brace control may be

successful. Orthoses and other types of external devices for trunk support may be of value in improving sitting balance, particularly for those patients in whom surgery is not indicated. If the patient can tolerate a total-contact low-profile orthosis, this is the most effective and economical means of providing improved trunk support, even if it is a relatively soft orthosis (36). This is often not the case, however, and a custom-molded trunk or total-body–supporting wheelchair insert is required. These devices are difficult to fit properly, often quickly outgrown, and expensive. They must provide adequate pelvic alignment, trunk control, and head support (37). Nevertheless, the ability to sit as erectly and comfortably as possible is essential for a totally involved patient. Good sitting improves the patient's mental outlook, communication ability, respiratory function, ease of feeding, gastrointestinal function, hand usage, and mobility in the environment (38).

Surgical stabilization of progressing scoliosis is the only way to stop such a curve, in most cases (39,40). The benefit of a procedure of this magnitude and expense has been questioned by some (41), but most orthopaedic surgeons strongly believe that the surgery is worthwhile particularly in preventing loss of the ability to sit (Figure 15-3). Postoperative patients with reasonably balanced nonprogressive scoliosis have much better endurance for sitting; this greatly improves their quality of life when they can sit up comfortably for several hours, or even all day, and not have frequent substantial back pain that requires recumbancy most of their waking hours. According to their caregivers they also are much easier to feed, dress, and transport than those with severe untreated scoliosis. Most likely, after fusion they have less back discomfort, better pulmonary function, and less decubitus skin ulceration than similarly involved patients with severe untreated scoliosis (but this has not been proven) (42).

FIGURE 15-3. Clinical (**A**) and radiographic (**B**) images of a girl with cerebral palsy who has severe, untreated scoliosis. She is unable to sit for more than a few minutes.

Once a curve exceeds 40 to 45 degrees magnitude it is likely to continue progressing, and surgery is usually indicated. Posterior internal fixation with a segmental system, such as double rods with cross-links connected to the spine by multiple hooks; sublaminar wires; interspinous wires; pedicle screws; or combinations of these techniques and an adequate posterior fusion mass is usually employed **[➥2.6]**. This is needed to achieve a balanced spine over a reasonably level pelvis, the objective of such surgery (42,43,44 and 45). Whenever possible, a larger and more rigid rod is preferable to provide better correction, resist deforming forces, and promote a solid arthrodesis. It is essential to achieve spinal balance in both the coronal and sagittal planes to maximize sitting balance. An abundance of allograft bone or an effective bone graft substitute should be available to generate the strong fusion mass.

Fusion limits are usually from the upper thoracic region (T1–T3) to L5, or more commonly, to the pelvis. When the fusion does not extend to the upper thoracic region there is an increased risk of developing a substantial junctional kyphosis cephalad to it. This may interfere with the ability of the patient to see at or above the horizontal, or may require constant and eventually painful neck hyperextension to do so. No matter how cephalad the upper fusion level or what type the fixation, some patients still develop a junctional kyphosis. Although applying a bilateral two-level clawed-hook configuration at the cephalad end of the rods (Fig. 15-4) with preservation of the uppermost posterior ligaments may help to prevent a junctional kyphosis, this has not been consistently successful.

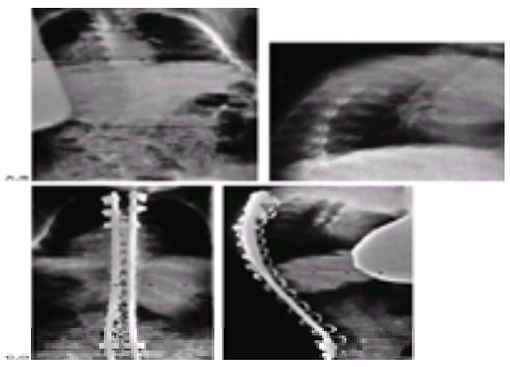

FIGURE 15-4. Treatment of scoliosis by posterior spinal fusion with segmental instrumentation, using mostly sublaminar wires. A two-level, transverse process, pedicle claw was used at the cephalad end in an attempt to prevent junctional kyphosis. **A:** Preoperative posteroanterior radiograph demonstrates a 45-degree lumbar curve. **B:** Preoperative lateral radiograph demonstrates associated thoracic kyphosis. **C:** Postoperative posteroanterior radiograph. **D:** Postoperative lateral radiograph demonstrates the cephalad claw configuration of the hooks.

Fusions should include the pelvis, if pelvic obliquity exceeds 10 degrees from the intercrestal iliac line to the top of L5 or L4, when measured on a sitting anteroposterior radiograph. Otherwise, pelvic obliquity may continue to progress and make sitting more difficult. Various techniques for pelvic fixation are available, including hooks, rods, and screws anchored to various bones, but none have withstood the test of time better than the Galveston technique **[➥2.6–2.7]** (46).

Routine anterior spinal surgery is not necessary in cerebral palsy. The most common indication for anterior spinal surgery in this condition is to improve curve correctability. Increased correction may be needed:

- to level the pelvis when pelvic obliquity is rigid and severe;
- to balance the spine in large, rigid curves that do not correct to less than 50 or 60 degrees during supine bending or maximum traction radiographs;
- to release the anterior tether of a kyphos; or
- to attempt to improve respiratory function or decrease the likelihood of the development of a pseudarthrosis in severe curves.

In such cases, a release of the deforming structures is accomplished by dividing the anterior longitudinal ligament, excising the annulus fibrosis, and removing all of the disc material and endplate cartilage back to the posterior annulus and posterior longitudinal ligament, and packing bone graft into the disc spaces. This may be done via an open thoracotomy, or, perhaps with less morbidity, by an endoscopic technique. Anterior internal fixation is rarely necessary when strong, rigid posterior fixation is performed. The anterior and the posterior operations are accomplished at the same surgical setting rather than staging them by several days or weeks (27).

There are several other important considerations when managing a spinal deformity by surgical means in a patient with cerebral palsy. One-third of the patients are malnourished (47) and may have gastroesphageal reflux, as discussed earlier. Detecting and correcting these conditions preoperatively helps prevent postoperative wound infection and healing problems by improving the patient's nutritional status (48). Determination of the serum transferrin level, albumin level, and total lymphocyte count are commonly used to assess nutritional status. An index using transferrin and albumin levels to identify malnourished patients has been developed (49).

Intraoperative blood loss should be calculated carefully, expressed in terms of percentage of blood volume, and appropriately replaced to avoid hypovolemia or dangerous coagulopathies, especially when blood loss nears 50% of the blood volume. With this method preoperative blood volume must be accurately estimated,

and suctioned blood loss plus blood in weighed sponges should be carefully measured. Another means of monitoring blood loss and replacement is by calculating erythrocyte mass and considering hematocrit measurements in the lost blood as well as in the replacement source.

Postoperative pulmonary problems, such as hypoventilation, atelectasis, aspiration pneumonia, and the adult respiratory distress syndrome may occur, and every preventive effort, including rapid mobilization of the patient, must be enlisted.

Spondylolysis and Spondylolisthesis

Although spondylolysis and spondylolisthesis do not occur in nonambulatory patients, they have been reported in ambulatory patients with cerebral palsy with an incidence similar to that in the general population. No increased severity of symptoms or relation to hip flexion contractures has been noted (50). Treatment is similar to that recommended for children who do not have cerebral palsy.

Hip Problems

About 70 to 90% of the hip problems in cerebral palsy occur with spastic quadriplegia. The common problems are contractures, hip at risk, subluxation, and dislocation. Causative factors of hip problems are probably combinations of muscle imbalance, acetabular dysplasia, pelvic obliquity, excessive femoral anteversion, increased femoral neck valgus, lack of weightbearing, and maldirected resultant force vectors across the hip joint. Femoral anteversion is greater at all age levels in children with cerebral palsy than in the normal population. It does not change significantly after age 6 years (51), and is greater in ambulatory children than in nonwalkers (52).

Because of increased muscle tone and some contracture, it can be difficult to detect even substantial hip abnormalities by routine physical examination. For this reason it may be wise to obtain an annual screening supine anteroposterior radiograph of the hips in children with spastic quadriplegia, and in patients with spastic diplegia who do not walk.

In all but the most severely involved children, hip dislocation should be prevented. Hip subluxation or dislocation, although more common before the age of 6 years, may occur at any age. Hips at risk and hips that are subluxated rarely cause discomfort, but dislocation can lead to pain. Studies have reported pain in approximately 50% of cerebral palsy patients with dislocated hips (53,54), and the associated increased contractures may make care more difficult and worsen sitting balance. One study, however, found that surgical reduction of dislocated hips did not improve pain or sitting ability (55). Until more studies with longer follow-up are available regarding treatment of dislocated hips in cerebral palsy, most surgeons follow the management described in the following section.

Hip Management

Hip at Risk. The hip at risk has increased valgus and anteversion and a shallow acetabulum, but no subluxation. Tightness and contractures in the adductor and flexor muscles are usually present. Without treatment, hips at risk often progress to subluxation or dislocation, particularly if there is less than 30 degrees of abduction in flexion or extension, and/or with hip flexion contractures of greater than 20 degrees. Such progression may be very slow (months to years) or occur much more rapidly. Because the literature lacks valid data regarding the likelihood of such hips worsening, it is not possible to predict the natural history of every hip at risk in cerebral palsy. That leaves the surgeon with the options of closely following hips at risk or intervening. Unless the patient is so cerebrally compromised as to preclude surgical treatment most surgeons will intervene, realizing that at least in some cases the hip pathology would not have been progressive. The use of stretching exercises alone as treatment for hips at risk is rarely, if ever, successful. In young children with hips at risk and mild or absent muscle tightness, night splinting, in an attempt to improve acetabular depth, is an option that some surgeons might choose. That night splinting can reliably increase acetabular depth, however, has not been confirmed by a well-controlled study.

Surgical treatment of the hip at risk consists of lengthening and weakening of the tight adductors and flexors **[➥3.17]** (56,57 and 58). The adductor longus may be all that needs releasing, especially in those who walk, but the gracilis, and occasionally part of the adductor brevis muscles also, may require release in order to gain abduction to at least 45 degrees for each extended hip and 60 degrees abduction for each hip in flexion. The issue of whether to release or transfer the adductors is discussed in the section on spastic diplegia. Tenotomy or elongation of the psoas tendon, sparing the iliacus fibers, should be performed. Psoas tenotomy, in a nonambulatory patient with spastic quadriplegia, may be performed either at the pelvic brim or at the lesser trochanter. Tenotomy at the more caudal site may produce more hip flexor weakness, a situation of no consequence to a nonwalker, but one that may be detrimental to an ambulatory patient who needs adequate hip flexor power to lift the limb for step climbing (2). Psoas tenotomy at the pelvic brim is performed in the manner described by Sutherland et al. (59). On rare occasions the psoas may not be tendinous at that level, and the tenotomy must be done more distally. Then it is wise to suture the proximal cut end of the tendon to the hip capsule in an attempt to maintain better hip flexor strength.

Postoperatively, some surgeons use abduction splinting for several months. This is applied at night, and always within the child's range of comfortable abduction. The value of such splinting is questionable. Postoperatively, physical therapy is begun as soon as the second postoperative day (60). In the past, anterior branch, or even complete, obturator neurectomy has been performed to denervate the adductor muscles, in addition to lengthening them. Now this is rarely done because most surgeons believe it to be unnecessary when an adequate adductor release (i.e., allowing 60 degrees of passive abduction) has been performed. If the child has an athetoid component, in addition to spasticity, obturator neurectomy should never be done. That can result in a severe, disabling abduction contracture.

Subluxation. Hip subluxation is defined as uncovering of more than one-third of the femoral head and a break in the Shenton line, but with the femoral head maintaining at least some contact with the acetabulum (45,61). Surgical treatment of a subluxation can prevent subsequent dislocation (62,63).

Soft tissue releases and prolonged splinting sometimes can be successful in very young children. When only soft tissue surgery is deemed necessary to treat unilateral subluxation and the patient is younger than 9 years, bilateral releases may be best because the contralateral hip is usually at least somewhat abnormal or likely to become so, if only unilateral surgery is done (64).

The subluxated hip most often has increased femoral valgus, anteversion, or both, and requires corrective proximal femoral osteotomy (63,65,66 and 67). To stabilize the hip joint, varus of the femoral neck is usually reduced to about 115 degrees in an ambulatory child, or even less in a nonambulator **[➥4.1–4.3, 4.6]**. In addition to appropriate tendon releases, derotation of the excessive femoral anteversion to approximately 10 to 20 degrees (or 30 to 45 degrees of passive internal hip rotation) is performed to prevent posterior subluxation (68,69) (Fig. 15-5). The younger the patient, the more likely is the valgus and anteversion to recur postoperatively, especially if the child is under age 4 years (70). If the magnitude of the subluxation exceeds 50%, an open reduction and capsulorrhaphy will improve the result (71).

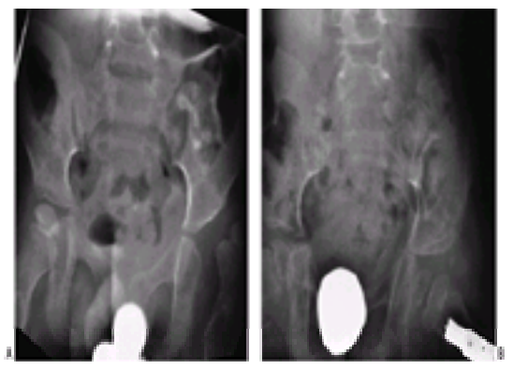

FIGURE 15-5. Dislocation of the left hip in this patient with spastic quadriplegia was treated by varization-derotation osteotomy and innominate osteotomy. **A:** Complete dislocation of left hip. **B:** Status, post-open reduction and femoral and pelvic osteotomies.

If bony surgery (a varus rotational osteotomy with or without a pelvic osteotomy) is required, prophylactic surgery on a well-covered contralateral hip with adequate

abduction is not necessary, regardless of the age or ambulatory status of the patient (72).

If acetabular dysplasia is present (acetabular index >25 degrees) (73), it almost always should be corrected surgically. An exception might be a child younger than 4 or 5 years with very mild dysplasia and recently fully corrected abnormal valgus and anteversion. In this situation acetabular remodeling may occur from the stimulation of redirecting the force vector across the hip joint from the lateral actebular rim to the center of the acetabulum. Older children have much less potential for biologic remodeling to normalize the acetabulum after femoral varization and rotation osteotomies.

The dysplastic acetabulum in cerebral palsy is shallow. In nonambulators, the acetabular deficit is superior, posterior, and usually more severe than in ambulatory patients. It is almost always associated with an increase in the femoral neck-shaft angle and femoral anteversion. The femoral anteversion is greater in ambulators (52).

Acetabular dysplasia is corrected surgically by choosing the appropriate pelvic osteotomy and being certain that its prerequisites are met. Arthrographic evaluation and, if necessary to define the pathoanatomy, three-dimensional reformatted CT scanning images can be helpful in the decision-making process (52,74).

The Salter, Steel, Sutherland, Pemberton, pericapsular, Dega (75), and Chiari osteotomies, and shelf augmentation of the acetabular rim, all have been successful in cerebral palsy when appropriate indications are met **[➥3.7–3.12]** (45,76,77,78,79,80,81 and 82). If the acetabulum is found to be deficient superiorly and anteriorly, or purely superiorly, an anterolateral rotational osteotomy, such as a Salter, Steel, or Sutherland procedure, or a Pemberton osteotomy, is appropriate. Often, there is superior and posterior deficiency, in which case, restoration of lateral and posterior coverage by a shelf-augmentation procedure, an Albee shelf, a Dega procedure (83), or a pericapsular osteotomy (68,73) may be more appropriate. The Chiari osteotomy can be performed if the superior acetabular rim has not been so proximally eroded that the cut will enter the sacroiliac joint.

Dislocation. Hip dislocation may be addressed by relocation procedures (84), by accepting the dislocation, by proximal femoral resection (85), or, less commonly, by hip arthrodesis or total hip replacement arthroplasty (86,87). If the dislocation occurred within 1 year, and/or if the anatomy does not appear excessively distorted, most surgeons elect to perform anterior open reduction and capsulorrhaphy, combined with appropriate soft tissue releases (usually adductors and psoas tendon) and a proximal femoral shortening, varization, and rotation osteotomy. Often, a degree of acetabular dysplasia is associated with the dislocation, and it is wise to correct this at the same time. The pelvic procedure should be tailored to the situation, as described in the previous discussion of the subluxated hip.

If the hip has been dislocated for longer than 1 year, achieving a painless, mobile, stable hip from open reduction and other surgery is less likely because of joint incongruity and eroded articular cartilage on the femoral head. When such a hip is painless, no treatment is required. When the hip is painful, proximal femoral resection with muscle interposition, as described by Castle and Schneider, has a high success rate **[➥3.16]** (85,88). This resection is performed at the subtrochanteric level, the thickened capsule and gluteus medius muscle are sewn over the acetabular inlet, and a muscle cuff of vastus lateralis is sewn over the beveled femoral stump (Fig. 15-6). It is critical to carefully save as much vastus lateralis as possible during the initial dissection, and to provide a good, thick muscle covering over the femoral stump. Postoperative management should consist of a bilateral pantaloon or a one-and-a-half–hip spica cast for about 3 to 4 weeks, then comfortable but effective exercises to assure maintenance of the desired range of hip motion. This range is the minimal flexion contracture: at least 100 degrees of flexion, neutral rotation, and abduction to at least 20 degrees. Postoperative traction or external fixators are rarely necessary. The result is usually good motion and good pain relief, but definite thigh-shortening, which must be accommodated in the seat of the wheelchair. Following proximal femoral resection, it is very common to have spasm and discomfort for several days, weeks, or even months. This usually will eventually resolve, but analgesics and antispasmodic medications may be necessary for a prolonged time. A successful trial of an intrathecal baclofen injection may indicate the use of a baclofen pump during this period. Heterotopic ossification about the hip is almost universally seen after proximal femoral resection, and single-dose radiation therapy should be considered to minimize its magnitude.

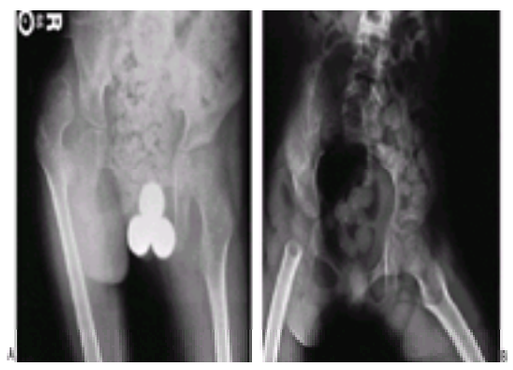

FIGURE 15-6. This nonambulatory child's painful dislocated right hip was treated by resection of the proximal femur just distal to the lesser trochanter and oversewing muscle flaps. This is known as the Castle procedure. His pain was relieved. **A:** Preoperative anteroposterior radiograph shows the dislocated right hip with femoral head deformity and acetabular dysplasia. **B:** Postoperative radiograph. The proximal femur has been resected at the distal end of the lesser trochanter.

Femoral head resection, combined with subtrochanteric valgus pelvic support osteotomy, has been successful in relieving the pain of chronic hip dislocation (89,90).

The Girdlestone intertrochanteric resection has been tried for the painful dislocated hip. The likelihood of continuing postoperative pain from femoral-iliac impingement has caused most surgeons to abandon this procedure.

Arthrodesis is another option, but may be difficult to accomplish in nonambulatory patients with severe spasticity. When enough flexion is provided to make sitting comfortable, it may limit the ability to comfortably lie supine. Arthrodesis, therefore, is not often performed.

The reported experience is small with replacement arthroplasty for painful dislocated hips (89). This procedure is indicated most often for the ambulatory adult with mild to moderate spasticity and severe degenerative arthritis of the hip.

Osteoarthritis. The located osteoarthritic hip in cerebral palsy need not be treated surgically, unless it is painful and nonsurgical methods have failed. In that case, arthrodesis and replacement arthroplasty have both been successful, the latter being preferred because of less postoperative morbidity and easier management (91). Arthrodesis **[➥3.13]** is usually performed in a position appropriate for walking, sitting, and lying: 30 degrees of flexion, 5 to 10 degrees abduction, and neutral rotation for an ambulatory patient, and 45 degrees of flexion for a nonambulator. Leg-length equalization should be considered in walking patients because it may defer the development of back pain (92).

Extension Contracture. Extension contracture of the hip occasionally occurs in the severely spastic child with quadriplegia. The probable cause is tightly contracted hamstrings, which are hip extensors, as well as knee flexors. Often it is seen with extensor thrust, a rigid and sustained hip extension that can greatly interfere with comfortable sitting, because the extension contracture does not allow adequate hip flexion. When severe it can literally push and slide the child out of the wheelchair. The treatment options for mild extension contracture are proximal lengthening of the hamstrings **[➥3.19]** or injections into the hamstrings of neuromotor blocking agents, such as botulinum A toxin or alcohol. For more than mild extension contractures, lengthening of the proximal hamstrings is indicated (21,42). If this is not adequate, posterior capsulotomy of the hip and release of the external rotator muscles may also be necessary. Unfortunately, recurrence of extension contractures is common and often rapid following proximal hamstring lengthening.

Extension Plus Abduction Contracture. Extension plus abduction contracture of the hip is not common. It most often occurs after injudicious release of the flexors and adductors in patients who have athetosis, and is also seen after aggressive flexor and adductor releases in patients who have severe spasticity or rigidity and previously undetected cospasticity in the hip extensor and abductor muscles. Cospasticity can be difficult to detect even by careful physical examination, but both flexion and extension of the joint are substantially limited, as are abduction and adduction. Gait analysis may detect cospasticity in ambulatory patients.

Because of their writhing movements patients who have athetosis rarely develop contractures that require surgical releasing. The problem is with the mixed spastic–athetoid patient with tightness, in whom the surgeon cannot determine precisely just how much to weaken the spastic muscle. It is definitely better to err on

the side of underrelease.

The treatment of mild cases of extension plus abduction contracture of the hip consists of stretching exercises and proper seating in the wheelchair. Data regarding the use of tone-reducing measures in this situation are currently lacking, but a trial of intrathecal baclofen may be useful. With more severe involvement, surgical treatment is necessary. This involves release of the proximal hamstrings, the femoral and iliotibial band insertions of the gluteus maximus, the external rotator muscles, and even posterior capsulotomy of the hip joint, if necessary. In long-standing severe contractures, femoral shortening may be necessary to prevent overstretching of the sciatic nerve (93).

Spastic Diplegia

Most children with spastic diplegia walk, although late walking is the rule, and it is not unusual for a diplegic child not to begin ambulation until age 4 years or even later (94). Motor improvement often reaches a plateau at about age 7 years, so that if a child is not walking by then there is little likelihood that he or she will walk (27,95). The severity of lower extremity involvement is the most important factor in walking ability. A seizure disorder, marked flaccidity, persistent abnormal primitive reflexes, or a dislocated hip are deterrents to walking, whereas intelligence, upper extremity severity index, or birth weight do not correlate closely with walking prognosis (95). Mental retardation has little or no effect on walking ability (27,96).

Bleck (Table 15-2) and Beals (Table 15-3) have described criteria for predicting the likelihood of walking in children with cerebral palsy (95,97,98 and 99), and Campos da Paz studied 272 children with cerebral palsy and found that achievement of head balance before age 9 months, independent sitting by 24 months, and crawling by 30 months were good prognostic indicators for walking, whereas lack of head control by age 20 months indicated a poor prognosis (100). Conversely, Molnar and Gordon, in a study of 233 children with cerebral palsy, found that in children younger than age 2 years, independent sitting was not a good predictor for walking ability, but that after age 4 years inability to sit predicted nonambulation (96).

1. Asymmetric tonic neck reflex (ATNR)
2. Neck-righting reflex (NRR)
3. Moro reflex (MR)
4. Symmetric tonic neck reflex (STNR)
5. Parachute reaction (PR)
6. Foot-placement reaction (FPR)
7. Extensor thrust (ET)

These tests are performed in order on nonambulatory children after the age of 12 months. When one of the following is present (ATNR, NRR, MR, STNR, ET) or absent (PR, FPR), one point is given. A score of zero gives a good prognosis for walking; patients with one point have a guarded prognosis; and two or more points indicates a poor prognosis.

(From ref. 27, with permission.)

TABLE 15-2. BLECK'S WALKING PROGNOSIS CRITERIA

Severity Index*	Walking Prognosis
>18	Free walking by age 3 years
12–18	Free walking by age 7 years
10–11	Free or crutch walking by age 6 years
0–9	Crutch or no walking

* The severity index is defined as the motor age in months at the chronologic age of 3 years.
(From ref. 27, with permission.)

TABLE 15-3. BEALS' WALKING PROGNOSIS CRITERIA

Hoffer and colleagues classified ambulation for meningomyelocele into four functional levels. This classification is also appropriate for use in children with cerebral palsy:

1. Community ambulators: These patients walk indoors and outdoors for most of their activities, and may need crutches, braces, or both. They use a wheelchair only for long trips out of the community.
2. Household ambulators: These patients walk only indoors and with apparatus. They are able to get in and out of the chair and bed with little or no assistance. They may use the wheelchair for some indoor activities at home and school, and for all activities in the community.
3. Nonfunctional ambulators: Walking for these patients is a therapeutic exercise at home, in school, or in the hospital. Afterward, they use their wheelchairs to get from place to place and to satisfy all their needs for transportation.
4. Nonambulators: These patients are wheelchair-bound, but usually can transfer from chair to bed (101).

Children with spastic diplegia are less-often afflicted with scoliosis, seizures, speech impediments, and major problems in other systems than are those with quadriplegia. Hip dislocation is also less likely, but excessive valgus and anteversion of the proximal femur, acetabular dysplasia, and hips at risk or subluxated are not uncommon.

The majority of children with cerebral palsy have problems with balance. In diplegia, posterior equilibrium is most often affected, but this does not obviate walking or require the use of cane or crutches. Crutches are necessary if anterior balance is defective. If lateral balance is significantly involved, a walker will be needed. Severe lateral equilibrium disturbances usually preclude any walking.

Gait Analysis. Gait analysis in cerebral palsy is an objective and well-established method of documentation that allows the careful study of the various components of pathologic gait, the energy expended (102), and the outcomes of treatment protocols. Gait analysis is discussed in Chapter 5 of this textbook, and in others devoted exclusively to the subject (1).

A recent study indicates that when experienced physicians added gait analysis data to their own clinical evaluations, they changed their surgical recommendations about half the time, with more decreases than increases in procedures (103). Whether this will improve surgical outcomes and reduce costs has not been studied. Although preoperative gait analysis is theoretically desirable, it is neither possible nor necessary for every child who undergoes surgery. Nevertheless, every surgeon who treats children with cerebral palsy should have a good knowledge of normal and pathologic human gait, and understand gait analysis and pattern recognition (104) (Fig. 15-7). The application of his or her observational gait assessment then will be more accurate.

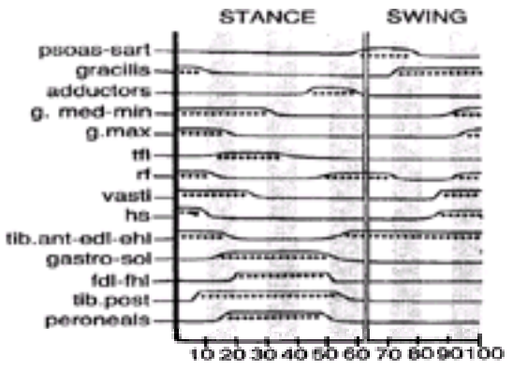

FIGURE 15-7. Chart of normal muscle-firing patterns (*dotted lines*) for the lower extremities. The patterns of a child with cerebral palsy are compared with these normal data.

The prerequisites for normal gait are:

- stability of the foot and entire lower extremity in stance phase;
- clearance of the ground by the foot in swing phase;
- appropriate prepositioning of the foot at the end of swing phase;
- adequate step length; and
- maximization of energy conservation (1).

Observational gait analysis is done by watching the child walk repeatedly while viewing the gait from the front, back, and side. Study only one component at a time (e.g., cadence, stride length, the foot, the knee, the hip, lower-extremity rotational alignment, the pelvis, the trunk), recognizing that often there are differences between the sides. Gage has described observational gait analysis in detail (1). For a given child, intraobserver observations are more accurate than interobserver observations (105). In either situation, the opportunity to study a videotape of the gait from the front, back, and sides, with zoom capability for the feet, increases accuracy.

Pattern recognition allows the surgeon to observe the gait cycles of the walking child, look for the priorities of gait and deviations from normal, and correlate this information to the findings on static physical examination. If all this information is consistent with a recognized standard pattern (e.g., one of the types of hemiplegia or a diplegic gait with equinovalgus feet, tight hamstrings, tight hip flexors and adductors, and increased femoral anteversion) there is a strong likelihood of success after applying the proper surgical procedures to address each problem.

It would be ideal to review a high-tech gait analysis on every ambulatory cerebral palsy patient preoperatively if cost and accessibility to sophisticated gait labs were not a problem. In reality, surgeons will be most comfortable without gait analysis with those patients who have apparently straightforward patterns of gait pathology (Fig. 15-8). Nevertheless, gait analysis provides a more precise definition of the gait abnormality in more complex cases, such as those with severe diplegia and those who have had previous surgery with little success.

FIGURE 15-8. An example of a common spastic diplegic gait pattern. Note the ankle equinus, knee flexion, hip flexion, internal rotation of the entire limb, and compensatory lumbar lordosis.

Treatment Methods

The treatment categories for patients with spastic diplegia are modulation of spasticity (oral medications, intramuscular injections, intrathecal injections, selective dorsal rhizotomy), physical therapy, orthotics and/or manipulation and casting, and musculoskeletal surgery. These modalities are discussed in this section.

Oral Medications. Ideally, an orally administered medication would appropriately temper spasticity and allow nearly normal voluntary muscle control to occur over the long term. Unfortunately, such an agent does not exist. Many types of muscle relaxants, antispasmodics, and neuroinhibitory medications have been tried to little or no avail, mostly because therapeutic doses are so large that the substantial accompanying drowsiness is unacceptable (106). Oral pharmacotherapy, widely accepted as effective for problems in cerebral palsy, has been limited to anticonvulsants for seizures and diazepam for superimposed postoperative myospasms, by its probable effect of increasing presynaptic inhibition (107), and perhaps for its tranquilizing effect on pain perception.

Intramuscular Injections. The purposes of injecting various substances into muscles or around nerves are:

- to weaken a muscle and improve the balance of forces across a joint in order to assess whether this will improve function. This is a temporary effect, but in some cases it may be of value to allow a stretching and strengthening physical therapy program to perhaps avoid or, more likely, defer the need for surgery;
- to separate severe spasticity from fixed-joint contracture;
- to determine which muscle is the major contributor to an abnormal posture; and
- to assess the performance of antagonistic muscles (108).

The most common lower-extremity muscle injected is the gastrocnemius to reduce equinus deformity. Other common sites are the hamstrings and hip adductors. Repeated injections may be necessary to achieve the desired effect, and injecting some substances can be painful unless general anesthesia is used.

The shortest-acting drug is a local anesthetic agent, injected in the immediate vicinity of a specific nerve to block its fibers and allow the physician to observe the effect. If the effect is beneficial, then repeating the injection with another longer-acting agent should reproduce the effect (109). If the goal is to make the effect permanent, phenol is used to destroy the nerve fibers.

Another means of weakening the muscle is to inject 45% alcohol into its fibers in a more regional distribution to inhibit nerve transmission and, thereby, muscle contraction. This is painful and requires general anesthesia. When successful, the effect of alcohol injection lasts for a variable period, but usually approximately 6 weeks (27,110).

Botulinum-A Toxin. A newer agent for intramuscular injection is botulinum-A toxin (BTX), a neurotoxin produced by *Clostridia* bacteria. It is delivered into or near sites of nerve arborization, and blocks the release of acetylcholine from presynaptic vesicles at the myoneural junction. Recovery of tone results from the sprouting of

new nerve terminals, which peaks at about 60 days (111,112). The agent is injected using a 23- or 25-gauge needle, usually without local or general anesthesia, but topical anesthesia will prevent the discomfort that rarely lasts more than 5 minutes. The muscles are located by palpation. To reach muscles that are deep or difficult to localize, electromyographic guidance and electrical stimulation have been used (113). BTX diffuses readily, so the injection should be placed in the muscle belly (114).

BTX is quite expensive, and optimal dosage regimens have not been agreed upon. It has been shown to be a safe technique, whose effects on muscles begin in 12 to 72 h, and usually last for 3 to 6 months or longer (115,116 and 117). Injections may be repeated after 2 or more weeks, and up to six injections may be given at a site, until the desired response in muscle tone reduction has been achieved. This treatment is contraindicated in the presence of fixed joint contractures. It is most useful in very young patients when a limited number of muscles are involved (117), and the surgeon wishes to defer surgical intervention until the child is older, has a stabilized gait pattern, or other components of the child's problem can be more precisely identified and addressed. A double-blind trial in 12 patients with equinovarus or equinovalgus foot deformities showed improvement in five of six treated patients, and improvement in two of six placebo-injected patients (118). A report of 14 children who had BTX treatment for equinus showed marked improvement (mean 6.7 months) in six, mild improvement in three, and no improvement in five (119). Other studies have found it to be longer-lasting with fewer side effects, and equally, or more efficient, at improving equinus gait than serial casting (110,120), but combining the two may be beneficial (121). In the upper extremity BTX has shown beneficial effects, particularly in relieving tight elbow flexors and thumb flexors. This has improved hygiene and cosmesis, but not fine motor function (122). Independent of motor function, BTX is usually effective in relieving pain from muscle spasms (119). Unanswered but essential questions are:

- whether or not the expensive and temporary tone reduction will allow physical therapy efforts to succeed in avoiding, rather than just delaying, the need for surgery;
- what is the optimal dosage protocol;
- when and what are the effects of BTX antibody formation; and
- what aberrations and their controlling muscles are most appropriate for this treatment?

Intrathecal Injections. Baclofen (Lioresal) is an agonist of the neuroinhibitor gamma-aminobutyric acid which interferes with release of excitatory transmitters that cause spasticity (107). When injected intrathecally, it acts on the spinal cord synaptic reflexes to broadly decrease lower-extremity spasticity for about 8 h (1). In the upper extremity, there is a lesser reduction of tone, about equal to that achieved by selective posterior rhizotomy, but no change in joint range of motion (123). It has poor lipid solubility and does not cross the blood–brain barrier very effectively, so when given orally large doses are required, and excessive lethargy is the result. Beneficial long-term effects are realized when administered intrathecally by a refillable, subcutaneously implanted pump. This provides a ten-times greater concentration in the spinal fluid than does comparable oral dosing (124). Problems and complications from using the pump are decreasing as experience improves, and include infection, catheter breakage, fistula, equipment malfunction, and the need for frequent refilling with the medication.

Large long-term outcome studies are not yet available. It appears that this treatment may be most helpful for patients with dystonia and spasticity who have hygiene problems or difficulty with sitting (121). Another group of patients may be those who are ambulatory and have underlying weakness. This second group cannot tolerate the additional weakness imposed by selective dorsal rhizotomy. Recognizing that adequate data on which to base a recommendation for its use in specific patients is weak or lacking, it appears that intrathecal baclofen is of definite benefit in about one-half the patients in studies thus far reported (124,125 and 126). It also may be of some aid in assessing the potential benefit of selective posterior rhizotomy. In the doses used to treat spasticity, baclofen has no effect on athetosis (127).

Selective Posterior Rhizotomy. This procedure has been employed for several decades (128), but only in the past 15 years has it been widely used in North America (129,130). Unlike earlier attempts to surgically or electrically alter the central nervous system beneficially (e.g., cerebellar stimulation) (131), it has met with growing acceptance. The principle of selective posterior rhizotomy is to reduce spasticity and balance muscle tone by altering the control exhibited by the anterior horn cells in the spinal cord. The normal inhibitory influences on the gamma efferent system, produced by higher centers in the brain and carried to the anterior horn cell by long intraspinal tracts are deficient in cerebral palsy, as is the ability to coordinate movement as mediated through the extrafusal fibers from the alpha motor neurons. Selective posterior rhizotomy attempts to limit the stimulatory inputs from the muscle spindles in the lower limbs that arrive by the afferent fibers in the dorsal roots. This is done by sectioning only those dorsal rootlets whose impulses exert excessive faciliatory influence on the anterior horn cell, and thus better balance these influences.

The operation is performed under general anesthesia without relaxants. The lumbar laminae and the intervening ligaments are removed as an en bloc laminoplasty from L1 to S1, preserving the facet joints. Then, individual posterior rootlets from the L1 to S1 posterior roots are carefully dissected out and electrically stimulated. The electromyographic and physical responses are noted, and those rootlets that supply the offending muscles are surgically divided. Rootlets are spared if they show decremental and squared-type electromyographic responses. They are divided if the responses are incremental, clonic, multiphasic, sustained, or contralateral, although this determination is not always easy. In most cases, up to 70 rootlets per root are stimulated, and 25 to 50% are sectioned. The laminae and ligament complex are then replaced. The theoretical advantages of laminoplasty compared to laminectomies, at each level, are that it is faster, may result in less scarring in the spinal canal, and replacement of the intact laminae may prevent some cases of lumbar instability or deformity.

The patient best served by selective posterior rhizotomy is the young child (age 3–8 years) with:

- spastic diplegic involvement;
- voluntary motor control;
- reasonable intelligence and motivation;
- no fixed contractures;
- good trunk control;
- the ability to walk with good underlying strength and balance; and who has
- severe, pure spasticity; and was
- preterm or of low birth weight (132).

Full-term children are more likely to have rigidity plus spasticity, and therefore may not respond as favorably to selective posterior rhizotomy (1,128). Availability for, and cooperation with, postoperative physical therapy are prerequisites for the procedure because therapy may be required three or four times per week for as long as a year to regain strength. The procedure is not indicated in children with athetosis, ataxia, rigidity, dystonia, antigravity muscle and truncal weakness or hypotonia, overlengthened tendons, and severe fixed contractures. Information regarding any benefits in those with spastic quadriplegia is limited (133). The results of unilateral rhizotomy in spastic hemiplegia are not available, but at least one source does not recommend it (128).

In the early postoperative period, the patient is weaker than before surgery and requires intensive physical therapy, but once the acute rehabilitation are complete, improvement in the lower extremities may be dramatic and perhaps lasting. Sometimes even improvements in upper-extremity function, seizure control, bladder function, swallowing, speech, and personality are seen after an overall reduction in muscle tone (134). Results thus far show lasting reduction in spasticity; increased hip, knee, and ankle range of motion; often a plantigrade foot in stance; increased stride length and walking speed; and no increase in sensory deficits (128,134,135,136,137 and 138). Three randomized trials comparing rhizotomy with physical therapy have now been published (139,140 and 141). These indicate that rhizotomy is more successful at reducing muscle tone, and often at improving motor function.

Although this procedure reduces spasticity and tone, it does not affect joint contractures or the overly contracted musculotendinous unit. These must be treated by orthopaedic surgical procedures after rehabilitation from the rhizotomy. It is estimated that up to 65% of patients require additional procedures, with those older than 4 years at the time of rhizotomy requiring more orthopaedic procedures (129,142,143).

Selective posterior rhizotomy can be beneficial, but it is not a miracle procedure, nor does it cure cerebral palsy. The patient will still have poor motor control and balance, muscle weakness, contractures, sensory involvement, and/or persisting primitive reflexes if he or she did so preoperatively.

As with virtually everything else in medicine, there are some caveats. An occasional patient develops rapid and severe hip subluxation or dysplasia after this type of rhizotomy (144). Heterotopic ossification around the hip has been reported to occur after varus derotation osteotomy of the proximal femur, with patients who have spastic quadriplegia who have previously had selective posterior rhizotomy (145). Patients with preexisting lumbar lordosis of more than 60 degrees on a sitting lateral radiograph are at risk for the development of postoperative lumbar hyperlordosis (146,147). Spondylolysis and spondylolisthesis have also been reported (148). Another study noted that after rhizotomy, its only consistent negative effect is some increase in sagittal plane anterior pelvic tilt in independent ambulators (137). Perhaps the most common problem after rhizotomy, other than weakness, is the development of planovalgus foot deformities reported in up to 50% of cases

(143,149). The deformity is often severe enough to require surgical correction.

Long-term results with many patients followed over several decades are not yet available, but thus far an increased risk of developing scoliosis or kyphosis has not been reported. Another question remaining to be answered is whether late neuropathic arthropathy will occur, but this seems unlikely.

Selective posterior rhizotomy is a demanding procedure for the patient, the family, and the professional staff. Although there is little risk involved, it is expensive, long-term results are not known, and careful patient selection and surgical technique are mandatory. Nevertheless, it can be of substantial benefit to many children.

Physical Therapy. There are several possible roles for physical therapy in cerebral palsy, some generally well accepted and some not. The brain lesion impacts on motor function in four major ways, with individual variation in the involvement of each. These are:

- loss of selective motor control and dependence on primative reflexes;
- abnormal muscle tone that is influenced by posture, position, or movement;
- muscle imbalance between agonists and antagonists; and
- impaired body-balance mechanisms.

Numerous attempts to modify the central nervous system, and to alter substantial motor dysfunction by external physical means, have been employed exhaustively over the past several decades. The goal is to produce major improvement in voluntary control, tone, and muscle and body balance. In general, most therapists work in a cephalocaudal sequence to try to establish head control, trunk balance for sitting, then reciprocal lower-extremity mobility for crawling, pulling to stand, and, hopefully, functional walking. The treatment methods include neurodevelopmental therapy, sensory integration therapy, patterning, conductive education, pressure-point stimulation, bracing, and stretching, and many recreation-based therapies (150). For any of these techniques to succeed, the brain probably has to be modified or reprogrammed to make new connections that function almost as well as those it originally made (2), and this may not be possible.

The results and benefits of most of these methods continue to be debated (151,152,153,154 and 155). There is considerable difference of opinion regarding which modalities should be employed, at what age, how often (from once per week to virtually continuous therapy for 18 h a day), by whom, and how the results are to be measured, documented, and assessed. Some published studies suggest that certain physical therapy programs can improve a cerebral palsy child's joint contractures, motor status, and social motivation (4,156,157), whereas others suggest that they do not (153). Significant problems with the literature include small heterogenous samples, nonrandomized treatment, lack of controlled data, and patient attrition from many studies (153). In many instances it is difficult or impossible to determine whether the therapy was of benefit, or if improvement in motor skills was the result of the child's obligatory neurologic maturation and the learning of substitution patterns and coping methods completely independent from any restructuring of neurocentral control patterns. For some children, certain therapy programs may make a difference. In this regard, it is important that motor function be documented periodically by the therapist during the child's early growth years. This can be done using such systems as the Movement Analysis of Infants, the Gross Motor Performance Measure, Pediatric Evaluation of Disability Inventory, and WeeFIM (158,159).

Much less controversial is that during the first 3 years of life a program that focuses on compensation techniques, showing parents how positioning can facilitate mobility, maintaining joint range of motion, and educating parents about cerebral palsy is helpful. A major source of psychological stress in mothers of handicapped children is the dependency of the child on the mother for accomplishing the activities of daily living. A therapy program that teaches mothers easier ways to work with their child is of great value (160).

Whenever possible, it is beneficial that a parent perform much of the physical therapy, and not rely totally on the physical therapist (4). This saves professional fees, minimizes trips to the therapist and interference with school time, and positively involves parents and even siblings with the child. Many parents, however, decline such involvement because of other family or career demands, or simply because they are too tired to commit the time and effort necessary.

Frequent sessions and protracted therapy programs are expensive and time-consuming, and generate hopes and expectations for all involved. If not of benefit, or if ineffective modalities are employed, the therapy process can raise false hopes, increase frustrations for the child and the family, waste large sums of money, and sometimes unbalance interactions among the members of the family unit (4,151).

There is general agreement that postoperative rehabilitative physical therapy is not only helpful but it is usually essential to maximize the benefits of most types of orthopaedic surgery in cerebral palsy. The patient and the therapist are the ones who will overcome the early postoperative weakness, stiffness, and discomfort. The goals are to maintain or improve joint range of motion, regain preoperative muscle strength, maximize ambulation, and improve function, if possible. How long should the postoperative therapy continue, and how frequently should it be done? This varies with the magnitude of the surgery performed. It may be necessary for as little as 1 or 2 weeks, or as long as several months. The family may be able to provide the treatments on a daily basis. If all treatments must be provided by the therapist, two or three times per week is standard.

Another potential benefit of physical therapy is the prevention of joint contractures by the supervision of a daily range of motion program for those who lack the motor strength and voluntary control to maintain their own ranges. This type of program can be done by a parent, an aide, or a caretaker, and does not require the services of a physical therapist, other than to develop and monitor the program. As previously noted, however, data proving the benefit of such a program are lacking. In some severely involved children, it is impossible to prevent contractures no matter how aggressive the treatment.

An unresolved issue is the duration of maintenance physical therapy. Although some parents want and even demand therapy two or three times a week for the life of their child, there is no evidence that any type of physical therapy can have a beneficial, lasting effect on motor function beyond early-to-middle childhood (age 4–8 years). Children older than this no doubt benefit more by devoting their time (and their families' and society's resources) to the development of communication, cognitive, and recreational skills, instead of endless therapy sessions.

It is irrefutable that the physical therapist can be of great benefit to the child and family. She or he is a resource, and sometimes a case manager for:

- adaptive and therapeutic equipment, including seating systems;
- fabricating some types of splints and basic orthotics;
- educating the family about cerebral palsy and the child's deficits and potential;
- advising the family regarding modifications in the home using community resources;
- acting as liaison with the school; and
- as a realistic, supportive health care professional (161).

Of great importance is a good two-way communication pathway between the therapist and the physician. The therapist is often the primary person who documents the child's neuromotor status, monitors progress, and may recommend surgery or other treatments.

A different therapy approach, described in a pilot study, is that of using low-intensity transcutaneous electric stimulation in an attempt to strengthen weaker antagonistic lower-extremity muscles. The treatment is applied only at night. In a small group of patients, some motor improvement was noted, but was lost after the stimulation was withdrawn (162). More investigation of this approach is necessary before its clinical relevance is determined.

Orthotics. Orthotic devices are classically used to prevent deformity, to improve function by substituting for a weakened muscle, or to protect a weakened part. In cerebral palsy, they are most commonly used to:

- stabilize feet, ankles, and knees;
- maintain nighttime hip abduction to prevent subluxation;
- possibly slow the progression of spinal deformity, to obtain beneficial growth or improve sitting balance; and
- as night splints to prevent hand and wrist deformity.

Progress has been made in understanding the biomechanics of the lower extremities in cerebral palsy, and developing strong, lightweight, comfortable new materials for the orthoses. Lower-extremity orthotics almost never will have to extend above the knee with patients who have spastic diplegia (163). For foot control, the UCBL (University of California Biomechanics Laboratory) orthosis is most popular. This can maintain forefoot, hindfoot, and subtalar alignment in a supple, not rigid, foot, but

cannot control the ankle.

Various types of ankle–foot orthoses (AFOs) include the solid-ankle type, to control the entire foot, provide mediolateral ankle stability, and maintain the ankle in a rigid plantigrade position to preserve the plantar flexion–knee extension couple. The solid-ankle AFO is the best choice for the spastic foot, and can be used in almost any instance. Modifications to the solid-ankle AFO have been made to improve foot and ankle function. An example is the posterior leaf-spring AFO, which does not provide mediolateral ankle stability, but allows some plantar flexion and dorsiflexion from neutral, while preventing footdrop. This type is used when spasticity is minimal. It stores minimal kinetic energy during dorsiflexion, and gives back minimal energy at push-off. Articulated AFOs have hinged ankles and plantar flexion stops, which prevent equinus and excessive extensor thrust while allowing free dorsiflexion during gait. They also allow more tibialis anterior muscle function. Although articulated AFOs better allow dorsiflexion activities, such as bending over and stair climbing, they provide less ankle support, are bulky, and do not fit into shoes well, and are more likely to cause heel irritation. They may also prevent a needed plantar flexion–knee extension couple, and may allow triggering of the gastrocnemius stretch reflex, causing the patient to fight the brace (158). Another type of AFO is the floor-reaction type, of which there are several varieties. It uses the plantar flexion–knee extension couple to prevent knee-flexion crouch and gain appropriate stance-phase knee extension during gait, provided that the foot is plantigrade, no significant knee flexion contracture is present (<10 degrees), hip extension is full, and no major rotational malalignments are present in the limb. This approach has essentially eliminated the need to ever prescribe a KAFO (knee-ankle-foot orthosis) in an ambulatory child with cerebral palsy. The main indication for KAFOs is to brace the lower limbs for ease of transfer in a nonambulatory patient.

Manipulation and Casting. Obtaining beneficial elongation of tight or contracted musculotendinous units or joint capsules can sometimes be accomplished by gentle, nonpainful, repeated passive stretching, followed by maintaining the correction with casts, splints, or adjustable orthotic devices. This treatment method has the potential to cause pain to the child, and to raise false hopes for improvement when applied to more than mild spasticity, tightness, or contractures, or when used in patients who are unable to accurately communicate their discomfort.

With properly selected patients, manipulation and casting can sometimes improve, at least temporarily, contractures of the ankle, knee, elbow, wrist, or hand (164). The process may be repeated from every few days to a week, and various casting materials, dropout casts, removable splints, and orthotics with dial-lock or ratchet hinges may be used. The use of nerve or muscle blocks as an adjunct may sometimes be worthwhile.

Another method, known as “inhibition casting,” has been employed for several years. This treatment is applied to the lower-extremities by carefully molding bilateral plaster below-knee casts in an attempt to inhibit certain normal tonic plantar reflexes, especially grasp, and thus reduce overall lower-extremity tone. A probable added benefit is stabilization of the foot and ankle by the well-molded cast. The casts are either left in place or changed weekly for 3 or 4 weeks, during which time intensive physical therapy is performed. Hinged AFOs are then substituted for the casts. This method has reportedly been successful in some hands (165,166,167,168 and 169), but because the noted improvement may not be maintained for more than a few months, others have not considered it to be of value (170).

Orthopaedic Surgery. Surgical treatment is a rapid and dramatic means of altering the structure and function of the musculoskeletal system in children with cerebral palsy. It is almost always the only effective means when fixed myostatic contracture exists. Lengthening a muscle also weakens it. This may help to gain muscle balance about a joint, but strengthening an antagonist may still be desirable, and difficult or impossible. In most cases, the muscles that contract eccentrically, producing deceleration and shock absorption, are the most appropriate for lengthening, and loss of function rarely occurs. Concentric or accelerator muscles initiate, rather than modulate, movement, and may be substantially weakened by lengthening. In these situations, such as with the iliopsoas muscle, it may be better to intramuscularly lengthen the tendinous portion and accept some residual contracture in exchange for preserving needed strength. What follows are recommendations for the treatment of the most common problems and deformities in an ambulatory child who has spastic diplegia.

Treatment of Specific Problems

In most cases, the patient has several abnormal elements in the disturbed gait. Best results are obtained from surgery if all of the abnormalities are identified preoperatively and corrected during the same surgical setting (171,172), requiring only one rehabilitation period. Little or no benefit is derived by simply performing one procedure, such as a triceps surae lengthening, and waiting to assess its effect on other abnormal elements of the child's gait before proceeding to correct them. This strategy does not improve the final result, and inflicts unnecessary discomfort, hospitalization, and rehabilitation on the child.

The best age to perform the surgery varies with the patient and the problems. Ideally it would be after the gait pattern has stabilized, which is about age 4 or 5 years in nonafflicted children, and then or later in children with cerebral palsy, but before age 8 years. Certainly, surgery can be successful in older children and adults. In cases in which the hips are at risk for dislocation, or when there is progressive or substantial acetabular dysplasia, surgery should not be delayed, regardless of age.

In the immediate postoperative period, the major concerns related to the orthopaedic surgical procedures are pain management, relief of superimposed myospasms, and minimization of the child's anxiety. Giving the analgesic medication through the existing intravenous access line, using patient-controlled analgesia when possible, routinely administering diazepam for 48 to 72 h to lessen myospasms, providing continuous caudal analgesia through a small catheter, and the presence of kind, supportive personnel, are most helpful to the child.

Overall, the postoperative management is aimed at restoration of joint motion, muscle strength, and improved gait as rapidly as possible. During this period, it may be beneficial to use night splints for comfort, and to prevent joint positioning that could contribute to recurrent contractures. Such splinting should never exceed the comfort tolerance of the child. In this regard, it is sometimes necessary to alternate control of one ankle and the opposite knee on successive nights, or use splinting only during the day, when it can be effectively monitored. The value of night splinting is not universally accepted, and valid well-controlled studies proving its efficacy are lacking. It is expensive and can be burdensome and uncomfortable for the patient because of malfitting splints, the frustration of substantially restricted mobility, or maintenance of a continuous overstretch on muscles.

When only soft tissue surgery has been done, ambulation may begin within a few days postoperatively. If osteotomies or subtalar arthrodeses were performed, partial weightbearing may begin as soon as 3 weeks postoperatively, assuming that the internal fixation is adequate. Full, unrestricted weightbearing should probably be deferred until radiographic evidence of adequate early bony healing is seen, usually by about 6 weeks. It may take at least 3 months, and sometimes longer, to regain the preoperative level of strength after most multiple lower-extremity surgical procedures with patients who have spastic diplegia.

Hallux Valgus. Hallux valgus and bunions occur commonly in cerebral palsy, most likely because of a combination of muscle imbalance with adductor hallucis overactivity and externally applied forces, such as inadequate clearance resulting from equinovalgus deformity of the foot and ankle, forcing the phalanges of the great toe into valgus (173,174). Equinus, and particularly valgus, of the foot must be corrected first to achieve a lasting good result from hallux valgus surgery in cerebral palsy.

Indications for surgery in this condition are pain and difficulty with proper shoeing; rarely is cosmesis alone an indication. There are myriad operations for the correction of hallux valgus, and most have been used with varying degrees of success in cerebral palsy **[➥7.12–7.14]**. When spasticity is mild, such procedures as ostectomy, capsulorrhaphy, adductor hallucis release or transfer, and proximal or distal first metatarsal osteotomy can be successful (175,176,177,178 and 179). With recurrence, or with patients who have more severe spasticity, the McKeever metatarsophalangeal arthrodesis (180), with the joint in a few degrees of valgus and 10 degrees of dorsiflexion relative to the floor, is an excellent procedure (174).

Ankle Equinus. Pure equinus of the ankle, without associated valgus or varus, is not common. It is the result of overactivity or contracture of the triceps surae group, which is normally six times stronger than the ankle dorsiflexors (181). Most of the overactivity is in the gastrocnemius muscle. The soleus is usually not the major problem. The equinus deformity can be treated by serial manipulation and casting, which is most successful with patients who are young, have less spasticity, and whose equinus in mild. Recurrence of the equinus deformity after several months is not uncommon after manipulation and casting.

Another nonsurgical method is the intramuscular injection of botulinum-A toxin into the gastrocnemius. This will not help in fixed myostatic contracture, but can improve or correct equinus temporarily in mild cases. Mostly, it simply delays the need for surgery. Further study is necessary to determine if patients who will realize permanent correction can be identified.

Lasting correction most often requires surgical elongation of the gastrocnemius unit, which, if performed as an isolated procedure, usually can be done as outpatient surgery (173,183). Elongation is most commonly done by lengthening the Achilles tendon (which also lengthens the soleus), by either multiple partial tenotomies, the Hoke triple-cut (184), or White double-cut (185,186) techniques (either percutaneously or open), or by an open step-cut lengthening **[➥7.16–7.17]**. When

percutaneous techniques are employed, care should be taken to avoid completely dividing the Achilles tendon. Some surgeons have advocated methods of attempting to quantify the exact amount of lengthening necessary (187,188). These methods have not gained wide acceptance.

Some authors advocate the Baker (189,190) or Vulpius (191,192) fascial division type of lengthening of the gastrocnemius aponeurosis alone. This method has the advantage of not only preserving, but actually generating more soleus strength for pushoff (193). Whether it results in a higher recurrence rate is debatable (194). Similar results have been reported in studies comparing tendon lengthening with muscle lengthening in the treatment of equinus deformity (195,196).

A less popular method is Achilles tendon advancement anteriorly (i.e., closer to the talus) on the calcaneus to decrease its power by decreasing its lever arm (197,198 and 199). This procedure is more complex than the tendon lengthenings, and has not been demonstrated to be superior. Its best results occur when it is combined with other procedures (195).

Regardless of the surgical technique selected, the result is usually good (200). Recurrence rates are inversely proportional to the age of the child at the time of surgery; lower rates are seen in older children. Before age 4 years, the recurrence rate is about 25%, whereas it approaches zero when the surgery is done after age 8 years (201,202). After surgical lengthening, some believe it is beneficial to control the ankle with a night splint and an orthosis to prevent recurrent deformity and improve function (203). Others have shown that orthotics do not prevent recurrent deformity (204). A reasonable approach is to use an AFO to improve functional stability or control weakness in those who need it, and to reserve night splinting for those who show signs of early recurrent tightness. If the patient has voluntary active foot dorsiflexion to more than 10 degrees, there is a good likelihood that an AFO will not be necessary.

The patient is treated with a below-knee cast for 2 to 3 weeks if only the gastrocnemius aponeurosis has been lengthened or an incomplete Achilles tenotomy (e.g., the Hoke technique) has been done. The below-knee cast is left in place for 4 to 6 weeks after step-cut lengthening of the Achilles tendon.

A problem to be avoided is the postoperative development of a calcaneus deformity from overlengthening the heel cord, particularly in a patient with athetosis. Treatment for an overlengthened heel cord is difficult, but some have had success with shortening the Achilles tendon by surgical reattachment or imbrication, and Tardieu and Tardieu suggest a period of casting the ankle in plantar flexion, followed by orthotic control at plantigrade during the day and in equinus at night (204).

Foot and Ankle Equinovarus. Ankle equinus, varus of the hindfoot, and, often, varus and supination of the forefoot are present in this deformity. It is most often seen in hemiplegia, but also may occur in children with diplegia and quadriplegia. The hindfoot varus is most likely caused by overactivity of the tibialis posterior muscle, whereas varus and supination of the forefoot are more likely the result of overactivity of the tibialis anterior, which may also contribute to hindfoot varus. Peroneal muscle weakness may also be a factor.

For treatment of hindfoot equinovarus, correction of the equinus, as described above, must be combined with lengthening or split transfer of the tibialis posterior tendon **[➥7.18]**. Lengthening may be by the step-cut method or by intramuscular tenotomy cephalad to the musculotendinous junction, which is also known as the "Frost procedure" (163,205). Some surgeons prefer to split the tendon and transfer the lateral half to the peroneus brevis tendon (206,207) in order not to weaken the muscle as much as would a lengthening. Others believe that some weakening is desirable. There are several reports of good results with the split transfer, and many indicate that preoperative gait analysis is not necessary for a successful outcome (208).

Although anterior transfer of the tibialis posterior tendon through the interosseous membrane to the dorsum of the foot has been advocated (150,209), it should not be done in cerebral palsy patients. This transfer can result in a calcaneovalgus deformity that is very difficult to correct (210).

In varus and supination foot deformities caused by overactivity of the tibialis anterior muscle, a split transfer of the lateral half of its tendon to the cuboid bone usually successfully balances the foot (211). DeGnore and Greene use hindfoot varus, which occurs in the swing phase of gait, and a positive confusion test as their indication for split anterior tibialis tendon transfer (212). The validity of the confusion test, however, has been questioned because it does not predict ankle kinematics in the swing phase of gait (213).

Nonrigid varus of the hindfoot often occurs with varus and supination of the forefoot. In this situation, split anterior tibialis tendon transfer, combined with posterior tibialis tendon lengthening, is appropriate.

When the hindfoot varus is rigid, bony surgery, in addition to addressing the triceps surae and tibialis posterior units, is necessary to correct the deformity (214). This can be accomplished by a laterally based, closing-wedge osteotomy of the calcaneus with staple or screw fixation, which is technically difficult to reduce and adequately fix. Easier and very effective is obliquely dividing the calcaneus in the coronal plane, posterior and parallel to the peroneal tendons, sliding the posterior fragment laterally, and fixing it with a cannulated or cancellous screw or pins. Assuming adequate internal fixation with either procedure, a below-knee cast is necessary until bony healing has occurred (usually 6–8 weeks). Subsequent orthotic control of the foot and ankle may or may not be necessary.

Foot and Ankle Equinovalgus. This is the most common situation with patients who have diplegia, followed by equinovarus and calcaneus with about equal prevalence (215). Its cause is probably muscle imbalance, with triceps surae overactivity and weakness of the tibialis posterior muscle, with relative overpull of the peroneal musculature (216). The equinus is addressed as described above. It should not be assumed that the valgus originates at the subtalar joint. It may be coming from the ankle, so weightbearing radiographs of the ankle should be studied as part of the surgical planning. If the ankle valgus is really in the distal tibia, it may be corrected by osteotomy, or, in some cases, by hemiepiphyseodesis, screw fixation, or stapling of the medial side of the physis, if sufficient growth remains.

Subtalar valgus, which is mild and supple, can be controlled by an orthosis, either an AFO or a UCBL type. The orthosis may be augmented by intramuscular lengthening of the peroneus brevis tendon which decreases the power of the muscle by one grade (217). The peroneus longus tendon should not be lengthened because a varus deformity may ensue. Transfer of the peroneus brevis to the tibialis posterior tendon has been performed, but published series with evaluations of results are lacking (216).

With more severe valgus that is passively correctable, surgery is usually required, because orthotic control rarely succeeds. This is particularly true if there has been failure of an orthosis to control the hindfoot valgus, such that painful calluses and blisters result on the medial side of the foot.

Most surgeons prefer either an Evans or modified Evans lateral opening-wedge lengthening osteotomy of the distal calcaneus (218), or a subtalar arthrodesis using internal fixation and bone grafting **[➥7.4, 7.10, 7.11]** (219) (Fig. 15-9). Calcaneal lengthening restores support of the talus, and does not involve fusion of a joint. It should be combined with medial plication and peroneal lengthening, as described by Mosca (220). Subtalar fusion with internal fixation rigidly fixes the subtalar joint, and yields a higher fusion rate than the classic Grice procedure or modifications thereof, which rely on bone graft alone (221,222,223,224 and 225).

FIGURE 15-9. Postoperative lateral radiograph of a subtalar arthrodesis stabilized by a cannulated screw and augmented by iliac autograft bone.

Stabilization also may be accomplished by arthroereisis, using a staple or an inert plastic block (226). This technique may be effective in some very young children,

but it is not widely accepted. Multiple series with adequate long-term follow-up are lacking.

Another method of correcting a supple valgus hindfoot deformity is by medial displacement of an oblique osteotomy of the calcaneus with screw or pin fixation. Although limited experience with this procedure has been reported, the osteotomy heals rapidly, preserves subtalar motion, and is easy to perform (227).

When rigid, nonreducible hindfoot valgus is present the options are a sliding medial-displacement calcaneal osteotomy (228), a lateral opening-wedge or medial closing-wedge osteotomy of the proximal calcaneus, a combined calcaneal-cuboid–cuneiform osteotomy (229) or a triple arthrodesis. Triple arthrodesis provides correction (230), but is best avoided in very young patients in whom growth of the foot will be substantially inhibited. For this reason, it probably should not be performed on a child who is not within about 2 years of the end of growth. Triple arthrodesis **[➥7.9]** appears to be successful over the long term with patients who have mild involvement and are community ambulators. It has been reported not to increase the risk of later development of midfoot and ankle osteoarthritis as the result of abnormal mechanical forces being transferred to those joints over a long period (231). It is always important to achieve the best possible muscle balance at the foot and ankle; otherwise, even a triple arthrodesis may deform in time.

External Tibial Torsion. External (lateral) tibial torsion is usually associated with excessive femoral anteversion and pes planovalgus. Inadequate foot clearance may also be a factor.

Profound external tibial torsion substantially shortens the lever-arm effect of the foot in generating the plantar flexion–knee extension couple, which facilitates knee extension in the midstance and late stance phases of gait and helps to prevent crouch. Stance phase is often shortened, the base of support is unstable, and pushoff power is compromised. The solution to this problem is distal derotational osteotomies of the tibia and fibula at the supramalleolar level to align the ankle and foot progression angle with the direction of gait and the axis of the knee **[➥6.8]**. The fibula is divided transversely just proximal to the syndesmosis, and the tibia is divided about 2.5 cm above the physis. In younger children fixation by crossed smooth Steinmann pins, cut and bent extracutaneously, and an above-knee cast is adequate. The pins are removed, and the cast changed to below-knee at 6 weeks. In older children, the surgeon may choose to use a T-plate and screws and a short-leg cast. As with any surgical procedure near to an open physis, care must be taken to avoid inadvertent damage to the growth plate.

Knee-flexion Deformity. Knee-flexion deformity may be a true flexion contracture, but is more often simply caused by spastic and tight hamstring muscles, without fixed capsular contracture (232). The medial hamstrings usually are the major problem (233). Very often there is an associated hip flexion contracture and a crouched gait. Rarely, knee flexion may be a coping mechanism for calcaneus deformity (hyperdorsiflexion) at the ankle. More often, the ankle is neutral or in equinus. Equinus must be corrected when hamstrings are lengthened or genu recurvatum may result. It is essential to assess and address all factors to appropriately manage a crouched gait.

As a general rule, the hamstrings require lengthening when straight-leg raising cannot exceed 70 degrees above the horizontal, or when the popliteal angle (i.e., the sagittal femorotibial angle with maximum knee extension, the patient supine, and the hip first flexed to 90 degrees) is less than 135 degrees (i.e., 45 degrees short of full extension). Lengthening the medial hamstrings is performed by incising the fascial aponeurosis of the semimembranosis muscle at a minimum of two levels, and step-cut lengthening or tenotomizing the semitendinosis and gracilis tendons **[➥4.23]**. If after these procedures the lateral hamstrings are still tight (popliteal angle less than 160 degrees), they may also require aponeurotic lengthening (234,235).

Postoperatively, hamstring lengthenings with or without distal rectus femoris transfers are managed in removable knee-immobilizer splints, which can easily fit over a below-knee cast. Passive range of motion exercises may begin on the second or third postoperative day. If no bony surgery has been performed walking training may begin as early as the fifth postoperative day. When adequate quadriceps strength has been regained, usually by the fourth postoperative week, the knee immobilizers may be discarded or used as night splints. Between physical therapy sessions sitting should be done with the knees alternately in extension and flexion.

Good results at the knee can sometimes be obtained by lengthening the hamstrings proximally (236) **[➥3.19]**. It has been found, however, that lumbar lordosis may increase after this procedure because of the overactive hip flexors; also, the desired effect on the distal hamstring tightness may not be achieved (237). It must be remembered that the hamstrings are also hip extensors, sometimes contributing up to a one-third of the extensor torque (238,239). Hip extensor power is somewhat lessened by hamstring lengthening, especially proximal hamstring lengthening. Therefore, this procedure may increase a preexisting hip flexion contracture, as well as increase the lumbar lordosis, if the iliopsoas unit is not addressed concomitantly. Gait analysis has shown that in some patients with a crouch gait, the hamstrings may be of normal or even excessive length. This is seen with simultaneous hyperflexion of the hip. In this situation hamstring lengthening alone may further weaken hip extensor power and increase the already severe hip-flexion deformity. To preserve some of the hip extensor power of the hamstrings, Gage has recommended transfer of the distal semitendinosis to the lateral femoral metaphysis. This may minimally augment external rotation at the hip (1).

Rectus Femoris Transfer. A finding commonly associated with knee-flexion deformity is cospasticity of the rectus femoris muscle and the hamstrings. The rectus may be firing continuously throughout the gait cycle, or mostly during swing phase, but the result often is a stiff-knee gait with less than 80% of normal knee motion. In this situation when the hamstrings alone are lengthened, a stiff, extended-knee gait frequently results. There is lack of adequate knee flexion in swing phase, and that interferes with foot clearance so that circumduction or vaulting may be necessary to compensate (240). The stiff-knee gait may be prevented by transferring the distal rectus femoris tendon medially and posteriorly **[➥4.24]**. The transfer does not affect gait abnormalities in the transverse plane (i.e., intoeing or out-toeing), and it makes no difference whether the transfer is attached to the sartorius, gracilis, semitendinosus, or iliotibial band (241,242). This transfer is successful in restoring adequate (60 degrees) knee flexion in the swing phase of gait. It has been shown that transfer is necessary to accomplish this, not just tenotomy of the distal rectus femoris tendon (242,243). The indication for distal rectus femoris transfer is a preoperative range of knee motion during gait of less than 80% of normal (less than 45 to 50 degrees) and hamstring–rectus femoris cospasticity, with nonphasic activity of the rectus during the swing phase of gait (243,244 and 245).

Unfortunately the static assessment of hamstring tightness by straight-leg raising or by measuring the popliteal angle, does not correlate with the dynamic range of knee motion during gait (246).

Without gait analysis, one is left to assess knee motion during gait either by clinical observation or the study of a videotape of gait. Recent work also suggests that a positive Duncan-Ely test does not predict abnormal EMG activity, and neither the type of abnormal EMG activity in the rectus nor the magnitude of the restricted preoperative knee range of motion are significant variables in determining the success of the transfer (242). The beneficial effects of rectus transfer (increased velocity, stride length, and knee range of motion) may diminish significantly over time (247).

Hip Adduction Contracture. Tightness in the hip adductors can result in a scissoring type of gait pattern, and predisposes the patient to hip dysplasia or subluxation. Generally, when the hips cannot be abducted beyond 30 degrees in flexion or extension, adductor release or transfer (either posteriorly to the ischial tuberosity, which has its advocates [87,248] or posteriorly and distally to the gracilis [249]) is indicated **[➥3.18]**. There seems to be little difference in the results from release or transfer (250,251), but one study reports a high incidence of pelvic obliquity and hip subluxation after adductor transfer to the ischium (252). Neurectomy of the anterior branch of the obturator nerve is rarely indicated in diplegic patients who can walk, because it excessively weakens the adductor brevis muscle and can result in a wide-based gait with hyperabduction of the hips (253). The hip adductors function to stabilize the hip against excessive abduction during gait, running, and in activities such as skiing, skating, and horseback riding. The gait stability they provide allows more effective hip flexor and extensor activity. Thus, it is important not to “go for broke” and overlengthen or overweaken the adductors in ambulatory patients.

Release of the tight adductors **[➥3.17]** is performed with the patient supine, through either a longitudinal or transverse incision, depending on the preference of the surgeon. The adductor longus is always completely divided. Often, this is adequate to accomplish the objective of adductor release for most surgeons. This is at least 60 degrees of passive abduction on each side, with the hip and knee flexed to 90 degrees, or at least 45 degrees of passive abduction with the hip and knee extended (the medial hamstrings are also hip adductors). At times, some of the adductor brevis may also need to be released, and it may be necessary to divide the gracilis muscle to achieve the desired abduction.

Hip Flexion Contracture. A hip flexion contracture is best detected by the Thomas test, the prone extension test, or both (254). When the contracture exceeds about 20 to 25 degrees it should be released. Most contractures are caused by a spastic, contracted iliopsoas unit, and often hamstring lengthenings and rectus femoris transfers are necessary, and are combined with psoas recessions. This combination of procedures has very little or no significant effect on pelvic tilt (255).

In ambulatory children release of the iliopsoas tendon by tenotomy at the lesser trochanter weakens hip flexor power excessively, and may prohibit enough hip flexion strength to lift the limb in climbing stairs (256). Ambulatory children should have tenotomy of the psoas tendon alone, not the iliacus fibers, performed over the brim of the pelvis (257). Care must be exercised to differentiate the psoas tendon from the femoral nerve. Occasionally, the psoas is not tendinous at this level. Then a

recession to the anterior hip capsule is performed via an adductor approach.

Hip flexor releases are treated postoperatively by lying prone several times per day. Painful muscle spasms are particularly common in the first few days after hip surgery, and may be treated with diazepam and analgesics. It is desirable to begin gentle passive range of motion exercises by the second or third day after flexor or adductor releases, and gait training may begin 5 to 7 days postoperatively. After 3 weeks, more vigorous muscle strengthening exercises are tolerated.

Lumbar Hyperlordosis. Hyperlordosis is usually the result of compensation for bilateral hip flexion contractures. Correcting the contractures corrects the excessive lordosis. It should be remembered that other conditions, such as compensation for a rigid thoracic kyphosis, also produce lumbar hyperlordosis.

Intoeing. Intoeing is most commonly the result of excessive femoral anteversion (frequently measuring 60 to 70 degrees), but occasionally is caused by increased spasticity in the internal rotator muscles of the hip (the medial hamstrings or the anterior fibers of the gluteus medius and tensor fascia lata) (233). Excessive femoral anteversion, causing intoeing, rarely exists as an isolated finding in spastic diplegia. It is usually accompanied by lower-extremity musculotendinous tightness or contractures that also require correction.

Derotational osteotomy of the femur is the treatment for increased femoral anteversion. The appropriate age for the osteotomy is whenever other lower-extremity surgery is being done. This usually means after age 4 years. The derotation may be at the supracondylar region **[➥4.18]** in younger children with mild to moderate spasticity, and may be secured either by crossed Steinmann pins (42) and a hip spica cast, or by an external fixator. In older children, and at any age with substantial spasticity, it is best to perform the osteotomy at the intertrochanteric level **[➥4.6]** and to preserve the attachment of the iliopsoas. Fixation with a strong blade-plate or screw-plate may avoid the need for a postoperative spica cast and allow early hip motion with patients who have adequate bone stock. Such strong internal fixation obviates the problems of loss of fixation and malunion, which occasionally occur after the pin and cast fixation of distal femoral osteotomies. The proximal osteotomy is facilitated by placing the patient in the prone position and using the approach described by Root and Siegal (258). If subluxation and/or coxa valga are present, varus can be added to the osteotomy. Another option for derotation in children older than age 10 years is in the subtrochanteric region with fixation by a locked intramedullary rod, but this cannot be combined with varization.

Femoral derotational osteotomies to correct excessive anteversion require external rotation of the distal segment, which tightens the medial hamstrings. To prevent this increased medial hamstring tightness, which may actually increase internal rotation, these hamstrings usually need to be lengthened when femoral derotation is performed.

Other methods of treating intoeing gait in children with cerebral palsy have been advocated. Two of these are transfer of the semitendinosus tendon to the distal lateral femur (1) and posteromedial transfer of the distal tendon of the rectus femoris. These techniques have not been shown to be effective for intoeing (241). It should be remembered that transfer of the distal tendon of the rectus femoris, either medially or laterally, does improve knee flexion for foot clearance during the swing phase of gait (241). Another reported technique is transfer of the greater trochanter **[➥4.9]**, with its attached gluteus medius muscle to the anterior proximal femur, so that it may function as an external rotator, as well as an abductor (259). This abductor transfer, although sometimes successful, can produce an abductor weakness type of gait and has not been widely adopted (42).

Spastic Hemiplegia

Children afflicted with spastic hemiplegia have involvement of one side of the body, with the arm and hand more severely involved than the lower extremity. On closer evaluation, very mild involvement on the contralateral side is often found, especially in those with more severe affliction (1).

The hemiplegia type comprises about 30% of all cerebral palsy cases. About 1 in 3 patients have a seizure disorder, and almost one-half have some degree of mental retardation (3). More common than mental retardation is an attention deficit, learning, or behavioral disorder (260). A history of head trauma or intracranial hemorrhage is frequently found in spastic hemiplegia. Virtually all patients are community ambulators, although only about half can walk by 18 months of age (3). Some limb-length inequality and a difference in foot size are the rule, but rarely require any treatment.

The stereotyped concept of the patient with hemiplegia includes equinovarus at the foot and ankle, flexion at the knee and hip, internal rotation of the lower limb, internal rotation at the shoulder, flexion at the elbow, pronation of the forearm, flexion and ulnar deviation at the wrist, and thumb-in-palm with finger flexion in the hand. Actually, the degree of involvement with spastic hemiplegia is a spectrum, which has been separated into four subtypes (155). It is essential in planning treatment to quantify the involvement. Surgical results should be predictably good.

Type I hemiplegia is characterized by weakness of the tibialis anterior muscle, and the triceps surae group is not tight. This type is manifest as a footdrop and a steppage gait, with plantar flexion disappearing during stance phase. It is easily treated with an appropriate AFO. A posterior leaf spring or an articulated ankle type is usually superior to a solid-ankle AFO in this condition (261). The most difficult part of management is to get the child to wear the orthosis if he or she has no other noticeable variation from normality. One reported surgical approach to this type of hemiplegic problem has been transfer of the flexor digitorum longus and flexor hallucis longus tendons to the dorsum of the foot (262). Experience with this technique is limited, and meaningful long-term results are not available.

Type II hemiplegia has tibialis anterior muscle weakness plus spasticity in the triceps surae group, and usually in the tibialis posterior muscle. This produces an equinovarus deformity of the foot and ankle, which persists throughout all phases of gait, and can produce some knee hyperextension late in stance phase. The problem is addressed by lengthening the gastrocnemius aponeurosis or the Achilles tendon, lengthening or performing a split transfer of the tibialis posterior tendon (206,207), and providing an AFO if needed. Split posterior tibial tendon transfer is useful for correction of the varus heel in stance phase when there is no fixed deformity and the muscle is firing in phase (during stance). Often the tibialis posterior is active throughout the gait cycle. In that case it is better to lengthen its tendon rather than perform the split transfer (3). Rarely, the tibialis anterior muscle, instead of being weak, is overactive during the swing phase of gait. Then, a split anterior tibialis tendon transfer can be effective in achieving transverse plane balance of the foot (211). This is usually combined with tibialis posterior tendon-lengthening.

Postopoeratively, an AFO may be needed to assist a weak tibialis anterior, or to aid in preventing recurrent equinus deformity. Some children are orthosis-free after the surgery. The risk of recurrence of the equinus deformity in hemiplegia decreases as the child grows older, being reported at about 25% below the age of 4 years and 12% thereafter (3).

In type III hemiplegia, not only are the triceps surae and tibialis posterior muscles spastic and usually contracted, but hamstring involvement is also present, often with cospasticity of the rectus femoris. This produces a stiff, flexed knee gait with equinovarus foot and ankle deformity. Successful treatment includes the tendon surgery discussed for type II and the addition of medial hamstring lengthenings, often combined with a distal rectus femoris tendon transfer, as described in the section on spastic diplegia. Again, the appropriate AFO may be necessary postoperatively, sometimes temporarily, and sometimes permanently.

Type IV hemiplegia has the features of type III, with the addition of hip flexor and adductor spasticity or contracture. Iliopsoas lengthening, by release of the psoas tendon over the pelvic brim, and appropriate adductor releases are added to the treatment recommended for those with type III involvement.

This classification is helpful in the management of most patients with spastic hemiplegia. It is not infallible, however, and patients occasionally are encountered who have profound equinus with little or no varus; who have increased ipsilateral femoral anteversion, in addition to type IV involvement; or who have other abnormalities.

Athetoid Cerebral Palsy

Children with athetoid cerebral palsy have abnormal muscle tension and tone, which may increase with voluntary activity. Their resting state often includes limb movements that are purposeless, involuntary, and almost continuously changing. The movements are coarse and irregular, often give the child the appearance of squirming or writhing, and extensor tone predominance is the rule. The movements disappear during sleep (263).

The muscle tension often changes with the emotional state. The athetoid movements are greater in the more distal parts of the limbs, and often rapidly flow from flexion to extension, adduction to abduction, and pronation to supination. Because of the almost constant motion, most of the joints are put through a full range of motion, and contractures are not common unless there is an asymmetric component of mixed spasticity present.

Most children with substantial athetosis are not able to walk. Their mobility is by power wheelchair, often with an adapted steering mechanism. The therapeutic

focuses for these children should be on communication methods, on facilitating their control over activities of daily living, and on wheelchair mobility (264).

The gait pattern of those few patients with athetosis who can walk is random, inconsistent, and influenced by many external stimuli. Without a consistent baseline, the results of soft tissue surgery are unpredictable. Tenotomies and muscle releases should be done infrequently, and then very carefully with patients who have significant athetosis, because often the result is a severe, almost untreatable deformity opposite the one originally addressed.

Scoliosis is not uncommon in athetoid patients, and responds well to the internal fixation and spinal fusion techniques described earlier. Adult athetoid patients may develop profoundly painful degenerative spondylosis and myelopathy in the cervical spine, sometimes with upper-extremity weakness and even instability. One study identified two-thirds of athetoid patients by age 44 years, and all patients older than age 55 years, with moderate or severe cervical disc degeneration (265). The most common motion segment is C5–C6. This usually responds well to anterior cervical fusion (266), but severe athetosis and dystonia can make postoperative immobilization very difficult. In this situation, the use of BTX injections into the neck muscles can be extremely beneficial in eliminating involuntary neck motions (267).

UPPER EXTREMITY INVOLVEMENT

Most upper-extremity involvement occurs with patients who have spastic hemiplegia and quadriplegia. When considering treatment, it is essential to consider the function of the entire upper limb, and of the child to whom it is attached. It has long been reported that the problems of spasticity, weakness, poor motor control, poor proprioception and stereognosis, and joint contractures, reduce or eliminate the possible benefits of tendon lengthenings, transfers, or other surgical treatment in most cases. Patients with hemiplegia have been reported to have better results than do patients who have quadriplegia, and postoperative function is usually better with right hemiplegia than with left (268). Mental retardation, visual deficits, behavioral problems, and particularly dyskinetic involvement also may contraindicate upper extremity surgery. Fewer than 5% of patients are appropriate candidates for such surgery (269). Nevertheless, a recent report of 718 procedures in 134 patients over a 25-year period indicates that only high motivation and fair-to-good motor control affect upper-extremity surgical outcome, and mentation, sensibility, and the type of cerebral palsy do not influence the surgical result (270).

Patients with hemiplegic involvement often have functional improvement after upper-extremity surgery. Substantial cosmetic improvement or facilitation of care, such as dressing and gloving, can be achieved in severely involved patients. Patients who are most likely to benefit from upper-extremity surgery in cerebral palsy are those with:

- spasticity, not athetosis;
- reasonable intelligence and good motivation;
- stable trunk and body position;
- good hand proprioception, stereognosis, touch, and other sensations;
- no fixed contractures and adequate passive range of motion of all upper-extremity joints;
- reasonable hand function, with good hand placement capability and voluntary control; and
- age between 5 and 20 years (111,271).

In some instances, the use of preoperative dynamic electromyographic studies aids in decision-making regarding lengthening or transferring musculotendinous units (272,273 and 274).

An important indication for surgical correction of wrist and elbow contractures can be cosmesis. Older children and adolescents with reasonable intelligence who function well in public may have a negative body image, with a rigid, contracted wrist and elbow. This may also have a negative effect on peer group acceptance. In such cases, correction of those deformities, although having no benefit for upper-extremity function, can be of immense psychological value to the patient.

Nonsurgical Treatment

Traditional nonsurgical treatment modalities include passive range of motion exercises and passive night splinting to attempt to prevent contractures and serial casting, or judiciously applied dynamic splinting to attempt correction of mild contractures in the absence of much spasticity. The daytime use of splints in attempts to improve function almost always meets with failure in hands with poor sensation and control, and may actually increase spasticity. Outcome studies of splinting are lacking. It is doubtful that the satisfaction of “doing something” alone justifies the cost.

Recently, BTX injections have shown promise in selected upper-extremity muscles, but the effects are temporary unless a stretching program or another means of lengthening the muscles succeeds during the temporary period. BTX will probably most help a hemiplegic child with spasticity, no joint contractures, and reasonable hand function. The best early results have involved blocking the biceps, pronator teres, flexor carpi ulnaris, and thumb flexors and adductors (114,122). Whether surgery is merely deferred or can sometimes be avoided with BTX treatment is not yet known.

Surgical Treatment

Before undertaking an upper-extremity surgery program it is essential for patients and families to understand that realistic goals are improved function and appearance. Normality is not a possible result, and any improvement will require careful evaluation and planning. As with the lower extremity, it is wise to perform all needed procedures at one operative setting. It is certainly possible to have different surgical teams operating on the upper and lower extremities at the same time. Some common upper-extremity surgical procedures and their indications in spastic patients follow. Those patients with athetosis almost never have enough voluntary control to benefit from upper-extremity surgery.

Shoulder

Although it is rarely necessary to operate on the shoulder with severe spasticity, adduction and internal rotation contractures may develop, caused by tightness of the subscapularis and pectoralis major muscles. If hand function is reasonable but the ability to position the hand in space is compromised, correction of shoulder contractures is appropriate. This is accomplished by releasing the tendon of the subscapularis and lengthening the tendon of the pectoralis major. If this does not provide the needed correction, a proximal humeral derotational osteotomy, fixed with a compression plate, usually solves the problem (269,271).

An uncommon problem for people with hemiplegia is shoulder abduction when running, caused by deltoid muscle spasticity. This may be relieved by musculotendinous lengthening of the deltoid (114).

Elbow

The elbow is prone to develop flexion and pronation contractures in children with substantial spasticity. The flexion contracture is caused by the spasticity of the biceps, brachialis, and brachioradialis. Serial casting, dropout casts (long-arm casts with the posterior plaster above the elbow removed to allow further extension while blocking further flexion), dynamic splints, and BTX have been discussed already.

Surgery is usually necessary to gain lasting correction. The indications are to improve the ability to position a functional hand in space, to improve hygiene or prevent skin breakdown, and to improve appearance. Most flexion contractures of the elbow can be corrected by resecting the lacertus fibrosus, and by fractional lengthening of the brachialis and the biceps, plus release of the brachioradialis origin (114). Occasionally, step-cut lengthening of the biceps and anterior capsulotomy of the elbow is necessary (269).

Pronation deformity of the elbow is the result of overactivity of the pronator teres, perhaps the pronator quadratus, and weakness of supination. When combined with a flexion contracture in a young child, dislocation of the radial head may occur. The pronation component forces the dorsum of the hand or forearm to assist in bimanual tasks. Correcting the contracture to permit supination allows use of the hand. Surgical treatment of pronation contracture consists either of distal release or transfer of the pronator teres muscle (269). If passive supination is full, some advocate transfer of the pronator teres tendon through the interosseous membrane (114) or posterior to the radius to an anterolateral insertion so that it can function as a supinator (268). Results of this transfer are not always good, and a fixed supination deformity is a larger problem than a pronation deformity (268). Release of the pronator alone is usually successful, and is preferred by most surgeons.

Wrist

Prior to operating across the wrist, the status of the finger flexors and extensors must be determined. Flexion deformity or contracture with some ulnar deviation is the usual finding at the wrist in spastic upper extremities. This is usually associated with pronation of the forearm and weakness of the wrist extensor muscles. If flexor spasticity is minimal and finger extension is good, simply lengthening the flexor carpi ulnaris or the flexor carpi radialis, but not both, may be helpful. Another usually effective means of weakening spastic wrist and finger flexors is the flexor and pronator release procedure (271,276). The disadvantage of this operation is that it is nonselective, releasing all wrist and finger flexors and the pronator teres from the medial epicondyle of the distal humerus (42).

Flexor spasticity often is very severe, and extensor weakness is profound. In such cases, flexor carpi ulnaris transfer is recommended **[➥1.7]** (276,277). Before transfer an electromyogram can be performed to determine the phase of the muscle if that cannot be determined by clinical examination. Transfer of the flexor carpi ulnaris tendon around the ulnar border of the wrist and into the extensor carpi radialis brevis, is indicated if the transferred muscle is active during grasp, and the patient has poor wrist extension and poor grasp but can actively extend the fingers with the wrist in neutral or dorsiflexion (8,278) (Fig. 15-10). If the flexor carpi ulnaris muscle is active during release and there is adequate grasp but poor release, it is transferred to the extensor digitorum comminus tendons. At least one long-term follow-up study has indicated that transfer to the wrist extensor is less predictable than transfer to the finger extensors (279). Regardless of the site of transfer, the flexor carpi radialis tendon should not be lengthened in association with flexor carpi ulnaris transfer because that risks overly weakening wrist flexion.

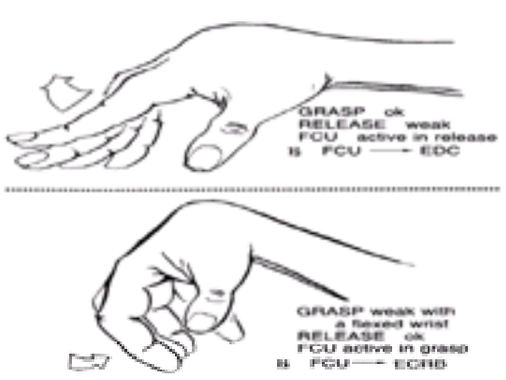

FIGURE 15-10. The spastic hemiplegic hand. The hand at top will benefit from transfer of the flexor carpi ulnaris (FCU) to augment the extensor digitorum communis (EDC). At the bottom, the hand needs augmentation of wrist extension by transferring the flexor carpi ulnaris to the extensor carpi radialis brevis (ECRB).

Wrist arthrodesis eliminates any useful compensatory or functional motion of the wrist, and prevents the wrist from any helpful participation in grasp and release by a tenodesis effect of the extrinsic muscles. It is indicated most often for the markedly deformed carpus in severely involved patients for hygienic or cosmetic reasons, such as putting the hand through a sleeve or into a pocket or a mitten.

Ulnar deviation of the wrist may be caused by overactivity in the extensor carpi ulnaris muscle with volar displacement of its tendon. Split transfer of its tendon to the extensor carpi radialis brevis has been recommended (271).

Hand

The common hand deformities are:

- flexion and adduction of the thumb; and
- either clawing with hyperextension of the finger metacarpophalangeal joints, with flexion contractures of the distal finger joints; or
- full flexion at all finger joints; or
- swan-neck deformities of the fingers.

Thumb-in-palm deformities are complex, and require careful assessment before the appropriate treatment can be recommended. In most cases, the adductor pollicis and first dorsal interosseus muscles overpower the abductor pollicis longus and the extensor pollicis longus and brevis muscles. Common patterns of deformity are:

- metacarpal adduction contracture;
- metacarpal adduction contracture with metacarpophalangeal (MCP) flexion contracture;
- metacarpal adduction contracture with MCP hyperextension contracture; and
- metacarpal adduction contracture with MCP and interphalangeal joint flexion contractures.

In all types, there are contractures of the skin of the first web and tight fascial bands in the first dorsal interosseous and adductor aponeuroses (114). There are different ways to surgically treat these deformities, but in principle all involve release of contractures of the skin, joints, and spastic muscles; joint stabilization; and augmentation of the weakened muscles **[➥1.8]** (269,271,280) (Fig. 15-11).

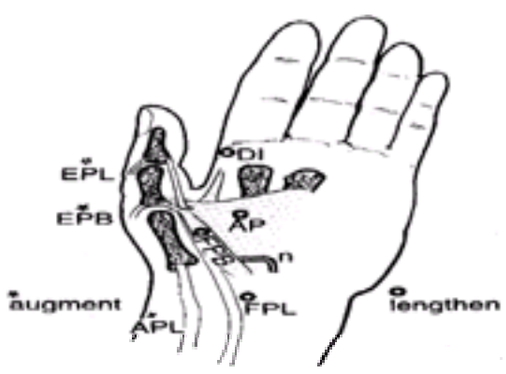

FIGURE 15-11. The repertoire of operations for the thumb-in-palm deformity. Shortened muscles should be lengthened, and weak long muscles should be shortened and augmented. An unstable metacarpophalangeal joint should be stabilized. *AP*, adductor pollicis; *APL*, abductor pollicis longus; *DI*, first dorsal interosseous; *EPB*, extensor pollicis brevis; *EPL*, extensor pollicis longus; *FPB*, flexor pollicis brevis; *FPL*, flexor pollicis longus.

Often the problem in the claw hand with wrist flexion and metacarpophalangeal hyperextension is imbalance between the wrist flexors and extensors. This is usually addressed by transferring either the flexor carpi radialis or the flexor carpi ulnaris to the extensor carpi radialis brevis (271).

If finger flexion deformity is a mild but functional problem, fractionally lengthening the flexor digitorum sublimis and profundus muscles is of benefit. This is done by complete transverse circumferential release of their aponeuroses in the proximal third of the forearm. In tightly flexed fingers that cannot be extended, even with the wrist flexed, an effective treatment is tenotomies of the flexor digitorum profundus and sublimis tendons at different levels in the distal forearm. With the fingers extended the proximal ends of the sublimis tendons are then sutured to the distal ends of the profundus tendons (sublimis to profundus transfers). Tenotomies of the wrist flexors usually are also necessary. With more severe involvement proximal row carpectomy can be used to gain additional length in the soft tissues, or wrist

arthrodesis may be necessary to stabilize the hand for assisting.

The often seen swan-neck deformities of the fingers result from intrinsic muscle spasticity and extrinsic extensor overpull, partly caused by the wrist-flexion deformity, by compensation for weak wrist extensors, or by both, with resultant overpull on the central slip of the extensor mechanism. With time the volar plate becomes incompetent and the proximal interphalangeal joint may subluxate and become fixed. In the latter situation it is unlikely that function can be improved with surgery. With early or mild deformities correction of the wrist flexion alone may suffice, and splinting may be added if the deformities are <40 degrees. With more severe deformities the surgical treatment is much more complex (114,269,271).

Appropriate postoperative care, especially after tendon transfers, is essential to the success of hand and upper extremity surgery in cerebral palsy. Recommended treatment for most patients is 4 weeks of complete immobilization, then an intensive exercise program with emphasis on reach, grasp, and release. Removable splints are used for several months during the day, and often at night, for several years (269). Although it is realized that only a small percentage of children with spastic cerebral palsy benefit from upper-extremity surgery, such reconstruction can be of substantial benefit for the appropriate patient.

CHAPTER 16

MYELOMENINGOCELE

RICHARD E. LINDSETH

Richard E. Lindseth: Department of Orthopaedic Surgery, Indiana University School of Medicine, Indianapolis, Indiana 46202.

Myelomeningocele is the most complex treatable congenital malformation of the central nervous system. Its effect on the child, the parents, and the medical community may be devastating. The initial treatment, which consists of closure of the meningocele and insertion of a ventriculoperitoneal shunt, is straightforward and well within the capability of most neurosurgeons. The child is then referred to the orthopaedist for rehabilitation.

The orthopaedic care of these patients is strongly influenced by factors beyond an orthopaedist's control, including changes in the neurologic system, urologic abnormalities, societal pressures, education, and the availability of medical resources. It is almost impossible to carry out the necessary treatment program without a coordinated interdisciplinary team consisting of a neurosurgeon, an orthopaedist, a urologist, a social worker, physical and occupational therapists, educators, a pediatrician, and a nurse specialist. If these services cannot be provided, the child should be referred to a clinic that can provide them.

CLASSIFICATION AND PATHOLOGY

The pathologic description of spina bifida and associated neurologic abnormalities was made by von Recklinghausen in 1886 (1). His observations remain current, and only recently have we begun to understand the pathologic processes that lead to the formation of myelomeningocele and other associated diseases.

Neural tube defects are grouped together under the generic terms “myelodysplasia,” “spinal dysraphia,” and “spina bifida aperta.” These are not to be confused with “spina bifida occulta,” which is a common radiographic finding of a lack of fusion of the spinous process of the lower lumbar and sacral spine without neurologic abnormalities. Neural tube defects can be divided into four subtypes: meningocele, myelomeningocele, lipomeningocele, and rachischisis.

A cyst involving only the meninges but not any neural elements is called a “meningocele.” It often requires surgical excision and closure by a neurosurgeon. However, it does not cause neurologic or orthopaedic abnormalities, and further treatment is not needed.

A myelomeningocele includes the abnormal neural elements as a part of the sac (Fig. 16-1). The sac may assume any size, form, or location along the spine. It is less likely to be epithelialized than a meningocele sac. The neural elements are abnormal, and pronounced peripheral neurologic deficits are common. Central nervous system abnormalities, including Arnold-Chiari deformity and hydrocephalus, are common.

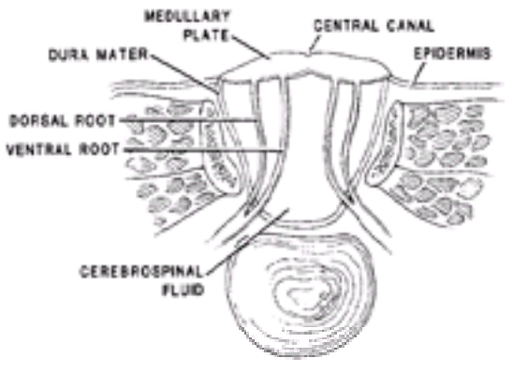

FIGURE 16-1. Cross-section of myelomeningocele. The abnormal cord is part of the sac, and is elevated out of the canal.

A “lipomeningocele” is a lesion in which the sac contains a lipoma that is intimately involved with the sacral nerves. These lesions often are epithelialized at birth. Children with lipomeningocele may not have hydrocephaly or other central nervous system abnormalities. Neurologic function, which is almost normal at birth, may become impaired with growth. This abnormality is similar to other abnormalities of the spine, including dermoid sinus, dermoid cyst, and diastematomyelia. When paralysis occurs, it rarely extends above the lumbosacral area. Progressive neurologic loss should be the major concern in the treatment of these children.

“Rachischisis” is a complete absence of the skin and sac, with exposure of the muscle and the presence of a dysplastic spinal cord without evidence of a covering. Occasionally even the bone is exposed, but usually there is a thin covering of muscle.

The embryologic development of myelomeningocele is unknown. There are two opposing schools of thought that have existed since the initial description of the disease (1): von Recklinghausen's hypothesis that the defect was caused by lack of closure of the spine, and Morgagni's proposal that it was caused by a rupture of a previously closed neural tube (2,3,4,5,6 and 7). Proponents of each theory have gained prominence.

The formation of the myelomeningocele occurs early in life, probably between the third and fourth weeks of gestation. This has two implications. The first is that if myelomeningocele is to be prevented by eliminating teratogenic factors and providing a nutritional supplement it must be done very early—preconception—if possible. The second implication is that the lesion has occurred before limb bud development, yet most often the limb bud of the lower extremity is essentially normal. This seems to suggest that at least initially neurologic function is normal and remains so until late in prenatal development. This has led some investigators to evaluate the benefit of delivery by cesarean section when maturity of the lungs permits, avoiding the trauma to the neural plate caused by the decrease in amniotic fluid as maturity

progresses, and by the birth process itself (8). However, the studies are inconclusive.

The roof of the myelomeningocele is composed of the spinal cord. It is open from the central canal posteriorly through the dorsal columns (Fig. 16-1). The anterior roots are intact, whereas the posterior roots to the dorsal cord are more likely to be involved in the pathologic process. The central canal of the cord is open and communicates with the fourth ventricle of the brain; this allows the cerebral spinal fluid to flow to the outside. Because of the probable involvement of the posterior columns, sensory and proprioception abnormalities probably are worse than the motor abnormalities. This abnormality of sensory feedback and crossing nerve fibers around the central cord may explain the lack of coordinated reciprocal functioning and the presence of spasticity frequently observed in children with myelomeningocele.

The attachment of the spinal cord to the meningocele sac prevents the normal upward migration of the spinal cord with growth. This produces the tethered cord. Even with surgical release of the spinal cord from all adhesions at the time of sac closure, there is a likelihood of reattachment of the cord during the healing process with recurrence of tethered cord syndrome later in life. The incidence of symptomatic retethering is unknown. However, it seems that the more it is looked for the more common it becomes.

Because of tethered cord, brain development, or hydrocephaly, almost all children with myelomeningocele have displacement of the brain stem through the foramen magnum into the cervical neural canal, known as Arnold-Chiari type II malformation. The extent of the displacement determines the type of deformity. Type I malformation has minimal deformity; type II deformity consists of the displacement of the medulla oblongata and the spinal cord to the extent that the cervical nerve roots must take an upward course to reach their outlet foramina (Fig. 16-2). This is the most common deformity in myelomeningocele. The type III deformity is more severe in displacement and includes part of the cerebellum.

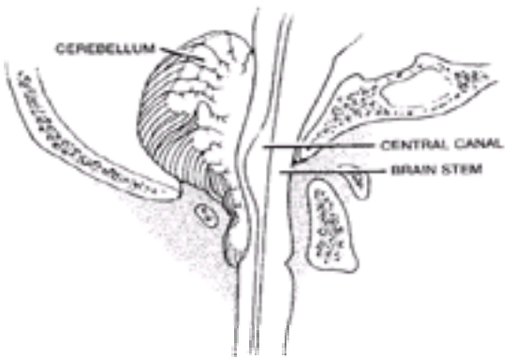

FIGURE 16-2. Arnold-Chiari type II malformation of the brain stem. This is the most common type of malformation seen in myelomeningocele. The medulla oblongata is displaced distally through the foramen magnum into the cervical neural canal. The ventricle communicates with the still-open central canal of the cord.

The final pathologic abnormality is hydrocephaly, which consists of excessive cerebral spinal fluid in the ventricles of the brain. Almost 90% of children with myelomeningocele develop hydrocephaly, which communicates to a persistently open central canal of the cord, which in turn communicates with the meningocele sac. This open communication of the central canal and the fourth ventricle permits the utflow of the cerebral spinal fluid, decompresses the ventricular pressure, and relieves the hydrocephaly. However, at the time of sac closure the fluid flow from the central canal is stopped and hydrocephaly returns. If hydrocephaly is not shunted, the fluid pressure increases in the brain and the spinal cord, which causes brain atrophy, hydromyelia, and eventually syringomyelia.

NEUROLOGIC ABNORMALITY

The neurologic abnormality defies simple classification (9) because of the complex abnormalities of the central nervous system, which include hydrocephaly, Arnold-Chiari deformity, hydrosyringomyelia, tethered cord, and injury to the posterior column of the spinal cord. Attempts to classify the level of paralysis by muscle function as though the defect is similar to a spinal cord injury seen in vertebral fractures are unsuccessful. Sharrard and Grosfield (10) initially formulated the classification by lumbar segmental levels based on motor segmental innervation using the level of the anterior horn cells in the spinal cord. This classification does not match the clinical observation of function in the lower extremities. For example, there is confusion in the literature about what is an L4 versus an L5 level of paralysis. The problem is using muscle activity to describe the level of paralysis when central nervous system dysfunction is common. If sensation, the most severely damaged nerve function, is used to describe the level of paralysis the classification better describes what is seen clinically. Muscles that can communicate with the brain through sensory feedback are functional. Muscles that cannot do this may be ignored by the brain and become flaccid or spastic, and function only by reflex. The author recommends that classification of function be made by sensory level, rather than motor level, because it will be more consistent between patients and between different observers. Another area of confusion is whether the level of paralysis is based on which muscles are working or upon which muscles are paralyzed.

Another confounding variable is abnormality of coordinated muscle function due to brain stem abnormalities. On manual testing the muscles contract to simple commands, such as “Extend (or flex) the knee.” However, on complex coordinated activities such as walking, the leg muscles do not contract as expected, but contract and relax simultaneously in a co-contraction rather than sequentially, as seen in normal gait (Fig. 16-3). This dynamic co-contraction is very common in the L3 to L5 level of paralysis, and may explain the knee flexion contractures in these patients, despite normal quadriceps strength. The author observed this phenomenon in a child with hydrocephalus and Arnold-Chiari deformity without myelomeningocele. This may suggest that it is related to the brain stem rather than to the meningocele itself.

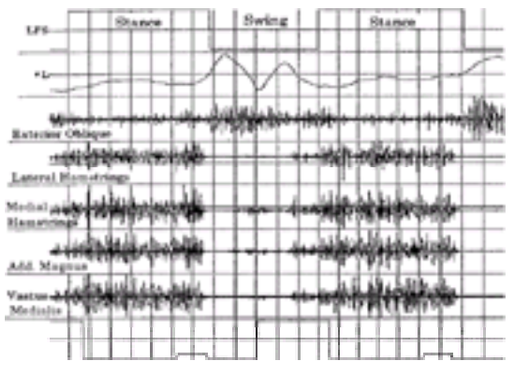

FIGURE 16-3. Dynamic electromyograms taken during a gait assessment analysis of a 5-year-old child with an L4 level of paraplegia and a type II Arnold-Chiari malformation. Surface electrodes were used during this analysis. The external oblique muscle is a swing phase muscle. The medial and lateral hamstrings, the adductor magnus, and the vastus medialis contract simultaneously throughout the stance phase. This observation has been checked using fine-wire electrodes, which show that the simultaneous contraction is not caused by crosstalk between the surface electrodes.

Other common neurologic defects that are not well understood, are decreased perceptual motor function of the hands and attention deficit disorder manifested by short attention span at school (11).

GENETICS, ETIOLOGY, AND PRENATAL DIAGNOSIS

Approxiamtely 6,000 infants in the United States are born each year with neural tube defects. This includes anencephaly, myelomeningocele, and related abnormalities. Gradual decrease in incidence worldwide has occurred over the last 30 years (12). The reason for this fluctuation is not clear, and probably involves

both genetic and environmental factors.

Most neural tube defects occur as isolated malformations caused by a variety of factors, both inherited and acquired (13,14). This pattern is known as “multifactorial inheritance.” In the United States, the overall incidence of neural tube defects is 0.15% among whites and 0.04% among African-Americans. After the birth of one affected child, the risk of a second affected child is higher (15,16). In the United States the occurrence of a neural tube defect in first-degree relatives of an affected member was 3.2%, in second-degree relatives, 0.5%, and in third-degree relatives, 0.17% (14).

Not all neural tube defects are multifactorially inherited; some are caused by chromosome abnormalities, and others are caused by single-gene abnormalities. Usually, children with chromosomal or single-gene abnormalities have other birth defects. Some cases of spina bifida and anencephaly are entirely produced environmentally. These abnormalities are caused by exposure during pregnancy to teratogenic agents such as valproic acid taken for seizure control (17).

Yates and colleagues (11) have shown an association between susceptibility of offspring with neural tube defects and depressed red cell folate levels which cannot be attributed entirely to low dietary intake of folate. They postulate that a factor that predisposes a person to the current neural tube defect is an inherent disorder of folate metabolism. This theory is supported by a study by Sellar and Nevin (18) in which a decreased incidence of neural tube defects was found in children of mothers taking periconceptional vitamin supplementation. The FDA recommends that all women of child-bearing age receive 0.4 mg folate before conception and during early pregnancy. The Centers for Disease Control and Prevention (17) recommends that women who fall into the high-risk group of bearing a child with a neural tube defect because of giving birth to a prior affected child, or having a first-degree relative with a neural tube defect, receive a larger dose of folate, 4.0 mg/day.

Prenatal diagnosis of a neural tube defect allows the family, in consultation with the medical community, to make informed decisions about its child. These decisions range from termination of pregnancy to attempts to improve the outcome of pregnancy by improved perinatal care in institutions medically prepared to provide optimal care for the child. The aim of any prenatal screen for open neural tube defect is to be able to pinpoint women with a sufficiently high risk of having an affected infant to justify carrying out special diagnostic procedures such as amniocentesis for amniotic fluid, alpha-fetoprotein and acetylcholinesterase determinations, and detailed ultrasonography for examination of the fetus (19). Women who have had an infant with a neural tube defect carry enough risk of having another affected child to justify undergoing amniocentesis. Longitudinal ultrasound examination of the fetal spine provides vital information about the presence or absence of neural tube defect. The sensitivity of ultrasound examination is excellent for studying women at high risk for carrying a fetus with neural tube defect. In almost all fetuses with anencephaly, and in at least 80% of fetuses with open spina bifida, diagnoses are correct. When no abnormalities are found on detailed ultrasound examination, amniocentesis is recommended for evaluation for alpha-fetoprotein and acetylcholinesterase (20).

NATURAL HISTORY

Most children born with myelomeningocele die in early infancy if left untreated. This has been documented in several series of untreated children in the late 1950s and early 1960s. The mortality rates range from 90 to 100% (21,22). The cause of death in most infants is meningoventriculitis. Surgical treatment is not necessary for survival if antibiotics are administered and nutrition is maintained. However, the surviving children are disabled further by a high level of paralysis and increased mental retardation resulting from the continued trauma to the spinal cord and the uncontrolled hydrocephaly, which would not have been present if surgical treatment had been carried out.

During the 1970s, there was an attempt to select patients for treatment according to the criteria suggested by Lorber (22). However, most neurosurgeons have had great difficulty in withholding all forms of treatment from selected infants with myelomeningocele. They are performing initial sac closure and ventriculoperitoneal shunts on most infants with myelomeningocele.

Because most patients are treated with initial closure and ventriculoperitoneal shunt, a new and different natural history of the disease following this early treatment is being studied and documented. Studies conducted in the 1960s cannot be equated with the disease course of the children of this decade. An important discovery about the nature of myelomeningocele during the last 15 years is that the disease is not static but may undergo progressive neurologic degeneration, manifested by increasing levels of paralysis and decreasing upper-extremity function (23,24 and 25). Neurologic deterioration can be sudden and dramatic, or very slow and insidious. It is extremely important that the orthopaedist carry out a detailed neurologic evaluation including upper and lower extremities and motor function at each clinic visit, and any change in function requires a referral to the neurosurgeon for appropriate diagnosis and treatment. Three major areas of deterioration of the central nervous system have been found: hydrocephaly and associated hydrosyringomyelia, Arnold-Chiari deformity, and tethered cord syndrome.

Hydrocephaly

Hydrocephaly is a common disabling abnormality found in myelomeningocele due to obstruction of fluid movement by complex deformities of the posterior fossa and brain stem. In 1974, Lorber showed that, of patients *without* hydrocephaly, 30% had IQs above 100, 50% had IQs between 80 and 99, 12% had IQs between 60 and 79, and 8% had IQs under 60. In contrast, of patients *with* hydrocephaly, only 20% had IQs above 100, 30% had IQs between 80 and 99, 30% had IQs between 60 and 79, and 20% had IQs under 60 (22). Perceptual motor abnormalities appeared to be the biggest factor in intellectual function. Most of these children perform well in their verbal scores but are considerably below average in their perceptual motor and hand function scores.

Although, in some children with myelomeningocele the hydrocephaly becomes arrested in infancy without evidence of increasing head size or symptoms of acute intracranial pressure, most children require a ventriculoperitoneal or ventriculoatrial shunt (26). Considerable improvements in the design and construction of the shunt have been achieved; however, it is still an unsophisticated device for controlling the right amount of ventricular pressure. Shunt failure can occur at any age, and must be evaluated at each clinic visit.

In the young child shunt failure is accompanied by the typical symptoms of hydrocephaly. However, in the older age groups shunt malfunction rarely is associated with signs of acute hydrocephaly, such as nausea, vomiting, and severe headache, except first thing in the morning (24,26,27).

Because of the communication of the fourth ventricle with the persistent central canal of the cord, increased hydrocephaly results in fluid entering the central canal, causing dilation and pressure in the cord when the child is upright (6). If left unresolved, this eventually causes the formation of hydrosyringomyelia. Three problems have been shown to result from hydrosyringomyelia. The first problem is increasing paralysis of the lower extremities, occasionally associated with increased spasticity and, to a lesser extent, back pain. This problem is seen usually when the child is in his or her early school-age years. The second problem is progressive scoliosis which may occur as early as 5 years of age, but is more likely to be seen in the 7-to-10-year-old group (26,27). The third problem is weakness of the hands and upper extremity (24). This occurs when the child is in the teenage years. Most of these symptoms are resolved by early correction of the hydrocephalus by shunt replacement.

Arnold-Chiari Deformity

Associated with hydrocephaly is the Arnold-Chiari deformity, which is classified into three types according to the degree of displacement of the brain stem and hindbrain through the foramen magnum. Most of these affected children have a type II anomaly, which is characterized by displacement of the medulla oblongata into the cervical neural canal through the foramen magnum, requiring the cervical roots to take an upward course to reach their outlet foramina (Fig. 16-2).

The symptoms of an Arnold-Chiari type II deformity in infants includes periodic apnea, stridor, nystagmus, weak or absent cry, and upper-extremity spasm and weakness. Symptoms come in episodes between which the infant may show minimal involvement. The cause of the episodic nature of the symptoms is not determined. During childhood symptoms include spastic weakness of the upper extremities and, occasionally, leg involvement. Children also have nystagmus, stridor, difficulties in swallowing, and depressed or absent cough reflex. Symptoms in older patients still are being determined, and probably include scoliosis, decreased upper-extremity function, neck pain, and decreased respiratory function. The most serious difficulties appear to be present in infancy and decrease as the child matures.

In many children, following initial placement of the ventriculoperitoneal shunt to control hydrocephalus brain stem symptoms usually resolve on their own and do not require surgical decompression procedures. In a few infants and children in whom the brain stem compressive symptoms persist or progress, the posterior fossa and upper spinal region are decompressed surgically. The effect of aggressive treatment of Arnold-Chiari deformity on overall survival and function has yet to be determined.

Tethered Cord Syndrome

Tethered cord syndrome is another major cause of decreased nerve function (28). During the formation of the myelomeningocele, the open neural elements are attached to the ectoderm at its periphery. This prevents it from migrating cephalad during the growth of the fetus. Consequently, all children with myelomeningocele have a degree of tethered cord at the time of birth. During closure of the sac, the everted spinal cord is dissected from the skin and allowed to fall back inside the neural canal. If any dermal elements are left attached to the spinal cord, dermoid cysts may develop and eventually cause decreasing function in the lumbosacral roots by direct pressure on the nerve elements.

After sac closure there still is a tendency for the spinal cord to become adherent to the meningocele repair. As the child grows this adherence again produces a tethered cord and prevents the spinal cord from migrating cephalad during growth. Although many children have a tethering of their spinal cord, only a few actually have symptoms of the condition and require surgical release. Because the posterior part of the spinal cord is adherent to the meningocele repair, and the cord proximal to the meningocele is held posteriorly where it is compressed by the posterior neural arch in the area of the lumbar lordosis, most symptoms are associated with posterior column abnormalities.

Pain appears to be a prominent symptom of the tethered cord syndrome and may occur in the lower lumbar spine, in the area of the myelomeningocele, or the sacral roots, with pain in the buttock and the posterior thigh. The pain is also activity-related, and becomes worse after walking long distances. In addition, increasing spasticity and decreasing function of the lower extremities are frequently present. Occasionally there is an associated progressive scoliosis associated with marked lordosis. Changes in dermatomal somatosensory-evoked potentials are present, and are helpful in making the diagnosis if serial examinations have been made (29). Changes in bladder function are common. The diagnosis of tethered cord syndrome is made on clinical evaluation, not by the presence or absence of a tethered cord on radiographic MRI study. The MRI describes the nature of the tether and confirms the diagnosis. The diagnosis of tethered cord syndrome in thoracic level paraplegics is rare, and becomes more common the lower the level of paralysis. In the author's experience surgical release of the tethered cord rarely provides complete return of lost function. The diagnosis must be made early, and appropriate care must be provided before major loss occurs.

Latex Hypersensitivity

During the past 10 years there have been increasing reports of severe immediate-type allergic reactions to latex exposure (30). Although anyone may become sensitized to latex, three groups appear to have a high risk: children with myelomeningocele, health care workers, and workers in the latex industry. The reported incidence is as high as 34% in myelomeningocele children, and may increase in the future (31).

All patients should be questioned about a history of latex allergy. A history suggesting sensitivity includes swelling or itching of the lips from blowing up balloons or after dental examinations, and swelling or itching of the skin after contact with any rubber products. Other information that may suggest increased risk of latex allergy includes hand eczema; oral itching after eating bananas, chestnuts, or avocados; and multiple surgical procedures in infancy.

There is no standard test for latex allergy. Skin testing with a latex extract or glove extract may be the best test available. However, anaphylaxis has occurred in spina bifida patients during skin testing. In vitro tests may not be sensitive enough to detect all persons who may be at risk for latex contact.

Because of the high incidence of latex allergy in myelomeningocele it is recommended that all patients, regardless of history, should have their surgery performed in a latex-free environment. There have been several lists published of latex-containing items. However, they are being revised almost daily, and no list should be considered complete. Some things that are labeled “latex,” such as latex paint, are not latex based. It is best to ask the manufacturer if there is any question. If the child is known to be allergic, the parents will be able to tell what things need to be avoided in the hospital environment. However, in surgery, it must be assumed that the child is sensitive to all latex material. A latex-free environment is one in which no latex gloves are used by any personnel in the operating room, and there should be no latex accessories (e.g., catheters, adhesives, tourniquets, anesthesia equipment) that come into direct contact with the patient.

EFFECT OF MYELOMENINGOCELE ON DEVELOPMENTAL SEQUENCE

The normal child undergoes a sequential development of fine motor, gross motor, personal, social, language, and cognitive skills, which are the result of the child's physical abilities and his or her interaction with the environment (11). Three major areas that interfere with normal development of the myelomeningocele child are residual physical deformity, iatrogenic factors, and restrictions by society.

Medical treatment of children with myelomeningocele contributes greatly to their delayed development. Prolonged and frequent hospitalization during the first years of life, although often necessary, considerably interferes with the learning experiences of the child. Hoppenfield (32) pointed out that because of this environmental deprivation a 1-month-old infant with myelomeningocele frequently cannot follow a light to a midline, fix both eyes on the light, and respond to the sound of a rattle.

Along with the frequent shunt malfunctions and repeated hospitalizations the child also is placed in casts and splints to treat physical deformity, which further interferes with mobility and physical contact with parents, and prevents parent–child bonding. As the child becomes older, individuality often is denied as he or she is treated as a disease entity rather than a person. In the clinic the children frequently are undressed to their diapers then paraded before members of the clinic without regard for their embarrassment. The tendency is to treat them as asexual beings. If it is necessary to present a physical function abnormality to a group for discussion or education, a picture or a video recording should be used.

The last impediment to normal development is the resistance of society to accept and accommodate handicapped persons. Although there have been considerable improvements in treatment of children with myelomeningocele during the last 10 years, there still are considerable societal barriers to these children. For example, access to schools, playgrounds, amusement parks, sporting events, movie theaters, and private homes are limited to some extent. Also, acceptance of handicapped people in the employment market is restricted.

Although many previously mentioned factors are beyond control, these myelomeningocele patients can be helped to overcome their handicap. Hospitalization and treatment programs must be planned to interfere as little as possible with the normal developmental sequence, particularly in infancy. We must work within the clinics, schools, and to a larger extent, society, to promote acceptance of these patients as individuals, and help them carry out the four principle tasks of childhood and adolescence: establishment of a stable self-image, acceptance of an adult sexual role, development of independence, and choice of a career (33).

Development of a positive self-image and adult sexuality is a difficult task. Because of the physical impairment of children with myelomeningocele, personal interactions among peers is severely restricted, beginning in early childhood and extending into adolescence. The child with myelomeningocele looks different because of braces, orthopaedic shoes, wheelchairs, and deformities; these are barriers to peer acceptance. These feelings of being different may never be erased, even if the cause of these feelings is eliminated (34). Sexual information for these patients often is avoided or erroneous. Shurtleff et al. (8) showed that many adults with myelomeningocele could have sexual relationships, including procreation; however, knowledge about the specific problems in myelomeningocele is meager, and a local resource person may be difficult to find.

Development of independence is a complex issue between the parents and their dependent, handicapped child. The parents are often overprotective of the child. This protective attitude is also present in school and in society at large, especially if the child is confined to a wheelchair.

The choice of a career is also difficult. High school counselors are not trained to advise disadvantaged children, especially those with perceptual motor abnormalities of the hands. Government programs are not available until the patient is 18 years old or has graduated from high school. This is too late. Employment opportunities also are limited by the lack of ability to get health insurance.

TREATMENT

Treatment of children with myelomeningocele is not a matter of what can be done, but what should be done for each child. The decision-making may begin prenatally if the diagnosis is made by alpha-fetoprotein testing or ultrasound examination. The option to continue or terminate the pregnancy can be made at this time. If it is continued, decisions must be made on how to improve the prognosis of the child. These include referral, before delivery, to a center experienced in the care of these children so that adequate planning and preparation for the family can be carried out. If the diagnosis is made after birth then the next decision is whether the

meningocele should be closed and the child treated. Most children are treated unless there are other deformities present that are not compatible with life, such as anencephaly, congenital heart disease, pulmonary insufficiency, and other congenital malformations. In some cases, the lesion may be surgically untreatable.

Orthopaedic treatment is intertwined with the neurosurgical treatment. It is also tied in with urologic treatment. Almost all of these children have urologic abnormalities that require bladder drainage by conduits or intermittent catheterization. Frequent infection may spread to orthopaedic surgical areas, and the orthopaedic treatment of spine deformity influences the ability of the patient for self-catheterization.

Orthopaedic treatment of myelomeningocele has three major goals. The first goal is to provide for maximal use of residual ability to maintain range of motion and stability of the spine and extremities. The second is to provide for mobility by means of a wheelchair and other wheeled devices or by ambulation. The third goal is to prevent deterioration of neurologic function. Although it is true that the actual treatment of the central nervous system is performed by the neurosurgeon, the diagnosis of decreased function is made from observations of the spine and extremities by the orthopaedist. It cannot be assumed, because these patients are being seen and followed-up by neurosurgeons, that subtle changes in function are going to be observed. Teamwork is essential in treatment of children with myelomeningocele.

The ability to walk is important and often necessary in our society, despite recent advances in wheelchair design and wheelchair accessibility in the community. It also is the desire of every child with spina bifida. Although it is possible for most paraplegic children to walk to some degree during preschool and school age, many adults are not able to continue walking. Abnormalities of the spine and legs are often the cause for this inability. There are four necessary requirements of walking: alignment of trunk and legs; range of motion; control of the hip, knee, and ankle joints; and power to provide forward motion.

The alignment of the spine and the legs must be such that the center of gravity passes through the joints of the pelvis, the hip, the knee, and the foot. Deformities of the spine, such as scoliosis, kyphosis, and pelvic obliquity, prevent the center of gravity from passing through the center of the hip joint. Contractures of the hip or knee also will prevent stable weightbearing.

Motion of the lumbosacral spine and the hip are essential for functional walking. Motion of the knee is less important, and is useful only in clearing the swing leg. Mobility of the spine must allow the center of gravity to be shifted from side to side over the stance leg. Motion of the hip is the most important part of walking. Analysis of spina bifida children who maintain walking ability has shown normal flexion/extension of the hip. Thirty degrees of motion is necessary for forward progression. If there is less motion than this, then pelvic motion must help compensate for this decreased motion.

The child must be able to control the position of the trunk and hip, knee, and ankle joints, during the gait cycle. If this cannot be performed by muscle activity then it must be provided by an orthotic device. The determination of available muscles to control the joints is dependent on the level of paralysis.

The thoracic-level paraplegic has no active muscle contraction across the hip joint, and no feeling below the groin or in the hip. The child has no control of the hip, and the hip is unstable, even though it may be reduced and appear stable on radiograph examination. Stability for walking can only be provided by an orthosis that crosses the hip joint.

The upper lumbar paraplegic child has several muscles crossing the hip joint. These muscles include the hip flexors and the hip adductors. These children have some sensation crossing the hip joint. Contraction of the hip flexors causes the hip to flex, pitching the child forward. In order to keep from falling it is necessary to place most of his or her weight on the arms and crutches or walker. This is not a useful posture for walking and must be corrected. There is no way of surgically providing stability to this hip, and, similar to the thoracic-level paraplegic, the stability must be provided by an orthosis.

The middle and lower lumbar paraplegic child has hip flexors and adductors, knee extensors, and weak knee flexors. These children do not have normal hip extension or hip abduction, which are the most important muscles for standing and walking. Their weak hamstring muscles have a tendency to extend the hip and make these children walk without the need for orthotic control of the hip. The result of this is knee-flexion contracture. The force imbalance around the hip results in eventual hip dislocation. A decrease in the force imbalance, and increase of the control of the hip, can be obtained only by moving muscles to a more functional position or by adding muscles to the hip. Muscles available for transfer include the iliopsoas, the abdominal muscles, and the adductor muscles. Control of the hip and knee can be achieved by muscle activity; however, the ankle requires an orthosis.

The sacral-level paraplegic child has sufficient muscle control around the hip, the knee, and the ankle to provide the necessary stability.

The force necessary to move forward is beyond the muscle contraction needed to control the joint. In normal individuals it is provided by the calf muscle, which pushes people forward into their next step, and the hip extensors, which pull forward after the foot hits the floor. Both of these muscles have sacral level innervation and are paralyzed in almost all spina bifida children. In the thoracic and upper-lumbar levels of paraplegia the arms become the power producers to move forward. The arms are not designed for this activity and are inefficient. Weight gain is also a problem because many of these patients become obese. Consequently, it takes increased energy to walk and the walking pace is much slower than normal. Eventually, most thoracic and upper lumbar–level paraplegic people discover that the wheelchair is a much more efficient means of transportation.

The middle and lower lumbar–level paraplegics substitute trunk shift and sway to produce the forward motion. Much of the motion is from side to side, rather than forward. This also is an inefficient method of walking, and some children abandon it for a wheelchair when they become adults. The use of muscle transfers to increase hip extension does aid in the efficiency of walking and may keep the patient walking longer.

Spine

Spine deformity is so common in myelomeningocele that it should be considered part of the disease complex (35). The spine deformities usually are progressive and may cause severe disability, interfere with rehabilitation, and negate previous treatment to maintain ambulation.

The most obvious and consistent abnormality of myelomeningocele spinal deformity is the incomplete posterior arch in the lumbosacral spine. This abnormality affects many aspects of scoliosis and kyphosis treatment. Other congenital malformations also may be present (36). Hemivertebrae and diastematomyelia may occur at any level along the spine. Similarly, unsegmented bars may occur at any level. They are particularly difficult to identify and evaluate if they occur in the area of the spina bifida, where the facet joints, lamina, and spinous processes are difficult to identify on standard radiographs.

The spinal curvature often appears at a younger age than that typical for most developmental abnormalities. It may be present by 2 to 3 years of age, becoming severe by age 7. Because of the early onset of the deformity, treatment plans need to anticipate growth of the spine. However, the projections for growth in children with myelomeningocele are different from those for children with normal growth potential. Children with myelomeningocele may have slow growth due to growth hormone deficiency, and mature earlier than usual, often by 9 to 10 years of age in girls and 11 to 12 years in boys. The cause of the hormonal abnormalities has not been discerned, but they are treatable if it is necessary for the overall management of the child.

Another factor that needs to be considered in the surgical treatment of these patients is the high infection rate (35,37,38 and 39). These patients are subject to frequent septicemias due to urinary tract infections. Most of these children have chronic contamination of the urinary tract, which always has the potential to progress into an infection. During surgical procedures adequate drainage of the bladder and appropriate antibiotics should be a routine part of the surgical management. The skin in the area of the meningocele repair is often of poor quality, and gives minimal coverage to the instrumentation.

These children also have deformity of the pelvis and hips that affects spine balance. For example, asymmetric hip contractures may cause lumbar scoliosis, pelvic obliquity, and abnormal lordosis in the standing or sitting position. Similarly, correction of the spine in the treatment of scoliosis can position the legs in a way that prevents functional sitting or standing.

As with all children with spinal deformities, the goals of treatment are the prevention of further deformity and the creation of a stable, balanced spine. Children with myelomeningocele, however, require more precise correction of the deformities. Residual deformity may prevent them from sitting, standing, or walking. Pressure sores are likely to develop if pelvic obliquity remains, and their sagittal plane alignment must allow them to perform intermittent self-catheterization.

Scoliosis and Lordosis

Scoliosis occurs in almost 100% of patients with thoracic-level paraplegia (40). Eighty-five percent of these curves are greater than 45 degrees. As the paralysis level lowers, so does the incidence of scoliosis. At the fourth lumbar level of paraplegia the instance of curvature decreases to about 60%, with only 40% requiring surgical intervention (40) (Fig. 16-4). Lordosis without concurrent scoliosis is rare, and usually is caused by hip-flexion contractures. Historically it has been seen after spinal–peritoneal shunting for hydrocephalus; however, this procedure is rarely performed.

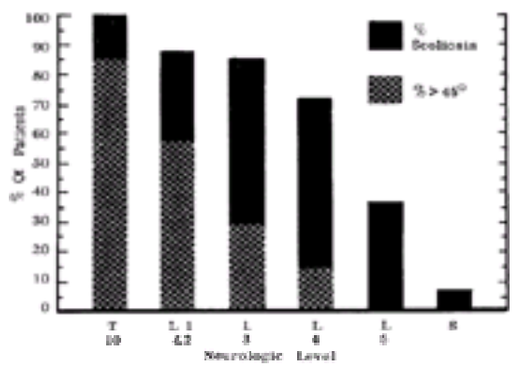

FIGURE 16-4. Incidence and severity of scoliosis, based on the level of paraplegia. (From ref. 41, with permission.)

Several causes for the scoliosis have been identified. A C-shaped scoliosis is usually caused by muscle weakness associated with high-level paraplegia. It also may be associated with asymmetric levels of paralysis or a spastic hemiplegia due to the hydrocephalus. This type of scoliosis may be associated with kyphosis rather than lordosis. Typically, this curve pattern occurs at a young age, often in infancy, and is usually progressive. If severe spasticity is present an intraspinal rhizotomy or cordectomy may be necessary (42).

Hydromyelia, or hydrosyringomyelia associated with uncompensated hydrocephalus, can cause scoliosis (24,25,26 and 27). The scoliosis is usually in the thoracic or the thoracolumbar region, and it is typically S-shaped. Because of stiffness in the area of the myelomeningocele in the lumbar spine, the compensation for the major curve may be incomplete and associated with pelvic obliquity. Scoliosis may be the only clinical sign of shunt malfunction or progressive hydromyelia, and may occur at any age, even early in childhood. Headache, nausea, vomiting, and vision changes—the usual signs of hydrocephalus—may be absent. Other symptoms of hydromyelia are back pain, weakness of the upper extremities, and increasing paralysis of the legs. It has been shown that reinserting a functional shunt may decrease the scoliosis if it is less than 50 degrees (27).

Another cause of scoliosis is the tethered cord syndrome (23,28,43). This abnormality is caused by attachment of the spinal cord to the area of the myelomeningocele, preventing its upward migration with growth. This syndrome may be associated with other intraspinal pathologies, such as dermoid tumors, lipomas, and diastematomyelia. The scoliosis is usually in the dorsal lumbar or lumbar spine with a marked increase in lumbar lordosis. Results of releasing the tethered cord are variable, but frequently curve progression is stopped; in a few cases, it improves. If the curve is more than 50 degrees, the scoliosis should be corrected and stabilized with spine fusion.

Congenital malformations, including the lack of formation and the lack of segmentation (36,44), may exist in combination with hydromyelia, tethered cord, or muscle paralysis. When evaluating a child with scoliosis the physician must consider each component of the scoliosis in the treatment program. Because of the high number of neurologic abnormalities associated with scoliosis a referral to a neurosurgeon should be made at the first sign of increasing scoliosis. It may be necessary to reinsert the shunt, untether the spinal cord, and treat the congenital scoliosis, if all are present.

Diagnostic Studies. At each visit a thorough neurologic examination of muscle strength, levels of sensation, and reflex activity of the upper and lower extremities should be carefully documented. If scoliosis is developing, the documented changes in neurologic function are of major diagnostic importance to the etiology of the scoliosis.

Radiographic evaluation should be carried out annually from the age of 1 year. These radiographs should be taken while the child is sitting, when the child can do so. This eliminates the problems related to hip flexion contracture and asymmetric abduction and adduction. If there is documented progressive scoliosis, additional radiographic examination is indicated. Magnetic resonance imaging (MRI) probably gives the most information without requiring invasive studies (45). MRI of the head and cervical spine evaluates the hydrocephalus and the degree of Arnold-Chiari malformation. The cervical, thoracic, and lumbar spine also should be scanned. The cervical and thoracic spine are evaluated for the appearance of syrinx or hydromyelia. The scan of the lumbar spine provides information on the posterior displacement of the conus and the presence of intraspinal tumors, such as lipoma or dermoid cysts. The MRI studies must be interpreted in association with the clinical findings to determine the cause of the scoliosis. The presence of a tethered cord is common, and it alone may not be the cause of the deformity. In the author's experience the scoliosis is in the lumbar spine with the apex at the last intact neural arch; the lordosis is in excess of 90 degrees; and other signs of tethered cord, such as changes in bladder function and neurologic function of the legs, are present.

Computed tomography (CT) also can be used. However, to get the maximum benefit from the study contrast material is usually necessary for evaluation of the spinal cord. Both MRI and CT studies usually require sedation or anesthesia in young children.

Treatment. If the scoliosis continues to progress after neurologic problems have been corrected, orthopaedic treatment is indicated. If the spine is balanced and the curve is 30 degrees or less, observation probably is indicated. However, if the curve is unbalanced or greater than 30 degrees the center of gravity falls outside of the pelvic base of support, the spine will become unstable, and progression of the deformity is almost assured. A trial of bracing is indicated in children younger than the age of 7 years if the curve is supple and can be corrected easily. However, because bracing in paralytic scoliosis is passive, the brace tends to deform the rib cage and produce pressure sores in the area of insensate skin. In infants special care is needed to avoid abdominal compression, which may make it difficult for the child to breathe and eat. Although the use of a brace is only temporary, it may delay the necessity of surgery until the child is 8 or 9 years old, when many of these children are beginning adolescence (36,46).

The most effective spinal orthosis is a two-piece, polypropylene, bivalved, molded body jacket. This design allows the brace to be expanded or contracted throughout the day, to allow for eating, and allows some adjustability for growth. Meticulous care is required because pressure sores are frequent, and once they develop, it is almost impossible to continue using the brace for control of the curve. In general, the child begins orthosis wear slowly, starting at 1 h intervals, after which the skin should be inspected. If any redness does not disappear within 4 h, the orthosis must be modified. The time in the brace is gradually increased over 2 to 3 weeks until the child is wearing it throughout the day except for naps and nighttime. If the family or caregivers are unable to provide this degree of care an orthosis is probably not indicated.

Most of these children require surgical correction and spinal fusion. Levels of fusion depend on the age of the child, the location of the curve, the level of paralysis, and the ambulatory status. As with all children with spinal deformities, the goals of treatment are the prevention of further deformity and the creation of a stable, balanced spine. Children with myelomeningocele, however, require more precise correction of their deformities; because of their paralysis, they are unable to compensate for any residual deformity, which may prevent them from sitting or from standing and walking. Pressure sores are likely to develop if pelvic obliquity remains, and their sagittal plane alignment must allow them to perform intermittent self-catheterization.

The treatment of the tethered cord, even if it is not symptomatic when correction of the scoliosis is performed, is an unsettled issue. Correction of the scoliosis lengthens the posterior spine, and puts the tethered cord on stretch. This may produce neurologic changes, even if they were absent before. Therefore, the neurosurgeons at the author's clinic believe that the tethered cord should be released either before or during the scoliosis surgery. If it is done before, the time between release and the spine surgery should probably be no more than 6 months because of the frequent retethering.

Generally, the same guidelines for instrumentation and fusion of idiopathic scoliosis are applicable to the myelomeningocele spine. The fusion should go from neutral vertebra to neutral vertebra, and the end vertebra should be located within the stable zone. This holds true for thoracic and thoracolumbar curves. However, in double

curves, uncompensated curves, and primary lumbar curves, the decision becomes more difficult. The guidelines for fusion and instrumentation in these cases differ from those for idiopathic scoliosis. In general, it is a mistake to fuse short; if there is a question, fuse long. A compensatory thoracic curve should be fused for its entire length, and the fusion should not end in the middle of a sagittal curve or at a junctional kyphosis.

The selection of the level at the distal end usually is complicated by the open vertebral arch, which prevents attachment of the instrumentation to the end vertebra. Lumbar hyperlordosis usually is present, compounding the problem of deciding on the distal level of fusion. In the past, the instrumentation was extended to the pelvis because of the difficulty of getting a firm attachment to the lower lumbar vertebrae **[➥2.5, 2.6]**(47). With the newer methods of pedicle fixation it may be possible to control some curves without fusing the lumbosacral joint. The indications for extending the fusion mass to the sacrum are not well established. Lumbosacral arthrodesis is difficult to obtain because of the lack of posterior vertebral arch to fuse **[➥2.6-2.8]**. Consequently, pseudoarthroses and instrumentation failures are common (39). Attempts to correct these problems require repeated surgical procedures and have an uncertain outcome. If a successful fusion to the sacrum is obtained it may deprive ambulatory patients of the ability to walk (48). In wheelchair-bound patients a lumbosacral fusion may cause difficulty because of increased occurrence of pressure sores if the residual pelvic obliquity is 15 degrees or greater. Movement in the lumbosacral spine absorbs much of the angular and rotational movements of the trunk during wheelchair activities. If the lumbosacral spine is fused, these torsional movements are transmitted to the pelvis, creating increased shear between the pelvis, the skin, and the wheelchair seat.

If the lumbosacral joint is not fused, the scoliosis tends to increase, unless the lumbar scoliosis can be corrected to less than 20 degrees and the pelvic obliquity to less than 15 degrees. Therefore, it is important to treat the scoliosis while the curve is small and can be corrected to less than a 20-degree lumbar curve and a 15-degree pelvic obliquity, whether fusion to the sacrum is planned or not. The delay of surgical correction of the scoliosis to allow the spine to grow may lead to an unsatisfactory correction. After spine correction residual pelvic obliquity greater than 15 degrees and less than 35 degrees can be corrected by a bilateral posterior iliac osteotomy, with transfer of a wedge of bone from the long side to the short side. The correction of the pelvic obliquity is necessary if there is difficulty sitting or an ischial ulcer develops (49).

Children with a thoracic or upper lumbar level of paraplegia should be fused to the sacrum (Fig. 16-5). In children with low lumbar and sacral levels of paraplegia, the lumbosacral joint should be spared if they are walkers, and the spine can be aligned satisfactorily (Fig. 16-6).

FIGURE 16-5. A 13-year-old girl has an L3-level paraplegia, but is not ambulatory. She is obese and has a progressive lumbar scoliosis and pelvic obliquity. A tethered spinal cord previously was released. **A:** Anteroposterior radiograph shows a 50-degree uncompensated lumbar scoliosis resulting in 35-degrees of pelvic obliquity. There is excessive lumbar lordosis. **B:** Postoperative anteroposterior radiograph shows complete correction of the scoliosis. The sacrum was included in the fusion because the lumbar scoliosis included the first sacral vertebra and the child was not ambulatory. Pedicle screws were used to secure the segmental instrumentation to L4 and L5. Anterior interbody fusion was performed from T10 to the sacrum. **C:** Postoperative radiograph shows restoration of normal sagittal alignment. Lumbar lordosis now measures 55 degrees. The patient has full extension of her hips, and is able to perform intermittent self-catheterization. (From ref. 59, with permission.)

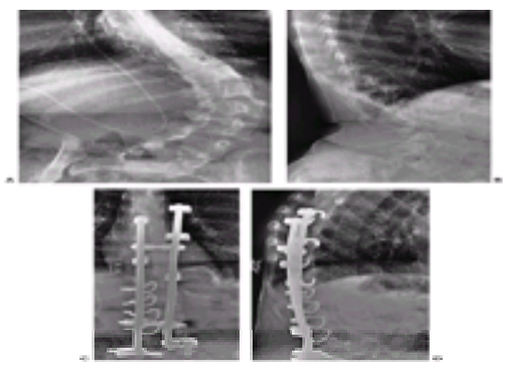

FIGURE 16-6. A mature 12-year-old girl with progressive lumbar scoliosis is an L4-level paraplegic, and is a community walker with ankle–foot orthoses and crutches. **A:** Anteroposterior radiograph shows 55-degree lumbar scoliosis from T10 to L3. There is a 20-degree compensatory curve from L4 to the sacrum. There is residual 30-degree pelvic obliquity. The last intact vertebral arch is L2. **B:** Lateral radiograph shows severe 120-degree lordosis, which is typical of the deformity associated with tethered cord. **C:** Anteroposterior radiograph shows correction of the scoliosis and pelvic obliquity. Pelvic screws are used to fix the distal end vertebrae at L5. The lumbosacral joint was left unfused to allow the patient enough pelvic mobility to continue walking. Release of the tethered cord was performed at the same time as the spine fusion. An anterior interbody fusion was performed from T9 to L5, without instrumentation. **D:** Lateral radiograph shows correction of the lordosis to 45 degrees and the achievement of a normal sagittal alignment. (From ref. 59, with permission.)

The sagittal deformity also must be evaluated because increased lumbar lordosis is a common deformity. Assessment of sitting, supine, and standing posture must be made before correcting the lumbar lordosis. These children often require a greater degree of lordosis than normal. Restoring the lumbar lordosis to the normal range may uncover a hip-flexion contracture and prevent the child from standing or walking. If too much lordosis is fused into the lumbar spine of a female patient she may not be able to carry out intermittent self-catheterization. The degree of lordosis left in the spine after fusion needs to be tailored to each patient. It is best to treat the hip contractures before correcting the spine. If the hip deformity is not corrected first, positioning of the spine on the operating table will be difficult and torque the spine postoperatively, leading to instrument failure and pseudarthrosis.

Ischial pressure sores also should be treated before spinal fusion to lessen the chance of infection. This is often difficult to do because the pelvic obliquity is a major cause of the ulceration and unless it is corrected, pressure cannot be relieved from the ulcer. In this circumstance, a gluteus maximus myocutaneous flap can be used to promote primary healing. The patient is maintained on an air mattress bed until the spinal correction can be performed. This may seem extreme, but is much less of a problem than an infected spinal fusion that requires instrument removal.

The age of the child at the time of surgery is an important consideration. If the child has not yet reached adolescence, as determined by the beginning of the appearance of pubic hair and a Risser sign of I, there is an almost 100% assurance that the curve will continue to progress despite posterior fusion unless the anterior spine is fused to the same level. The lumbar spine usually is fused anteriorly as well as posteriorly because of the deficient posterior vertebral arch, but if the posterior fusion extends up into the thoracic spine, it must be fused anteriorly as well.

In a child with a progressive curve that cannot be controlled by a brace and who is younger than 8 years old, the preferred treatment is extraperiosteal segmental Luque instrumentation without spinal fusion. Distal fixation of the rods in the area of the open spine is difficult. The author prefers use of the first sacral foramen as the anchor point. The “S” rod attached to the ala is also a possibility. The ilium is also a possibility, although the author has experienced loosening of the rod in the ilium with loss of fixation and erosion of the rod through the skin. Postoperative brace treatment is still indicated, and complications from this approach include rod

breakage, wire breakage, and spontaneous fusion. To provide a definitive solution, reoperation is often necessary when the child reaches maturity.

Instrumentation. Spinal fusion is still the most important part of surgical treatment of scoliosis despite the recent advances in spinal instrumentation. The role of the instrumentation is to improve spinal alignment and the fusion rate, and reduce the need for recumbency or postoperative immobilization. Whatever the instrumentation used, the degree of correctability of the curve is limited. It is important to carry out an early fusion when the deformity is manageable. The amount of correction that is possible is probably limited to about 60 degrees, despite the size of the curve. Occasionally it is possible to produce amazing degrees of correction, but this is not the rule. It is better to correct completely a 60-degree curve than to correct a 120-degree curve to 60 degrees.

It is agreed that anterior and posterior fusion is necessary in the area of the lumbar spine (40,50,51 and 52). However, there is no agreement about whether the anterior spine needs to be instrumented. The more severe the deformity to be corrected the greater the indication for using anterior instrumentation. However, there is still a great risk of producing kyphosis of the lumbar spine or at least flattening the normal lumbar lordosis, although some of the newer devices using thicker rods may control the sagittal alignment of the lumbar spine. Anterior instrumentation to the sacrum is difficult, and it is questionable whether an anterior interbody fusion of L5-S1 is necessary. Normally this is a very stable joint, and adequate posterior fusion can be obtained by grafting from the lamina and transverse process of L5 to the sacral ala. However, if the anterior longitudinal ligament is destroyed along with the annulus fibrosis, instability and severe deformity of this joint may occur if the child develops a pseudarthrosis of the lumbosacral joint. Because repair of this deformity and pseudarthrosis can be difficult, it is preferable to end the anterior instrumentation at L4 **[➥2.11]** in those patients who have a dorsal lumbar curve that ends or is stable at L3-L4. If it is necessary to extend the fusion down to the pelvis, perform an anterior fusion only down to L5, and posteriorly to the pelvis.

Posterior instrumentation has evolved considerably over the last 20 years. Initially, Harrington instrumentation was used **[➥2.2-2.4]**, but because of the lack of posterior vertebral arch, distal fixation of the fusion was difficult unless the instrumentation was extended down to the sacral ala. The alar hooks frequently became displaced, and the pseudarthrosis and complication rates were unacceptably high (52). The child also required postoperative immobilization which increased the occurrence of pressure sores.

Luque instrumentation has become the standard instrumentation for these children (47). Because of the segmental fixation to each vertebra, there is much better control over the spine and postoperative immobilization is not required **[➥2.5]**. However, it does not fix the length of the spine as a rod with hooks does; therefore, the spine may settle or collapse along the rod, with loss of some correction in the immediate postoperative period. If the rod is contoured to maintain a normal sagittal alignment there is a tendency for the rod to twist into the coronal plane deformity with loss of correction. This is lessened by the use of the unit rod or multiple transverse rod connectors. Fixation to the open posterior spine in the lumbar area by wires around the pedicle is weak, and extension of the instrumentation to the ilium is usually necessary. Even this distal attachment of the Luque rods is weak because there may be significant osteoporosis of the pelvis. Loosening of the instrumentation and pseudarthrosis of the lumbosacral joint is frequent. Although this is not usually symptomatic, the author has observed increased scoliosis, pelvic obliquity, and pressure sores.

The development of instrumentation that allows segmental fixation **[➥2.9]**, distraction, and compression on the same rod, along with the use of pedicle screws **[➥2.8]**, may solve many problems of instrumentation of the distal spine. The pedicle screws allow the end vertebra to be positioned in three planes, and provide stable segmental instrumentation. This instrumentation may lessen the desirability of anterior instrumentation. Long-term studies have not yet been performed, but early experience indicates that satisfactory results can be obtained (Fig. 16-5 and Fig. 16-6).

Whatever the instrumentation used posteriorly, it should be low-profile in design. In the area of the meningocele sac there is poor skin and soft tissue coverage. Prominence of hardware invariably leads to ulceration over the hardware, eventual infection, and the need to remove the instrumentation.

Congenital Scoliosis

Congenital scoliosis may occur anywhere along the spine, including the cervical, the thoracic, and the lumbosacral spines. Congenital malformations may be caused by the lack of formation or segmentation, or a combination of the two. If the malformation occurs in the lumbosacral area the progression of deformity is usually rapid and uncompensated, causing severe pelvic obliquity. Nonoperative methods of treatment do not correct congenital scoliosis, or even prevent it from worsening. These children, because of their neurologic abnormalities, are unable to tolerate an unbalanced spine. Therefore, it is important that treatment be carried out in infancy when the deformity is small, rather than waiting until the child is older and heroic measures are needed to obtain satisfactory alignment.

Posterior fusion of the malformation is rarely successful in preventing progression. Anterior and posterior fusion is the procedure of choice, and it should be performed when a diagnosis of progressive scoliosis is made, usually at 1 year of age. The spine may be approached in staged or separate anterior and posterior procedures, or anterior and posterior interbody fusions may be performed through a posterior approach, using the pedicle as the access conduit to the anterior spine (53) The posterior approach is useful when the malformation is in the upper thoracic spine, where the anterior approach is difficult. If the lumbar curve is already so severe that the pelvic obliquity is greater than 15 degrees, an osteotomy of the spine to correct the deformity should be considered. Another possibility in a child over 10 years of age is to perform a bilateral posterior iliac osteotomy to balance the pelvis after the spine has been fused (49).

Kyphosis

Lumbar kyphosis is a major deformity that occurs in 8 to 15% of patients with myelomeningocele (32,38,54,55,56 and 57). It often measures 80 degrees or more at birth, and usually progresses with growth. Children with extensive kyphosis are unable to wear braces, have trouble sitting in a wheelchair, and often have ulcerations over the prominent kyphos. Progression of the kyphosis may lead to breathing difficulty because the abdominal contents are crowded into the chest cavity by increasing upward pressure on the diaphragm. These children also have difficulty eating because of loss of abdominal size, which results in a failure to thrive. They are underweight and short in stature. The increased flexion of the trunk also may interfere with drainage of urine if the child has a urethrostomy, a vesicotomy, or an ileostomy.

Kyphosis is almost always progressive, and attempts to delay definitive treatment until the child is older leads to a more severe deformity (7,58). The aorta and the vena cava do not follow the anterior border of the spine across the kyphosis (59); they take the short route, like a bowstring, limiting the amount of surgical correctability. Therefore, it is important to carry out treatment early, even though it may be only a temporizing procedure. A more definitive procedure can be performed later.

The goals of treatment is to increase abdominal height, to allow more room for the abdominal contents, and relieve pressure on the diaphragm and the lungs. In addition, the kyphosis must be minimized to lessen the incidence of pressure sores and move the center of gravity posteriorly to center it over the ischium. This improves the child's ability to sit without using the arms for support.

The kyphosis deformity can be divided into two types (60) (Fig. 16-7). The first type is a collapsing kyphosis; it is often C-shaped and supple, at least during the initial stages. The apex may occur anywhere from the lower dorsal spine to the lumbosacral joint. The second type is a rigid S-shaped lumbar kyphosis with a proximal dorsal lordosis. The kyphosis is usually centered at L2 and the proximal rigid lordosis at about T10. This is the most common variety in the older child because the C-shaped curve often progresses to the S-shaped curve with time.

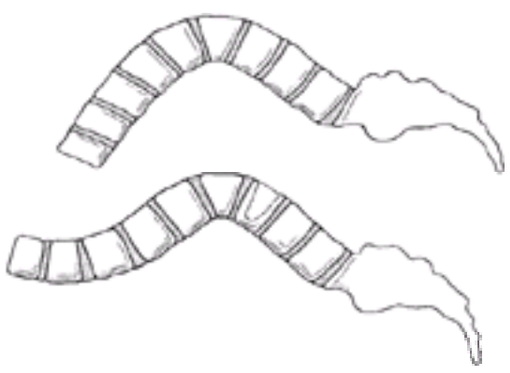

FIGURE 16-7. Two types of lumbar kyphosis: the C-shaped collapsing curve (**top**) and the S-shaped curve (**bottom**). (From ref. 59, with permission.)

Collapsing Kyphosis. Conservative treatment, which consists of observation, is usually futile. The curve progresses rapidly, and it is not unusual to see a 2- or 3-year-old child with a kyphosis greater than 100 degrees. In those few instances in which the collapsing curve does not progress rapidly and is less than 20 to 30 degrees, an initial period of observation may be worthwhile. If the curve is supple and the skin is in excellent condition, a brace can be tried. However, because any orthotic device must push over the apical vertebra posteriorly and against the protuberant abdomen anteriorly, it may lead to pressure sores over the gibbus and increased pressure on the abdominal contents. The kyphosis almost always requires surgical correction; this should not be delayed if brace treatment is unsatisfactory.

Collapsing scoliosis in the immature child is difficult to treat surgically. Posterior spinal fusion without instrumentation usually fails because of tension forces in the fusion mass. When instrumentation is used instrument failure is common. Attempts to provide stability by anterior strut fusion with a strut graft also tend to fail in young patients. The fusion creates an anterior unsegmented bar, with growth potential remaining posteriorly. As the child grows, the kyphosis increases. If the surgeon waits until the child is older to carry out anteroposterior fusion with instrumentation along the dorsal lumbar spine, the curve is often so severe that satisfactory correction is difficult if not impossible to obtain. If the anteroposterior fusion is carried out in infancy the resulting spine is too short to allow sufficient room for abdominal volume and respiratory sufficiency.

The anterior structures, including the abdominal wall, the aorta, and the vena cava, are of insufficient length to allow correction to occur without shortening the spine to remove tension from these structures (61,62). Many different procedures have been described to shorten the posterior spine to allow the spine to be straightened and put into more normal sagittal alignment (55,56 and 57,63,64,65 and 66). Most of these techniques require fusion of the spine to maintain correction, and therefore should be performed only in an adolescent child; otherwise, the lumbar spine will be too short.

A method used to shorten the spine which does not require spinal fusion is to remove the ossific nuclei from the vertebrae above and below the apical vertebra, which is left intact (Fig. 16-8 A, B). The pedicle and posterior arch are removed from these two vertebrae. The apical vertebra is pushed forward, correcting the kyphosis (60) (Fig. 16-8 C). Approximately 100 degrees of kyphosis can be corrected. Because the vertebral body growth centers are left intact the growth of the spine continues, often producing a gradual increase in the lordosis. The spine is not fused so the procedure can be performed in children of any age, even in newborns. It is also possible to perform this surgery without mobilizing the spinal cord or dividing any of the nerve roots. Therefore, it can be performed when nerve function is intact below the level of the kyphosis. If the child is younger than 1 year old, tension-band wiring between the pedicles of the apical vertebra and the vertebrae above and below the osteotomy appears to be sufficient. If the child is older than 1 year Luque instrumentation, placed extraperiosteal and modified to attach to the sacrum without fusion, should be performed (68) **[➥2.7]**. At least three sublaminar wires on each rod superior to the kyphosis are needed to provide sufficient support (Fig. 16-9). If the child is an adolescent, posterior spinal fusion can be added to the instrumentation.

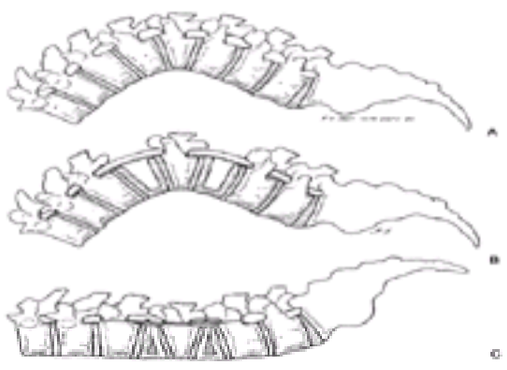

FIGURE 16-8. The C-shaped curve is corrected by removing the ossific nucleus of the vertebrae above and below the apical vertebrae. **A:** The C-shaped kyphosis before removal of the ossific nucleus from the vertebrae. **B:** Spinous processes, laminae, pedicles, and ossific nucleus have been removed from the vertebrae above and below the apical vertebrae. The growth plate, disc, and anterior cortex are left intact. **C:** The deformity is reduced by pushing the apical vertebrae forward. Tension band wiring around the pedicles maintains the reduction. (From ref. 67, with permission.)

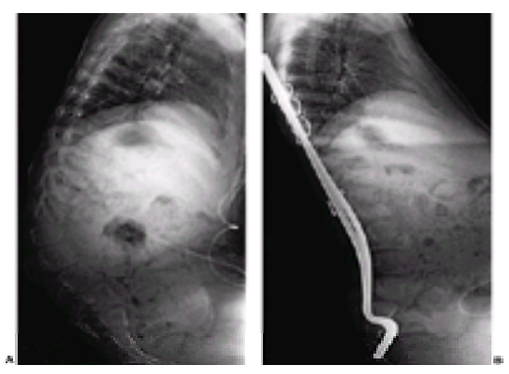

FIGURE 16-9. A 2-year-old child with 65 degrees of progressive kyphosis. **A:** After excision of the ossific nucleus above and below the apical vertebrae the correction is held with a specially modified Luque rod which is inserted into the first sacral foramen.

Skin coverage is often a problem. If the skin is exceedingly scarred or ulcerated over the kyphosis wound breakdown and infection are likely. The problem with skin coverage should be addressed prior to the spinal correction. A myocutaneous flap should be planned and prepared beforehand (69).

Rigid S-shaped Kyphosis. Treatment of the rigid form of upper lumbar kyphosis is difficult and controversial. Conservative nonoperative treatment invariably leads to an increased deformity and difficulty in later correction. In 1968, Sharrard (57) first described resection of the apical vertebral body for the treatment of kyphosis; since then, most authors have recommended vertebral excision as a part of the operative treatment (69). Most of these reports also showed that excision of the apical vertebra may lead to initial correction of the deformity. However, the deformity has a tendency to recur, often to a worse degree than the initial kyphosis (56), leading to feelings of futility and frustration.

Treatment of the rigid form of kyphosis requires a different approach. Because both the kyphosis and the proximal lordosis are rigid it is necessary to correct both deformities at the same time. This can be accomplished by excising the vertebra(e) (usually two) between the kyphosis and lordosis (56,62,64) (Fig. 16-10) and fusing the apical vertebra to the distal end of the thoracic spine at the level of the resection. In a young child, this is the only area fused, and the osteotomy is held in position by tension-band wiring around the pedicle above and below the resected vertebrae (55,62) (Fig. 16-11). It is important that the paraspinous muscles be sutured behind the area of the spine in order to add a corrective force, decreasing the likelihood of recurrence of the deformity. The correction can also be held by use of rods anchored in the first sacral foramen distally and sublaminal wires proximally, similar to the fixation used in the collapsing kyphosis. If the child is Risser sign I or above, the spine may be fused along the length of the instrumentation.

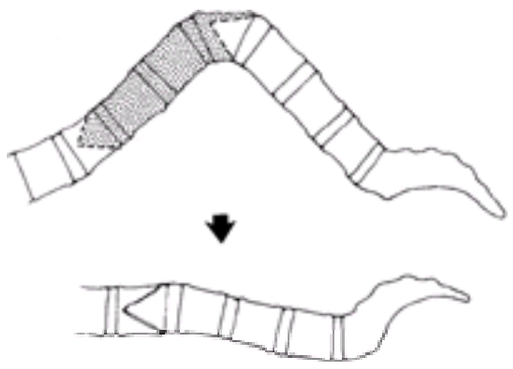

FIGURE 16-10. Bone is removed for correction of a rigid dorsal kyphosis (*shaded area*). The area removed usually includes one or two vertebrae proximal to the apical vertebrae in the area of the fixed lordosis. The vertebrae proximal to the resection and the apical vertebrae are shaped to receive each other in a tongue-and-groove joint to provide stability until bony union is achieved.

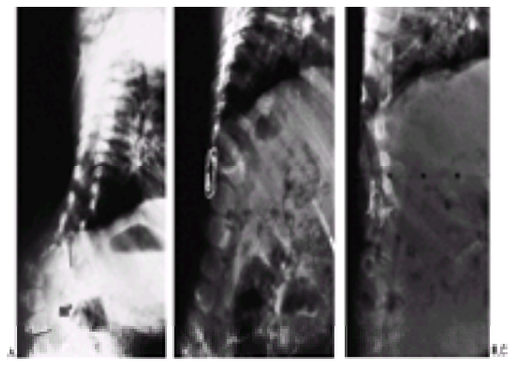

FIGURE 16-11. A: A 1-year, 10-month-old child with an 88-degree kyphosis. **B:** Two years after surgery, the kyphosis is at 13 degrees, and the lumbar spine has increased in height from 6.1 to 9 cm. **C:** Twelve years after surgery, the kyphosis is unchanged, and the spine height has increased to 14 cm.

Hip

The function of the hip joint depends on neurologic level. The treatment program therefore is based on the level of sensory and motor paralysis (70,71 and 72). In a large proportion of myelomeningocele patients, the hips are reduced at birth, with the exception of those children who are breech position (Fig. 16-12). Following birth, normal hips may become dislocated or dysplastic because of the position of the infant following closure of the back. If the infant is laid on his or her side, continued adduction of the superior hip eventually leads to dislocation. However, if the child can be placed in the prone position with the hips in the “human position” of flexion and 60 degrees of abduction, the hips can be maintained in the reduced position while the spine heals without being soiled by urine or feces (Fig. 16-13). This position also does not preclude placement of a shunt and the therapist can have access to the feet and knees. If abduction splinting is maintained during nap time and night-time after discharge from the hospital most children survive the first year of life with their hips reduced. Generally, the author does not maintain the splinting after the first 3 months of life; however, in other medical centers splints are maintained throughout the first year.

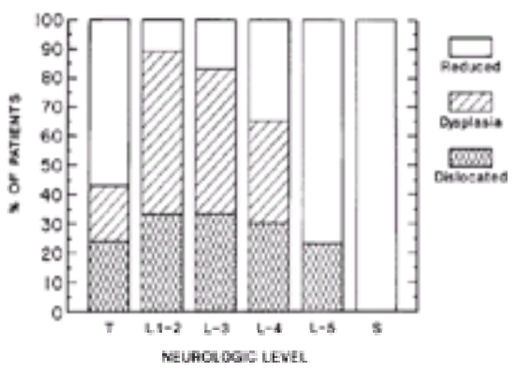

FIGURE 16-12. An evaluation of 100 consecutive infants with myelomeningocele who had not received treatment for their hips.

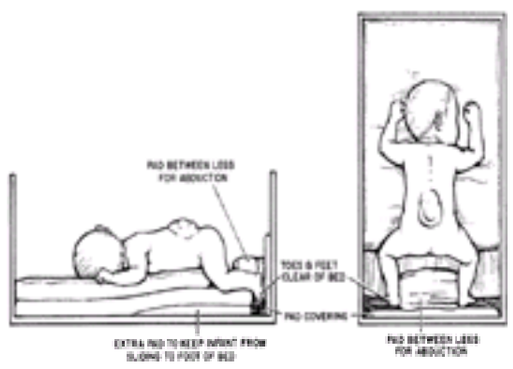

FIGURE 16-13. Position of infant after closure of the spine. This position allows gentle abduction of the hips in the neonatal period. (From ref. 73, with permission.)

Thoracic Paraplegia

The thoracic-level paraplegic child does not have sensation or muscle control over the lower extremities. Surgery cannot provide stability; it must be provided by an orthosis. Without sensation and motor control reduction of the hip is not necessary for sitting and walking using orthotic aids (74). However, the child needs a functional range of motion without contracture (51). Surgical procedures should be used to provide range of motion so that the child can sit satisfactorily in a wheelchair, lie comfortably in bed, and use orthoses for standing and walking, if indicated.

Treating hip contractures in paraplegics is often frustrating because many contractures return promptly, often to a worse degree than before surgical release. A simple sectioning of tight tendons and release of tight ligamentous structures does not appear to be sufficient. The use of a free fat graft to fill the dead space formed by the release of tendon and capsule has helped prevent the recurrence of contracture in a few of the author's patients. It is important that prolonged bracing and physical therapy be used to maintain whatever motion has been obtained by surgery.

Fortunately, dislocation of the hip is not usually found in the thoracic-level paraplegic person because of the lack of muscle function. If a hip is becoming dysplastic or is dislocating the cause should be found and treated. Increased muscle tone or spasticity should be treated by muscle release, or perhaps by neurectomy. Pelvic obliquity caused by developing scoliosis should be treated. Attempts to reduce a dislocated hip are difficult and often unsuccessful. The principal risk of surgically reducing the hip is stiffness. Multiple surgical procedures should be avoided because the risk of stiffness increases with each surgical procedure. It is better to have a supple dislocated hip than a stiff located hip.

The limitation of motion from a dislocated hip usually does not interfere with the overall function of the child. Even in unilateral dislocation, a dislocated hip does not prevent standing in an orthosis, sitting, or lying down, unless an associated adduction contracture is present.

The increased incidence of pressure sores, because of unilateral or bilateral hip dislocation in the absence of contractures or pelvic obliquity, has not been documented. Because of the loss of the greater trochanter as a pressure-accepting area, more pressure is placed on the ischium and sacrum. This would seem to increase the possibility of ulceration. In the presence of hip dislocation, special attention must be made to wheelchair seating.

The orthosis must provide pelvic, hip, knee, ankle, and foot stability. The standing frame, the parapodium, the swivel walker, and hip control orthosis all provide stability (75). At approximately 18 to 24 months of age, if the child has developed head control and sitting balance, a standing orthosis is prescribed. Orthotic devices are needed to provide stability to the lower extremity. The child usually finds these devices to be confining because they are too slow, they require too much energy, and they are too difficult to apply. Consequently, most of these children give up walking by the time they are 8 or 9 years of age, and use a wheelchair for their mobility (72).

Two designs in orthotic devices may change this prognosis for walking. The first is a *reciprocating orthosis* that allows controlled flexion and extension of the hip during walking (76). This decreases the energy requirement and increases walking speed (77). However, this orthosis allows for almost no contractures of the hips or knee, and orthotic breakage may be a frequent occurrence. The second development is a *hip guidance orthosis*, which allows for limited hip motion, while still providing stability (78). These braces may be tried after the age of 3 years and the child is large enough to fit into the smallest size of the orthosis. However, these devices are quite expensive and need to be replaced frequently.

Upper Lumbar Paraplegia

The upper lumbar paraplegic (L1–L2) has sensation in the anterior hip joint and thigh. Motor function includes the iliopsoas and the adductors producing hip flexion and adduction. Flexion adduction contracture of the hip, because of the unrestricted contraction of the hip flexors and adductors, is typical. There is a high incidence of hip dislocation. Attempts to reduce the hip without correcting the muscle imbalance are doomed to failure, and severe ankylosis of the hips often results. Although providing hip stability for the child without the use of orthosis is possible, up to the present surgical attempts have been unsuccessful. Iliopsoas transfer is contraindicated in children with upper lumbar paraplegia, and often leads to severe extension contractures and increased disability (79,80).

The preferred treatment of children with upper lumbar paraplegia is obtaining range of motion by release of the contracture, including the iliopsoas and adductor tendons, then treating the child in a manner similar to that done for a thoracic-level paraplegic. If range of motion can be obtained, the dislocated hip does not cause disability for either walking or sitting (74,80). Because of the intact sensation across the hip joint, the reciprocating brace and the hip guidance orthosis are useful, and often succeed in continued walking as a mode of mobility into young adulthood (77,78).

Middle and Lower Lumbar Paraplegia

The middle to lower lumbar paraplegic (L3–L5) patient has sensation to below the knee. Muscle function includes hip flexion and adduction, knee extension, and weak knee flexion. Foot dorsiflexion and eversion also may be present. These patients have the potential for control of the hip and knee, and therefore the potential for independent walking.

Gait studies show almost normal sagittal plane motion of the hip, which is responsible for the movement of the child forward. There is an associated increase in hip rotation and abduction and adduction more than normal. This indicates that range of motion and control of the hip are probably the most important factors in walking for these children.

The hip in the middle to lower lumbar-level paraplegic is also a major source of deformity and disability. The natural history of the hip is to undergo progressive dysplasia and dislocation associated with hip-flexion contracture, which becomes evident when the child begins to walk. Muscle imbalance is caused by strong hip flexors, adductors, and absent or weak hip abductors and extensors. This muscle imbalance is exaggerated by the forces of walking when the hip flexors and adductors are used to stabilize the hip during the stance phase of walking, instead of during their typical function in the swing phase. The contraction of the hip flexors and adductors during the stance phase of gait causes the hip to flex and adduct, which produces a shear force across the acetabulum. It is not unusual for these paraplegic children to survive infancy with hips that are not dislocated, then to have them become dislocated at age 3 or 4 years. Attempts to reduce the hip and correct the progressive deformity are unsuccessful unless there is correction of the forces around the hip.

Historically, muscle balance has been obtained at the hip by performing muscle releases. However, taking the muscle control away from the hip does not increase its stability although the hip stays reduced, but increases its instability because of weakness, and requires the use of an orthosis to stabilize the hip for walking (74). This conclusion is not surprising, considering the severely weakened hip made unstable by surgical procedures.

Sharrard initiated another approach to hip instability by transferring the iliopsoas tendon to the greater trochanter, a modification of procedures suggested by Garceau and Mustard to treat instability of the hip following poliomyelitis (81,82,84). The purpose of the tendon transfer was to produce an abduction force across the hip joint during the stance phase of walking, and thereby eliminate the deforming hip flexion force of the iliopsoas. Long-term studies have shown that this transfer is successful in maintaining hip reduction and decreasing the hip-flexion contracture (79,81,83). However, the iliopsoas is transferred out of phase to normal walking, and may decrease the necessary sagittal plane motion necessary for walking, stepping up on a curb, or climbing stairs. The weakness of the hip flexion requires the child to use the rectus femoris and sartorius muscles to flex the hip. This in turn results in extension of the knee, which also makes stair climbing difficult. Because the iliopsoas normally is used as a hip flexor, it continues to contract during the flexion activity of the hip, and also may prevent the hip from flexing, leading to an extension contracture.

Bunch and Hakala (79) have shown that with careful selection of patients preservation of the nerve to the sartorius muscle and intensive physical therapy, stair climbing can be achieved. In many instances, in the lower lumbar-level paraplegic person without pelvic or hip deformity, without spasticity, and with good knee control, gait can be improved to the point that patients may be able to “cruise the mall” using their braces, crutches, or walker, rather than a wheelchair (85).

Transfer of the external oblique muscle from the abdomen to the greater trochanter; posterior transfer of the adductor longus, brevis, and gracilis to the ischium **[➧ 3.18]**; and transfer of the tensor fascia lata muscle posteriorly on the ilium and to the tendon of the gluteus maximus, have been used to control the hip (86,87 and 88). Studies have shown a maintenance of hip reduction and improvement in the acetabular index and the cente–edge angle after those muscle transfers, similar to the results obtained with Sharrard iliopsoas transfer (Fig. 16-14). In addition, after the three muscle transfers children with L3–L5 paraplegia have shown marked improvement in their walking ability, 70% of whom demonstrated a marked increase in endurance and walking speed. They also have required less bracing. Fifty percent of these children have developed enough stability around their hip to learn to walk independently without crutches or a walker (86). These muscle transfers are performed after the child has reached 2 years of age and learned to walk.

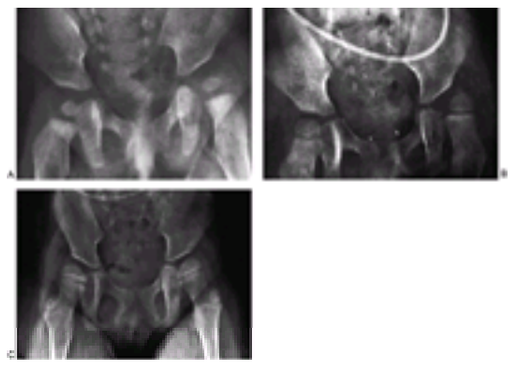

FIGURE 16-14. A: A 2-year-old child with L4 paraplegia begins to walk with ankle–foot orthoses and a walker. The hips are reduced. **B:** One year later, the left hip becomes dysplastic. **C:** Two years after bilateral transfer of the external oblique and adductor muscles the hips are reduced, and the child remains ambulatory.

Although improvement in the hip indices can be produced by muscle transfers around the hip, they are not sufficiently forceful to correct major anatomic deformities. It is therefore necessary to reduce the hip and correct femoral and acetabular deformity at the time of, or prior to, the muscle transfer. Continued radiographic evaluation must be made following the reconstruction because recurrent dysplasia is possible.

If the hip is dislocated at birth the author prefers to wait until the child is 1 year of age before carrying out hip reduction to avoid interfering with motor development. If the child is between 1 and 6 years of age an open reduction and capsular plication are carried out to provide stability **[➥3.2]**. If there is deformity of the femoral neck, a varus femoral shortening osteotomy is indicated **[➥4.1-4.3]**. Pelvic osteotomy is indicated for severe acetabular dysplasia (89). The type of pelvic osteotomy performed depends on the deformity and the surgeon's preference **[➥3.7-3.12]**. An arthrogram and a CT scan may help to establish the area of acetabular insufficiency so that a correct procedure can be selected. The muscle transfers are then performed to help maintain reduction. The muscle transfers work better on a reduced hip than a dislocated one. Therefore, the author reduces the hips, even bilateral dislocations, before the age of 4 years. After that age the dysplasia is so great that the success rate is poor and the hips are left dislocated.

Sacral-level paraplegics have intrinsic stability to their hip with sensation and motor control. Dislocation of the hip in these children is rare; however, when it occurs it should be treated as a developmental dislocation of the hip.

Knee

The function of the knee is important to a child with myelomeningocele. Function of the knee is dependent on both the absence of deformity and the presence of stability. It must be stable during stance to accept the weight of the child without buckling, and flex sufficiently during swing to clear the foot. However, it is possible to walk with a stiff knee, and stability is more important than motion. The three deformities that may seriously diminish the ambulatory ability are extension or hyperextension contractures, flexion contractures, and valgus rotational deformities.

In a study of 16 patients with residual hyperextension contractures of the knee, only three were able to walk (72). These children also had difficulty sitting. Fortunately, the incidence of extension contractures is relatively low. There are several causes of extension contractures. One of the most common causes is seen in a child born with a breech presentation and with hyperflexed hips, hyperextended knees, and clubfoot. In these infants, the hamstring tendons usually have displaced anterior to the knee axis perpetuating the hyperextension deformity, although the child may be an L4 or L5 level paraplegic. The next most common cause appears in the middle lumbar level paraplegic person in which the child has quadriceps function, but no perceptible knee flexors. The least-common cause is seen in high-level paraplegic people in whom there is spasticity of the quadriceps muscle. Most of these cases can be treated by passive range of motion and splinting during the neonatal period of life. Although normal range of motion is rarely achieved, 60 to 70 degrees of flexion is common.

For those paraplegic children who do not respond to physical therapy, surgical treatment is indicated. If the child has voluntary function of the quadriceps, a modification of the V-Y plasty of the quadriceps tendons should be performed (Fig. 16-15). This procedure is modified by detaching the vastus medialis and the vastus lateralis from the medial and lateral hamstrings, which slide posterior to the knee axis. This approach often restores the hamstring function, and the child develops both active flexion and extension of the knee. If the quadriceps are not under voluntary control and are spastic, use sectioning of the patellar tendon and the retinaculum.

FIGURE 16-15. The V-Y quadricepsplasty for hyperextension contracture of the knee. **A:** In addition to the detachment of the rectus femoris tendon from the muscle of the rectus femoris, the vastus medialis, and the vastus lateralis muscles, the vastus medialis and lateralis muscles are separated from the iliotibial band, the lateral hamstrings, the medial hamstrings, and the sartorius muscles. **B:** When the knee is flexed, the hamstring muscles and tensor fascia lata slip posterior to the knee axis, restoring their normal function. The quadriceps muscles are then repaired in the lengthened position. (From ref. 90, with permission.)

Flexion deformities are common in these children, even in the face of normal quadriceps function (91). A small degree of contracture, below 20 degrees, seems to be tolerated well, but contraction greater than 30 degrees decreases the likelihood that the child will continue to walk. Contractures over 20 degrees in the adult have a high incidence of patellofemoral pain (92).

The cause of the flexion contracture is not always apparent. In some children spasticity of the hamstrings or gastrocnemius can be implicated. In most middle and low lumbar paraplegic people, the cause appears to be a co-contraction of the hamstring and the quadriceps during the entire stance phase of gait. This lack of coordinated activity occurs only during walking and may not be present during manual testing of muscle activity during the neurologic examination. It appears to be related to brain stem abnormalities. The result of the tug of war between the knee flexors and extensors is persistent knee flexion during stance and decreased knee flexion during swing. A gait study, including EMGs, may be helpful in deciding the cause and treatment of the contracture. However, in most cases, the gait study is for research purposes and the treatment decision is made on clinical evaluation.

In the neonatal period and in infancy, physical therapy may be helpful in decreasing the flexion contracture. In those children who do not respond to physical therapy by 18 months to 2 years of age, surgical correction is indicated.

If the child with flexion contractures has some voluntary function of the medial hamstrings, the hamstrings should be lengthened rather than sectioned. The biceps femoris and the posterior part of the iliotibial band can be sectioned. The gastrocnemius origin should be resected. Almost all children with this deformity need to have a posterior capsulotomy extending from the posterior aspect of the medial collateral ligament to the posterior aspect of the lateral collateral ligament **[➥4.23]**. In most

patients, the anterior cruciate ligament also needs to be partially, if not completely, resected to allow the tibia to slide forward on the femur into extension.

In most children functioning at the low lumbar level the hamstring muscles contract at the same time as the quadriceps muscle throughout the stance phase of walking (Fig. 16-3). For these children the author transfers the insertion of the biceps femoris and the semimembranosus muscles to the cut end of the gastrocnemius muscle on the distal femur. This transfer will assist in extension without flexing the knee. The transfer can be performed at any age because the attachment to the distal femoral epiphysis will allow for future growth. By removing two of the hamstring muscles from the knee flexion, the quadriceps usually will be able to maintain knee extension during stance.

Postoperatively, the patient must wear an above-the-knee orthosis for a prolonged period to prevent the development of knee instability. In the child older than 6 or 7 years, sufficient deformity may have developed in the femoral condyles to preclude satisfactory soft tissue correction of the contracture, and a distal femoral osteotomy is needed. The osteotomy must be as close to the knee as possible to prevent an anteriorly offset knee joint. There is a tendency for recurrence of deformity with growth, and repeat surgery may be necessary.

Valgus and rotational deformities of the knee primarily are caused by tightness of the iliotibial band and the forces of ambulation. During the Trendelenburg gait pattern, the shift of weight lateral to the hip joint, along with contraction of the adductors and fixed position of the foot to the floor, produce a valgus thrust to the knee. The young child is best treated by muscle transfers to the hip to stabilize his or her gait pattern; by sectioning of the distal iliotibial band if it is contracted; and by placing the child in a knee-ankle-foot orthosis to resist the valgus thrust to the knee. If the deformity becomes fixed, a distal femoral osteotomy **[➥4.17]** is required to realign the knee.

Stability for the knee in thoracic and upper lumbar paraplegics is provided by an orthosis. Sufficient sensation and motor control of the knee is not present unless the child has functioning of the L4–L5 nerve roots. Without a good quadriceps, some medial hamstring function, and sensation to the tibial tubercle, the child cannot control the knee adequately. Attempts to stabilize the thoracic upper and middle lumbar-level paraplegic patients with a below-the-knee orthosis by means of equinus positioning or with other types of foot positioning should be avoided. Because the child is unable to raise his or her center of gravity to vault over a plantar flexed foot the knee must hyperextend or externally rotate, producing degenerative changes because of a lack of protective sensation (Fig. 16-16).

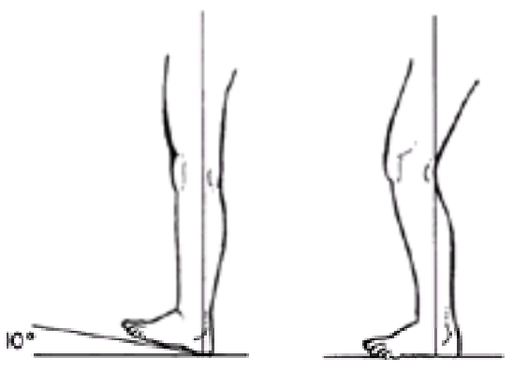

FIGURE 16-16. A 10-degree dorsiflexion of the foot is needed for the leg to progress beyond midstance. If the foot is held in neutral or plantar flexion the tibia cannot progress beyond the vertical without raising of the body—a difficult activity for a paraplegic. Dorsiflexion can be provided by manufacturing the orthosis in dorsiflexion or by elevating the heel of the shoe.

Foot

The function of the foot of a child paralyzed by myelome-ningocele is significantly impaired (120). The severe deformity of the leg and foot, limited ankle and subtalar motion, absent weak or spastic muscles, and the lack of sensation make it almost impossible for the foot to function normally by providing shock absorption, control of floor reaction forces, and the transfer of weight that is necessary for gait (93). Almost all of the myelomeningocele children require treatment of their feet. Even nonambulatory children require adequate positioning of the foot to accept shoe wear, placement on wheelchair foot rests, and prevent pressure sores. Ambulatory children require an accurate correction of deformity. They are unable to compensate for malposition of the foot because of weakness of the trunk, the hip, and the knee, which causes the weightbearing line and the floor reaction force to fall outside the zone of stability of the hip, the knee, and the ankle. For example, a foot that has residual inward rotation produces a varus deformity at the knee and inward rotation of the leg during the stance phase of gait. Outward rotation of the foot causes a valgus deformity to the knee and an exaggerated outward rotation of the leg during stance. Residual equinus deformity causes hyperextension of the knee and the inability of the child to move the center of gravity beyond midstance. On the other hand, calcaneus deformity allows the tibia to fall forward during midstance, producing knee flexion and a crouched gait. The foot must also be able to compensate for deformity of the knee. For example, a knee-flexion contracture requires the ability of the ankle to dorsiflex so that the heel will contact the floor.

The correction of the deformity by itself is not sufficient. Muscle balance must be achieved in the foot as well. If this muscle imbalance is left uncorrected when the alignment of the foot is obtained the deformity will recur. There are only two choices available to correct the muscle imbalance: removing the muscle force by excising the tendon or transferring the force to another location by tendon transfer. The preservation or removal of muscle activity must be considered carefully in relation to the function of the foot during walking. If the child needs an orthosis to walk then muscle control of the foot is of little importance, and the deforming forces should be eliminated; however, if the child has enough muscular control and sensation to walk without an orthosis, the muscle balance must be obtained by performing the appropriate tendon transfer.

The goals of treatment are to align the foot to allow transfer of the floor reaction force through the center of the ankle and to produce stability of the knee and hip during the stance phase of gait. The motion of the joints in the foot should be preserved which allows preservation of the shock-absorptive capacity of the foot and lessens the possibility of joint degenerations. A rigid foot also has a high incidence of ulceration even if the deformity has been corrected by subtalar arthrodesis or triple arthrodesis (94). It is also important to avoid bony prominences in the weightbearing area to lessen the likelihood of pressure sores (25).

Talipes Equinovarus Deformity

Talipes equinovarus, or clubfoot, is the most common deformity in these children and occurs in well over 50% (10). It is present in all levels of paraplegia, but the treatment differs at each level as a result of the muscle function that may be present. The correction of the equinovarus deformity in myelomeningocele patients is rarely accomplished by nonoperative means. An attempt to manipulate the foot and cast the deformity during the newborn period is worth a try if the foot is reasonably supple, and can be manipulated into a satisfactory position prior to the casting (1). However, most of these feet are rigid and the success rate with manipulation and casting has been poor. The cast cannot be used to obtain correction because pressure sores will develop. Occasionally after cast treatment the foot appears to be in satisfactory position; however, evaluation of the foot–thigh axis shows that the foot is still internally rotated approximately 45 degrees. This is the result of the severe deformity of the neck of the talus. As the foot is manipulated into the proper relation to the axis of the leg the calcaneus is moved laterally from underneath the talus, depriving it of its support and allowing the talar head to drop plantarward, producing a foot that resembles a congenital vertical talus. If this occurs then further attempts at nonoperative treatment should be abandoned. If satisfactory correction has been achieved then the child must be placed in splints to prevent recurrence of deformity. The splints must be worn continuously until the age of standing. If the foot has not achieved satisfactory correction by the time the infant is 3 months of age the author abandons conservative treatment and recommends surgical correction when the child is 1 year old. This interim period between nonoperative and surgical treatment allows for normal development of the child without the problem of constant cast change and braces. The advantage of performing surgery at the time the child is ready to stand is that weightbearing can be used to maintain the correction along with the orthosis used for ambulation.

The surgical correction of the clubfoot **[➥7.1]** rarely is accomplished by limited surgery. A radical complete circumferential subtalar release is necessary in order to allow the calcaneus to rotate sufficiently underneath the talus to align the axis of the foot to the axis of the ankle and knee (95). Because of the deformity of the neck of the talus it is then necessary to displace the calcaneus medially beneath the talus so that the posterior facet and the anterior facets are reduced, in order to prevent the talar head from sagging or falling into a vertical position. It is important to repair the tibial calcaneal ligaments with nonabsorbable suture to prevent lateral

migration of the calcaneus into valgus. A plantar release and capsulotomy of the calcaneal cuboid joint is usually necessary as well.

Unless the child has a sacral level of paralysis all of the contracted tendons should be resected rather than lengthened because they are spastic and nonfunctional. A simple cutting of the tendons often results in the tendon being caught in the scar, then acting as a tether as the foot grows. This causes recurrence of the deformity. In the L5-level paraplegic person, the anterior tibialis and peroneal tendons also should be released. Leaving them intact often results in a calcaneal valgus deformity. It is better to have a flaccid braceable foot than a deformed foot with muscle activity that is inappropriate for standing. This aggressive treatment gives a satisfactory result in the majority of patients (96).

A major problem during surgical correction of the deformity is skin coverage for the posteromedial aspect of the foot. Many incisions have been tried, but no one incision is free of complications. For the relatively mild deformity, a Cincinnati incision gives adequate results (97). It provides excellent exposure to the medial and lateral side of the subtalar joint. The drawback to this incision is exposure of the heel cord; however, in most of these children, the tendon is sectioned rather than lengthened, and lack of exposure is not critical. The medial and lateral calcaneal vessels must be carefully preserved to provide circulation to the heel. Other incisions, such as the Turco or the two incisions described by Carroll, are equally effective (91,98,99).

With severe deformity, the Cincinnati incision does not appear to be sufficient. The axis of the foot often must rotate almost 90 degrees in relation to its ankle at the time of surgery. The skin on the medial aspect of the foot is insufficient to allow this degree of correction. If the skin is closed with excessive tension it will slough and heal by scar. This scar then contracts as the foot grows and causes recurrent deformity. On the other hand, if the deformity is not completely corrected in order to allow skin closure, then a satisfactory position of the foot is not obtained. The author now uses a modified posterior medial incision (Fig. 16-17). It starts posterolaterally, approximately 5 cm above the ankle at the posterior edge of the fibula. It curves obliquely downward to 1 cm below the medial malleolus. It then curves distally along the medial border of the foot to the first cuneiform, where it curves dorsally over the dorsum of the foot to a point just in front of the lateral malleolus. The incision over the dorsal aspect of the foot is only through the skin, preserving the dorsal veins and nerves of the foot. After the foot has been positioned and pinned in the corrected position an assessment is made about the integrity of the medial skin. If the skin is excessively tight, the incision is extended across the dorsum of the foot. The proximal flap is freed by blunt dissection from the fascia for a distance of 2 cm. There is no subcutaneous dissection of the distal skin. The skin is then allowed to find its normal position without tension. This permits the skin of the proximal flap to keep its normal relation with the leg while the foot rotates underneath it. The incision is then closed with interrupted subcutaneous sutures and a running dermal stitch. This incision relieves the tension on the medial side of the incision and decreases the redundant skin on the lateral aspect of the foot.

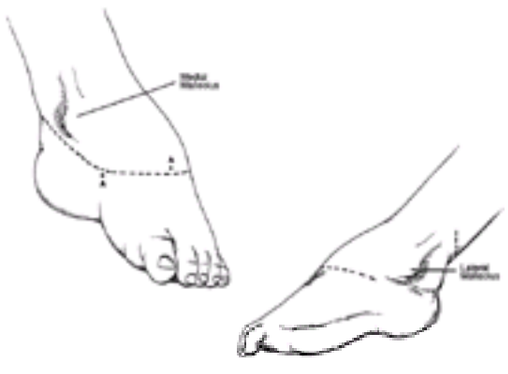

FIGURE 16-17. The incision begins posterolaterally, approximately 5 cm above the ankle at the posterior edge of the fibula. It extends obliquely downward to 1 cm below the medial malleolus. It then curves distally along the medial border of the foot to a point 1 cm distal to the anterior border of the medial malleolus. After the correction of the foot deformity the incision is extended to the first cuneiform, where it curves dorsally over the dorsum of the foot to a point at the anterior edge of the lateral malleolus. The incision over the dorsum of the foot is only through the skin, preserving the dorsal veins and nerves of the foot. The proximal flap is freed by blunt dissection from the fascia for a distance of 2 cm. There is no dissection of the distal skin. The skin is then allowed to find its position relative to the tibia and foot without tension. Usually the two points marked “A” will come together.

Another approach to obtain skin coverage is to insert a subcutaneous balloon (i.e., tissue expander), well before the planned correction of the foot (100). The balloon is gradually expanded by the injection of saline, stretching the skin and subcutaneous tissue. At the time of correction of the foot deformity the balloon is removed and the redundant skin is used to close the incision without tension.

It is rarely possible to correct the metatarsus adductus at the same time as the correction of the hindfoot. The author prefers to do this as a separate procedure when the child is 3 or 4 years of age. Although not always necessary, it needs to be done more often than in idiopathic clubfoot. Soft tissue release is rarely effective in achieving a permanent correction of the metatarsus adductus. A closing-wedge osteotomy of the cuboid and an opening osteotomy of the first cuneiform, with transfer of the wedge of bone from the cuboid to the first cuneiform, is preferred (101,102). The metatarsals II and III are then osteotomized at their base **[➥7.6]**. The correction is held with multiple pins that are removed in 1 month. The child is held in a walking cast for 1 additional month then placed in suitable orthoses, as needed, for ambulation.

Recurrent equinovarus deformity may be treated by talectomy; however, the deformity has a tendency to recur, and its short distance from the medial malleolus in the plantar aspect of the foot makes it difficult to fit with an orthotic device (95). Another problem with brace wear is that the pressure in the plantar surface of the foot is not distributed evenly, although the foot appears plantigrade. These areas of high pressure may predispose these patients to ulcerations (103,104 and 105). Persistent wear of an orthosis is essential despite the difficult fit. In the older child severe residual deformity may be corrected by a triple arthrodesis (106). This procedure should be limited to only the extreme cases because of the danger of joint degeneration and skin ulceration caused by the stiffness of the foot. Less severe deformities may be managed by a tarsal metatarsal osteotomy to correct the midfoot deformity and a calcaneal osteotomy to correct the varus deformity of the heel (99).

Calcaneus Deformity

Calcaneal deformities of the foot in the newborn are primarily due to the unopposed contraction of the anterior tibial muscle, the toe extensor muscles, or the peroneal muscles (107). There is flaccid paralysis of the triceps surae. The deformity may be calcaneal valgus, calcaneus, or calcaneal varus, depending on the predominant muscle activity. The deformity is usually progressive, and the calcaneus eventually becomes positioned vertically underneath the talus (Fig. 16-18). The deformity prevents the forefoot from contacting the floor, interfering with balance, preventing the floor reaction force from stabilizing the knee, and causing the child to walk in a flexed-knee or crouched gait. Because of the lack of sensation this deformity leads to heel ulcerations in the teenage years.

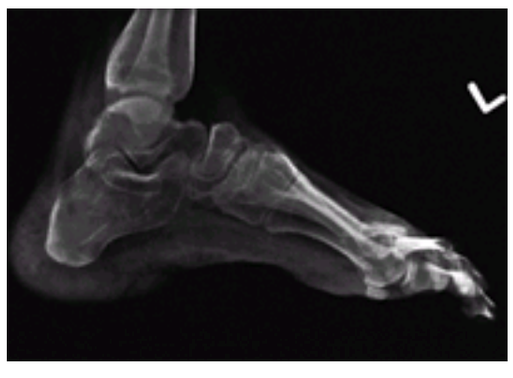

FIGURE 16-18. Lateral radiograph of an L5 paraplegic patient shows the vertical position of the os calcis. Note the hypertrophy of the heel pad.

Nonoperative treatment is rarely successful. Manipulations of the foot in the newborn period, and bracing as the child becomes older, may provide satisfactory position. However, in most cases the muscles continue to shorten, making brace and shoe wear difficult. In the child younger than 5 years of age with a minor deformity, which includes vertical alignment of the calcaneus, the anterior tibial tendon should be transferred through the interosseous membrane and attached to the calcaneus or released if the deformity is not severe. The decision to transfer or release is made by the strength of the toe extensors. If they are strong, transfer the anterior tibial tendon. At the time of surgery the deformity can be fully corrected; often the anterior tibial tendon is sectioned; then the tendon is not transferred. The remaining tight anterior structures should be released so that the foot can be brought into satisfactory position for bracing (108,109). The purpose of the anterior tendon transfer is to relieve a deforming force and to counteract the function of the toe extensors. The transfer is insufficient in power to substitute for the gastrocnemius soleus muscles. Although these patients may learn to walk without an orthosis following the tendon transfer, gait studies have shown they walk better with, than without, the orthosis (110).

In children older than 5 years of age soft tissue procedures rarely are sufficient. These patients also require osteotomy of the calcaneus with posterior displacement of the posterior fragment (111).

If the child has already developed ulceration underneath the calcaneus the treatment must provide correction of the foot deformity, followed by removal of the prominent part of the calcaneus, excision of the ulcer, and primary closure by means of a local flap. To allow the ulcer to heal by secondary intention will not provide reconstitution of the normal weightbearing fat pad. Repeat ulcerations are common. The weightbearing skin and fat pad must be restored in order to prevent recurrence of the ulceration. Posthealing orthotic wear is essential.

Valgus Deformity in the Newborn

Valgus deformities usually are associated with contracture of the lateral musculature of the foot, equinus deformity of the calcaneus, and a lateral displacement of the calcaneus from beneath the talus (112,113). The external appearance of the foot resembles that of a congenital vertical talus, but usually it is less rigid. Nonoperative treatment is rarely successful, despite the observation that the foot often can be manipulated back into a satisfactory position by plantar flexing the foot and rotating the calcaneus beneath the talus. The lack of active function of the posterior tibial muscle and the spastic activity of the peroneal muscles cause frequent recurrence. Occasionally a rigid form of congenital vertical talus may be found in myelodysplasia (103).

If the foot cannot be manipulated passively into the correct deformity and held with an orthosis, then an aggressive surgical approach is needed at about 1 year of age. The author prefers an extensive subtalar release to allow reduction of the calcaneus beneath the talus. This may require resection of the Achilles tendon and the peroneal tendons. The posterior ankle capsule is divided along with the fibular calcaneal ligaments. The anterior tibial tendon can be resected or transferred back to the neck of the talus. The author prefers to resect the tendon and do the subtalar arthrodesis. The function of the anterior tibial muscle is difficult to determine and it may not perform as expected. In most cases an extraarticular subtalar arthrodesis is needed (31,114,115).

Valgus Deformity in the Older Child

Valgus deformity is common in the ambulatory child and frequently is associated with outward rotation deformity of the foot and the ankle (112,116). The cause of the deformity is undetermined, but is probably related to the floor reaction force during stance without the appropriate muscle control of the posterior tibial muscle. There usually is a lateral tilt to the ankle mortis with shortening of the fibula. The subtalar joint may be deformed as well. The location of the deformity can be determined by standing anteroposterior radiographs of the ankle mortis and foot. The outward rotation of the ankle axis in relation to the knee should be assessed. It may exceed 60 degrees. Pressure sores caused by shoes and orthotic devices are common.

Nonoperative care, including casts, manipulation, and orthoses, will not correct or prevent the deformity. Most children will require surgical correction. The deformity in the tibia and fibula can be corrected by supramalleolar osteotomy that corrects both the valgus and rotation **[➥6.8]**. If there is minimal outward rotation of the ankle the valgus deformity of the ankle mortis can be treated by a medial tibial epiphysiodesis (117). If the child is young then staples can be used, so they can be removed later after the correction has been obtained. If the valgus deformity is mild and associated with a calcaneus deformity and a minimal outward tibial rotation, a calcaneal fibular tendo Achilles tenodesis can prevent progression of the deformity in about 70% of the patients (117,118). However, stretching of the tenodesis is a major problem, and Shafer and Dias recommend the addition of an anterior tibial tendon transfer to the calcaneus (25). If there is subtalar valgus the foot should be treated like the valgus deformity in the newborn.

Cavus Deformity

Cavus deformity of the foot usually is accompanied with claw toe deformity, and is seen in the sacral-level paraplegic child. These children have normal strength of the anterior tibial and toe extensor muscles, which pull up the midfoot at the base of the first metatarsal and dorsiflex or hyperextend the metatarsal phalangeal joints. The normal functioning peroneus longus plantar flexes the first metatarsal. The paralysis of the gastrocnemius soleus muscles leave the hindfoot in calcaneus position. Active toe flexors flex the interphalangeal joints, and with paralysis the foot intrinsic muscles cannot flex the metacarpal phalangeal joints or extend the interphalangeal joints. These children have enough sensation and muscle control to walk without an orthosis, but frequently develop progressive deformity and ulcerations under their toes, their metatarsal heads, and their heels. Their gait is also abnormal, because of the lack of sufficient power in the gastrocnemius soleus muscles. The cavus deformity is often progressive and may be associated with secondary varus deformity of the foot as the child attempts to use flexor hallucis and digitorum longus muscles to compensate for paralysis of the gastrocnemius soleus muscles.

Conservative treatment by means of an ankle–foot orthosis often provides a temporary solution; however, once the child can walk without the brace, it is difficult to get him or her to wear it again. Therefore, most of these children come to surgical correction.

Surgical treatment must include correction of the bone deformity and soft tissue contracture and restoration of the muscle imbalance. In the young child with mild deformation a plantar fascia release, followed by an ankle–foot orthosis, may provide satisfactory correction of the deformity. Rigid cavus, due to midfoot deformity, can be corrected by a tarsal metatarsal osteotomy associated with plantar release **[➥7.7, 7.8]**. If the deformity is due to a dorsiflexion deformity of the calcaneus, a calcaneal osteotomy is necessary (119). The calcaneus is moved backward or laterally, as needed, to correct the cavus or cavovarus deformities. Muscle-balancing procedures must consider the phase of the muscle during gait, the power of the muscle available, and the required muscle power necessary for walking (120,121). The primary goal is to have a plantigrade braceable foot without recurrent deformity or pressure sores. If the residual muscle power in the foot is in the poor-to-fair range, then the foot cannot be made functional by muscle transfers, and it is best to lengthen or resect the tendon of the deforming muscle and brace the foot. However, if there is sensation on the sole of the foot and the strength of the toe flexor is good-to-normal, it may be possible to transfer the muscles to the heel to achieve force balance and a satisfactory brace-free gait.

The anterior tibial muscle is a swing-phase muscle, and cannot be made into a stance-phase muscle to substitute for the gastrocnemius soleus muscle unless electromyelogram gait studies show the contrary. In most circumstances it is better to lengthen the tendon and preserve its necessary function of foot clearance during swing. If the foot is in varus, then transfer of its anterior tibial tendon to the midfoot may be useful. Muscle imbalance of the toes can be helped by transfer of the long extensor tendons to the metatarsal heads, with fusion of the interphalangeal joints. This transfer helps elevate the metatarsal heads and prevent recurrent cavus. When the foot is in cavovalgus deformity, the peroneus brevis also can be transferred to the calcaneus.

Charcot Arthropathy

Charcot, or neurotrophic, arthropathy is a progressive degeneration of a joint caused by a lack of protective sensation. This is a problem that primarily affects ambulatory young adult patients who have decreased sensation of the knee, the ankle, and the foot. Because of the pathologic anatomy of the myelomeningocele, the sensory level is usually higher than the motor level. Consequently, these patients often are able to stand and walk, but do not have protective sensation. The patient with paralysis at the L4–L5 level appears to be the most vulnerable (Fig. 16-19). The pathologic process begins following an initial traumatic episode. The initial episode may follow a minor fall that the patient does not consider to be a major injury-producing event. Following this initial traumatic episode, there usually is a considerable amount of swelling and redness around the joint. The appearance of the joint resembles an infection and cellulitis. There may be some minor discomfort but usually no severe pain. Because of the lack of pain the patient often does not seek medical advice and continues to walk on the joint, causing further microfractures to occur. Even if the patient obtains medical consultation the initial radiographs often are unremarkable and the patient is often given antibiotics for the mistaken diagnosis of infection. Once the joint degeneration has become evident on radiograph the joint has been destroyed, and satisfactory outcome is difficult to

achieve.

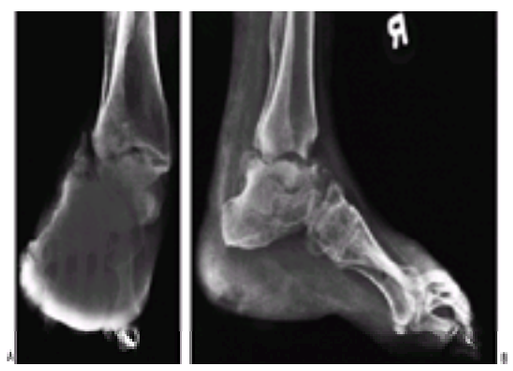

FIGURE 16-19. This Charcot degeneration occurred in a 16-year-old, L5 paraplegic girl who refused to wear her ankle–foot orthosis.

Treatment of the Charcot arthropathy must be instituted early and based on suspicion rather than waiting for radiographic confirmation. The best treatment is a vigorous protection of the joint following the initial episode before additional injury occurs. This may be accomplished by a splint or a cast and by nonweightbearing. If the early treatment has been successful radiographic changes may never be identified. Typically the swelling and erythema subside after 1 or 2 weeks. If they recur after the beginning of weight bearing, then the protection must be resumed for a longer time. The healing usually takes 6 to 8 weeks. However, if the diagnosis and treatment are delayed until the radiograph becomes positive for joint deformity or degeneration, prolonged immobilization and protection must be provided until the process has run its course. This may take 6 to 8 months or longer. The joint protection should be maintained until there is radiographic evidence of healing of the avascular segment of the joint and all swelling and erythema has disappeared. Continued orthotic protection of the foot and ankle or knee is essential.

Orthotic Devices

The goal of treatment of the myelomeningocele foot is a braceable plantigrade foot. Only the sacral-level paraplegic has sufficient sensation and muscle control to gain stability of the foot and ankle without orthotic support. The orthosis must provide stability to the foot and ankle, and ideally should be lightweight and cosmetically acceptable. It should limit all unwanted motion of the foot and ankle, and transmit the floor reaction force to the anterior shin where the child has sensation. The ideal orthosis has not been developed. The closest we can come is a brace made of polypropylene that controls and limits the ankle motion (122). If the ankle is in valgus, or if there is instability of the subtalar joint, the brace can be modified with a supramalleolar strap which uses the principle of the T-strap of the double upright style of orthosis (123). This helps release the pressure on the medial malleolus and the head of the talus.

The author prefers the floor reaction force ankle–foot orthosis that is closed anteriorly over the tibial tubercle so that the floor reaction force can be transmitted directly to the area of intact sensation (Fig. 16-20). It also gives a firm support to the tibia to help extend the knee during midstance (124). Because the orthosis is in part a cylinder, it is much more resistant to rotation and valgus deformation during walking than the more common posterior polypropylene ankle–foot orthosis. Because the ankle is rigid the heel of the shoe must act as the shock absorber at heel strike, and should be of a relatively soft, shock-absorbing material. The foot also must be allowed to simulate 10 degrees of dorsiflexion in order to get the tibia beyond midstance to take the next step (125) (Fig. 16-16). This can be adjusted by the height of the heel or the position of the foot when the mold is made for the brace. The drawback to the floor reaction orthosis is that it is difficult to make and requires a skilled orthotist. There is little margin of error permitted, or maximum gait cannot be achieved.

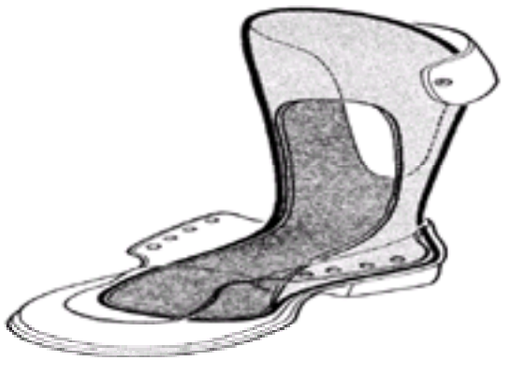

FIGURE 16-20. An ankle–foot orthosis made of a polypropylene shell with a Plastizote lining. The orthosis is closed anteriorly over the tibial tubercle so that the floor reaction force can be transmitted directly to the area of intact sensation. (From ref. 117, with permission.)

The downside to an ankle–foot orthosis is that the ankle–foot joint complex cannot absorb the transverse plane forces of gait. The forces are consequently transferred to the knee which is not designed to accept them. A recent study showed that in the S1–2-level paraplegic the brace may be more detrimental to the knee than a benefit to the gait pattern (96).

Shoe inserts and modifications are rarely successful in providing correction of alignment and position deformities of the foot. Most of these children do not have the muscle control or the sensation to take advantage of these devices. They may be helpful in protecting the foot of an S1 level paraplegic.

Fractures of the Femur and Tibia

Fractures of the femur and tibia occur commonly in children with myelomeningocele (66,125). The trauma needed to produce the fracture is often minimal, particularly after cast immobilization. The fractures are usually epiphyseal or metaphyseal (126,127,128 and 129). The peak incidence of fracture appears to be between the ages of 3 and 7 years, but fracture may occur at any age. Fracture is related to the level of paralysis and postoperative immobilization. Metabolic abnormalities have been investigated and found not to be present (130).

Diagnosis of fracture often is missed because of the minimal trauma. If the fracture is not diaphyseal, no instability of the leg may be present, which aids in the diagnosis. The local and systemic response to the fracture also is exaggerated, and consists of swelling of the leg, local warmth, erythema, and fever (131). These signs and symptoms often are misdiagnosed as cellulitis or osteomyelitis. Any unexplained fever in these children in association with a swollen warm leg that appears to be cellulitis should be treated as a fracture until radiographs prove otherwise.

Fracture following postoperative cast immobilization is common, and several studies have reported an incidence of 18 to 45%. Prevention of fractures in the postoperative period include starting the child on weightbearing as soon as possible, and keeping the plaster immobilization time to a minimum. After the cast has been removed extreme caution must be exercised for at least 1 week. Once a fracture has occurred it is best to carry out minimal immobilization and begin weightbearing as soon as possible. If these children are treated with the usual routine of plaster cast and inactivity the osteopenia increases, and repeated fractures are more likely to occur.

In most instances the author prefers a soft cast made of cast padding about 1 inch thick, followed by an elastic bandage and, if necessary, a single lightweight plaster splint. The swelling decreases rapidly, and the soft cast has to be reapplied within 2 or 3 days. The family rewraps the elastic bandage daily. Usually, there is sufficient callus to begin weightbearing in 2 or 3 weeks after casting. If a plaster cast is used weightbearing should be started as soon as possible. If the fracture is

close to the hip internal fixation may be necessary to obtain early mobility.

CHAPTER 17

OTHER NEUROMUSCULAR DISORDERS

GEORGE H. THOMPSON
FRANK R. BERENSON

G. H. Thompson: Department of Orthopaedic Surgery and Pediatrics, Case Western Reserve University; Pediatric Orthopaedics, Rainbow Babies and Children's Hospital, Cleveland, Ohio 44106.
F. R. Berenson: Department of Pediatrics, Mercer University, Macon, Georgia 31207; Department of Pediatrics, Children's Healthcare of Atlanta at Scottish Rite, Atlanta, Georgia 30342.

Neuromuscular disorders other than cerebral palsy and myelodysplasia are less common, but nevertheless appear in pediatric orthopaedic and neuromuscular clinics. These disorders include the muscular dystrophies and congenital myopathies, spinal muscular atrophy, Friedreich ataxia, hereditary motor sensory neuropathies (HMSN), and poliomyelitis. It is important that an accurate diagnosis be established so that an effective treatment program can be planned and initiated. Delaying the diagnosis may lead to inappropriate treatment and perhaps further pregnancies with involved children in the presence of genetic diseases (1). Accurate diagnosis requires a careful history, physical examination, and appropriate diagnostic studies (2).

HISTORY

The history should include the details of pregnancy, delivery, and growth and development of the involved child. Questions regarding *in utero* activity, complications of delivery, birth weight, Apgar score, problems during the neonatal period, age at achievement of developmental motor milestones, age at onset of the current symptoms, and information regarding whether the condition is static or progressive should be asked. Systemic symptoms, such as cardiac disease, cataracts, seizures, or other abnormalities, should also be ascertained.

The family history is important in diagnosis because these disorders, with the exception of poliomyelitis, are genetic in origin. Family members of an involved child or adolescent may need to be examined for subtle expressions of the same disorder. These same family members may also require hematologic or other studies to arrive at an accurate diagnosis.

PHYSICAL EXAMINATION

Most children who present for evaluation of a suspected neuromuscular disorder have either a delay in developmental milestones, abnormal gait, or foot deformity. There usually is a history of progression. Physical examination consists of a thorough musculoskeletal and neurologic evaluation. Observing the child walking and performing simple tasks, such as arising from a sitting position on the floor, can be beneficial. Observing the gait may reveal decreased arm swing, circumduction of the legs, scissoring, or short cadence. Standing posture may reveal increased lumbar lordosis or wide base position for balance. Also, in the standing position the appearance of the feet should be observed. Pes cavus or cavovarus deformities are common physical findings in many of these disorders. Having the child walk on

the heels and toes gives a gross assessment of motor strength, whereas having the child run may reveal an increase in muscle tone or ataxia.

Inspection of the skin should be performed for evidence of skin rashes or other abnormalities. Typical facies of the patient with spinal muscular atrophy and congenital myotonic dystrophy should become familiar to orthopaedic surgeons. The tongue should be examined to detect evidence of fasciculation suggestive of anterior horn cell diseases. Excessive drooling is common in both cerebral palsy and congenital myotonic dystrophy. In the latter, nasal speech may also be present. A thorough ophthalmologic examination is necessary to elicit external ophthalmoplegia or retinitis pigmentosa. Cataracts may develop during adolescence in myotonic dystrophy.

Muscle testing should be carefully performed. Generally, myopathic disorders selectively affect proximal limb muscles before distal muscles. They also demonstrate proportionally greater weakness than the degree of atrophy early in the disease process. The converse is true in neuropathies.

A careful neurologic evaluation usually completes the musculoskeletal examination. Sensory responses must be checked individually and recorded. Decreased vibratory sensation may be present in HMSN, such as Charcot-Marie-Tooth disease. In spinal muscular atrophy the deep tendon reflexes may be absent, but they are increased in cerebral palsy. A positive Babinski sign confirms upper motor neuron disease. Abnormalities in the Romberg test and rapid alternating movements may indicate cerebellar involvement. Mental function evaluation may be necessary, because organic mental deterioration may be part of some neurologic syndromes. In many cases the assistance of a pediatric neurologist can be invaluable in performing a careful neurologic and mental evaluation because minor subtleties may be a clue to diagnosis.

DIAGNOSTIC STUDIES

Appropriate diagnostic studies are imperative in the accurate diagnosis of the myopathic and neuropathic disorders (3,4,5 and 6). These can be divided into hematologic studies, electromyography (EMG) with both nerve conduction studies and needle electrode exam, muscle biopsy, and nerve biopsy. Molecular diagnostic studies have become available for several disorders, such as Duchenne and Becker muscular dystrophies.

Hematologic Studies

The measurement of serum creatine phosphokinase (CPK) is the most sensitive test for demonstrating abnormalities of striated muscle function (7,8). The level of elevation parallels the rate and amount of muscle necrosis and decreases with time as the muscle is replaced by fat and fibrous tissue. The highest CPK levels are typically seen in the earliest stages of Duchenne or Becker muscular dystrophy in which increases of 20 to 200 times normal may be found (4). The level of elevation does not correlate with the severity or rate of progression of the disorder. The highest levels are usually found in Duchenne muscular dystrophy. Umbilical cord blood CPK levels should be obtained in all male infants who are suspected of having this disorder (9). Birth trauma may elevate the CPK in umbilical cord blood, but in the normal child this elevation disappears promptly. The enzyme level remains elevated in true muscular dystrophy. Serum CPK may be mildly or moderately elevated in other dystrophic disorders, such as fascioscapulohumeral muscular dystrophy, Emery-Dreifuss muscular dystrophy, and spinal muscular atrophy. It is also mildly elevated in female carriers of Duchenne muscular dystrophy, although they are asymptomatic. In congenital myopathies and peripheral neuropathies, the CPK levels are usually normal to only mildly elevated. In other neuromuscular disorders that do not directly affect striated muscle, the CPK levels are normal. Serum enzymes, such as aldolase and serum glutamic oxaloacetic transaminase (SGOT), are also important in the study of striated muscle function. Aldolase levels correlate well with the CPK levels (6).

Electromyography

EMG can differentiate between a myopathic and neuropathic process but is rarely helpful in establishing a definitive diagnosis. Characteristics of neuropathic disorders include the presence of fibrillation potentials, increased insertional activity, and high amplitude and increased-duration motor unit potentials (4). The fibrillation potential represents denervated individual muscle fibers firing spontaneously.

Myopathic EMG is characterized by low-voltage, short-duration polyphasic motor unit potentials (4). Myopathies rarely demonstrate EMG changes characteristic of a neuropathy, although in an inflammatory muscle disease with significant muscle breakdown there may be prominent fibrillations. The use of an experienced electromyographer is imperative in the accurate performance and interpretation of EMG data.

Nerve Conduction Studies

Nerve conduction studies are important in the establishment of the diagnosis of peripheral neuropathy in children. Nerve conduction velocities are normal in children with anterior horn cell diseases, nerve root diseases, and myopathies. The normal value in the child older than 5 years of age is 45 to 65 m/s. In infants and younger children, the velocity is lower because myelinization is incomplete.

Motor conduction velocity may be lowered in HMSN (e.g., Charcot-Marie-Tooth disease) before clinical deficits are present. The nerve conduction studies can help determine whether the neuropathy involves an isolated nerve or is a disseminated process.

Muscle Biopsy

Muscle biopsy is the most important test in determining the diagnosis of a neuromuscular disorder (10,11). Muscle biopsy material is usually examined by routine histology, special histochemical stains, and electron microscopy. The criterion for selecting the muscle for biopsy is clinical evidence of muscle weakness. Muscles that are involved but are functioning are selected in chronic diseases such as Duchenne muscular dystrophy because they demonstrate the greatest diagnostic changes. A more severely involved muscle may be chosen in an acute illness because the process has not had sufficient time to progress to extensive destruction. In patients who have proximal lower extremity muscle weakness biopsy of the vastus lateralis is performed, whereas in those with distal weakness the gastrocnemius is biopsied. Biopsy of the deltoid, biceps, or triceps is performed for shoulder girdle or proximal upper extremity weakness.

Muscle biopsies can be performed as an open procedure (10,12) or by percutaneous needle (13). The open technique as described by Banker is preferred (10). The biopsies are obtained under general anesthesia, spinal anesthetic, regional nerve block, or with a field block surrounding the area of incision. It is important that local anesthetic not be infiltrated into the muscle because this may alter the morphology of the muscle. The vastus lateralis is the most common muscle chosen. A 4-cm incision is made and the underlying fascia is incised longitudinally. The muscle is looked at directly to avoid including normal fibrous septae in the specimens. Muscle clamps are used to obtain three specimens. The clamps are oriented in the direction of the muscle fibers. A 2- to 3-mm piece of muscle is grasped in each end of the clamp. The muscle is cut at the outside edge of each clamp and a cylinder of muscle excised. Using a muscle clamp keeps the muscle at its resting length and minimizes artifact. One specimen is quickly frozen in liquid nitrogen (–160°C) to prevent loss of soluble enzymes. This specimen is used for light microscopy with a variety of special preparations. The other specimens are used for routine histology and electron microscopy. The wound is subsequently closed in layers. Electrocautery may be used during the closure. If it is used before the biopsy, it may inadvertently damage the specimens and alter the morphology.

Nerve Biopsy

Occasionally biopsy of a peripheral nerve is helpful in demyelinating disorders. Usually the sural nerve is selected for biopsy because of its distal location and lack of autogenous zone of innervation. The patient notices no sensory change or only a mild diminution after excision of the 3- to 4-cm segment of the nerve. Hurley et al. (12) reported a single incision for combined muscle and sural nerve biopsy. An incision over the posterolateral aspect of the calf allows access to the nerve and either the soleus or the peroneal muscles. This avoids the necessity for two incisions. This technique was demonstrated to be accurate in diagnosing disorders in which both a muscle and nerve biopsy may be necessary.

Other Studies

Other studies that may be beneficial in establishing the diagnosis of a neuromuscular disorder include electrocardiogram (ECG), pulmonary function studies, magnetic resonance imaging (MRI), ophthalmologic evaluation, amniocentesis, and pediatric neurology evaluation.

Duchenne muscular dystrophy, Friedreich ataxia, and myotonic dystrophy demonstrate ECG abnormalities. Duchenne muscular dystrophy frequently has mitral valve prolapse secondary to papillary muscle involvement (14,15). Arrhythmias under anesthesia have been reported with both Duchenne and Emery-Dreifuss muscular

dystrophies (16,17).

Pulmonary function studies demonstrate involvement of respiratory muscles but do not establish the diagnosis. If respiratory muscle involvement is present the rate of deterioration can be followed with periodic studies. This is important if surgery is contemplated in children or adolescents with muscular dystrophy, spinal muscular atrophy, or Friedreich ataxia. The forced vital capacity (FVC) is the most important study after arterial blood gas measurements (18).

MRI has been demonstrated to distinguish muscles in neuropathic and myopathic disorders (19). Imaging estimates of the disease severity by degree of muscle involvement correlate well with clinical staging. MRI may also be important in selecting appropriate muscles for biopsy.

Ophthalmologic evaluation may demonstrate subtle or more obvious ocular changes associated with specific disorders.

GENETIC AND MOLECULAR BIOLOGY STUDIES

Genetic research through molecular biologic techniques has tremendously enhanced our understanding of the genetic aspects of many of these disorders (20,21). The exact location of chromosomal and gene defects has led to the possibility of genetic engineering with correction of these disorders. In each of the various disorders, the current status of genetic and molecular biology research, if any, is discussed.

MUSCULAR DYSTROPHIES

The muscular dystrophies are a group of noninflammatory inherited disorders with progressive degeneration and weakness of skeletal muscle without apparent cause in the peripheral or central nervous system. These have been divided by clinical distribution, severity of muscle weakness, and pattern of genetic inheritance (Table 17-1). An accurate diagnosis is important, both for prognosis and management of the individual patient and for identification of genetic factors that may be crucial in planning for subsequent children by the involved family.

TABLE 17-1. CLASSIFICATION OF MUSCULAR DYSTROPHIES

SEX-LINKED MUSCULAR DYSTROPHIES

Duchenne Muscular Dystrophy

Duchenne muscular dystrophy is the most common form of muscular dystrophy. Transmission is by an X-linked recessive trait. A single gene defect is found in the short arm of the X chromosome. The disease is characterized by its occurrence in males, except for rare cases associated with Turner syndrome. In this rare event, the XO karyotype who carries the defective gene may demonstrate the phenotype found in involved males (4). This disorder has a high mutation rate, and a positive family history is present in approximately 65% of cases. Duchenne muscular dystrophy occurs in about 1 in 3,500 live male births, with about one-third of involved children having the disease based on a new mutation.

Becker muscular dystrophy is a similar but less common and less severe form of muscular dystrophy. It occurs in about 1 in 30,000 live male births, becomes apparent later in childhood, and has a more protracted and variable course than Duchenne muscular dystrophy. This disorder is discussed later but is introduced here because of the similar inheritance pattern and molecular biology abnormality.

Clinical Features

Duchenne muscular dystrophy is generally clinically evident when the child is between 3 and 6 years of age. Earlier onset may also occur. The family may have observed that the child's ability to achieve independent ambulation was delayed or that he has become a toe walker. Children 3 years of age or older may demonstrate frequent episodes of tripping and falling, in addition to difficulty in reciprocal motion, such as running or climbing stairs. Inability to hop and jump normally is commonly present.

In Duchenne muscular dystrophy there is progressive weakness in the proximal muscle groups which descends symmetrically in both lower extremities, particularly the gluteus maximus, gluteus medius, quadriceps, and tibialis anterior muscles. The abdominal muscles are involved. Involvement of the shoulder girdle muscles (i.e., trapezius, deltoid, and pectoralis major muscles) and lower facial muscles occurs later. Pseudohypertrophy of the calf muscles caused by the accumulation of fat is common but not invariably present. Most patients have cardiac involvement, most commonly a sinus tachycardia and right ventricular hypertrophy. Life-threatening dysrhythmia or heart failure ultimately develops in about 10% of patients. Many also have a static encephalopathy, with mild or moderate mental retardation (22). Death from pulmonary failure and occasionally from cardiac failure occurs during the second or third decades of life.

During gait the child's cadence is slow and he or she develops compensatory changes in gait and stance as weakness progresses. Sutherland et al. (23,24) documented disease progression by measuring the gait variables of cadence, swing phase, ankle dorsiflexion, and anterior pelvic tilt. The hip extensors, primarily the gluteus maximus, are the first muscle group to be involved. Initially the patient compensates by carrying the head and shoulders behind the pelvis, maintaining the weight line posterior to the hip joint and center of gravity (Fig. 17-1). This produces an anterior pelvic tilt and increases lumbar lordosis. Cadence and swing-phase ankle dorsiflexion decrease, and the patient develops a waddling, wide-based gait with shoulder sway to compensate for gluteus medius weakness. Muscle weakness requires that the force line remain behind the hip joint and in front of the knee joint throughout single limb support (23,24 and 25), and hip abductors and quadriceps muscles force the patient to circumduct during the swing phase of gait, while at the same time shifting the weight directly over the hip joint. The generalized pelvic weakness requires considerable forward motion to be generated by the spine for the patient to advance. Ankle plantar flexion becomes fixed and the stance phase is reduced to the forefoot, resulting in even more difficulty with balance and cadence. Foot inversion develops as peroneal strength diminishes. The tibialis posterior muscle, which is one of the last muscles to be involved, is responsible for the inversion or varus deformity of the foot.

FIGURE 17-1. A: A 7-year-old boy with Duchenne muscular dystrophy demonstrates precarious stance due to mild hip abduction contractures. Observe the pseudohypertrophy of the calves. **B:** Posterior view demonstrates mild ankle equinus in addition to the calf pseudohypertrophy. **C:** Side view shows an anterior tilt to the pelvis and increased lumbar lordosis, and the head and the shoulders are aligned posterior to the pelvis. This characteristic posture maintains the weight line posterior to the pelvis and center of gravity, compensates for the muscle weakness, and helps maintain balance.

Weakness in the shoulder girdle, which occurs 3 to 5 years later, precludes crutch usage to aid in ambulation. It also makes it difficult to lift the patient from under the arms. This tendency for the child to slip a truncal grasp has been termed “Meyeron sign.” As the weakness in the upper extremities increases, the child becomes unable to move his or her arms. Although the hands retain strength longer than the arms, use of the hands is limited because of weakness of the arms.

Clinical diagnosis of Duchenne muscular dystrophy is established by physical examination, including gait and specific muscle weakness, and by the absence of sensory deficits. The upper extremity and knee deep-tendon reflexes are lost early in the disease, whereas the ankle reflexes remain positive until the terminal phase. A valuable clinical sign is the Gower sign. The patient is placed prone or in the sitting position on the floor and asked to rise. This is usually difficult, and the patient may require the use of a chair for assistance. The patient is then asked to use his or her hands to grasp the lower legs and force the knees into extension. The patient then walks his or her hands up their extremities to compensate for the quadriceps and gluteus maximum weakness. This sign may also be found in congenital myopathies and spinal muscular atrophy. Appreciation of the contracture of the iliotibial band can be measured by the Ober test. To perform this test, the child is placed on his or her side with both hips flexed. The superior leg is then abducted and extended and allowed to fall into adduction. The degree of abduction contracture can be measured by the number of degrees the leg lacks in coming to the neutral position. Tendo Achillis contractures also occur. Contracture of the tendo Achillis and the iliotibial band are the most consistent deformities noted during the physical examination. Macroglossia is also a common finding.

Duchenne muscular dystrophy progresses slowly but continuously. A rapid deterioration may be noted after immobilization in bed, even for short periods after respiratory infections or perhaps extremity fractures. Every effort should be made to maintain a daily ambulatory program. Children are usually unable to ambulate effectively by 10 years of age in the absence of treatment (3,26,27 and 28). With loss of standing ability, the child becomes wheelchair-dependent. This results in a loss of the accentuated lumbar lordosis, which protects the child from kyphoscoliosis (28). As a consequence most develop a progressive spinal deformity.

Myocardial deterioration is also a constant finding. ECG changes are present in more than 90% of children with Duchenne muscular dystrophy. The average intelligence quotient of these patients has been shown to be about 80 (22).

Hematologic Studies

The serum CPK is markedly elevated in the early stages of Duchenne muscular dystrophy. This may be 200 to 300 times normal, but decreases as the disease progresses and muscle mass is reduced. CPK levels are also elevated in female carriers, although not as high as in affected boys (two to three times that in normal women and girls). There is an 80% accuracy when the CPK level is repeated at three consecutive monthly intervals (30). Aldolase and SGOT levels also may be elevated, but the elevations are not unique to striated muscle disease.

Electromyography

EMG shows characteristic myopathic changes with reduced amplitude, short duration, and polyphasic motor action potentials (4).

Muscle Biopsy

The muscle biopsy specimen reveals degeneration with subsequent loss of fiber, variation in fiber size, proliferation of connective tissue, and subsequently, of adipose tissue (10,11). Increased cellularity with occasional internal migration of the sarcolemmal nuclei is present. Histochemical loss of clear-cut subdivisions to fiber types, especially with adenosine triphosphatase reaction and tendency toward type I fiber predominance, are also seen.

Genetic and Molecular Biology Studies

A single gene defect in the short arm of the X chromosome has been identified as being responsible for both Duchenne and Becker muscular dystrophies (31,32). The status of genetic and molecular biology in Duchenne muscular dystrophy has been summarized by Shapiro and Specht (4). The gene is located at the Xp21.2 region and spans 2 million base pairs (20,23). It includes 65 exons (i.e., coding regions) and encodes the 400-kd protein dystrophin (33,34). The large size of the gene correlates with the high rate of spontaneous mutation. Dystrophin is a component of cell membrane cytoskeleton and represents 0.01% of skeletal muscle protein. Its distribution within skeletal, smooth, and cardiac muscle and within the brain correlates well with the clinical features in Duchenne and Becker muscular dystrophies. A structural role for the dystrophin protein is suggested by studies demonstrating concentration of the protein in a lattice organization in the cytoplasmic membrane of skeletal muscle fibers (35,36). Demonstrable mutations, deletions, or duplications of dystrophin are found in 70 to 80% of involved males (33,34,37,38). The reading frame hypothesis defines which mutations correlate with the more severe Duchenne muscular dystrophy or with the less severe Becker muscular dystrophy. Mutations that disrupt the translational reading frame or the promoter (i.e., the specific DNA sequence that signals where RNA synthesis should begin) result in a presumably unstable protein, which correlates with Duchenne muscular dystrophy. In contrast, mutations that do not disrupt the translational reading frame or the promoter have a lower molecular weight and semifunctional dystrophin, which correlates with the less severe Becker muscular dystrophy (33,39).

Dystrophin testing (dystrophin immunoblotting), DNA mutation analysis (polymerase chain reaction or DHA [Southern] blot analysis), or both provide an aid to differentiate between Duchenne and Becker muscular dystrophies, and other initially similar disorders, such as dermatomyositis, limb-girdle muscular dystrophy, Emery-Dreifuss muscular dystrophy, and congenital muscular dystrophy (38,40,41). In the latter disorders the dystrophin is normal. In patients with Duchenne muscular dystrophy there is a complete absence of dystrophin, whereas in Becker muscular dystrophy, dystrophin is present but is altered in size, decreased in amount, or both. Nicholson et al. (42) reported a positive relation between the amount of dystrophin and the age at loss of independent ambulation in 30 patients with Duchenne muscular dystrophy and 6 patients with Becker muscular dystrophy. They found that even low concentrations of dystrophin in Duchenne muscular dystrophy may have functional significance and may explain the variability of age when ambulation ceases. The presence of partially functional dystrophin protein is sufficient for minimizing the phenotypic expression leading to the milder disorder of Becker muscular dystrophy (33,37,40). The same tests can be used to improve detection of female carriers (38,41). Based on smaller-than-normal dystrophin protein, two atypical forms of Becker muscular dystrophy have been recognized. These include myalgia without weakness in male patients similar to metabolic myopathy, and cardiomyopathy in male patients with little or no weakness (43).

Research involves the possibility of dystrophin replacement in diseased muscles. This involves the implantation of myoblasts, or muscle precursor cells, into the muscles of patients with Duchenne muscular dystrophy (44). This has been successful in producing dystrophin in the murine mdx model of Duchenne muscular dystrophy (45). Unfortunately, the results in involved males has been disappointing (46,47,48,49 and 50).

Several forms of experimental treatment of Duchenne muscular dystrophy are being investigated. Prednisone has been demonstrated to have short-term benefits in slowing the progressive weakness for at least 3 years (51,52). However, the associated side effects of weight gain, osteoporosis and myopathy limit its usefulness (53,54 and 55). Azathioprine has also been evaluated in Duchenne muscular dystrophy, but has not shown beneficial effects (56).

Treatment

The orthopaedic problems in children with Duchenne muscular dystrophy include decreasing ambulatory ability, soft tissue contractures, and spinal deformity (2,3 and 4,57). The goals of treatment should be designed to improve or maintain the functional capacity of the involved child or adolescent.

The treatment modalities in Duchenne muscular dystrophy have been outlined by Drennan (58) and include physical therapy, functional testing, orthoses, fracture management, surgery, wheelchair, cardiopulmonary management, and genetic and psychologic counseling.

Physical Therapy. Physical therapy is directed toward prolongation of functional muscle strength, prevention or correction of contractures by passive stretching, gait training with orthoses and transfer techniques, ongoing assessment of muscle strength and functional capacity, and wheelchair and equipment measurements.

After the diagnosis of Duchenne muscular dystrophy has been established and before muscle strength has deteriorated, a program of maximum-resistance exercises performed several times daily, should be instituted (5,59). This may help prolong strength and delay the onset of soft tissue contractures. Contractures are more effectively delayed or prevented than corrected by physical therapy. Contractures develop in the ambulatory patient because muscle weakness progression results in development of adaptive posturing to maintain lower extremity joint stability. A home exercise program can be effective in minimizing hip and ankle soft tissue contractures. Drennan recommended that exercises be performed twice daily on a firm surface and should include stretching of the tensor fascia lata, hamstrings, knee flexors, and ankle plantar flexors (58). Occasionally serial casting may be useful to correct existing deformities before physical therapy. Knee flexion contractures of less than 30 degrees may benefit by serial or wedge casting. This enhances the use of knee-ankle-foot orthoses (KAFOs). Unless orthoses are used after casting and in conjunction with physical therapy, these contractures rapidly recur.

Functional Testing. Functional testing predominantly involves periodic muscle testing. Muscle strength is tested by measurement of the active range of motion of a joint against gravity. This type of testing allows assessment of the rate of deterioration as well as the functional capacity of the individual.

Orthoses. Lightweight molded plastic ankle-foot orthoses (AFOs) or KAFOs are used in independently ambulatory patients when gait becomes precarious, when early soft tissue contractures of the knees and ankle are developing, and after surgical correction of these deformities (60,61,62 and 63). KAFOs usually are supplemented with a walker because of the excessive weight and the fear of falling. Important prescription components include partial ischial weightbearing support, posterior thigh cuff, and a spring-loaded, drop-lock knee joint with an ankle joint set at a right angle. Ambulation may be extended for up to 3 years by the combined use of surgery and orthoses. The maintenance of a straight lower extremity also enables the nonwalking patient to stand with support and thereby assist in transfers.

Spinal orthoses are usually of no value in progressive spinal deformities, but wheelchair-bound patients, especially those with severe cardiopulmonary compromise and severe scoliosis, may benefit from the use of a custom wheelchair, a thoracic suspension orthosis, or custom thoracic-lumbar spinal orthosis (TLSO) (52). A mobile arm support orthosis attached to the wheelchair may benefit the patient in performing personal hygiene tasks and self-feeding activities (64,65).

Fracture Management. Fractures of the lower extremities occur frequently in children with Duchenne muscular dystrophy. This occurs predominantly after ambulation has ceased and the child is wheelchair-bound. These fractures are best treated by closed reduction and cast immobilization. Occasionally open reduction and internal fixation may be needed. In children who are still ambulatory, it is important that they be placed on a program of early mobilization to allow weightbearing. This may require the use of an electrically powered circle bed. Once early healing is present, the child can be returned to the KAFO to decrease weight and enhance mobility.

Surgery. Contractures of the lower extremities and progressive weakness impair ambulation. Surgery is indicated when independent ambulation becomes precarious and when contractures are painful or interfere with essential daily activities. The major contractures amenable to surgical intervention include equinus and equinovarus contractures of the ankle and foot, knee flexion contractures, and hip flexion and abduction contractures. In thin individuals, these contractures may be released by percutaneous techniques (57,66,67). Orthotic measurements for ambulatory patients should be obtained before surgery. This allows them to be applied shortly after surgery to assist in rapid restoration of ambulation. Correction of contractures and the use of orthoses can prolong effective ambulation by 1 to 3 years (3,25,60,61, and 63,67,68,69,70,71,72,73 and 74). Hsu and Furumasu (25) reported a mean prolongation of walking of 3.3 years in 24 patients with Duchenne muscular dystrophy, ranging in age from 8 to 12 years at the time of surgery. It is usually not possible to restore functional ambulation once the patient has been unable to walk for more than 3 to 6 months (60,68,70). Each patient must be individually assessed to determine the functional needs and the best procedures. Common contraindications for correction of lower extremity contractures include obesity, rapidly progressive muscle weakness, or poor motivation in those who prefer to use a wheelchair rather than attempt ambulation (4).

Foot and Ankle. Equinus contractures occur first, then equinovarus contractures. This is due to a combination of tendo Achillis contracture and muscle imbalance induced by the stronger tibialis posterior muscle. This latter muscle retains good function despite the progression of muscle weakness in other areas. These equinovarus deformities can be managed by a combination of tendo Achillis lengthening (percutaneous open tenotomy [57,60,62,63,69,71] **[➥7.17]**, with or without resection [70]; Vulpius [3,75]; or open Z-lengthening [68,74] **[➥7.16]**) and tibialis posterior lengthening, tenotomy, or transfer through the interosseous membrane to the dorsum of the foot **[➥7.19]** (3,5,28,57,61,62 and 63,68,69,70 and 71,76,77 and 78). Tibialis posterior transfer prevents recurrence of equinovarus deformities and maintains active dorsiflexion of the foot. Some authors, however, have questioned the necessity of a transfer because it is a more extensive procedure and they prefer tenotomy, recession, or lengthening (5,57,61,69). Postoperative gait analysis has shown that the transferred tibialis posterior muscle is electrically silent (79). Greene (76) has reported that tibialis posterior myotendinous junction recession in 6 patients (12 feet) had an increased recurrence rate when compared with transfer in 9 patients (18 feet), which made the former a less desirable procedure. Percutaneous tendo Achillis lengthening under local anesthesia has been reserved for nonambulatory patients who have a typically equinus deformity and cannot wear shoes. The nonambulatory patient with a moderately severe equinovarus deformity may require open tenotomies of the tendo Achillis, the tibialis posterior, and long toe flexors. Severe equinovarus contractures have been managed effectively by talectomy.

Knee. Knee flexion contractures coexist with hip flexion contractures and develop rapidly when the patient is wheelchair-bound. These contractures limit proper positioning in bed and may lead to the development of hamstring spasm, causing considerable discomfort when the patient attempts to transfer. A Yount procedure (80), (release of the distal aspect of the tensor fascia lata and iliotibial band) is the most common procedure used in correcting knee flexion contractures (57,61,62 and 63). Hamstring tenotomies (68), recession or Vulpius-type lengthening (75), and formal Z-lengthening may also be necessary **[➥4.23]**. These procedures enhance quadriceps power and function as well as relieve symptoms. Postoperatively KAFOs are necessary to prevent recurrence.

Hip. Hip flexion and abduction contractures increase lumbar lordosis and interfere with the ability to stand and to lay comfortably supine. Patients with hip flexion contractures may complain of low back pain. Correction of flexion contractures involves release of the tight anterior muscles, including the sartorius, rectus femoris, and tensor fascia femoris (4,57). Abduction contractures are improved by release of the tensor fasciae lata proximally with use of the Ober procedure (81), modified Soutter release (82), the Yount procedure distally (80), or by complete resection of the entire iliotibial band (28,72).

Upper Extremity. Upper extremity contractures are common in adolescents with Duchenne muscular dystrophy but usually do not require treatment. These contractures include shoulder adduction, elbow flexion, forearm pronation, wrist flexion, metacarpophalangeal and proximal interphalangeal joint flexion, and others. These usually do not preclude the use of wheelchairs. Muscle weakness is the most devastating aspect of upper extremity involvement. Wagner et al. (83) demonstrated wrist ulnar deviation and flexion contractures in addition to contractures of the extrinsic and intrinsic muscles of the fingers, producing boutonniere and swan-neck deformities and hyperextension of the distal interphalangeal joints in adolescents with Duchenne muscular dystrophy. The treatment of upper extremity contractures involves physical therapy with daily passive range of motion exercises. When passive wrist dorsiflexion is limited to neutral, a nighttime extension orthosis may be beneficial. Surgery for these contractures is rarely indicated.

Spinal Deformity. Approximately 95% of patients with Duchenne muscular dystrophy develop progressive scoliosis (29,72,84,85,86,87,88,89,90 and 91). This typically begins to occur when ambulation ceases, and it is rapidly progressive. About 25% of older ambulating patients, however, have mild scoliosis (26,92). Prolongation of ambulation by appropriate soft tissue releases of the lower extremity contractures, which maintains accentuated lumbar lordosis, can delay the onset of scoliosis (73). The curves are usually thoracolumbar, associated with kyphosis, and lead to pelvic obliquity. Scoliosis cannot be controlled by orthoses or wheelchair seating systems (72,84,93,94,95,96 and 97). Orthotic management, although it may slow curve progression, does not slow the systemic manifestations of Duchenne muscular dystrophy (e.g., decreasing pulmonary function and cardiomyopathy). These may complicate spinal surgery at a later time. As the scoliosis progresses, it can result in a loss of sitting balance, produce abnormal pressure, and occasionally cause the patient to become bedridden (98). Heller et al. (99) reported improved sitting support with an orthosis in 28 patients who either refused surgery or who were felt to be inoperable.

Surgical correction of scoliosis both improves sitting balance and minimizes pelvic obliquity (84,85,96,97 and 98,100,101). It is usually recommended that a posterior spinal fusion be performed once the curve is greater than 20 degrees (84,85,95,96,97 and 98,101,102,103 and 104). Fusion extends from the upper thoracic spine (T2 or T4) to L5 or the pelvis. It is important to center the patient's head over the pelvis in both the coronal and sagittal planes. This usually allows complete or almost complete correction of the deformity. This maintains sitting balance, improves head control, and allows more independent hand function. Although autogenous bone grafting is used in most patients, there appears to be no difference in fusion rates when allograft bone is used (105,106,107 and 108). Segmental spinal instrumentation techniques using Luque rod instrumentation are most commonly used **[➥2.5,2.6]** (57,84,85,88,95,100,101,105,106,109,110,111 and 112). Other segmental instrumentation systems, such as Cotrel-Dubousset, TSRH, Isola, and others, can also be used (105,106,110,113). These allow sufficient fixation, so that postoperative immobilization is not necessary (Fig. 17-2). Fixation to the pelvis is achieved using the Galveston or other techniques (102,105,109,110,112,113,115). The latter is felt to maintain better correction of pelvic obliquity. Some authors believe that fusion to L5 is sufficient and that there will be no spinopelvic deformity throughout the remainder of the patient's life (55,107,116,117). However, a postoperative spinopelvic deformity can occur and progress and most authors recommend fusion to the pelvis. Mubarak et al. (88,116) recommend fusion to L5 if the curve is greater than 20 degrees, the FVC is greater than 40%, and the patient is using a wheelchair full time, except for occasional standing. If the patient's curve is greater than 40 degrees or if there is pelvic obliquity greater than 10 degrees, then fusion to the sacropelvis is recommended.

FIGURE 17-2. A: An 11-year-old boy with Duchenne muscular dystrophy with a rapidly progressive right thoracolumbar scoliosis and decreasing sitting balance. He uses his hands to maintain sitting balance. **B:** Side view shows an associated mild kyphotic deformity. **C:** Preoperative sitting posteroanterior radiograph demonstrates a long, sweeping, 48-degree thoracolumbar curve between T11 and L5. Six months earlier, no clinical or radiographic deformity was evident. **D:** Postoperatively, an immediate improvement in spinal alignment and sitting balance is noted. **E:** Side view demonstrates correction of the associated kyphosis. **F:** Postoperative sitting radiograph after posterior spinal fusion and Luque rod instrumentation from T4 to the sacrum. The Galveston technique, with insertion of the Luque rod into the wing of the ilium, was used for pelvic fixation. Almost complete correction of his spinal deformity was achieved. **G:** Postoperative lateral radiograph shows improved sagittal alignment.

Careful preoperative evaluation, including pulmonary function studies and cardiology consultation, is mandatory because of the associated pulmonary and cardiac abnormalities and the risk for malignant hyperthermia (98,118,119,120 and 121). Children with Duchenne muscular dystrophy have a decreased FVC beginning when they are about 10 years of age due to weakness of the intercostal muscles and associated contractures. There is a linear decrease over time (18,85,91,98,101,104,118). Kurz et al. (18) observed a 4% decrease in percentage of FVC for each year of age or each 10 degrees of scoliosis. It stabilizes at about 25% of normal until death. The presence of severe scoliosis may increase the rate of decline in the FVC. Jenkins et al. reported that when the FVC is 30% or less there is an increasing risk for postoperative complication, such as pneumonia and respiratory failure (118). Other authors have made similar observations (18,98,101). Smith et al. (91) found that most patients with curves of more than 35 degrees had FVC less than 40% of predicted normal values, and therefore recommended that spinal arthrodesis be considered for all patients with Duchenne muscular dystrophy when they can no longer walk. Nevertheless, successful surgery can be performed in many patients with FVC as low as 20% of predicted normal valves (106).

It is debated whether spinal stabilization increases the quantity of life, although it definitely increases the quality of the remaining life (85,106,109). In a study of 55 patients with Duchenne muscular dystrophy, of which 32 underwent spinal fusion and 23 did not, Galasko et al. (85) found that FVC remained stable in the operated group for 36 months postoperatively and then fell slightly. In the nonoperated group it progressively declined. The survival data showed that a significantly higher mortality rate was seen in the nonoperated group. This study indicated that spinal stabilization can increase survival for several years if it is done early before significant progression has occurred. Other studies, however, have shown that posterior spinal fusion has no effect on the steady decline in pulmonary function when compared with unoperated patients (103,106,122,123 and 124). In addition to correction and stabilization of the spine, patients experience improved quality of life measures, such as function, self image, and cosmesis (103,109,110,125). Parents also reported improved ability to provide care to their child.

Complications are common during and following surgery (85,95,96 and 97,103,110,116). These include excessive intraoperative blood loss, neurologic injury, cardiopulmonary compromise, postoperative infection, wound healing, curve progression, hardware problems, and late pseudarthrosis. With respect to intraoperative blood loss, this can be minimized by early surgery and the use of hypotensive anesthesia (107). The increased intraoperative blood loss in patients with Duchenne muscular dystrophy appears to be due to the lack of dystrophin in the smooth muscle, which inhibits normal vasocontraction (126).

The role of intraoperative spinal cord monitoring in children with Duchenne muscular dystrophy is controversial. Noordeen et al. reported that a 50% decrease in amplitude was suggestive of neurologic impairment (127).

Wheelchair. A wheelchair is necessary for patients who are no longer capable of independent ambulation. This is typically a motorized wheelchair to allow the patient to be independent of parents or aides, especially while attending school. The wheelchair may be fitted with a balanced mobile arm orthosis for the purpose of facilitating personal hygiene and feeding (64,65).

Cardiopulmonary Management. Respiratory failure in Duchenne muscular dystrophy is a constant threat and is the most common cause of death early in the third decade of life. Kurz et al. (18) found the vital capacity peaks at the age when standing ceases, then declines rapidly thereafter. The development of scoliosis compounds the problems and leads to further diminution of the vital capacity (123). The complication rate in spinal surgery increases when the FVC is less than 30% of expected. Programs of vigorous respiratory therapy and the use of home negative-pressure and positive-pressure ventilators may allow patients with Duchenne muscular dystrophy to survive into the third and fourth decades of life (128,129,130 and 131).

Cardiac failure may also occur in the second decade of life. After initially responding to digitalis and diuretics, the involved cardiac muscle becomes flabby and the patient goes into congestive heart failure. Myocardial infarction has been reported in boys as young as 10 years of age. There is no correlation between the severity of pulmonary dysfunction and cardiac function or between age and cardiac function (132). The cardiomyopathy of Duchenne muscular dystrophy exists clinically as a separate entity.

Genetic and Psychologic Counseling

Proper diagnosis and early genetic counseling may help prevent birth of additional male infants with Duchenne muscular dystrophy. It must be remembered that approximately 20% of families have already conceived and delivered a second involved male infant before the diagnosis is made in the first (63,133). Genetic counseling with parents and family groups is important in the management of psychological problems arising when the genetic nature of the diagnosis becomes known.

Becker Muscular Dystrophy

Becker muscular dystrophy is similar to Duchenne muscular dystrophy in clinical appearance and distribution of weakness, but it is less severe (134,135). Onset is generally after the age of 7 years and the rate of progression is slower. The patients usually remain ambulatory until adolescence or early adult years. The Gower maneuver may occur as the weakness progresses (Fig. 17-3). Pseudohypertrophy of the calf is common, and eventually equinus and cavus foot deformities develop

(Fig. 17-4). Cardiac involvement is frequent. There may be a family history of atypical muscular dystrophy. Pulmonary problems are less severe and the patient's life expectancy is longer.

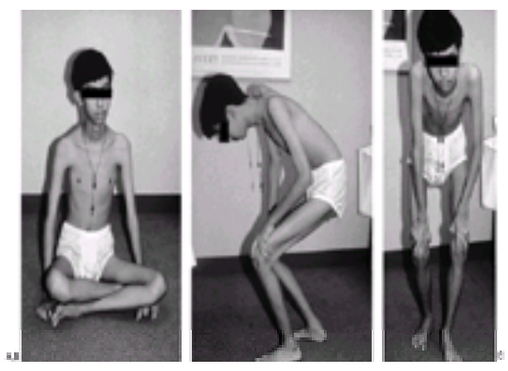

FIGURE 17-3. A: A 13-year-old boy with suspected Becker muscular dystrophy uses the Gower maneuver to stand from a sitting position. **B:** Manually assisted knee extension is necessary to achieve upright stance. **C:** Front view.

FIGURE 17-4. A: Pseudohypertrophy of the calves in an 18-year-old man with Becker muscular dystrophy. He is a brace-free ambulator. **B:** Posterior view.

Treatment

The treatment of the musculoskeletal deformities associated with Becker muscular dystrophy is essentially the same as with Duchenne muscular dystrophy. Ankle and forefoot equinus occur commonly. Shapiro and Specht (4) have reported good success with the Vulpius tendo Achillis lengthening in patients with equinus contractures. A tibialis posterior tendon transfer is performed if necessary **[➥7.19]**. Forefoot equinus may require a plantar release and possibly a midfoot dorsal-wedge osteotomy for correction. The use of orthotics is also beneficial because the rate of progression is slower and the remaining muscle strength greater than in Duchenne muscular dystrophy. The incidence of scoliosis is high, especially in those adolescents who have ceased walking. These patients require careful evaluation and periodic spinal radiographs. Posterior spinal fusion and segmental instrumentation, usually Luque, are beneficial when progression occurs **[➥2.5,2.6]** (134).

Emery-Dreifuss Muscular Dystrophy

Emery-Dreifuss muscular dystrophy is an uncommon sex-linked recessive disorder characterized by early contractures and cardiomyopathy (16). The typical phenotype is seen only in males, although milder or partial phenotypes have been reported in female carriers (137,138,139 and 140). Involved males show mild muscle weakness in the first 10 years of life and a tendency for toe walking. The Gower maneuver may be present in young children. The distinctive clinical criteria occur in late childhood or early adolescence. These include tendo Achillis contractures, elbow flexion contractures, neck extension contracture, tightness of the lumbar paravertebral muscles, and cardiac abnormalities involving brachycardia and first-degree, and eventually complete, heart block (139,140 and 141). The muscle weakness is slowly progressive but there may be some stabilization in adulthood. Most patients are able to ambulate into the fifth and sixth decades of life. Obesity and untreated equinus contractures can lead to the loss of ambulatory ability at an earlier age (4).

The CPK level in patients with Emery-Dreifuss muscular dystrophy is only mildly or moderately elevated. EMG and muscle biopsy are myopathic. The diagnosis of this form of muscular dystrophy should be considered in patients with a myopathic phenotype after Duchenne and Becker muscular dystrophies have been ruled out, usually by dystrophin testing (4). The condition must also be distinguished from scapuloperoneal muscular dystrophy and the rigid spine syndrome (142).

Genetic and Molecular Biology Studies

The gene locus for Emery-Dreifuss muscular dystrophy has been localized to the long arm of the X chromosome at Xq28 in linkage studies (143,144).

Treatment

The treatment of Emery-Dreifuss muscular dystrophy is similar to that used for other forms of muscular dystrophy. The goals are to prevent or correct deformities and maximize function. Treatment modalities include physical therapy, correction of soft tissue contractures, spinal stabilization, and cardiologic intervention.

Physical Therapy. This can be useful in the management of neck extension contractures, elbow flexion contractures, and the tightness of the lumbar paravertebral muscles. Decreased neck flexion, which is characteristic of this disorder, can begin as early as the first decade, but usually is not present until the second decade. This is due to contracture of the extensor muscles and the ligamentum nuchae. According to Shapiro and Specht (4), this does not progress past neutral. Lateral bending and rotation of the neck also become limited as the extensor contractures progress. Physical therapy can be beneficial in maintaining limited flexion of the neck.

Soft Tissue Contractures. Tendo Achillis lengthening and posterior ankle capsulotomy combined with anterior transfer of the tibialis posterior tendon can be beneficial in providing long-term stabilization of the foot and ankle **[➥7.1,7.16,7.19]** (4,139). Elbow flexion contractures usually do not require treatment. These contractures can be as severe as 90 degrees, although most do not exceed 35 degrees (4,98). Full flexion from this position and normal forearm pronation and supination are preserved. Physical therapy may be beneficial to slow the progress of the elbow flexion contractures. Surgery has not been shown to be beneficial.

Spinal Stabilization. Scoliosis is common in this form of muscular dystrophy, but it has a lower incidence of progression. This has been attributed to contractures at the lumbar and ultimately the thoracic paravertebral muscles, which seem to prevent progression (4,139). Those patients with scoliosis need to be followed closely, but most do not require treatment. Curves that progress beyond 40 degrees may require surgical stabilization.

Cardiologic Intervention. Sudden death due to severe bradycardia caused by complete heart block has been a major cause of death in these patients. Most do not have cardiac symptoms preceding death. Merlini et al. (141) reported that 30 of 73 patients with Emery-Dreifuss muscular dystrophy died suddenly, and only four were symptomatic. It is recommended that a cardiac pacemaker be inserted shortly after confirmation of the diagnosis (141,145).

AUTOSOMAL RECESSIVE MUSCULAR DYSTROPHIES

Limb-girdle Muscular Dystrophy

Limb-girdle muscular dystrophy is common and may be more benign than the other forms of muscular dystrophy. It is a rather heterogeneous group of disorders with various classifications proposed for it over the years. The age of onset and rate of progression of muscle weakness are variable. It usually begins in the second or third decade of life. It is transmitted as an autosomal recessive trait, but an autosomal dominant pattern of inheritance has been reported in some families (146,147).

The symptoms of limb-girdle muscular dystrophy are similar to fascioscapulohumeral muscular dystrophy, except that the facial muscles are not involved. The initial muscle weakness involves either the pelvic or shoulder girdle. The rate of progression is usually slow, with soft tissue contractures and disability developing 20 years or more after the onset. The patients remain ambulatory for many years.

The distribution of weakness is similar to that seen in Duchenne and Becker muscular dystrophies. The iliopsoas, gluteus maximus, and quadriceps muscles are involved early in the disease process. Usually, shoulder girdle involvement occurs at about the same time. The serratus anterior, trapezius, rhomboid, latissimus dorsi, and sternal portions of pectoralis major muscles are affected most often. The disease later spreads to involve other muscles, such as the biceps brachia and the clavicular portion of the pectoralis major. Deltoid involvement may occur but is usually late. Weakness may involve the distal muscles of the limbs, such as the wrist and finger flexors and extensors, in the more severely involved individuals.

Two forms of limb-girdle muscular dystrophy include a more common pelvic-girdle type and a scapulohumeral form. The latter is rare, with symptoms involving primarily the shoulder girdle. Involvement of the pelvic girdle may not occur for many years. In the pelvic-girdle type, there is weakness of the hip extensors and abductors, resulting in accentuated lumbar lordosis, gait abnormalities, and hip instability.

The CPK level is moderately elevated in patients with limb girdle muscular dystrophy. The clinical characteristics are indistinguishable from those of sporadic Becker muscular dystrophy, carriers of Duchenne or Becker muscular dystrophies, and those of childhood acid-maltase deficiency (4). Thus, a dystrophin assay is essential in establishing the diagnosis.

Treatment of limb-girdle muscular dystrophy is similar to that for Duchenne and Becker muscular dystrophies. Significant scoliosis rarely occurs because of the late onset of the disease process. When present, it usually is mild and does not require treatment (136). Involved individuals usually succumb to their disease process before 40 years of age.

Genetic and Molecular Biology Studies

The autosomal recessive form has been linked to chromosome 15q and the autosomal dominant form to 5q (148,149).

Infantile Fascioscapulohumeral Muscular Dystrophy

Infantile fascioscapulohumeral muscular dystrophy (IFSH MD) has been recognized with increasing frequency. It is a more severe variant of the more common later-onset fascioscapulohumeral muscular dystrophy (150,151,152 and 153). It appears to be autosomal recessive, but the affected gene has not been identified. Facial diplegia is noted in infancy, followed by sensorineural hearing loss in childhood (mean age, 5 years). A Möbius type of facial weakness may also be present and progress asymptomatically at a relatively slow pace (154). Ambulation begins at a normal age, but because of progressive muscle weakness, most patients become wheelchair-bound during the second decade of life. Weakness causes the child to walk with the hands and forearms folded across the upper buttocks to provide support for the weak gluteus maximus muscles (4,150,153). This marked lumbar lordosis is progressive and is almost pathognomonic for IFSH MD (Fig. 17-5). The lordosis leads to fixed hip flexion contractures after the patient is wheelchair-dependent. Equinus or equinovarus deformities and scoliosis occur less frequently.

FIGURE 17-5. Marked lumbar lordosis in a 15-year-old girl with infantile fascioscapulohumeral muscular dystrophy. She is still ambulatory but having increasing back pain.

Treatment

The treatment of patients with IFSH MD is individualized because most patients do not have significant orthopaedic deformities. These patients usually have severely compromised pulmonary functions and succumb in early adolescence. Shapiro et al. outlined the possible treatment modalities for children with IFSH MD. Flexible equinus and equinovarus deformities respond well to AFOs (153). Occasionally, a Vulpius-type tendo Achillis lengthening may be necessary (75). Hip flexion contractures usually do not require treatment in ambulatory patients and it may decrease function. Spinal orthoses control the lordosis but do not provide correction because the spine remains flexible early in the course of the disorder. Because an orthosis interferes with ambulation it is usually not employed. When wheelchair use is full-time, a modified wheelchair with an orthosis may be beneficial, or perhaps a posterior spinal fusion and segmental instrumentation, depending on the severity of the deformity (88). Scapulothoracic stabilization is not necessary because the severity of dysfunction is so severe that minimal or no improvement in shoulder function can be achieved.

AUTOSOMAL DOMINANT MUSCULAR DYSTROPHIES

Fascioscapulohumeral Muscular Dystrophy

Fascioscapulohumeral muscular dystrophy is an autosomal dominant disorder having variable expression (155). The disease is manifest by muscular weakness of the face, shoulder girdle, and upper arm. It is caused by a gene defect, *FRG1,* on chromosome 4q35 (156,157). There is selective sparing of the deltoid, the distal part of the pectoralis major muscle, and the erector spinae muscles. This results in decreased scapulothoracic motion, with scapular winging and a marked decrease in shoulder flexion and abduction. Glenohumeral motion is usually preserved. The onset may occur at any age but is most common in late childhood or early adulthood. It occurs in both genders but is more common in females. Abortive or mild cases are common. Progression is insidious and periods of apparent arrest may occur. Cardiac involvement and central nervous system involvement are absent. Life expectancy is relatively good.

Initially, the face and shoulder girdle muscles are involved but they may be affected only mildly for many years. Facial signs, which may be present at infancy, include lack of mobility, incomplete eye closure, pouting lips with a transverse smile, and absence of eye and forehead wrinkles. It tends to produce a “popeye” appearance. The shoulder girdle weakness leads to scapular winging. The weight of the upper extremities, together with the weakness of the trapezius, permits the clavicles to assume a more horizontal position. It also leads to a forward-sloping appearance of the shoulders. As the disease progresses, pelvic girdle and tibialis anterior

muscle involvement may also occur (150). Scoliosis is rare because of the late onset of the disease process (5).

The CPK levels in patients with fascioscapulohumeral muscular dystrophy are usually normal. The diagnosis is made by physical examination and muscle biopsy (158).

Treatment

The winging of the scapula, with weakness of shoulder flexion and abduction, is the major orthopaedic problem in fascioscapulohumeral muscular dystrophy. The deltoid, supraspinatus, and intraspinatus muscles are usually normal, however, or minimally involved. Posterior scapulocostal fusion or stabilization (scapuloplexy) by a variety of techniques can be beneficial in restoring mechanical advantage of the deltoid and rotator cuff muscles (159,160,161,162,163,164 and 165). This can result in increased active abduction and forward flexion of the shoulder and improved function, as well as cosmesis. Jakab and Gledhill (162) reported the results of a simplified technique for scapulocostal fusion. The technique involves wiring of the medial border of the scapula to ribs three through seven. Internal fixation is achieved with 16-gauge wire. The wires ensure firm fixation and eliminate the need for postoperative immobilization and subsequent rehabilitation. The child uses a sling for 3 to 4 days postoperatively, then begins a physical therapy program. They found that shoulder flexion increased 28 degrees (range, 20–40 degrees) and abduction 27 degrees (range, 20–35 degrees) at a mean follow-up of 2.9 years. This allowed all patients to raise their arms and hands above their heads, conferring a greater mechanical advantage. The beneficial effects do not seem to deteriorate with time (159,160 and 161,165).

Distal Muscular Dystrophy

This is a rare form of muscular dystrophy. It is also known as Gower muscular dystrophy. It typically begins after 45 years of age. It is transmitted as an autosomal dominant trait. The initial involvement is in the intrinsic muscles of the hand. The disease process spreads proximally. In the lower extremities the calves and tibialis anterior are first involved. The absence of sensory, especially vibratory, abnormalities differentiates this from Charcot-Marie-Tooth disease.

Ocular Muscular Dystrophy

Ocular muscular dystrophy, also known as “progressive external ophthalmoplegia,” is another rare form of muscular dystrophy. It typically begins in the adolescent years. The extraocular muscles are affected, resulting in diplopia and ptosis. This is followed by limitation of ocular movement (166). The upper facial muscles are often affected. The disease is slowly progressive and may involve the proximal upper extremities. The pelvis can be involved late in the disease process. Most patients with this disorder have an identifiable mitochondrial myopathy (167).

Oculopharyngeal Muscular Dystrophy

This form of muscular dystrophy begins in the third decade of life and is particularly common in French Canadians (168,169). Pharyngeal muscle involvement results in dysarthria and dysphasia, which leads to repetitive regurgitation and weight loss. This condition necessitates cricopharyngeal myotomy, which does not alter pharyngeal function (170,171). Ptosis develops in middle life. This disorder is inherited in an autosomal dominant pattern with complete penetrance (168).

MYOTONIA

Myotonia is a group of disorders characterized by the inability of skeletal muscle to relax after a strong contraction from either voluntary movement or mechanical stimulation. This is best demonstrated by a slow relaxation of a clenched fist. The most common myotonias include myotonic dystrophy, congenital myotonic dystrophy, and myotonia congenita. These are all rare disorders that are transmitted by autosomal dominant inheritance (4,20).

Myotonic Dystrophy

Myotonic dystrophy is a systemic disorder characterized by myotonia, progressive muscle weakness, gonadal atrophy, cataracts, frontal baldness, heart disease, and dementia (172). The genetic defect is located on chromosome 19q (19,173). The distal musculature is affected first and the myotonia begins to disappear as muscle weakness progresses. Onset is usually in late adolescence or early adulthood. In women the diagnosis is frequently made only after they have given birth to a child who is more severely involved. The disease spreads slowly proximally and involves the quadriceps, hamstrings, and eventually the hip extensors. The lower extremities are more involved than the upper extremities. The most common presenting symptoms are weakness of the hands and difficulty in walking. Patients may be unable to relax the fingers after shaking hands and may need to palmar flex the hand to open the fingers. Muscles of the face, mandible, eyes, neck, and distal limbs may also be affected. The levels of serum enzymes are normal. Muscle biopsies show type I atrophy of the muscle fibers and the presence of some internal nuclei (11). These are nonspecific findings. The “dive-bomber” pattern on EMG is diagnostic (4).

Examination reveals an expressionless face, ptosis, and a fish mouth that is difficult to close. There is marked wasting of the temporal, masseter, and sternocleidomastoid muscles. Deep tendon reflexes are diminished or lost. Slit lamp examination of the eyes reveals that most patients have lenticular opacities, cataracts, and retinopathy. Cardiac involvement is also common and includes mitral valve prolapse and arrhythmias (174). Organic brain deterioration may also occur. Frontal baldness in men and glaucoma in both genders occurs in midadult life. The course of the disease is one of steady deterioration. Most patients lose the ability to ambulate within 15 to 20 years of onset of symptoms (174). There are no characteristic orthopaedic deformities, although a slight tendency toward increased hindfoot varus has been observed (4). Life span is shortened, and death is usually caused by pneumonia or cardiac failure.

Treatment of myotonic dystrophy is primarily orthotic because the onset is usually after skeletal maturity. An AFO may be beneficial in patients with a drop foot due to weakness of the tibialis anterior and peroneal muscles.

Congenital Myotonic Dystrophy

This is a relatively common muscle disorder of variable expression that occurs most frequently with a mother who has either a forme fruste or mild clinical involvement (175,176,177 and 178). Although it has autosomal dominant transmission, it is predominantly transmitted maternally (177). This is an exception in autosomal dominant disorders and indicates additional maternal factors. Approximately 40% of patients have severe involvement or die in infancy, whereas 60% will be affected later (179). The child may have an expressionless, long, narrow face; hypotonia; delayed developmental milestones; facial diplegia; difficulty feeding due to pharyngolaryngeal palsy; respiratory failure; and mild mental retardation (180). Swallowing improves with growth but the hypotonia persists. Examination shows diffuse weakness and absent deep tendon reflexes. It can appear to be similar to spinal muscular atrophy. Ambulation is usually delayed. If the mother is the carrier, there may be other organic disorders later in life (180). Cataracts usually occur after 14 years of age.

The defective gene has been localized to chromosome 19, and a test for prenatal diagnosis is available (181). There appears to be an expansion of a highly repeated sequence of three nucleotides: cytosine, thymine, and guanine. The trinucleotide repeat is at the 3' end of a protein kinase gene on chromosome 19, which lengthens as it passed from one generation to another. The length of the sequence correlates with the severity of the disorder.

Orthopaedic problems in congenital myotonia dystrophy include congenital hip dislocation and talipes equinovarus (i.e., clubfeet). There is a tendency to develop soft tissue contractures of other major joints of the lower extremities. Clubfeet may behave like those in arthrogryposis multiplex congenita (182). Serial casting may be tried, but most require surgery, such as an extensive, complete release **[➥7.1]**. If this fails, a talectomy or Verebelyi-Ogston procedure may be useful (183). Scoliosis is also common and may require orthotic or surgical intervention (136). Because life expectancy is at least to the early adult years, aggressive orthopaedic management improves the quality of life.

Myotonia Congenita

Myotonia congenita is usually present at birth, but does not become clinically apparent until after 10 years of age. In some cases it may present as low back pain or impaired athletic ability (184,185 and 186). The severity of the myotonia varies considerably. The distribution is widespread, although it is more marked in the lower extremities than the upper extremities (187). Myotonia is most evident with initial movement. Repetitive movement decreases the myotonia and facilitates later movements. Usually, within 3 to 4 minutes stiffness disappears and normal activities including running are possible. Some patients appear herculean because of generalized muscle hypertrophy, particularly in the buttocks, thighs, and calves. Children with myotonia congenita have no associated weakness and no other

endocrine or systemic abnormalities. The disease is compatible with a normal life span. A patient's disability is not great when the limits of the disease have been accepted. Procainamide and diphenylhydantoin (Dilantin) have been used with some success to decrease the myotonia, but they should be used only in severe cases (188). There are no characteristic orthopaedic deformities (4). The disorder, a chloride channelopathy, is caused by various mutations in the skeletal muscle voltage-gated chloride channel gene *ClC-1* (189,190).

CONGENITAL MYOPATHIES AND CONGENITAL MUSCULAR DYSTROPHY

Congenital myopathies and congenital muscular dystrophy present as a hypotonic or floppy baby at birth or in early infancy. When these conditions occur in an older child, they can present as muscle weakness (191,192,193 and 194). These disorders are not well understood clinically or at the molecular level. The diagnostic categorization is not uniform or predictive. They are defined histologically from muscle biopsies (4,10,11,192,194,195 and 196). When the biopsy findings are abnormal but not dystrophic, the patient is diagnosed as having a nonspecific myopathy (4). When considerable fibrosis is present along with necrotic fibers, congenital muscular dystrophy may be diagnosed (194).

CONGENITAL MYOPATHIES

The congenital myopathies include: central core disease, nemaline myopathy (rod-body myopathy), myotubular myopathy (centronuclear), congenital fiber-type disproportion and metabolic myopathies. Differentiation between these types can be accomplished through histochemical analysis and electron microscopy of muscle biopsy specimens (4,10,11,194,195 and 196).

Central Core Disease

Central core disease is a nonprogressive autosomal dominant congenital myopathy that frequently presents in infancy with hypotonia or in young children with delayed motor developmental milestones (10,192,195,196,197 and 198). Independent ambulation may not be achieved until 4 years of age. The distribution of muscle involvement is similar to that found in Duchenne muscular dystrophy, with the trunk and lower extremities being more involved than upper extremities and the proximal muscles more than the distal muscle groups. The pelvic girdle is more involved than the shoulder. Use of the Gower maneuver is common. No deterioration in strength occurs with time, sensation is normal, and the deep tendon reflexes are either deceased or absent. Muscle wasting is a common finding, but progression of muscle weakness is rare. Muscle biopsies show mostly type I fibers containing central round or oval regions that are devoid of oxidative enzymes, adenosine triphosphate activity, and mitochondria. Serum CPK and nerve conduction studies are normal, whereas EMGs show myopathic abnormalities. Scoliosis, soft tissue contractures, congenital hip subluxation and dislocation, talipes equinovarus, pes planus, and hypermobility of joints (especially the patella) are the most common musculoskeletal problems and can require treatment (197,198,199,200 and 201). Scoliotic deformities have patterns similar to those of idiopathic scoliosis, progress rapidly, and tend to be rigid. Posterior spinal fusion and segmental instrumentation yields satisfactory results **[➥2.9]** (200). Soft tissue contractures about the hip and knee may need to be released. Clubfeet require extensive soft tissue releases to achieve correction **[➥7.1]**. Congenital dislocation of the hip can be treated by open or closed reduction techniques, but the recurrence rate is high and may require osseous procedures, such as pelvic or proximal femoral osteotomies (201). Central core disease is one of the disorders in which patients are susceptible to malignant hyperthermia. This association with malignant hyperthermia has led to linkage of both disorders to the long arm of chromosome 19 (202,203).

Nemaline Myopathy

Nemaline, or rod-body myopathy, is a variable congenital myopathy that usually begins in infancy or early childhood, with hypotonia affecting all skeletal muscles (4,10,194,195 and 196,204,205 and 206). There is no involvement of cardiac muscle. Elongated facies, with a high-arched palette and a nasal, high-pitched voice, frequently are noted. Skeletal changes may resemble those seen in arachnodactyly. Martinez and Lake, in a review of the literature regarding 99 patients, recognized these forms: neonatal (severe), congenital (moderate), and adult onset (204). The neonatal form is characterized by severe hypotonia, with 90% mortality in the first 3 years of life due to respiratory insufficiency. The mean survival after birth was 16 months. The moderate congenital form, which is the most common and prototypic, is diagnosed during or after the neonatal period and has mild or moderate hypotonia, weakness, and delayed developmental milestones. Most patients begin to walk at 2 to 4 years of age, and the weakness is usually nonprogressive or only slowly progressive. The mortality rate is about 5%. Those who die are usually neonates. Death is typically from severe involvement of the pharyngeal and respiratory muscles (207,208 and 209). The adult-onset form is characterized by proximal weakness that occasionally progresses acutely. There is no correlation between the number of rods and the phenotype in nemaline myopathy (205).

Soft tissue contractures are uncommon in nemaline myopathy. The major musculoskeletal problems are scoliosis and lumbar lordosis. Posterior spinal fusion and segmental instrumentation **[➥2.9]** may be indicated in progressive scoliotic deformities (4). Lower extremity orthoses can be beneficial in providing joint stability and aiding ambulation. Because of diminished pulmonary function and a risk for malignant hyperthermia, patients undergoing surgery require careful administration of anesthesia and monitoring (210).

Centronuclear Myopathy

Centronuclear (i.e., myotubular) myopathy is a disorder of considerable variability (10,195,196,211). Muscle biopsies demonstrate persistent myotubes of fetal life (212,213). There are X-linked recessive, autosomal recessive, and autosomal dominant forms (211,214). The defect in the X-linked recessive form is at the locus Xq28. Children have varying degrees of weakness, generally noted in infancy. Patients with X-linked recessive forms are usually severely involved and die in infancy. The autosomal recessive form is hypotonic at birth, but is not progressive and may improve with time. Most of these children are able to walk. They may have a myopathic facies, high-arched palate, and proximal muscle weakness. There is an increased incidence of cavovarus foot deformities, scoliosis, lumbar lordosis, and scapular winging (10). By late adolescence or early adult life, some patients lose their ability to ambulate.

Congenital Fiber-type Disproportion

Congenital fiber-type disproportion is characterized by generalized hypotonia at or shortly after birth. The histologic criteria from muscle biopsies to diagnose this disorder include a predominance in number and a reduction in size of type I fibers and relatively large type II fibers (10,11). It is recognized as a nonspecific pathologic change that occurs in many patients and has a myopathic, neuropathic, or central nervous system origin (10,215). The degree of weakness is variable, and sequential examinations determine the prognosis. Most patients become ambulatory. The most serious problem is life-threatening respiratory infections during the first years of life. Proximal muscle weakness is frequently associated with acetabular dysplasia (215,216). To prevent postural contractures from developing an appropriate lower extremity splint should be used until the patient achieves ambulation. Severe, rigid scoliosis can occur. Orthoses are usually ineffective, and early spinal arthrodesis may be necessary (4).

Metabolic Myopathies

These myopathies represent a broad spectrum of metabolic abnormalities that are generally clinically evident in the first two decades of life (217). These include disorders of glycogenesis and mitochondrial dysfunction. Myopathies caused by metabolic error in the first step of glycolysis are clinically associated with exercise intolerance, in which there are myophosphorylase and phosphofructokinase deficiencies, or with progressive muscle weakness and wasting, in which there are acid maltase or debrancher enzyme deficiencies (218). Defects in the second step of glycogenesis are associated with exercise intolerance. Myopathies caused by deficiencies in mitochondrial enzymes are less well defined and may be associated with severe benign exercise intolerance and progressive myopathic syndromes (218,219 and 220).

CONGENITAL MUSCULAR DYSTROPHY

Congenital muscular dystrophy is a rare disorder that generally presents as a floppy baby during infancy, with generalized muscle weakness with involvement of respiratory and facial muscles (221). It is a muscle disorder in which the muscle biopsy demonstrates dystrophic features characterized by considerable perimysial and endomysial fibrosis (194). It is different from Duchenne muscular dystrophy and Becker muscular dystrophy because it affects both males and females, is not associated with massively elevated levels of CPK, does not involve abnormalities of the dystrophin gene or protein, and is associated with a more variable prognosis (4). There are several forms of congenital muscular dystrophy. In one, the infant is weak at birth. Many have severe stiffness of joints, whereas others do not. A few infants have rapid progression and do not survive after the first year of life. Most, however, stabilize and survive into adulthood (222). Another type is seen in Japanese infants and has been termed “Fukuyama congenital muscular dystrophy.” It is characterized by a marked developmental defect in the central nervous system (223,224). There is progressive muscle degeneration and mental retardation. Severe joint contractures develop, and many involved children die in the first

decade of life. Merosin-deficient congenital muscular dystrophy is associated with white matter changes on brain MRI, and has been linked to chromosome 6q2 (225,226).

Common orthopaedic problems include congenital hip dislocation and subluxation, tendo Achillis contractures, and talipes equinovarus (Fig. 17-6). Because most survive, aggressive orthopaedic management is warranted. This may include physical therapy, orthoses, soft tissue releases, and perhaps osteotomy (4,227). Early physical therapy may be beneficial in the prevention of soft tissue contractures. Soft tissue releases in the treatment of congenital dislocation of the hip are characterized by a high incidence of recurrent dislocation (Fig. 17-7) (227). Progressive scoliosis may be initially treated by an orthosis, although most require surgical stabilization similar to other forms of muscular dystrophy.

FIGURE 17-6. A: Clinical photograph of a 3-year-old girl with congenital muscular dystrophy. Observe the position of the upper and lower extremities. **B:** The hips are flexed, abducted, and externally rotated. **C:** Moderate knee flexion contractures are present.

FIGURE 17-7. Pelvic radiograph of an 11-year-old girl with congenital muscular dystrophy, 3 years after posterior spinal fusion and Luque rod instrumentation, including the Galveston technique. She is wheelchair-dependent and has developed bilateral asymptomatic hip dislocations despite extensive soft tissue releases in early childhood.

SPINAL MUSCULAR ATROPHY

Spinal muscular atrophy is a group of disorders characterized by degeneration of the anterior horn cells of the spinal cord and occasionally the neurons of the lower bulbar motor nuclei, resulting in muscle weakness and atrophy (228,229,230,231 and 232). They are autosomal recessive disorders that occur in about 1 in 20,000 live births (233). The loss of anterior horn cells is considered to be an acute event without progression. The neurologic deterioration may stabilize and remain unchanged for long periods (234,235). The progression of muscle weakness is a reflection of normal growth that exceeds muscle reserve. Respiratory function is compromised, and atelectasis and pneumonia are the usual causes of death.

Clinical Classification

The clinical features of spinal muscular atrophy vary widely and are based on the age at onset and the functional capacity of the child at the time of diagnosis. This has led to the disorder being classified into three types. These include type I (severe), or acute Werdnig-Hoffman disease; type II (intermediate), or chronic Werdnig-Hoffman disease; and type III (mild), or Kugelberg-Welander disease (236,237). All three are a spectrum of the same disorder, but each has specific diagnostic criteria and prognosis. There is a considerable overlap between these three disorders, however, and most authors consider them to be a single disorder—spinal muscular atrophy (238). Generally, the earlier the onset, the worse the prognosis.

Type I, Acute Werdnig-Hoffman Disease

The Type I spinal muscular atrophy is characterized by clinical onset between birth and 6 months of age. These children typically have severe involvement with marked weakness and hypotonia. They usually die from respiratory failure between 1 and 24 months of age. Because of their young age and severe involvement, they usually do not require orthopaedic intervention. Pathologic multiple fractures may occur due to *in utero* osteoporosis secondary to decreased movement at birth and suggest osteogenesis imperfecta (239). These fractures heal rapidly with immobilization.

Type II, Chronic Werdnig-Hoffman Disease

The clinical onset of type II spinal muscular atrophy varies between 6 and 24 months of age. These children are less involved than those with type I spinal muscular atrophy, but are never able to walk. They may, however, live into the fourth and fifth decades.

Type III, Kugelberg-Welander Disease

The clinical onset of type III spinal muscular atrophy occurs after 2 years of age and usually before age 10 years. Walking is usually possible until late childhood or early adolescence. These patients usually are not able to run. Their motor capacity decreases with time, however, and they have difficulty rising from the floor because of weakness of the pelvic-girdle muscles; this is known as the Gower sign. There is atrophy of the lower limbs, with pseudohypertrophy of the calves. Cranial nerve muscles are usually not affected. They have normal intelligence and may function effectively in society. Both the quality and quantity of life may be extended in type II and type III spinal muscular atrophy by the use of nighttime or full-time assisted ventilation (240).

Functional Classification

Evans et al. (241) have developed a four-group functional classification that may be useful prognostically.

Group I

Children never sit independently, have poor head control, and develop early progressive scoliosis.

Group II

Children have head control and the ability to sit if placed in a sitting position but are unable to stand or walk, even with orthotics.

Group III

Children have the ability to pull to stand and to walk with external support, such as orthoses.

Group IV

Children have the ability to walk and run independently.

Other studies have supported the use of this classification (230,235,237,242).

Genetic and Molecular Biology Studies

Linkage studies have established that the genetic homogeneity for the three types of spinal muscular atrophy occur at the same locus on chromosome 5q (19,228,233,243,244 and 245). Two genes have been found to be associated with disease, the survival motor neuron gene (*SMN*) and the neuronal apoptosis inhibitory protein gene (*NAIP*) (229,246,247). The presence of large-scale deletions involving both genes corresponds to a more severe phenotype. Prenatal diagnosis is available with the use of polymerase chain reaction amplification assays. No specific gene therapy is available.

Clinical Features

The clinical features of spinal muscular atrophy vary according to the clinical classification. The clinical characteristics common to all groups are relatively symmetric limb and trunk weakness and muscle atrophy that affects the lower extremities more than the upper extremities and the proximal muscles more than the distal muscles. Hypotonia and areflexia are present. Sensation and intelligence are normal. In infants, gross fasciculations of the tongue and fine tremors of the fingers are commonly present (234,248). The only muscles not involved are the diaphragm, sternothyroid, sternohyoid, and the involuntary muscles of the intestine, bladder, heart, and sphincters (228,237).

Diagnostic Studies

The studies used in the initial diagnosis of spinal muscular atrophy include laboratory studies, EMG, nerve conduction studies, and muscle biopsies. Hematologic studies in spinal muscular atrophy are not particularly useful (232). The CPK and aldolase levels are normal to only slightly elevated. Electrophysiologic studies, such as EMG, in patients with spinal muscular atrophy show typical neuropathic changes, such as increased amplitude and duration of response (232). Nerve conduction studies in spinal muscular atrophy are typically normal. Muscle biopsies are usually diagnostic, demonstrating muscle fiber degeneration and atrophy of fiber groups (232). However, with the recent advent of genetic testing for this disorder muscle biopsy is usually not necessary.

Radiographic Evaluation

There are no specific radiographic characteristics that are useful in making the diagnosis of spinal muscular atrophy. The most common radiographic abnormalities are nonspecific and include hip subluxation or dislocation and progressive spinal deformity (232). Bowen and Forlin (249) recommended that spinal radiographs, posteroanterior and lateral, be obtained in the sitting position to avoid the compensations seen in the standing and supine positions.

Treatment

The major orthopaedic abnormalities associated with spinal muscular atrophy include the presence of soft tissue contractures of the lower extremities, hip subluxation and dislocation, and spinal deformity (231,232,235).

Lower Extremity Soft Tissue Contractures

Soft tissue contractures of the lower extremities are the result of progressive muscle degeneration and replacement with fibrous tissue. Ambulation may be promoted and soft tissue contractures delayed by the use of orthoses, such as KAFOs (250). Contractures tend to occur most frequently after the child becomes wheelchair-bound. The prolonged sitting posture enhances hip and knee flexion contractures. Hip soft tissue contractures may also result in abnormal growth of the proximal femur and predisposes the patient to coxa valga and progressive hip subluxation. Soft tissue contractures without an associated osseous deformity usually do not require treatment. Even when they are released, the sitting posture of the child enhances their recurrence.

Hip Subluxation and Dislocation

Progressive hip subluxation leading to dislocation occurs predominantly in spinal muscular atrophy types II and III. It is important that this be prevented to provide comfort, sitting balance, and maintain pelvic alignment. A comfortable sitting posture is important if the adolescent or young adult is to function in society. Periodic anteroposterior radiographs of the pelvis, beginning in midchildhood to late childhood, are important to allow early recognition of coxa valga and subluxation. Once diagnosed, it is usually progressive because of the continued muscle weakness and soft tissue contractures. Procedures that have been used with some success in the past include soft tissue releases, such as adductor tenotomy, iliopsoas recession, and medial hamstring lengthening **[➥3.17,3.18]**. This restores some balance to the proximal musculature. Most children will benefit by varus derotation osteotomy if the hip is severely subluxated **[➥4.2,4.3]** (232). If the hip is dislocated, an open reduction with capsulorrhaphy **[➥3.2]** and pelvic osteotomy of the Chiari type may be beneficial **[➥3.11]**. The usual rotation osteotomies (e.g., Salter, Sutherland, Steel) sacrifice posterior coverage to gain lateral (superior) and anterior coverage. In the child who will be predominantly in a sitting position, this lack of posterior coverage may predispose the patient to a posterior subluxation. Therefore, the pelvic osteotomy method chosen must allow improved posterior coverage. This is usually accomplished with the Chiari osteotomy **[➥3.11]** or perhaps a shelf procedure **[➥3.12]**. Even after satisfactory alignment of the hip, resubluxation and dislocation can occur due to the progressive degeneration of the proximal muscles (251). These children require annual clinical and radiographic evaluation to assess the hips postoperatively. Thompson and Larsen (251) reported four cases of recurrent hip dislocation after corrective surgery. Two patients had second operations followed by recurrent dislocation. They questioned the advisability of treatment of hip dislocations in patients with spinal muscular atrophy.

Spinal Deformity

Most children who survive into adolescence develop a progressive spinal deformity. This occurs in 100% of the spinal muscular atrophy children and adolescents with type II and most of those with type III, especially when they lose their ability to walk (235,241,249,252,253,254 and 255). As in other neuromuscular disorders, as the curve progresses there is an adverse effect on pulmonary function (249,255).

The deformity typically begins in the first decade due to severe truncal weakness. Once the deformity begins, it is steadily progressive and can reach severe magnitude unless appropriately managed. The thoracolumbar paralytic C-shaped and single thoracic patterns, usually curved to the right, are most common. About 30% of children also have an associated kyphosis, which is also progressive (253,256). In type II spinal muscular atrophy, the mean expected increase in scoliosis is 8.3 degrees per year, whereas in type III it is 2.9 degrees per year.

Orthotic Management. Bracing is ineffective in preventing or halting the progression of scoliosis or kyphosis in children with spinal muscular atrophy (231,235,241,242,253,254,256,257,258,259 and 260). However, it can be effective in improving sitting balance and slowing the rate of progression in young ambulatory children (249,260). This has the advantage of allowing them to reach an older, more suitable age for undergoing surgical intervention. Bowen and Forlin (249) recommended orthotic treatment to help maintain posture or slow curve progression in a child 9 years of age or younger with a deformity between 20 and 40 degrees. The thoracolumbar spinal orthosis (TLSO) is the most common orthosis used in children with spinal muscular atrophy. This orthosis must be carefully molded to distribute the forces over a large surface area to prevent skin irritation and breakdown, a major problem for children with neuromuscular diseases.

Furumasu et al. (261) found that orthoses decreased function because of less spinal flexibility.

Occasionally, wheelchair modifications can also be effective in controlling truncal alignment and improving sitting posture (232). This also may be beneficial in slowing the rate of curve progression.

Surgery. The criteria for surgical spinal stabilization in spinal muscular atrophy include curve magnitude greater than 40 degrees, satisfactory flexibility on supine lateral bending radiographs, and an FVC greater than 40% of normal (232). When these criteria are met, a posterior spinal fusion using segmental spinal instrumentation techniques, such as Luque rod instrumentation and sublaminar wires **[➥2.5,2.6]**, is used (Fig. 17-8) (100,109,111,112,231,235,242,249,252,253 and 254,257,258 and 259,261,263,264). Other segmental systems, such as Cotrel-Dubousset, TSRH, Isola, and others, can also be utilized. These, however, do not usually distribute the forces of instrumentation throughout the spine as well as the Luque rods with sublaminar wiring. The spine is usually osteopenic, and there is a risk for bone failure unless the forces of instrumentation are minimized through extensive distribution. Fixation to the pelvis using the Galveston technique (113,114) or other techniques is common (115,263). In most children who are nonambulatory and have pelvic obliquity, fusion to the pelvis provides improved spinopelvic stability and alignment. Anterior spinal fusion and instrumentation are rarely indicated because of the compromised pulmonary status of these children. This may predispose the patient to pulmonary complications postoperatively (242,257). Anterior fusions alone are also too short and do not adequately stabilize the entire spine. When performed, it is combined with a simultaneous or staged posterior spinal fusion, usually with Luque rod instrumentation (100,249). Whatever posterior instrumentation system is used, it is important that no postoperative immobilization be necessary; this enhances sitting balance and pulmonary status and makes transfers easier.

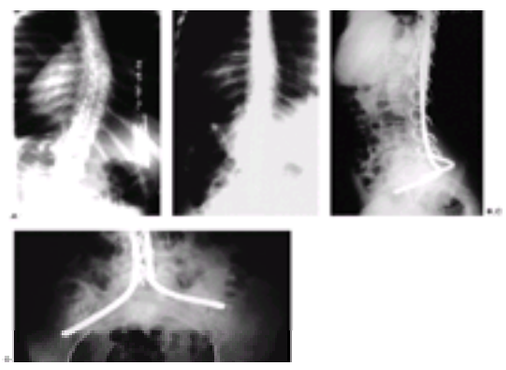

FIGURE 17-8. A: Sitting posteroanterior spinal radiograph of an 18-year-old woman with spinal muscular atrophy. A slowly progressive scoliosis has affected her wheelchair sitting balance. **B:** Postoperative radiograph after posterior spinal fusion and Luque rod instrumentation using the Galveston technique provided almost complete correction of the spinal deformity. Thirteen years postoperatively she functions independently despite the subsequent need for a tracheostomy and ventilator support. **C:** Lateral view demonstrates preservation of lumbar lordosis, which is important for proper sitting balance. **D:** Anteroposterior view of the pelvis shows proper positioning of the Luque rods in the ilium. They should penetrate as far into the ilium as possible for maximum strength.

Decreased function has been observed after spine fusion (252,261). Although spinal alignment and sitting balance are improved, the loss of spinal mobility decreases the function of the upper extremities and activities of daily living, such as performing transfers and personal hygiene. Askin et al. (262) recommended early surgery to preserve function. They too found that patient function may not improve following surgery, but the cosmetic results were gratifying, and there may be improved caregiver ability. However, Bridwell et al. (109) reported improved function, self-image, cosmesis, and caregiver ability in 21 patients with spinal muscular atrophy followed for a mean of 7.8 years postoperatively (range 2 to 12.6 years).

Operative complications are similar to other neuromuscular disorders. These include excessive blood loss, pulmonary complications, neurologic injury, wound infection, loss of fixation due to osteopenia, pseudarthrosis, and death (100,111,127,252,254,256,257,259,263). The use of segmental spinal instrumentation techniques and aggressive preoperative and postoperative respiratory therapy can result in decreased complications. Hypotensive anesthesia and intraoperative spinal cord monitoring may be beneficial in decreasing intraoperative blood loss and neurologic injury. Noordeen et al. reported that a 50% decrease in amplitude may be indicative of an impending neurologic injury (127).

FRIEDREICH ATAXIA

Spinocerebellar degenerative diseases are a group of relatively uncommon disorders that are hereditary and progressive. Friedreich ataxia is the most common form and has orthopaedic implications because of its high incidence of scoliosis. Friedreich ataxia is characterized by slow, progressive spinocerebellar degeneration. It occurs in about 1 in 50,000 live births (265). It is autosomal recessive and occurs most commonly in North America in people of French Canadian heritage. Males and females are affected equally.

Clinical Features

Friedreich ataxia is characterized by a clinical triad consisting of ataxia (which is usually the presenting symptom), areflexia of the knees and ankles, and a positive plantar response, or the Babinski sign (232,266). Geoffroy et al. (267) established strict criteria for the clinical diagnosis of typical Friedreich ataxia. This has been modified by Harding (268). The primary symptoms and signs that occur in all involved patients include onset before the age of 25 years; progressive ataxia of limbs and gait; absent knee and ankle deep tendon reflexes; positive plantar response; decreased nerve conduction velocities in the upper extremities, with small or absent sensory action potentials; and dysarthria. The secondary symptoms and signs that are present in more than 90% of cases include scoliosis, pyramidal weakness in the lower extremities, absent reflexes in the upper extremities, loss of position and vibratory sense in the lower extremities, and an abnormal ECG. Accessory symptoms and signs present in fewer than 50% of cases include optic atrophy, nystagmus, distal weakness and wasting, partial deafness, pes cavus, and diabetes mellitus.

The mean age at onset is between 7 and 15 years, although the range is wide, from 4 years to as late as 25 years of age (232,266,267,268,269,270 and 271). Most involved individuals lose their ability to walk and are wheelchair-bound by the second or third decade. Labelle et al. (272) demonstrated that the muscle weakness is always symmetric, initially proximal rather than distal, more severe in the lower extremities, and rapidly progressive when the patients become nonambulatory. The first muscle to be involved is the hip extensor (gluteus maximus). They also demonstrated that muscle weakness is not the primary cause of loss of ambulatory function. Ataxia and other factors also play a role. Death usually occurs in the fourth or fifth decade, due to progressive hypertrophic cardiomyopathy, pneumonia, or aspiration (266,268,273).

Nerve conduction studies show decreased or absent sensory action potentials in the digital and sural nerves. Conduction velocity in the motor and sensory fibers of the median and tibial nerves are moderately slowed. An EMG shows a loss of motor units and an increase in polyphasic potentials. The ECG in adults typically shows a progressive hypertrophic cardiomyopathy. Hematologic tests such as CPK are normal, but there is increased incidence of clinical and chemical diabetes mellitus.

Genetic and Molecular Biology Studies

Chamberlain et al. have demonstrated that individuals with Friedreich ataxia have a defect on chromosome 9q13 (274). Additional studies have identified two loci on chromosome 9 (*D9S5* and *D9S15*) that are linked to Friedreich ataxia (265). It is now known that Friedreich is due to a trinucleotide repeat of GAA, which results in loss of expression of the frataxin protein. There is an inverse relationship between number of trinucleotide repeats and age of onset of the disease (275).

Treatment

The major orthopaedic problems in Friedreich ataxia are pes cavovarus, spinal deformity, and painful muscle spasms (232,266).

Pes Cavovarus

Pes cavovarus is common in patients with Friedreich ataxia. It is slowly progressive and tends to become rigid. When combined with ataxia, it can result in decreased ability to stand and walk. Orthotic management is usually ineffective in preventing the deformity, but an AFO can be used after surgery to stabilize the foot and ankle and to prevent recurrent deformity. Surgical procedures can be used in ambulatory patients to improve balance and walking ability. Procedures that have been shown to be effective include tendo Achillis lengthening and tibialis posterior tenotomy, lengthening, or anterior transfer to the dorsum of the foot **[➥7.16,7.19]** (232,266). The tibialis anterior muscle may also be involved and may require either tenotomy, lengthening, or centralization to the dorsum of the foot to prevent recurrence. In fixed, rigid deformities, a triple arthrodesis **[➥7.9]** may be necessary to achieve a plantigrade foot.

Spinal Deformity

Scoliosis occurs in essentially all patients with Friedreich ataxia (266,268,269,271,276,277). The age at onset is variable and usually begins while the patient is still ambulatory. The incidence of curve progression has been shown to correlate to the age at clinical onset of the disease process. Labelle et al. (277) demonstrated that when disease onset is before 10 years of age and scoliosis occurs before 15 years of age, most patient curves progress to greater than 60 degrees and require surgical intervention. When the disease onset is after 10 years of age and the scoliosis occurs after 15 years of age, curve progression is not as severe; most do not reach 40 degrees by skeletal maturity or progress thereafter. There was no correlation between curve progression, degree of muscle weakness, level of ambulatory function, and duration of the disease process. The patterns of scoliosis in patients with Friedreich ataxia are similar to those of adolescent idiopathic scoliosis, rather than to those of neuromuscular scoliosis. The pathogenesis of scoliosis in Friedreich ataxia appears to be not muscle weakness but the ataxia that causes a disturbance of equilibrium and postural reflexes. Double major (i.e., thoracic and lumbar) and single thoracic or thoracolumbar curves are the most common curve patterns (269,270,277,278). Only a few patients have lumbar or long C-shaped thoracolumbar curves. About two-thirds of patients with Friedreich ataxia develop an associated kyphosis greater than 40 degrees (270,277). The treatment of scoliosis in Friedreich ataxia can be either by orthotic or surgical methods.

Orthoses. A thoracolumbar spinal orthosis may be tried in ambulatory patients having 25- to 40-degree curves. It is usually not well tolerated, but it may slow the rate of progression, although rarely does it stabilize the curve (266,269,278). In ambulatory patients, an orthosis may interfere with walking because it prevents compensatory truncal movement necessary for balance and movement.

Surgery. In progressive curves greater than 60 degrees, especially in older adolescents confined to a wheelchair, a single-stage posterior spinal fusion stabilizes the curve and yields moderate correction. Curves between 40 and 60 degrees can be either observed or treated surgically, depending on the patient's age at clinical onset, the age when scoliosis was first recognized, and evidence of curve progression. Posterior segmental instrumentation using Harrington rods and sublaminar wires **[➥2.3]** or Luque rod instrumentation **[➥2.5]** has been demonstrated to be effective in achieving correction and a solid arthrodesis (100,111,269,270,276,278). Other segmental systems (e.g., Cotrel-Dubousset, Isola, TSRH) should also be effective **[➥2.9]**. Fusions are typically from the upper thoracic (T2 or T3) to lower lumbar regions. Fusion to the sacrum is usually unnecessary, except in C-shaped thoracolumbar curves with associated pelvic obliquity (270,278). Autogenous bone supplemented with banked bone, when necessary, usually produces a solid fusion. Anterior surgery, with or without instrumentation, usually followed by a posterior spinal fusion and instrumentation is limited to rigid curves greater than 60 degrees associated with poor sitting balance (278). Surgery is performed only after a thorough cardiopulmonary evaluation and under careful intraoperative and postoperative monitoring. Postoperative immobilization should be avoided. Vertebral osteopenia and spinal stenosis is not a problem in Friedreich ataxia.

Painful Muscle Spasms

Painful muscle spasms occur in some patients with Friedreich ataxia (232). They usually begin in the late adolescent or early adult years and worsen with time. The spasms are characterized by a sudden onset and short duration. The hip adductors and the knee extensors are commonly involved. Initial treatment is usually by massage, heat, and perhaps muscle relaxants, such as diazepam and baclofen. In adults, if the adductor or quadriceps spasms are interfering with perineal care or sitting balance, the patient may benefit by tenotomies. This is rarely necessary.

HEREDITARY MOTOR SENSORY NEUROPATHIES

HMSNs are a large group of variously inherited neuropathic disorders (232,266,279). Charcot-Marie-Tooth disease is the prototype, but there are other disorders with similar but different manifestations.

Classification

The classification system for HMSN is presented in Table 17-2. HMSN types I, II, and III are encountered predominantly in pediatric orthopaedic and neuromuscular clinics, whereas HMSN types IV, V, VI, and VII tend to be late-onset and occur in adults (232).

Type	Terminology	Inheritance
I	Charcot-Marie-Tooth syndrome (hypertrophic form) or Roussy-Levy syndrome (areflexic dystaxia)	Autosomal dominant
II	Charcot-Marie-Tooth syndrome (neuronal form)	Variable
III	Dejerine-Sottas disease	Autosomal recessive
IV	Refsum disease	
V	Neuropathy with spastic paraplegia	
VI	Optic atrophy with peroneal muscle atrophy	
VII	Retinitis pigmentosa with distal muscle weakness and atrophy	

TABLE 17-2. CLASSIFICATION OF HEREDITARY MOTOR SENSORY NEUROPATHIES

HMSN type I is an autosomal dominant disorder and includes disorders referred to as peroneal atrophy, Charcot-Marie-Tooth disease (hypertrophic form), or Roussy-Levy syndrome. It is a demyelinating disorder that is characterized by peroneal muscle weakness, absent deep tendon reflexes, and slow nerve conduction velocities. HMSN type II is the neuronal form of Charcot-Marie-Tooth disease. It is characterized by persistently normal reflexes, sensory and motor nerve conduction times that are only mildly abnormal, and variable inheritance patterns (232). These two types are clinically similar, although HMSN type II often causes less severe weakness and has a later onset than HMSN type I. HMSN type III is the autosomal recessive disorder, Dejerine-Sottas disease. This disorder begins in infancy and is characterized by more severe alterations in nerve conduction and by sensory disturbances that are more extensive than in HMSN types I and II. The HMSN types I and III are due to demyelinization of peripheral nerves. These are characterized by muscle weakness in the feet and hands, absent deep tendon reflexes, and diminution of distal sensory capabilities, particularly light touch position and vibratory sensation (232).

The four additional types are late onset and rarely seen by pediatric orthopaedists or in pediatric neuromuscular clinics: HMSN type IV, Refsum disease, is characterized by excessive phytanic acid; HMSN type V is an inherited spastic paraplegia, with distal weakness in the limbs presenting in the second decade of life with an awkward gait and equinus foot deformities; HMSN type VI is characterized by optic atrophy in association with peroneal muscle atrophy; and HMSN type VII has retinitis pigmentosa, with distal weakness in the limbs and muscle atrophy.

Diagnostic Studies

Diagnosis of HMSN is made by physical examination in combination with EMG with nerve conduction studies and genetic testing. The EMG findings in HMSN show typical neuropathic changes, with increased amplitude and duration of response. Nerve conduction studies show marked slowing of the rate of impulse conduction in the involved muscles. A biopsy specimen of muscles such as the gastrocnemius demonstrates typical neuropathic findings, including atrophy of the fiber group, with

all of the fibers in an abnormal group having uniformly small diameter. A biopsy specimen of a peripheral nerve, usually the sural nerve, shows typical demyelinization, confirming the diagnosis of peripheral neuropathy.

Genetic and Molecular Biology Studies

Many individuals with the HMSN type I have a DNA duplication of a portion of the short arm of chromosome 17 in the region of p 11.2 to p 12 (20,280,281 and 282). Additional studies have shown a human peripheral myelin protein-22 gene to be contained within the duplication (283,284 and 285). It is thought that the abnormality in the peripheral myelin protein-22 gene, which encodes the myelin protein, has a causative role in Charcot-Marie-Tooth disease. Either a point mutation in peripheral myelin protein-22 or duplication of the region that contains the peripheral myelin protein-22 gene can result in the disorder (286).

Treatment

Children with HMSN typically present with gait disturbance or foot deformities. The severity of involvement is variable. In severe involvement, there may be proximal muscle weakness. The major orthopaedic problems include pes cavovarus, hip dysplasia, spinal deformity, and hand and upper extremity dysfunction.

Pes Cavovarus

The pathogenesis of cavovarus deformities in children with HMSN and other neuromuscular disorders is becoming better understood (287,288,289,290,291 and 292). The components of the pes cavovarus deformity include claw toes; plantar flexed first metatarsal with adduction and inversion of the remaining metatarsals; midfoot malposition of the navicular, cuboid and cuneiforms, leading to a high arch (cavus); and hindfoot varus malposition between the talus and calcaneus (Fig. 17-9). Initially HMSNs affect the more distal muscles. The mildest cases affect the toes and forefoot, whereas the midfoot and hindfoot are progressively affected with progression of the disease process. In a computed tomography study of 26 patients with HMSN I, II, or III, Price et al. (293) found that the interossei and lumbrical muscles of the feet demonstrated earlier and more severe involvement compared with the extrinsic muscles. These intrinsic muscles have the most distal innervation. Even with minimal weakness the invertor muscles, such as the tibialis anterior and tibialis posterior muscles, are stronger than the evertors, such as the peroneus longus; this relation favors the development of adduction and varus deformities.

FIGURE 17-9. A: Front view of the lower legs and feet of a 16-year-old boy with hereditary motor sensory neuropathy type I (i.e., Charcot-Marie-Tooth disease). His calves are thin, and he has mildly symptomatic cavus feet. Clawing of the toes is minimal. **B:** Posterior view demonstrates moderate heel varus. **C:** The cavus foot deformity is most apparent when viewed from the medial side. A mild flexion deformity of the great toe interphalangeal joint is present.

Pes cavovarus deformities are progressive, but the rate is variable, even among involved family members. Initially, the deformity is flexible but later becomes rigid. Shapiro and Specht point to the plantar flexed first metatarsal as the key finding (232). As the first metatarsal becomes increasingly plantar flexed, this is followed by increasing hindfoot varus and forefoot and midfoot supination and cavus. The block test is useful in defining the mobility of the remainder of the foot in children with a rigid plantar flexed first metatarsal (291).

The goals in the treatment of foot deformities in children with HMSN include maintenance of a straight, plantigrade, and relatively flexible foot during growth (288). This maximizes function and minimizes the development of osseous deformities that may require more extensive surgery in adolescence and early adult years, such as triple arthrodesis.

The treatment options for the management of foot deformities include: plantar release, plantar-medial release, tendon transfers, calcaneal osteotomy, midtarsal osteotomy, triple arthrodesis, and correction of toe deformities.

Plantar Release. In children younger than 10 years of age who have a mild cavovarus deformity, a plantar release may be beneficial in correcting the plantar flexed first metatarsal and providing correction of the associated flexible hindfoot and midfoot deformities (294). In the radical plantar release described by Paulos et al. (291), selective Z-lengthening of the long toe flexor tendons and tibialis posterior tendon is performed if there is a bowstring effect after plantar release.

Plantar-medial Release. If the hindfoot deformity in the child younger than 10 years of age is rigid, leading to fixed varus deformity, the plantar release may be combined with a medial release (291). The medial structures to be released include the ligamentous and capsular structures between the talus and calcaneus **[➥ 7.11]** (except the posterior talocalcaneal ligament), and the capsule of the talonavicular joints. The navicular is then reduced onto the head of the talus and secured with a smooth Steinmann pin. The posterior ankle and subtalar joint ligaments and the tendo Achillis are not disturbed because they are necessary for counter-resistance during postoperative serial casting. Once the incision has healed a series of corrective weightbearing casts are applied. Excellent correction of the entire foot has been reported after this technique.

Tendon Transfers. In children and adolescents who have a flexible cavovarus deformity in which active inversion is associated with relative weakness of the evertor muscles, a transfer of the tibialis anterior tendon to the dorsum of the midtarsal region in line with the third metatarsal may be helpful (295). The transfer is designed to balance strength, but the foot must be aligned initially by a plantar release and perhaps the plantar-medial release.

Other tendinous procedures that may be used depend on the individual needs of the patient. These may include tendo Achillis lengthening **[➥7.16]**, anterior transfer at the tibialis posterior tendon **[➥7.19]**, long toe extensors to the metatarsals or midfoot, and flexor-to-extensor tendon transfers for claw toes (288,291,295,296). Tendo Achillis lengthening is rarely necessary, as the equinus is due to the plantar flexed first metatarsal and forefoot. The hindfoot is typically in a calcaneus position.

Calcaneal Osteotomy. In children who are younger than 10 years of age and who have mild but fixed deformity, a calcaneal osteotomy may be beneficial in correcting the varus deformity of the hindfoot (232). This osteotomy does not interfere with growth because it is not made through a cartilaginous growth area. To allow lateral translation, the osteotomy is cut slightly obliquely, passing from a superior position on the lateral surface to a more inferior position on the medial surface. It is possible to translate the distal fragment as much as one-third of its transverse diameter, thus allowing conversion of weightbearing from varus to slight valgus. In patients who are older than 10 years of age or who are more severely affected, a lateral closing-wedge calcaneal osteotomy, with lateral translation of the distal and posterior fragments, is performed (Fig. 17-10) (232). In both procedures the osteotomy is stabilized with staples or Steinmann pins.

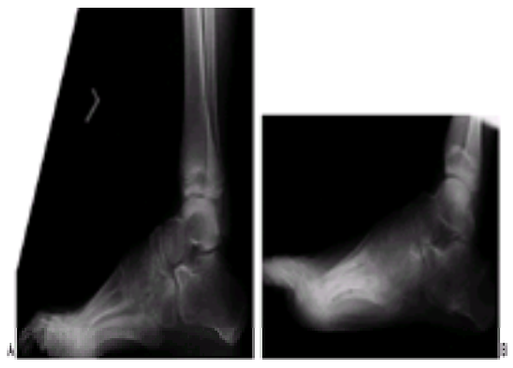

FIGURE 17-10. A: Moderate cavovarus deformity of the left foot in a 14-year-old male with Charcot-Marie-Tooth disease. He was managed by a closing wedge valgus osteotomy at the calcaneus, an opening wedge, plantar-based osteotomy of the medial cuneiform, and soft tissue balancing. **B:** Postoperatively, the cavovarus deformity has been improved. He is a brace-free ambulator due to restoration of muscle balance.

Midtarsal Osteotomy. The midtarsal osteotomy provides correction by removal of a dorsal and slightly laterally based wedge, with the proximal osteotomy cut through the navicular and cuboid bones and the distal cut through the cuboid and three cuneiforms (296). Moderate deformities can be corrected satisfactorily with this procedure, especially if it is augmented with a plantar release, calcaneal osteotomy, and perhaps an anterior transfer of the tibialis anterior tendon. Equinus deformities of the midfoot and varus deformities of the forefoot can be corrected with appropriate wedge resections. Growth retardation and limitation of mobility are minimal compared with after a triple arthrodesis.

Triple Arthrodesis. In adolescents who have reached skeletal maturity and have a severe deformity, walk with difficulty, and cannot run, a triple arthrodesis **[➥7.9]** may be performed. Every attempt should be made to avoid this procedure because of the associated complications of undercorrection, overcorrection, pseudarthrosis of the talonavicular joint, and degenerative changes in the ankle and midfoot joints (297,298,299,300 and 301).

Wetmore and Drennan (300) reported unsatisfactory results in 23 of 30 feet (16 patients) at a mean follow-up at 21 years. The progressive muscle imbalance resulted in recurrent pes cavovarus deformities. There was also an increased incidence of degenerative osteoarthritis of the ankle as a consequence to the deformity and the loss of subtalar joint motion. They felt triple arthrodesis should be limited to patients with severe, rigid deformities. Saltzman et al. reported similar results in 67 feet in 57 patients, including 6 feet in patients with Charcot-Marie-Tooth disease at 25 and 44 years of mean follow-up (302). However, 95% of the patients were satisfied with their clinical results. Ghanem et al. also reported long-term satisfactory results in children who had a triple arthrodesis (288).

The Ryerson triple arthrodesis is preferred because the joint surfaces of the talocalcaneal, talonavicular, and calcaneal cuboid joints are removed, along with appropriate-sized wedges to correct the various components of the hindfoot and midfoot deformities (Fig. 17-11) (296). In patients who have marked equinus of the midfoot and forefoot in relation to a relatively well-positioned hindfoot, the Lambrinudi triple arthrodesis may be performed (296,303). Once an arthrodesis has been performed to straighten the foot, tendon transfers to balance muscle power are of great importance.

FIGURE 17-11. A: Standing anteroposterior radiograph of severe cavovarus deformity of the right foot in a 14-year-old male with Charcot-Marie-Tooth disease. **B:** Lateral radiograph demonstrates a varus hindfoot and midfoot, and a plantar flexed first metatarsal. **C:** Postoperative standing anteroposterior radiograph following a Ryerson triple arthrodesis, soft tissue balancing, and correction of his claw toe deformities. **D:** Lateral radiographs show markedly improved alignment.

Toe deformities in adolescents or after a triple arthrodesis may be corrected by proximal and distal interphalangeal fusion or flexor-to-extensor tendon transfer (304). The great toe may require an interphalangeal joint fusion and transfer of the extensor hallucis longus from the proximal phalanx to the neck of the first metatarsal (Jones procedure). The latter then serves as a foot dorsiflexor.

Hip Dysplasia

Hip dysplasia in HMSN occurs in about 6 to 8% of involved children (305,306). Occasionally, hips may be dislocatable at birth, although the neuropathy does not become apparent for several years. It is more likely to occur in HMSN type I than HMSN type II because of the more severe neurologic involvement in the former. Walker et al. (306) thought that the slight muscle weakness about the hip in growing children with HMSN may be sufficient to distort growth and development, leading to dysplasia. Usually, hip dysplasia is diagnosed between 5 and 15 years of age because of mild discomfort (305,306,308). Dysplasia may be present in asymptomatic patients, however (Fig. 17-12). Annual anteroposterior radiographs of the pelvis have been recommended to allow early diagnosis and treatment. Typical radiographic findings include acetabular dysplasia, coxa valga, and subluxation. The treatment of HMSN hip dysplasia includes soft tissue releases to correct contractures and restore muscle balance and pelvic or proximal femoral varus derotation osteotomies or both to stabilize and adequately realign the hip (305,307,308,309 and 310). The type of pelvic osteotomy is determined by the patient's age and severity of the dysplasia. Rotational osteotomies (Salter, Steel) **[➥3.5,3.10]** are useful in many children with mild dysplasia, while periacetabular osteotomies are useful in adolescents and young adults, and the Chiari osteotomy **[➥3.11]** when there is severe dysplasia.

FIGURE 17-12. Anteroposterior pelvic radiograph of a 15-year-old girl with Charcot-Marie-Tooth disease. Asymptomatic acetabular dysplasia of the left hip is visible. The medial joint is slightly widened. The Shenton line is disrupted, and the center-edge angle is 16 degrees. This condition was first observed 6 years previously and did not progress.

Spinal Deformity

Scoliosis was initially thought to occur in about 10% of children with HMSN (311,312). These children were usually ambulatory, with age of onset of spinal deformity of about 10 years. A study by Walker et al. (313) found a 37% incidence of scoliosis or kyphoscoliosis in involved children. The incidence increases to 50% in those who were skeletally mature. Spinal deformity is more common in girls and HMSN type I. Curve progression requiring orthoses or surgery is uncommon. The curve patterns and management are similar to those for idiopathic adolescent scoliosis, except for an increased incidence of kyphosis. As a consequence, orthotic management can be effective in arresting progression of the deformity. If progression reaches 45 to 50 degrees, a posterior spinal fusion and segmental spinal instrumentation can effectively stabilize and partially correct the deformity **[➥2.9]** (311,312). Intraoperative spinal cord monitoring with somatosensory cortical evoked potentials may show no signal transmission. This is due to the demyelination of the peripheral nerves and perhaps to degeneration of the dorsal root ganglion and dorsal column of the spinal cord (314). A wake-up test may need to be performed.

Hand and Upper Extremity Dysfunction

The upper extremities are involved in about two-thirds of individuals with HMSN (315,316). The involvement tends to be milder, however, and does not appear until a later age. Intrinsic muscle weakness with decreased stability is a relatively common finding. In a study of 68 patients with Charcot-Marie-Tooth disease, the mean age at onset of symptoms in the hands and upper extremities was 19 years. Intrinsic muscle function was initially impaired, and patients became aware of motor weakness and a lack of dexterity. Sensory changes such as numbness are usually present concomitantly. Physical and occupational therapy may be helpful. In some patients operative intervention, such as transfer of the flexor digitorum sublimis to restore opposition, nerve compression releases, soft tissue contracture releases, and joint arthrodeses, may be effective in improving function. Preoperative EMG has been shown to aid in selecting optimal forearm muscles for tendon transfers to the hand (317).

POLIOMYELITIS

Acute poliomyelitis results from an acute viral infection, with localization in the anterior horn cells of the spinal cord and certain brain stem motor nuclei. It is caused by one of three polioviruses known as Brunhilde (type 1), Lansing (type 2), and Leon (type 3). Humans are the natural host for poliovirus, transmitting the disease by the oropharyngeal route. Each one of the polioviruses has varying virulence. Most poliovirus infections have an abortive course, with only mild gastrointestinal symptoms. Fewer than 1% of infections develop the paralytic form of the disease. Development of prophylactic vaccines has greatly reduced the incidence of polio, although the disease remains a major health problem in developing countries. Fewer than 10 cases occur in the United States annually, and these most commonly result from the use of the active oral polio vaccine (318,319).

Pathology

The poliovirus invades the body through the oropharyngeal route and multiplies in the gastrointestinal tract lymph nodes before spreading to the central nervous system by the hematogenous route. The incubation period ranges from 6 to 20 days. Motoneuron cells of the anterior horn cells of the spinal cord and brain stem are acutely attacked. In the spinal cord, the lumbar and cervical regions are particularly involved. The medulla, cerebellum, and midbrain may be involved also. Except for the motor areas, the white matter of the spinal cord and the cerebral cortex are uninvolved.

Damage to the anterior horn cells may be due directly to viral multiplication, toxic byproducts of the virus, or indirectly from ischemia, edema, and hemorrhage in the glial tissues surrounding the anterior horn cells. In addition to acute inflammatory cellular reaction, edema with perivascular mononuclear cuffing occurs.

The inflammatory response gradually subsides, and the necrotic ganglion cells are surrounded and partially dissolved by macrophages and neutrophils. After 4 months, the spinal cord is left with residual areas of gliosis and lymphocytic cell collections occupying the area of the destroyed motor cells. Evidence exists of continuous disease activity in spinal cord segments examined two decades after the onset of the disease. Histopathologic sections demonstrate a loss or atrophy of motor neurons, severe reaction gliosis, and mild-to-moderate perivascular interparenchymal inflammation, with sparing of corticospinal tracts. Skeletal muscle demonstrates gross atrophy and replacement by fat and connective tissue histologically. The percentage of motor units destroyed in an individual muscle varies markedly, and the resultant clinical weakness is proportionate to the number of lost motor units. Sharrard has stated that clinically detectable weakness is present only when more than 60% of the motor nerve cells supplying the muscle have been destroyed (320). Involved muscles can range from those of one extremity to those of all four extremities, the trunk, and the bulbar musculature.

Muscles innervated by the cervical and lumbar segments are most frequently involved. However, involvement occurs twice as frequently in the lower extremity than in the upper extremity muscles. Sharrard (321,322) combined clinical and histologic studies which demonstrated that muscles with short motor nerve cell columns often are severely paralyzed, whereas those with long motor cell columns are more frequently left paretic or weak. The quadriceps, tibialis anterior, medial hamstrings, and hip flexors are the lumbar innervated muscles most frequently involved. The deltoid, triceps, and pectoralis major are most frequently affected in the upper extremities. The sacral nerve roots are usually spared, resulting in the characteristic preservation of the intrinsic muscles of the foot (323).

Recovery of muscle function depends on return to function of those anterior horn cells damaged but not destroyed. Clinical recovery begins during the first month after the acute illness and is nearly complete by the sixth month, although there is limited potential for additional recovery through the second year. Sharrard has stated that the mean final grade of a muscle is two grades above its assessment at 1 month and one grade above it at 6 months (320).

Disease Stages

Management of poliomyelitis varies according to the stage of the disease process. These are designated acute, convalescent, and chronic stages. Because the acute and convalescent stages are rarely encountered in this country, orthopaedic management is usually confined to the chronic stage. Most pediatric orthopaedic programs see several children or more per year with poliomyelitis in the chronic stage. These children are usually adopted from nonindustrialized nations or from parents who have immigrated from such countries.

Acute Stage

Acute poliomyelitis may cause symptoms ranging from mild malaise to generalized encephalomyelitis with widespread paralysis. Diagnosis is based on clinical findings because there are no diagnostic laboratory tests. This phase generally lasts 7 to 10 days. The return to normal temperature for 48 h and the absence of progressive muscle involvement indicates the end of the acute phase. This phase is usually managed by pediatricians because there may be medical problems, especially respiratory, that may be life-threatening.

The orthopaedist should be familiar with the clinical signs of acute poliomyelitis. Meningismus is reflected in the characteristic flexor posturing of the upper and lower extremities. Involved muscles are tender, even to gentle palpation. Clinical examination can be difficult because of pain during the acute stage.

Orthopaedic treatment during this phase emphasizes prevention of deformity and comfort. This approach consists of physical therapy with gentle, passive range of motion exercises and splinting. Muscle spasms, which can lead to shortening and contractures, may respond to the application of warm, moist heat. This can relieve muscle sensitivity and discomfort. Sharrard (320) emphasized that rapid loss of elasticity, coupled with shortening of tendons, fascia, and ligaments, leads to contractures.

Convalescent Stage

The convalescent phase of poliomyelitis begins 2 days after the temperature returns to normal and progression of the paralytic disease ceases. The phase continues for 2 years, during which spontaneous improvement of muscle power occurs. The assessment of the rate of recovery in poliomyelitis is made by serial examination of the muscle strength. Muscle assessment should be performed monthly for 6 months and then at 3-month intervals during the remainder of the convalescent stage.

Johnson (324) demonstrated that an individual muscle demonstrating less than 30% of normal strength at 3 months should be considered to be permanently paralyzed. Muscles showing evidence of more than 80% return of strength require no specific therapy. He emphasized that muscles that fall between these two parameters retain the potential for useful function and that therapy should be directed toward recreating hypertrophy of the remaining muscle fibers.

The treatment goals during this phase include efforts to prevent contractures and deformity, restoration and maintenance of normal joint range of motion, and assisting individual muscles in achieving maximum recovery (316). Physical therapy and orthotics are the main treatment modalities. Physical therapy is directed toward having individual muscles assume maximum capability within their pattern of normal motor activity and not permitting adaptive or substitute patterns of associated muscles to persist. Hydrotherapy can also be helpful in achieving these goals. Orthoses, both ambulatory and nighttime, are necessary to support the extremity during this phase.

Chronic Stage

The chronic stage of poliomyelitis begins after 2 years, and it is during this stage that the orthopaedist assumes responsibility for the long-term management resulting from muscle imbalance.

The management goal during the chronic stage is to achieve maximal functional capacity. This is accomplished by restoring muscle balance, preventing or correcting soft tissue contractures, correcting osseous deformities, and directing allied personnel, such as physical therapists, occupational therapists, and orthotists.

Treatment

Soft Tissue Contractures

Flaccid paralysis, muscle imbalance, and growth all contribute to soft tissue contractures and fixed deformities in poliomyelitis. Contractures occur from increased mechanical advantage of the stronger muscles and continue the attenuation of their weaker antagonists. The greater the disparity in muscle balance, the sooner a contracture may develop.

Joint instability does not result in fixed deformity, except in cases in which it is allowed to occur over a period of years in a growing child. Static instability can be controlled readily and indefinitely by orthoses. Dynamic joint instability readily produces a fixed deformity, and orthotic control is difficult. Deformities are initially confined to soft tissues, but later, bone growth and joint alignment may be affected.

The age at onset of poliomyelitis is important. The osseous growth potential of young children makes them more vulnerable to secondary osseous deformities. The worst deformities occur in young children and those with severe muscle imbalance. Release of soft tissue contractures and appropriate tendon transfers performed in a young child are important in preventing structural changes.

Tendon Transfers

Achievement of muscle balance in patients with dynamic instability effectively halts progression of paralytic deformity (326). Tendon transfers are performed when dynamic muscle imbalance is sufficient to produce deformity and when orthotic protection is required. Transfers should be delayed until the paralyzed muscle has been given adequate postural treatment to ensure that it has regained maximum strength and that the proposed tendon transfer is required. The objectives of tendon transfer are to provide active motor power to replace function of a paralyzed muscle or muscles, to eliminate the deformity caused by a muscle when its antagonist is paralyzed, and to produce stability through better muscle balance. The principles of tendon transfer have been well established (327,328).

The muscle to be transferred should rate good or fair before transfer and must have adequate strength to actively perform the desired function. On the average, one grade of motor power is lost after muscle transfer. The length and range of motion of the transferred muscle and that of the muscle being replaced must be similar. Loss of original function resulting from tendon transfers must be balanced against potential gains. Free passive range of motion is essential in the absence of deformity at the joint to be moved by the tendon transfer. A transfer as an adjunct to bony stabilization cannot be expected to overcome a fixed deformity (329). The smooth gliding channel for the tendon transfer is essential. Atraumatic handling of the muscle tissue can prevent injury to its neurovascular supply and prevent adhesions. The tendon should be rooted in a straight line between its origin and new insertion. Attachment of the tendon transfer should be under sufficient tension to correspond to normal physiologic conditions and should allow the transferred muscle to achieve a maximum range of contraction.

Osteotomies

Osseous deformities may produce joint deformities that impair extremity alignment and limit function. This most commonly occurs in the lower extremity. Osteotomies can be beneficial in restoring extremity alignment and improving function. Because of possible recurrence during subsequent growth, these procedures are usually postponed, if possible, until late childhood or early adolescence.

Arthrodeses

Arthrodeses are usually performed for salvage, except in the foot where a subtalar, triple, or pantalar arthrodesis may be useful in stabilization and realignment.

Treatment Guidelines

The basic treatment guidelines for chronic or postpoliomyelitis in children have been outlined by Watts (330). These guidelines include restoring ambulation, correcting factors that cause deformities with growth, correcting factors that obviate or reduce dependency on orthoses, correcting upper extremity problems, and treating spinal deformities. Understandably, these guidelines allow the child or adolescent to achieve maximum functional level. The specific methods to achieve each guideline are multiple, sometimes complex, and based on careful evaluation of the patient. Because children with previous poliomyelitis are infrequently encountered, specific details on the various procedures are not presented. Such information can be obtained from the references in the various sections.

The orthopaedist must establish a comprehensive plan for each child based on a thorough musculoskeletal examination—in particular, joint range of motion, existing deformities, and manual testing of the individual muscles of the extremities and trunk. The latter should be individually recorded on a worksheet so that it can be used for future reference. It is important to remember that a muscle normally loses one grade of power when transferred. To be functionally useful, a muscle grade of at least 4 is necessary, although a grade 3 muscle, when transferred, may be an effective tenodesis in preventing deformity by balancing an opposing muscle.

Upper Extremity

In polio upper extremity involvement tends to be less severe than in the lower extremity. A stable upper extremity, especially the shoulder, is necessary for support of the body weight with a walker or crutches. It is also necessary for transfers or shifting the trunk if wheelchair-bound. A functional elbow, wrist, and hand is necessary for maximum independent function.

Shoulder. Shoulder stability is essential for all upper extremity activities. Satisfactory level of function of the hand, forearm, and elbow is a prerequisite for any shoulder reconstructive surgery. The major problems affecting the shoulder are predominantly muscle paralysis of the deltoid, pectoralis major, subscapularis, supraspinatus, and infraspinatus muscles. Rarely are all muscles involved because of the multiple levels of innervation. Tendon transfers can occasionally be effective in restoring shoulder stability. When there is extensive weakness, shoulder arthrodesis may be helpful. It can also be indicated whether there is a painful subluxation or dislocation. A strong trapezius serratus anterior muscle is necessary to allow increased function after fusion.

Elbow. The major problem affecting the elbow is loss of flexion. When the biceps and brachialis are paralyzed, a tendon transfer may be helpful in restoring useful elbow flexion. Possible procedures include a Steindler flexorplasty, which transfers the origin of the wrist flexors to the anterior aspect of the distal humerus (331). The best functional results occur in patients whose elbow flexors are only partially paralyzed and whose fingers and wrist flexors are normal. Transfer of the sternal head of the pectoralis major also may be considered. Other possible procedures include transfer of the sternocleidomastoid, latissimus dorsi, and anterior transfer of the

triceps brachii. Paralysis of the triceps brachii muscle may occur in poliomyelitis, but seldom interferes with elbow function because gravity passively extends the elbow. Triceps brachii function is necessary, however, in activities in which the body weight is shifted to the hands, such as in transferring from bed to wheelchair or in crutch walking.

Forearm. Fixed deformities of the forearm seldom create major functional disabilities in children and adolescents with poliomyelitis. Pronation contractures are the most common disability. Function can be improved with release of the pronator teres and transfer of the flexor carpi ulnaris muscle.

Hand. Tendon transfers and fusions to improve hand function can be considered in selected cases. The number of possible transfers is extensive, and each patient requires a careful evaluation to ensure maximum functional improvement. Carpal tunnel syndrome has also been reported as a long-term sequela of poliomyelitis (332). This is associated with prolonged use of crutches or cane.

Lower Extremity

Lower extremity problems are most common in poliomyelitis. They can have a significant impact on function, especially ambulation.

Leg-length Discrepancy. This is a common problem when there is asymmetrical neurologic involvement. If the discrepancy is greater than 2 cm, this can produce a great disturbance. An appropriately timed contralateral epiphysiodesis is the usual procedure of choice (see Chapter 28). Greater discrepancy may be treated orthotically. Lengthening is rarely a consideration. However, D'Souza and Shah recently demonstrated that circumferential periosteal sleeve resection of the distal femur and/or distal tibia can produce a transient growth stimulation that can be beneficial in mild discrepancies, usually 2 to 3 cm (325).

Hip. Hip problems in poliomyelitis include muscle paralysis, soft tissue contractures, internal or medial femoral torsion, coxa valga, and hip subluxation and dislocation. Periodic anteroposterior radiographs of the pelvis are necessary to assess growth and the relation between the femoral head and acetabulum. Function can be improved and subluxation-dislocation prevented with appropriate soft tissue releases, tendon transfers, proximal femoral varus derotation osteotomy, and pelvic osteotomy (Fig. 17-13) (322,323). It is important that the procedures be coordinated to provide as balanced a musculature as possible so that hip stability can be maintained. Lau et al. (333) reported good or satisfactory results in 70% of patients with paralytic hip instability due to poliomyelitis. The key factors for success were muscle balance, the femoral neck shaft and anteversion angles, and the acetabular geometry.

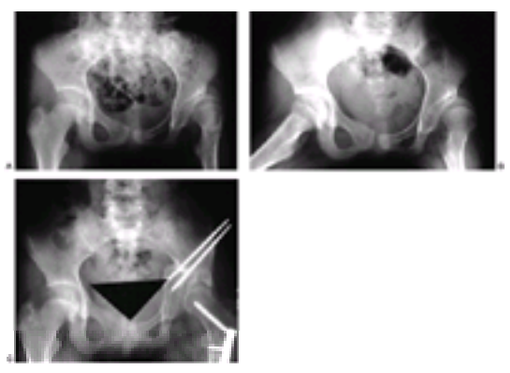

FIGURE 17-13. A: Anteroposterior radiograph of the pelvis of a 13-year-old Korean girl who had poliomyelitis. She has a painful subluxation of her left hip. The acetabulum is dysplastic, the center-edge angle is 6 degrees, and a coxa valga deformity of the proximal femur is present. **B:** Frog-leg or Lauenstein lateral. **C:** Two years after a proximal femoral varus derotation osteotomy and Chiari pelvic osteotomy there is markedly improved alignment of the left hip, and she is asymptomatic.

Knee. Flexion contractures, extension contractures, genu valgum, and external rotation of the tibia are common knee deformities in poliomyelitis that can have an adverse effect on functional ambulation. Hamstring release, distal femoral extension osteotomy, proximal femoral extension osteotomy, and rotational tibial osteotomies are common procedures (334,334,335,336 and 337). One of the most common soft tissue procedures is that described by Yount, in which the distal iliotibial band, including the intermuscular septum, is released (80). This may be combined with an Ober release proximally if hip flexion contractures are also present (81). Shahcheraghi et al. recently reported that anterior hamstring tendon transfer significantly improved active knee extension and function in patients with paralysis of the quadriceps femoris muscle following poliomyelitis (338).

Foot and Ankle. Deformities of the foot and ankle are among the most common in adolescents with poliomyelitis. Drennan has discussed possible procedures to correct the deformities and improve muscle balance (339). This is again achieved with a combination of correction of soft tissue contractures, tendon transfers, and bone-stabilizing procedures, such as calcaneal osteotomy, subtalar arthrodesis, triple arthrodesis, and pantalar arthrodesis (340,341,342,343,344 and 345). The patient requires a careful evaluation to determine the appropriate procedures. Arthrodeses produce good long-term results with a low incidence of ankle-degenerative arthritis, due to lower functional demands and stresses of patients with poliomyelitis (302,340,342).

Spine

Scoliosis occurs in about one third of patients with poliomyelitis (346). The type and severity of the curvature depends on the extent of paralysis and residual muscle power of the involved trunk muscles and pelvic obliquity. The most common curve patterns are the double major thoracic and lumbar curves, followed by the long paralytic C-shaped thoracolumbar curve (347). Pelvic obliquity occurs in about 50% of cases of spinal deformity. Because of severe rotation, kyphosis in the lumbar spine and lordosis in the thoracic spine are also common.

The goals of treatment are to obtain a balanced vertical torso over a level pelvis. This permits stable sitting and hands-free activities. It also helps prevent decubiti and paralytic hip dislocation. In young children with curves between 20 and 40 degrees orthotic management with a TLSO can be tried. It rarely provides complete stability, but can be effective in slowing the rate of progression and allowing the child to reach a more suitable age for surgery. In severe cases in young children segmental spinal instrumentation without fusion may be considered. Eberle (348), however, reported failure of segmental spinal instrumentation in 15 of 16 children with poliomyelitis between 5 and 12 years of age. Thus, children who undergo instrumentation without fusion should be treated with TLSO and undergo fusion as soon as possible to prevent late complications. For adolescents with a supple spine and a curve of less than 60 degrees a posterior spinal fusion with segmental instrumentation, usually Luque rod instrumentation, provides stability and a low pseudarthrosis rate **[➥2.5]** (100,346,347,349). Other segmental systems (e.g., TSRH, Cotrel-Dubousset, Isola) should also be effective **[➥2.9]**. In severe curves of 60 to 100 degrees, a combined anterior and posterior spinal fusion is usually necessary. Anterior spinal instrumentation with a Dwyer or Zielke system may be used in thoracolumbar and lumbar curves **[➥2.11]**. Anterior discectomy and fusion is preferred for thoracic curves. The posterior spinal fusion and instrumentation may be performed the same day or performed 1 or 2 weeks later. Leong et al. (350) and others (349,351) have demonstrated that combined anterior and posterior spinal fusions provide excellent correction for postpoliomyelitis spinal deformity, including the associated pelvic obliquity (Fig. 17-14). Rarely is preoperative traction or traction between staged anterior and posterior procedures necessary for additional correction. Fusion to the pelvis or sacrum is usually necessary in patients with severe pelvic obliquity (346,352,353).

FIGURE 17-14. A: Anteroposterior sitting spinal radiograph of a 17-year-old girl from the Middle East who has a severe paralytic scoliosis. There is a 123-degree left thoracolumbar scoliosis and a 70-degree right thoracic scoliosis. She contracted poliomyelitis at the age of 2 years, which left her with flail lower extremities and essentially normal upper extremities. She is wheelchair-dependent and has pain from rib–pelvis impingement. **B:** Postoperative radiograph after staged anterior spinal fusion and Zielke instrumentation and posterior spinal fusion using Isola instrumentation from T3 to the sacrum. Pain relief was complete and sitting balance improved. The left thoracolumbar curve has been reduced to 70 degrees and the right thoracic curve to 47 degrees.

POSTPOLIOMYELITIS SYNDROME

Postpoliomyelitis syndrome is a true entity occurring in adults, and a sequela to previous poliomyelitis. Reactivation of the poliovirus has been confused with amyotrophic lateral sclerosis. Postpoliomyelitis syndrome is thought to be an overuse syndrome (354). Diagnosis is based on five criteria and is essentially a diagnosis of exclusion. The criteria include:

1. A confirmed history of previous poliomyelitis.
2. Partial to fairly complete neurologic and functional recovery.
3. A period of neurologic and functional stability of at least 15 years duration.
4. Onset of two or more of the following health problems since achieving a period of stability: unaccustomed fatigue, muscle and joint pain or both, new weakness in muscles previously affected or unaffected, functional loss, cold intolerance, and new atrophy.
5. No other medical diagnosis to explain the aforementioned health problems (170).

Postpoliomyelitis syndrome is more likely to develop in those with onset later than 10 years of age because older children are more likely to have severe poliomyelitis. Management of these patients is conservative and consists of muscle strengthening, decreasing the duration of effort, and orthotics (354). Reconstructive surgery is rarely indicated or necessary.

CHAPTER 18

IDIOPATHIC AND CONGENITAL SCOLIOSIS

PETER O. NEWTON
DENNIS R. WENGER

P. O. Newton: Department of Orthopaedic Surgery, University of California–San Diego; Department of Orthopaedic Surgery, Children's Hospital and Health Center, San Diego, California 92123.
D. R. Wenger: Department of Orthopaedic Surgery, University of California–San Diego; Pediatric Orthopedics, Children's Hospital and Health Center, San Diego, California 92123.

CHILDHOOD AND ADOLESCENT SCOLIOSIS

“Idiopathic scoliosis” defines a common and potentially severe musculoskeletal disorder of unknown etiology, the diagnosis and treatment of which have been central in the development of orthopaedic surgery as a specialty. In its milder forms scoliosis may produce only trunk shape change, but when severe, can be markedly disfiguring as well as producing cardiac and pulmonary compromise (Fig. 18-1). The goal of this chapter is to present the key elements in diagnosis, natural history, and treatment of both idiopathic and congenital scoliosis.

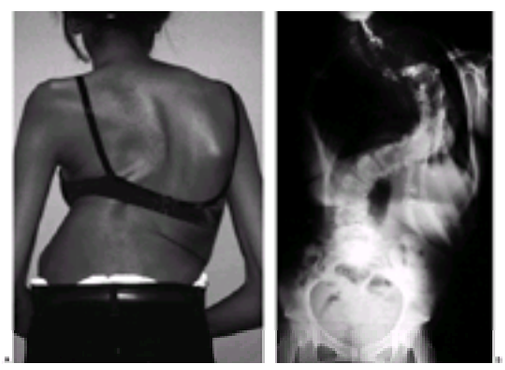

FIGURE 18-1. A: This 16-year-old female with severe scoliosis refused early surgical treatment and had severe curve progression. Her clinical examination demonstrates marked trunk and rib cage deformity, and she had reduced pulmonary function. **B:** The posteroanterior radiograph demonstrates a right thoracic curvature of 125 degrees.

The etiology of typical adolescent scoliosis remains unknown; thus, the term “idiopathic” remains appropriate. Scoliosis can also be classified based on associated conditions, since it occurs in many neuromuscular disorders (cerebral palsy, muscular dystrophy, and others) as well as in association with generalized diseases and syndromes (neurofibromatosis, Marfan syndrome, and bone dysplasia). Congenital scoliosis, caused by failure in vertebral formation or segmentation, causes a more mechanically understandable type of scoliosis.

The etiology of a scoliotic deformity (idiopathic, neuromuscular, syndrome related, and congenital) largely dictates its natural history, including the risk for and rate of curve progression, as well as the effect the curve will have on the cardiopulmonary function, mobility, and appearance. Although scoliosis includes both sagittal plane and torsional malalignment of the spinal column, the deformity is most readily noted as frontal plane deformity. Better understanding of the three-dimensional nature of scoliosis has led to many recent advances in its treatment.

Definitions

The normal spine is straight in the frontal plane, but has sagittal plane contours including thoracic kyphosis averaging 30 to 35 degrees (range 10 to 50 degrees, T5–T12) and lumbar lordosis averaging 50 to 60 degrees (range 35 to 80 degrees, T12–S1) (1,2 and 3). The scoliotic spine deviates from midline in the frontal plane, and rotates maximally at the apex of the curve (4). The vertebral rotation toward the convexity of the curve, through the attached ribs, produces the typical chest wall prominence (Adams sign) that allows early diagnosis (5,6) (Fig. 18-2).

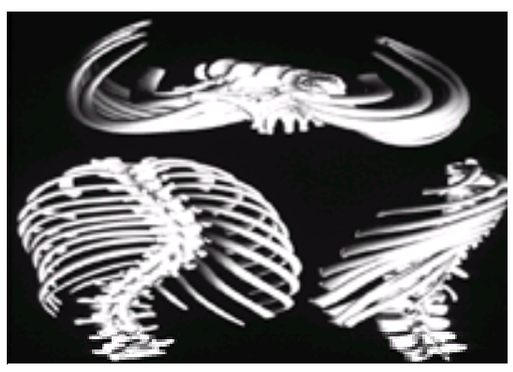

FIGURE 18-2. A three-dimensional reconstruction of the scoliotic spine and trunk demonstrates the three-plane deformity of the spine and attached ribs. The torsional deformity is maximal at the apex of the curvature. (Courtesy of St. Justine Hospital, Montreal, Canada.)

In the past, it was thought that the lateral curvature of scoliosis was also kyphotic (increased roundback). It is now understood that the apparent “hump” on the back is due to rib prominence secondary to the rotational deformity of the vertebrae and rib cage, and that most thoracic idiopathic scoliosis is associated with a *decrease* in normal thoracic kyphosis (7,8). Dickson and others have postulated that an early evolution to lordosis in the normally kyphotic thoracic spine leads to an unstable mechanical environment, leading to rotational collapse (9,10) (Fig. 18-3). This is not to say that all thoracic scoliosis is hypokyphotic, since many congenital, neuromuscular, and a few idiopathic cases have a true kyphotic component.

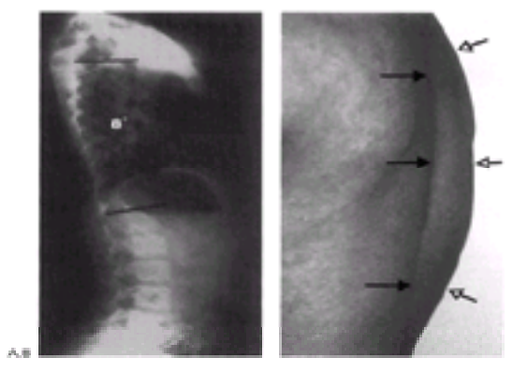

FIGURE 18-3. A: This standing lateral radiograph demonstrates the decreased kyphosis of the thoracic spine (“hypokyphosis”), commonly seen in thoracic curves in patients with idiopathic scoliosis common in adolescent idiopathic scoliosis. **B:** An oblique view clinical photograph of the patient demonstrates both the prominence of the rib cage due to the rotational deformity (*open arrows*), as well as the flattening of the thoracic kyphosis along the midline (*closed arrows*).

In addition to global deformity of the spine and trunk, wedging of individual discs and vertebral bodies develops, due to the Hueter-Volkmann effect (suppression of growth on the concave side of the curve) (11) (Fig. 18-4). This includes asymmetric growth and/or remodeling of the vertebral bodies, pedicles, laminae, and facet joints, as well as the transverse and spinous processes.

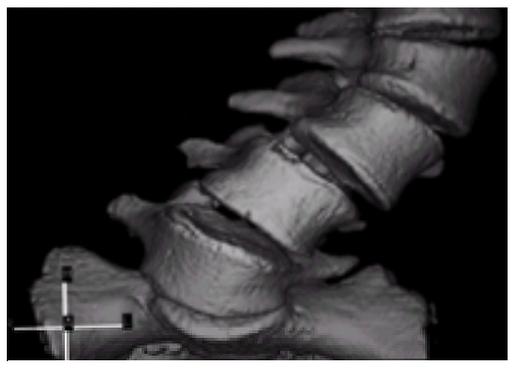

FIGURE 18-4. A three-dimensional CT scan in a patient with severe lumbar scoliosis demonstrates the wedging of both the discs and vertebral bodies, which occurs through asymmetric loading and growth (Hueter-Volkmann effect).

Etiology

Although the etiology of idiopathic scoliosis remains unknown, substantial research has been performed with many theories proposed. These range from genetic factors to disorders of bone, muscles, and disc, as well as growth abnormalities and central nervous system causes.

Genetic Factors

Several studies have demonstrated an increased incidence of scoliosis in the family members of affected individuals, confirming a genetic etiologic component to the etiology of scoliosis (12,13,14,15 and 16). Risenborough and Wynne-Davies found scoliosis in 11.1% of first-degree relatives of 207 patients with idiopathic scoliosis (16). These familial studies suggest a polygenic inheritance pattern.

Examination of scoliosis in birth twins has led to further confirmation of genetic etiologic factors. In a meta-analysis of scoliosis in twins, Kesling and Reinker demonstrated 73% concordance in 37 pairs of monozygotic twins. They found that in 37 pairs of identical twins in which at least one twin was identified with scoliosis, 27 of the pairs had both twins affected. However, only 36% of the 31 dizygotic twins were concordant. In addition, the severity of the scoliosis was statistically similar for the monozygotic twins, but not for the dizygotic twins (17). Inoue et al. demonstrated even greater concordance in twins. DNA fingerprinting confirmed the zygosity, and found concordance of idiopathic scoliosis in 92% of monozygotic and 63% of dizygotic twins (18). Despite this confirming evidence of a genetic etiology, the genes and gene products responsible for the development of idiopathic scoliosis remain unknown.

Tissue Deficiencies

Competing theories propose that the primary pathology of scoliosis is centered in each of the structural tissues of the spine (bone, muscle, ligament/disc). There are known conditions in which each of these tissues are pathologic and associated with scoliosis. For example, fibrous dysplasia (bone collagen abnormality) resulting in dysplastic, misshapened vertebrae (19); muscle disorders such as Duchenne muscular dystrophy leading to a collapsing scoliosis; and soft tissue-collagen disorders, such as Marfan syndrome, each have a clear association with the development of scoliosis.

In Marfan syndrome there is a defective gene coding for fibrillin. Fibrillin is found in many soft tissues including ligament, cartilage, and periosteum (20). The fibrillin abnormality found in Marfan syndrome is associated with scoliosis in 55 to 63% of cases (21,22). Although fibrillin has been ruled out as a cause of idiopathic scoliosis (23), similar subtle deficiencies in any of the tissues of the spine could result in idiopathic scoliosis (24). For instance, several (25,26 and 27) have suggested that adolescent idiopathic scoliosis (AIS) may be related to osteopenia. They found the vertebral bone mineral density to be lower in girls ages 12 to 14 years with scoliosis compared to matched controls, with the density lower not only in the vertebrae, but also in the proximal femur (25). The mechanism by which osteopenia alone leads to scoliosis, however, remains undefined.

Vertebral Growth Abnormality Theories

Abnormalities of spinal growth mechanisms also provide an attractive etiology theory because scoliosis development and progression are temporally related to the time of rapid adolescent growth (28,29). Differential growth rates between the right and left sides of the spine could generate an asymmetry that would be accentuated with asymmetric biomechanical loading and the Heuter-Volkmann effect (11,30,31). Milner and Dickson (32), as well as others (10,31,33,34 and 35), have postulated that the etiology of scoliosis relates to the development of relative thoracic lordosis. Dickson believes that anterior spinal growth outpaces posterior growth, producing hypokyphosis with subsequent buckling of the vertebral column, leading to the rotational deformity of scoliosis; however, the cause for this theorized “mismatch” of anterior and posterior spinal column growth has not been presented, and may be secondary rather than primary. Interestingly, it has been documented that thoracic kyphosis tends to decrease in normal children during the normal adolescent growth spurt (36). Thus, irregularities in the changing sagittal shape of the spine during the rapid period of adolescent growth may be important in the development of scoliosis.

Several studies suggest that adolescents with scoliosis are taller than their peers (37,38,39,40,41 and 42). Increased levels of growth hormones (43,44) and characteristic body morphometry (thin, physically less developed appearance) (45,46,47,48 and 49) may also relate to scoliosis development.

Central Nervous System Theories

Clearly, disorders of the brain, spinal cord, and muscles may result in scoliosis with the role of the central nervous system in idiopathic scoliosis having been studied in detail (50,51,52,53,54,55,56 and 57). Goldberg et al. noted greater asymmetry of the cerebral cortices in scoliotic patients (55). Also, abnormalities in equilibrium and vestibular function have been noted in patients with scoliosis (50,58,59,60,61,62 and 63); however, it is difficult to know if these findings are primary or secondary (64). Woods et al. have suggested a neurologic etiology to scoliosis based on the surprising finding that hearing-impaired children seem to have a lower incidence of scoliosis (63). Syringomyelia is associated with an increased incidence of scoliosis (65,66) possibly due to direct pressure on the sensory or motor tracts of the spinal cord. Alternatively, there may be no relation to the dilation of the central canal, but instead, brain stem irritation from an associated Chiari malformation or enlargement of the fourth ventricle of the brain as the cause.

Recently, it has been postulated that melatonin and the pineal gland may be related to scoliosis. This is based on research of pinealectomy in chickens that resulted in a high incidence of severe scoliosis (67,68 and 69). In these studies, presumably melatonin deficiency led to scoliosis in the chicken (70). Melatonin receptors are located in the brainstem and spinal cord dorsal gray matter, areas associated with postural control. Subsequent studies of human melatonin levels have been conflicting and inconclusive. Machida et al. found lower than normal melatonin concentration in the serum of patients with progressive scoliosis compared to those with stable curves (71). In contrast, Hilibrand et al. (72) and Fagan et al. (73) found no difference in urine melatonin levels between patients with scoliosis and normal control subjects. In addition, Bagnall et al. found no difference in serum melatonin levels of patients with scoliosis (74). Thus confirmation that melatonin deficiency in humans is associated with scoliosis, as seen in chickens, is lacking.

Histologic analysis of paraspinous muscles has revealed denervation changes suggestive of a neuropathic cause (75), as well as ultrastructural changes in the sarcolemma at the myotendinous junction, supporting the concept of a primary muscle disorder (76). As in the findings relating to equilibrium, it is difficult to determine a causal relationship, and the findings in muscle could be secondary, reflecting the muscle's response to asymmetric spine loading (77).

In summary, the etiology of scoliosis remains puzzling. From a biomechanical standpoint the vertebral column is a naturally unstable construct, made of multiple mobile segments. As Stagnara has noted, one should not be surprised that a minor disturbance in the structure, support system, or growth of the spine could lead to scoliosis, particularly in a complex structure where the “normal” state includes multiple curves (sagittal plane), and is based on an oblique foundation (the sacrum) (78). There are likely several causes of idiopathic scoliosis, and active research continues in an attempt to find a unifying theory as to its cause.

Classification

Curve Location

Scoliotic deformities assume a variety of curve patterns, and several useful classification systems have been developed. The terminology committee of the Scoliosis Research Society (SRS) defines the following technical description of curve locations (this is in contrast to curve pattern descriptions developed for the purpose of planning surgical correction; see “Surgical Correction of Idiopathic Scoliosis”):

- Cervical: apex between C2 and C6
- Cervicothoracic: apex between C7 and T1
- Thoracic: apex between T2 and T11
- Thoracolumbar: apex between T12 and L1
- Lumbar: apex between L2 and L4
- Lumbosacral: apex at L5 or below

The apex of a curve defines its center, and is the most laterally deviated disc or vertebra of the curve. Usually a single vertebra can be defined, but in other cases a pair of vertebrae are at the apex (in this case the “apical disc” is used to define the level of the apex). The apical vertebra(e) are also the most horizontal. The end vertebrae of a curve define the proximal and distal extent of a curve, and are determined by locating the vertebrae most tilted from the horizontal (these vertebrae are used to make the Cobb measurement). The central sacral vertical line, a vertical line which bisects the sacrum, is used to assess the balance of the spine in relation to its base (the pelvis) (Fig. 18-5).

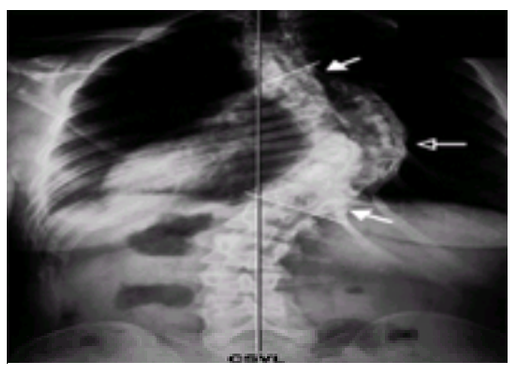

FIGURE 18-5. The end vertebrae (*solid arrows*), apical vertebra (*open arrow*), and central sacral vertical line (*CSVL*) are demonstrated on this upright film. The CSVL is commonly used to determine the distal-most extent of a spinal fusion that classically extends to the “stable vertebra.” In this radiograph, the stable vertebra is arguably L1 or L2.

Age at Onset

Age at diagnosis is also used to define idiopathic scoliosis groups as follows:

- Infantile (ages 0 to 3 years)
- Juvenile (age 4 to 10 years)
- Adolescent (11 to 17 years)
- Adult (³l18 years)

The age when idiopathic scoliosis develops is one of the most important factors in determining the natural history of the disorder, with early onset cases more likely to be progressive. Scoliosis onset before the adolescent growth spurt is more likely to have an underlying spinal cord abnormality as the cause of the deformity with the incidence of abnormality approximately 20% in the juvenile group and as high as 50% in the infantile group (79).

Primary and Secondary, Structural and Nonstructural Curves

Curves may also be described as primary or secondary. The primary curve is the first to develop; however, at times two or even three curves of equal severity exist that make the determination of a primary versus secondary curve difficult. Secondary or compensatory curves develop after formation of the primary curve as a means of balancing the head and trunk over the pelvis. Similar compensation occurs in the sagittal plane in which the typical lordotic thoracic curve may end both cranially

and caudally with a junctional kyphosis. Sagittal plane abnormalities have only recently been well understood and considered when planning surgical correction.

The terms structural and nonstructural have also been used to describe the flexibility of scoliotic curves with structural curves being more rigid (i.e., do not correct well with side-bending). The degree of curve rigidity that differentiates a structural and nonstructural curve, however, has not been clearly defined.

Etiologic Classification

Classification of scoliosis by etiology may be broadly described as idiopathic (or idiopathic-like), neuromuscular, syndrome related, and congenital. It is important to consider a patient presenting with scoliosis as a patient presenting with a sign (i.e., scoliosis), rather than a diagnosis. Most scoliosis (approximately 80%) is idiopathic; however, the remaining cases are associated with a wide variety of disorders in which scoliosis is often the presenting complaint.

The SRS has classified scoliosis as associated with each of the diagnoses seen in Table 18-1. The scoliosis associated with these conditions is discussed in other chapters of this text. Neuromuscular disorders of either neuropathic or myopathic etiology make up a large proportion of the nonidiopathic causes of scoliosis in childhood. Intra- or extraspinal tumors or abnormalities must also be considered as a cause of scoliosis. Congenital scoliosis and kyphosis also may lead to progressive spine deformity. An awareness of each potentially associated condition helps when analyzing the various proposed etiologic factors in idiopathic scoliosis, and, more importantly, the diagnosis of idiopathic scoliosis requires the exclusion of these conditions.

TABLE 18-1. CLASSIFICATION OF SCOLIOSIS

Clinical Features

History

Understanding what prompted a physician visit for evaluation of scoliosis is key. For example, in North America, a screening examination (either in school or at a routine primary care visit) often leads to referral. History-taking should include questions about family history of scoliosis, recent growth, and the physical changes of puberty (onset of menses). When an affected sibling or parent has scoliosis, prevalence increases seven times (sibling) and three times (parent), respectively, compared to the general population (14). A record of height increases over the prior few years is important in predicting remaining spinal growth and the risk for curve progression (80). This information may be available from the primary care physician or, at times, from measurements on the wall/door marked in the family's home. The onset of menses forms an important maturational time point in females (81). The family history, as well as the review of systems, should identify disorders known to be associated with scoliosis (Table 18-1).

The presence or absence of severe back pain is important, because most idiopathic scoliosis patients have only mild discomfort. Patients seen after scoliosis has been diagnosed (in a screening setting) commonly develop “pain” that continues until the exact diagnosis, and particularly the prognosis, have been clarified by an orthopaedic consultant who can provide reassurance. Despite the common belief that mild idiopathic scoliosis is not painful, a recent study suggests that adolescents with mild curves often report discomfort of a mild fatigue variety. Ramirez et al. noted back pain in 23% of 2,442 patients with “idiopathic” scoliosis. Only 9% of those with pain were subsequently found to have an underlying pathologic condition to explain it (diagnoses such as spondylolysis/spondylolisthesis, Scheuermann kyphosis, syringomyelia, herniated disc, tethered cord, and intraspinal tumor) (82).

In evaluating a child with scoliosis, a significant complaint of back pain is a clue that should raise one question, “Is this truly an idiopathic curve?” A child or adolescent who presents with *severe* back pain, and is subsequently found to have scoliosis requires a very careful history, physical examination, and radiographic study (a bone scan and MRI study may be required), because an underlying etiologic cause is more likely (82,83 and 84). However, the clinician must distinguish between “severe pain” (requiring further workup) and the mild fatigue pain (noted above) reported by Ramirez et al. and others (82,85). During adolescence, activity-related musculoskeletal low back pain occurs at a frequency greater than in childhood, but less than in adults (86,87).

Age at onset, rate of curve progression, and the presence of neurologic symptoms and signs are the most useful findings in identifying nonidiopathic scoliosis. In younger patients (less than 10 years) with a neurologic cause, actual neurologic findings on physical examination are often absent, and often the spinal curvature itself must be considered the initial sign of a neural axis abnormality (79,88,89 and 90). The most common intraspinal abnormality found in this age group is syringomyelia (dilation of the central spinal canal) with an associated Chiari malformation (brain stem below the level of the foramen magnum) (Fig. 18-6).

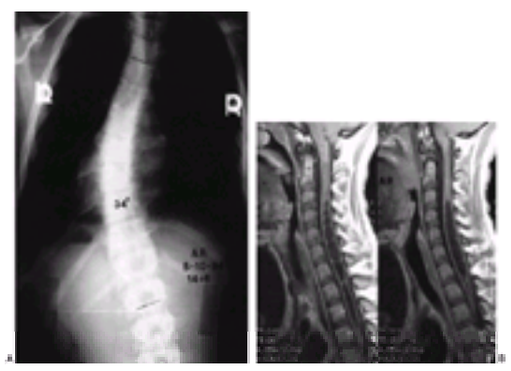

FIGURE 18-6. A: This 14-year-6-month-old male who presented with a 34 degree left thoracic scoliosis was asymptomatic with a normal physical examination, except for the absence of a left abdominal reflex. This finding, in addition to the presence of a left thoracic curve—an “abnormal” pattern for idiopathic scoliosis—was the indication for further evaluation with an magnetic resonance imaging (MRI) scan. **B:** The sagittal MRI scan showed a large cervical spinal cord syrinx.

Rapid development of a severe curve suggests a nonidiopathic type of scoliosis. Neurologic symptoms such as weakness, sensory changes, and balance/gait disturbance suggest intraspinal pathology (syringomyelia, tethered cord, tumor, etc.) as the cause of spinal curvature (83,89,90). The neurologic history should therefore focus on difficulties with walking, running, and stair-climbing. A history of radiating pain, numbness, and tingling in the limbs, and difficulties with bowel or bladder control, should also be sought.

Physical Examination

Physical examination of a scoliosis patient includes evaluation of trunk shape, trunk balance, the neurologic system, limb length, skin markings, and associated

skeletal abnormalities. Assessment of pubertal development includes assessment of the stages of breast development and the presence of axillary/pubic hair (Tanner stages). This can be done discretely without fully undressing the patient. Examination of girls while dressed in a two-piece swimsuit (patient instructed at time of telephone appointment to wear a swimsuit for the examination) reduces anxiety and apprehension, yet allows assessment of breast development and axillary hair.

With the patient standing, the back and trunk are inspected for asymmetry of shoulder height, scapular position, and shape of the waist (Fig. 18-7) viewed from both behind and in front. Potential pelvic tilt, (an indicator of limb-length difference) is determined by palpating the iliac crests and posterior inferior iliac spines bilaterally in the standing patient with both hips and knees fully extended. Lateral translation of the head can be measured in centimeters of deviation from the gluteal cleft by dropping a plumb line from C7 (Fig. 18-8). Deviation of the chest cage (trunk shift) should also be assessed, since patients can have full head compensation (return of the head and neck back to midline), yet have marked lateralization of the trunk.

FIGURE 18-7. The clinical appearance of this 11-year-old female with right thoracic scoliosis demonstrates asymmetry of the waistline and scapulae as well as slight elevation of the right shoulder.

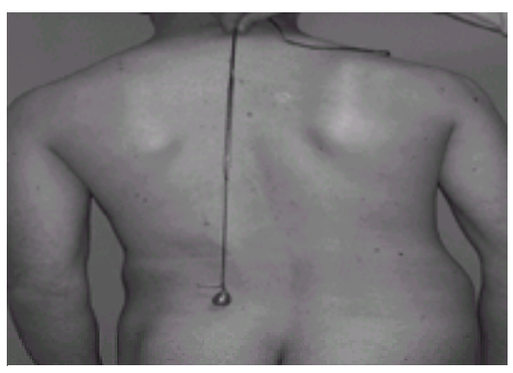

FIGURE 18-8. A small weight hanging from a string (“plumb bob”) serves as a simple tool for quantifying trunk deviation. In this case, the plumb line is measured from C7 and quantified as a deviation in centimeters from the gluteal cleft below (5 cm).

Forward-bend Test. The forward-bend test, first described by Adams in Britain (91), has the patient bend forward at the waist, with their knees straight and palms together. This examination should be performed from behind (to assess lower trunk rotation), from in front (to assess upper trunk rotation), as well as from the side (to assess kyphosis). Any asymmetry of the upper thoracic, midthoracic, thoracolumbar, and lumbar regions should be quantitated with a scoliometer (92) (angle of trunk rotation—ATR), or by measuring the height of the prominence in centimeters (Fig. 18-9). This prominence reflects the rotational deformity of the spine associated with scoliosis (93,94). Although not always exactly correlated, in general an angle of trunk rotation of 5 to 7 degrees is associated with a radiographic Cobb angle measurement of 15 to 20 degrees. (This is a guideline—occasionally patients have little trunk rotation yet have significant radiographic scoliosis, and vice versa (95)).

FIGURE 18-9. The Adams forward bend test is performed to detect small degrees of trunk rotation frequently associated with scoliosis. The scoliometer is used to quantify the angle of trunk rotation in degrees. This simple device is utilized in screening patients for scoliosis, as well as for quantifying the degree of trunk rotation in patients being followed clinically.

An inability to bend directly forward at the waist, or decreased range with forward/side bending, may be due to pain, lumbar muscle spasm, and/or hamstring tightness; any of which should suggest underlying pathology. These findings, plus abnormalities in straightleg–raise testing suggests irritation of the lumbar roots due to spondylolysis, disc herniation, infection, neoplasm, or other causes.

Skin, Limb Length. Additional components of a comprehensive scoliosis examination include inspection of the skin (both on the back and elsewhere) for cutaneous evidence of an associated disease. Café au lait spots and/or axillary freckles suggest possible neurofibromatosis, while dimpling or a hairy patch in the lumbosacral area may suggest an underlying spinal dysraphism. Excessive skin or joint laxity may be related to a connective tissue disorder, such as Marfan or Ehlers-Danlos syndrome.

Limb length should also be measured in the supine position if pelvic tilt is noted on the standing examination. A spinal curvature which results from a limb-length difference is usually compensatory and serves to rebalance the trunk over the pelvis. A short right leg results in a compensatory right lumbar curve. There is no rotational deformity of the spine with these curves, and in the lumbar region the rotational prominence noted on the forward-bend test is on the concave side of the curve (the long leg makes the iliac crest and lumbar spine more prominent on that side). This is the opposite of what is seen in true lumbar scoliosis, in which the rotational prominence noted on the bending test is found on the side of the curve convexity. Presence of the bending-test rotational prominence, on the “wrong” side in a lumbar curve, is almost always diagnostic of limb-length discrepancy spinal asymmetry, rather than true scoliosis. The prominence disappears if the pelvis is leveled with an appropriately sized block underneath the short leg.

Neurologic Examination

The neurologic examination should evaluate balance, motor strength in the major muscle groups of all four extremities, as well as sensation. Watching the patient

walk, toe and heel walk, tandem walk, squat deeply, and single-leg hop allows rapid assessment of balance and motor strength. Reflex testing includes upper- and lower-extremity deep-tendon reflexes, as well as abdominal reflexes that are obtained by lightly stroking the abdominal wall with a blunt instrument (key, end of reflex hammer) adjacent to the umbilicus, with the patient supine and relaxed. The expected brisk and symmetric unilateral contraction of the abdominal musculature, pulling the umbilicus toward the side being stroked, indicates normalcy. When persistently abnormal (reflex absent on one side and present on the other), intraspinal disorders, particularly syringomyelia, should be considered and an MRI study ordered (65,96).

Radiographic Assessment

The ideal screening radiograph for scoliosis is an upright (standing) posteroanterior (PA) projection of the entire spine exposed on a single cassette. In an adolescent, due to body size, this requires a three-foot length film to visualize the entire spine, as well as the head and pelvis on a single radiograph. Many radiology units do not have long cassettes and a chest-film–size cassette can be substituted, with the film centered on the area of maximal deformity (usually the thorax). If a lumbar curve is present, a separate film must be performed. Clearly, the child is better served if they can be referred to a center that uses long cassettes, allowing a single film.

The patient must be standing, since diagnostic and treatment standards developed over the years are based on upright films. In young patients, or those with severe neuromuscular involvement, sitting or even supine radiographs may be the only position possible. Curve magnitude is greater when the patient is upright (compared to supine), and is of particular importance in infantile and congenital curves with films taken before and after walking age. “Curve progression” may be noted with the first upright radiograph, compared to prior supine views, when in fact one has simply documented that gravity causes a curve to be more severe. A lateral film is not required as part of the initial x-ray screening of a thoracic curve, unless back pain or sagittal deformity are noted. A lateral view of the lumbosacral junction is often performed in lumbar scoliosis to assess for spondylolysis/spondylolisthesis as a possible cause (Fig. 18-10).

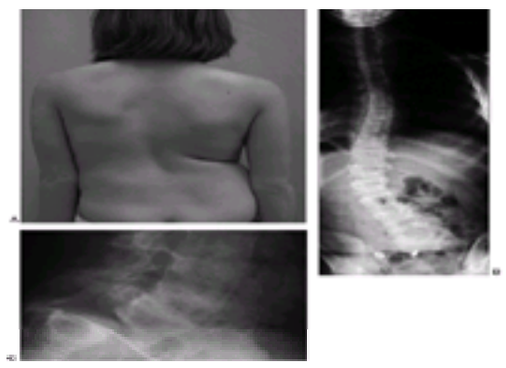

FIGURE 18-10. A: This 10-year-old female presented with complaints of increasing trunk decompensation, as well as low back pain and posterior thigh discomfort. She has obvious trunk shift to the left, suggesting scoliosis. **B:** The standing PA radiograph confirms a 43-degree left lumbar scoliosis. **C:** A standing lateral view focused at the L5-S1 level demonstrates severe spondylolisthesis. The majority of her lumbar deformity is related to an asymmetric forward slipping of L5 on S1, with the rotational deformity translated to the lumbar spine above.

Radiographic techniques used to minimize radiation of sensitive organs (breast, thyroid, ovaries, bone marrow) include taking only the required number of x-rays, utilizing rare earth radiographic enhancing screens with fast film, and a posterior to anterior exposure (97,98 and 99). The lifetime risk for developing cancer of the breast and thyroid has been suggested to increase by 1 to 2% for patients exposed to multiple x-rays associated with scoliosis treatment; however, this rate was generated in the 1960s and 1970s, before new radiation reducing techniques were available. The greatest reduction to breast and thyroid exposure is associated with the posteroanterior exposure (compared to the anteroposterior), which reduces breast/thyroid exposure 3- to 7-fold (99). Shielding of the breasts with anteroposterior (AP) projection is possible, but not recommended, because of the increased thyroid exposure (shielding the thyroid obstructs the view of the upper spine) (Fig. 18-11). Wise doctors counsel their patients by telling them that only the minimum number of x-rays required to treat the disorder correctly will be performed, and that the benefit of having the x-rays outweighs the risk of not knowing the type and severity of the scoliosis.

FIGURE 18-11. A: Positioning of a patient for a posteroanterior radiograph. **B:** Positioning of a patient for an anteroposterior radiograph with breast shielding.

When surgical treatment is being considered, lateral-bend radiographs to assess curve flexibility as well as a standing lateral view are required. Side-bending radiographs allow one to determine curve flexibility, and to decide what levels to include in the instrumented and fused segment. Controversy remains regarding the best method for obtaining bending films, with supine AP views (patient maximally bent to the right and left) being standard at many institutions (Fig. 18-12), whereas others believe that a standing bend film is a better indicator, particularly in the lumbar spine. Lateral bending over a bolster provides somewhat greater correction, and has been proposed as a more accurate predictor of the correction obtained with the more powerful modern surgical instrumentation methods (100,101). In curves greater than 60 to 70 degrees, longitudinal traction films may also be helpful in evaluating curve flexibility (102,103).

FIGURE 18-12. A: Standing PA radiograph of a premenarchal female demonstrating a 35-degree left upper thoracic scoliosis, 60-degree right thoracic scoliosis, and 50-degree left lumbar scoliosis. **B:** The bend film to the right is useful in determining the flexibility of the main right thoracic curve. In this case, the right thoracic curve decreased only to 50 degrees on supine side bending. **C:** The side-bending film to the left is useful in determining the curve flexibility of the left upper thoracic curve, which decreased to 28 degrees, and the left lumbar curve, which decreased to 23 degrees.

The Stagnara oblique view, taken perpendicular to the rib prominence rather than in the PA direction, provides a more accurate picture of large curves with a large rotational component. Taken in this manner the true magnitude of the scoliosis can be measured (104).

Reading Scoliosis Films. Assessment of the standing PA film begins by looking for soft tissue abnormalities, congenital bony abnormalities (wedged vertebra, etc.), then by assessing curvature (coronal plane deviation). Bone assessment includes looking for wedged or hemivertebrae (Fig. 18-13), bar formation bridging a disc space, as well as midline irregularities, such as spina bifida or a bony spike suggesting diastematomyelia. The pedicles should be inspected to be certain that they are present bilaterally and that the interpedicular distance is not abnormally increased, suggesting an intraspinal mass (105,106). Absent pedicles or vertebral body lucency are associated with lytic processes, such as tumor or infection. If a curve is noted, the symmetry and levelness of the pelvis are analyzed. A limb length discrepancy can be estimated by determining iliac wing and hip joint height differences, assuming the patient had both hips and knees fully extended when the film was exposed.

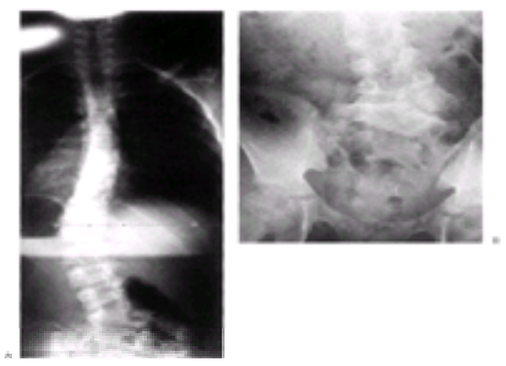

FIGURE 18-13. A: This adolescent patient presented with spinal deformity, with the standing PA radiograph demonstrating an obvious left thoracolumbar deformity. On more careful examination, an abnormality at the lumbosacral junction is suggested. **B:** A cone-down radiograph of the lumbosacral junction demonstrates a clear hemivertebra. This congenital malformation is the primary deformity, and the thoracolumbar deformity above is a compensatory curve.

Curve measurement by the Cobb method (107) allows quantification of the curve. A protractor with single-degree demarcations that is not bent or warped allows more accurate measurements. The caudal and cranial end vertebrae to be measured are the vertebrae that are the most tilted, with the degree of tilt between these two vertebrae defining the Cobb angle (in a normal spine this angle is 0 degrees). One outlines the superior end plate of the cranial end vertebra and the inferior end plate of the caudal end vertebra, constructs a perpendicular to these lines, then measures the angle where the perpendicular lines cross. When more than one curve exists, a Cobb angle measurement is made for each curve (Fig. 18-14). When comparing serial radiographs of the same patient, the end vertebra chosen should generally remain constant; however, adjustments may be required over time, due to brace-influenced change or other curve pattern changes. The wide variation of inter- and intraobserver error (about 5 degrees for any curve measurement) should be understood by the surgeon and the anxious parents (and patient) (108,109 and 110). Carman et al. state that to be 95% certain that two measurements are truly different, a 10-degree change must be measured (111). A useful maneuver for both the neophyte and expert surgeon includes viewing the current film, the prior-visit film, and the original film side by side. (A good scoliosis clinic needs at least three long view boxes mounted side-by-side). Then, before making a Cobb measurement, one should use the “eyeball method” to see whether the radiographic curve appears to be getting worse. Patients and their parents often want to make this assessment with you. This type of exercise puts the Cobb measurement in perspective (and sometimes humbles you as to your accuracy and reproducibility in measurement).

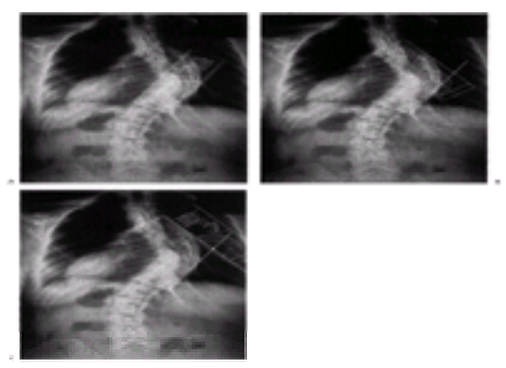

FIGURE 18-14. A: Measurement of the Cobb angle. The end vertebrae of a curve must be selected before any measurement can be made. The end vertebrae of a curve are those which are most tilted from the horizontal. **B:** The end plates of the superior and inferior end vertebrae are marked as seen in this figure. Perpendicular lines are then constructed at right angles to the mark on each of the end vertebra. **C:** The angle constructed by the two perpendicular lines is measured and defined as the Cobb angle.

Vertebral rotation, maximal at the apex of a curve, is demonstrated radiographically by asymmetry of the pedicles and a shift of the spinous processes toward the concavity. Two methods are available for quantifying it: Nash and Moe (112), and Perdriolle (113). Vertebral rotation is not routinely measured clinically, and both methods have substantial inaccuracies, which limit their usefulness (114).

Skeletal maturity should be assessed radiographically to estimate remaining spinal growth, an important predictor of risk for curve progression. The most widely used method in scoliosis patients is that of Risser (115), who noted that the iliac crest apophysis ossifies in a predictable fashion, from lateral to medial, and that its fusion to the body of the ilium mirrors the fusion of the vertebral ring apophysis, signifying completion of spinal growth. The lateral to medial ossification of the iliac crest apophysis occurs over a period of 18–24 months, finally capping the entire iliac wing. Risser classified the extent of apophyseal ossification in stages, with Risser 0 indicating absence of ossification in the apophysis and Risser 5 indicating fusion of the fully ossified apophysis to the ilium (spinal growth complete) (116). Risser 1 through 4 are assigned to the intermediate levels of maturity as seen in Fig. 18-15.

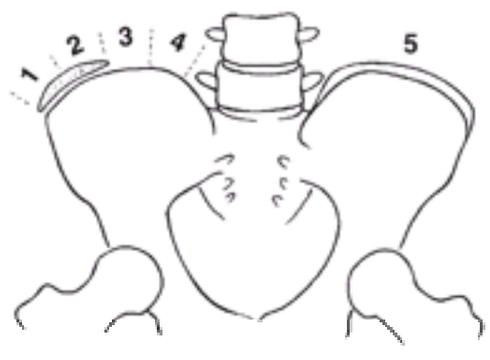

FIGURE 18-15. Risser sign. The iliac apophysis ossifies in a predictable manner, beginning laterally and progressing medially. This capping of the iliac wing is correlated with slowing and completion of spinal growth occurring over an 18- to 24-month period.

The status of the triradiate cartilage of the acetabulum also provides a landmark for assessing growth potential. The triradiate growth cartilage usually closes before the iliac apophysis appears (Risser 0) at about the time of maximal spinal growth (117,118). Skeletal age can also be measured using the Greulich and Pyle atlas to compare hand radiographs against illustrated standards, although these readings become less accurate (large standard deviations) in the adolescent age group (119).

Specialized Imaging Studies

Most idiopathic scoliosis cases do not require imaging beyond plain radiography. Specialized imaging methods that can be used to evaluate cases with unusual features include magnetic resonance imaging (MRI), computed tomography (CT), and bone scintigraphy, each with specific indications and advantages.

In the developed world, MRI has almost completely replaced myelography for the study of the neural elements in spine disorders. An exception is the patient who has had prior placement of stainless steel hardware (making MRI visualization nearly impossible) who has continued or new symptoms that require study.

MRI study of the spine is indicated for all infantile and juvenile idiopathic patients (79,120,121), as well as those with congenital bony anomalies, if surgical correction is planned (122,123). Left thoracic curves and scoliosis in boys have been shown to have an increased association with spinal cord anomalies and may be an indication for MRI study (120,124). Indications for routine MRI study in patients with typical idiopathic scoliosis prior to corrective surgery (and who have a normal clinical neurologic examination), remain unclear (125). At present there is no prospective study that confirms the efficacy of MRI screening for preoperative assessment (spine and brain) of all patients with idiopathic scoliosis, although a few centers have made this the routine for all operative cases. Clearly, patients with an abnormality in the neurologic examination (120), or with cutaneous findings (suggesting dysraphism or neurofibromatosis), should have an MRI study of the spine and/or brain. Severe angular and rotational deformities may be difficult to analyze with an MRI, because the spinal canal deviates into and out of the planar cuts of the sagittal and coronal images. CT myelography that produces a dye column may be better for revealing stenosis or an intraspinal filling defect in extremely severe cases of scoliosis.

The workup of patients with substantial back pain with no obvious cause may require a bone scan to evaluate for possible tumor, infection, or spondylolysis. The bone scan is an excellent screening test for studying the painful scoliotic patient, allowing one to screen for conditions ranging from osteoid osteoma to hydronephrosis. A single proton emission computed tomography (SPECT) type bone scan (computerized tomographic enhancement) is very useful in identifying spondylolysis and its varying presentations (unilateral, bilateral, cold scan, hot scan, etc.). If an area of increased activity is noted on the bone scan, additional imaging (either MR or CT) may be required. CT studies can be performed with increasing sophistication, and provide the best method for imaging the bony anatomy in complex deformities and congenital anomalies. Standard two-dimensional transverse images are less helpful in scoliosis, compared to coronal, sagittal, and three-dimensional reformatted images. Additional multiplanar (curved along the deformity) reformatted coronal and sagittal images are particularly helpful in imaging the scoliotic spine when congenital anomalies are suspected (Fig. 18-16).

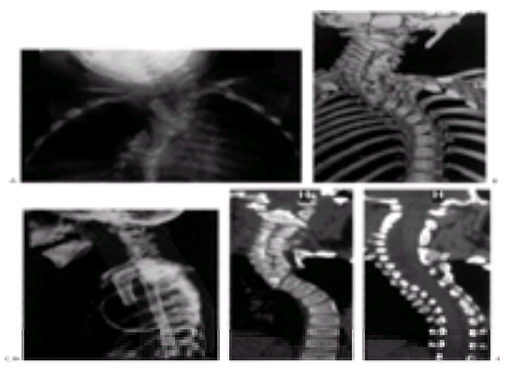

FIGURE 18-16. A: This 3-year-old patient presented with severe cervicothoracic scoliosis. The AP radiograph demonstrates a congenital etiology to the deformity; however, the details of the malformation are difficult to appreciate on the plain radiograph. **B:** A three-dimensional CT scan demonstrates much more clearly the anatomic deformities in the vertebral bodies. **C:** Frontal plane reformatted images are helpful in analyzing the size and number of hemivertebrae, as well as detecting unsegmented bars. The ability to obtain these images along a curved surface (produced with special software) is particularly useful in following the curvature of the spine in either the AP or lateral projections. Here the sagittal plane (lateral) curved scout film is seen. **D:** The anteroposterior reformatted images through the mid-portion of the vertebral bodies allows identification of the hemivertebrae and associated wedged vertebrae throughout the cervical and upper thoracic spine. **E:** An anteroposterior reformatted image, through the level of the pedicles, demonstrates two areas of an unsegmented bar in the concavity of the cervicothoracic deformity.

Imaging the kidneys and urologic collecting system is important in patients with congenital scoliosis (126,127), because identification of a congenital spinal deformity may be the first clue of an abnormality of the genitourinary (GU) system (which, if unrecognized, could lead to permanent kidney damage). An ultrasound study is the most practical screening test for detecting GU system abnormalities and should be obtained once a congenital spinal abnormality has been identified (126).

IDIOPATHIC SCOLIOSIS—DETAILS OF DIAGNOSIS AND TREATMENT

Idiopathic scoliosis makes up the largest subset of patients with spinal deformity, and because its etiology is unknown, this diagnosis is one of exclusion made only after a careful evaluation has ruled out other causes of scoliosis. Clinical features and treatment vary by age group (infantile, juvenile, adolescent), and are summarized below.

Prevalence and Natural History of Idiopathic Scoliosis

The prevalence of idiopathic scoliosis (with a curve of greater than 10 degrees) in a childhood and adolescent population has been reported to be from 0.5 to 3 per 100 (128,129,130,131,132,133 and 134). The reported prevalence of larger curves (greater than 30 degrees) ranges from 1.5 to 3 per 1,000 (135,136) (Table 18-2). Thus small to moderate curves are common, and severe (life threatening) curves are rare.

		[% of Patients with Curves of this Magnitude]			
Author (Ref)	No. Patients	>5 degrees	>10 degrees	>20 degrees	>30 degrees
Stirling et al. (131)	15,799	2.7	0.5		
Bruszewski & Kamza (130)	15,300	3.8	3.0	0.5	0.15
Rogala et al. (133)	26,947	5.3	2.2		
Shands & Eisberg (129)	50,300	1.9	1.4	0.5	0.29
Kane & Moe (128)	75,296				0.13
Huang (54)	33,596		1.5	0.2	0.04
Morais et al. (134)	29,195		1.8	0.3	
Soucacos et al. (171)	82,901		1.7	0.2	0.04

TABLE 18-2. PREVALENCE OF SCOLIOSIS

The percentage of cases seen in each age group demonstrates a strong predominance of adolescent curves, with a series of patients from Boston showing 0.5% infantile, 10.5% juvenile, and 89% adolescent (16). The natural history for each group varies substantially.

Although classically idiopathic scoliosis has been divided into three groups according to the age of onset (infantile, juvenile, adolescent), there is a movement in Britain to simplify this to early-onset scoliosis (before age 10 years) and late-onset scoliosis (typical adolescent scoliosis) (131). Dickson and Weinstein believe that only early-onset scoliosis has the potential for evolution to severe thoracic deformity with cardiac and pulmonary compromise (137). This simpler classification has not been fully evaluated, thus the traditional three–age-group division remains the standard in North America.

Infantile Idiopathic Scoliosis

Infantile idiopathic scoliosis (IIS) cases have been more commonly reported from Britain, compared to North America (16,138,139). More recent reports, however, have suggested a decrease in the frequency of infantile cases more closely paralleling the North American experience (140).

IIS presents as a left thoracic curve in approximately 90% of cases with a male:female ratio of 3:2 (138,139,141,142). The curvature is associated with plagiocephaly, hip dysplasia, congenital heart disease, and mental retardation (14,143). The series from Britain suggests that the vast majority (up to 90%) of these curves are self-limited and resolve spontaneously (142); however, the few that are progressive can be difficult to manage (Fig. 18-17).

FIGURE 18-17. A: This 3-year-old male presented before 1 year of life with a 45-degree left thoracic scoliosis. An MRI evaluation of his brain and spinal cord was normal; therefore, he was diagnosed as having infantile idiopathic scoliosis. The initial PA radiograph demonstrated a severe left thoracic scoliosis with a rib–vertebral angle difference (RVAD) of 40 degrees. **B:** Progression was noted despite bracing and corrective casting and by age 2 years the curve was greater than 90 degrees.

Prediction of Progression in Infantile Curves. Risk factors which predict a high likelihood for curve progression have been identified by Mehta who, in a study of 135 patients with infantile idiopathic scoliosis, determined radiographic prognostic factors: 1) rib vertebral angle difference (RVAD) and 2) phase of the rib head (144). The RVAD is the most commonly utilized measure, and is determined at the apical vertebra on an AP radiograph. The difference in the obliquity between the two ribs attaching to the apical vertebra (right versus left) is known as the RVAD. The ribs in the concavity of progressive infantile scoliosis are relatively horizontal, while those on the convex side are more vertically aligned (Fig. 18-18). Eighty-three percent of Mehta's reported cases resolved when the RVAD was less than 20 degrees compared to 84% progressing when the RVAD was greater than 20 degrees (144,145).

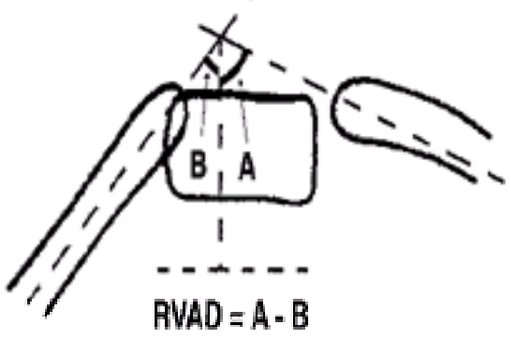

FIGURE 18-18. In infantile idiopathic scoliosis the rib–vertebral angle difference (*RVAD*) helps in predicting curve progression. The RVAD is constructed by first determining the angle of the right and left ribs at the apical level of the deformity. The slope of the ribs relative to the transverse plane is measured for each rib. The difference in the angle between the right and left sides is the RVAD.

Juvenile Idiopathic Scoliosis

Juvenile idiopathic scoliosis (JIS), defined as scoliosis with an onset between the age of 4 to 10 years, makes up approximately 8 to 16% of the childhood idiopathic scoliosis (146,147 and 148), and in many respects, represents a transitional group between the infantile and adolescent groups. Curves with onset in this age group are often progressive with potential for trunk deformity and eventual cardiac and pulmonary compromise. Many patients who present in adolescence (previously undiagnosed and untreated), with severe thoracic curves requiring immediate surgery, have had the onset of their curve in the juvenile age period, making differentiation of the juvenile versus adolescent grouping problematic.

In JIS, boys seem to be affected earlier than girls (146,149). In a series of 109 patients evaluated by Robinson and McMaster, the boys presented at a mean age of 5 years 8 months, compared to an age of 7 years 2 months for the girls. The ratio of girls to boys was 1:1.6 for those younger than 6 years and 2.7:1 for those older than 6 years at presentation. Additionally, there were equal numbers of right- and left-sided curves in the younger group (less than 6 years), with a predominance of right sided curves (3.9:1) in the patients older than 6 years (146). When curves reach 30 degrees they are nearly always progressive if left untreated (150). The rate of progression is 1 to 3 degrees per year before age 10 years, and sharply increases to 4.5 to 11 degrees per year after that age (146). This is particularly true for thoracic curves, which despite brace treatment, require arthrodesis greater than 95% of the time (146,150). The surgical treatment of JIS is similar to that for adolescent idiopathic scoliosis; however, anterior growth ablation (fusion), in addition to posterior instrumentation and fusion, is more commonly indicated to prevent “crankshaft” rotational growth following posterior fusion (see p. 729). In very young cases, instrumentation using a system that can be periodically lengthened is sometimes used (instrumentation without fusion-fusion only at proximal and distal hook sites).

Adolescent Idiopathic Scoliosis

This most common category of adolescent idiopathic scoliosis (AIS) theoretically develops a curve after the age of 10 years, associated with the rapid growth of adolescence. Again, the separation of adolescent and juvenile curves is somewhat arbitrary, since an 11-year-old girl who presented with a 70-degree scoliosis almost certainly had the onset of scoliosis in the juvenile age period. Thus the European view is that scoliosis should be considered either early-onset or late-onset. As noted previously, the prevalence data range between 0.5 and 3% for curves ³l10 degrees. These data have been collected from a variety of sources, including screening chest x-rays as well as school screening programs (Table 18-2). Roughly 2% of adolescents have a scoliosis of ³l10 degrees, but only 5% of these cases have progression of the curve to greater than 30 degrees. The ratio of boys to girls is equal for minor curves, yet is dominated by girls as the curve magnitude increases, reaching 1:8 for those requiring treatment (151).

Risk Factors for Progression

Knowledge of which curves will likely worsen and which will not is critical in deciding whom to treat. Risk factors for scoliosis progression that have been identified include gender, remaining skeletal growth, curve location, and curve magnitude with scoliosis progression being most rapid during peak skeletal growth (early infancy and adolescence). The peak growth velocity of adolescence averages 6 to 8 cm of overall height gain per year (28,118) with half of this growth coming from the trunk (spine) (152) (Fig. 18-19). Several determinants are useful in predicting the remaining growth. The age of the patient is obvious; however, substantial variation in skeletal growth exists for patients of the same chronologic age; therefore, bone age is a more consistent indicator (153). Menarchal status helps determine the growth spurt in females with the onset of menses generally following the most rapid stage of skeletal growth by approximately 12 months.

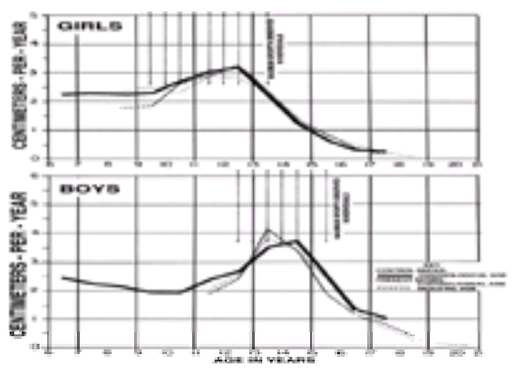

FIGURE 18-19. Increase in sitting height during the adolescent growth spurt for girls and boys is noted in this graph. The peak gain in trunk height ranges between 3 and 6 cm per year. (From ref. 152, with permission.)

The Risser sign, associated with the stages of vertebral body end-plate growth, has been demonstrated to be a useful measure for assessing risk for curve progression. When the Risser sign is 1 or less, the risk for progression is up to 60 to 70%, while if the patient is Risser 3, the risk is reduced to less than 10% (29,154).

Unfortunately many of the readily identified markers of maturity (menarchal status and Risser sign) are quite variable, and appear just after the adolescent growth spurt. It is therefore impossible to tell if a premenarchal, Risser 0 patient is approaching, in the midst of, or past the time of most rapid growth and risk for scoliosis progression, if there is no accurate record of prior growth. Recently, closure of the triradiate cartilage of the acetabulum has been identified as a radiographic sign which more closely approximates the time of peak growth velocity (118).

Curve pattern has also been identified as an important variable for predicting the probability of progression. Curves with an apex above T12 are more likely to progress than isolated lumbar curves (154). Curve magnitude at initial diagnosis appears to be a factor predicting progression (29,155) (Fig. 18-20). In a series of skeletally immature patients (Risser 0 or 1), curve progression occurred in 22% of cases with a curve at initial diagnosis of 5 to 19 degrees compared to 68% incidence of curve progression when the initial curve was 20 to 29 degrees (29). This rate increases to 90% when the initial curve is 30 to 59 degrees (156).

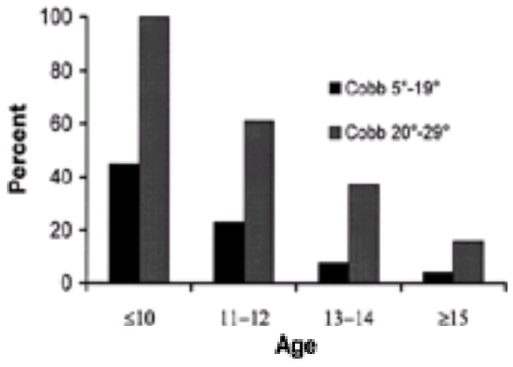

FIGURE 18-20. The incidence of scoliosis curve progression is greatest at a younger age and for larger curves. (From ref. 29, with permission.)

Natural History in Adulthood

The long-term effects of idiopathic scoliosis in adults should be understood when considering treatment in childhood and adolescence. The risk of curve progression is greatest during the rapid phases of growth as discussed above; however, not all curves stabilize after growth stops. In the long-term studies performed at the University of Iowa, greater than two-thirds of patients experienced curve progression following skeletal maturity. Curves of less than 30 degrees tended not to progress with the most marked progression occurring in curves that were between 50 and 75 degrees at the completion of growth (continuing at a rate of nearly 1 degree/year). Lumbar curves generally progressed if they were greater than 30 degrees at skeletal maturity (157,158). Several studies have been performed which provide insight into what the future holds for affected individuals. Early studies of untreated scoliosis patients, with up to 50-year follow-up, claimed a mortality rate twice that expected in the general population with cardiopulmonary problems as the most common cause of death (159,160). Disability and back pain were common in the living patients (160,161). Unfortunately the etiology of the scoliosis in these studies was mixed (idiopathic, congenital, neuromuscular), and the severity of the scoliosis was not known for many of the patients, making correlations to those with idiopathic scoliosis impossible.

In more recent studies in which only adolescent idiopathic scoliosis patients were included, the increased mortality rate reported previously has not been confirmed (162). Mortality from cor pulmonale and right heart failure was seen only in severe thoracic curves (>90 to 100 degrees) (162,163).

Pulmonary function becomes limited as thoracic scoliosis becomes more severe (>80 to 90 degrees curve) (162,164,165). Forced vital capacity (FVC) and forced expiratory volume in one second (FEV_1) decrease linearly with approximately a 20% reduction in predicted values with curves of 100 degrees (162) (Fig. 18-21). The associated deformity of the chest cavity causes restrictive lung disease. Thoracic lordosis also decreases lung volume and increases the deleterious effects of scoliosis on pulmonary function (166).

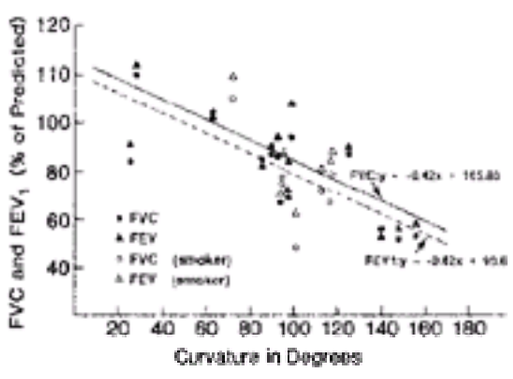

FIGURE 18-21. Pulmonary function as it relates to curve severity in both nonsmoking and smoking patients. (From ref. 162, with permission.)

Estimates regarding the frequency of back pain and associated disability in adults with scoliosis vary, but most studies have demonstrated slightly higher rates of back pain compared to control groups (162,167,168 and 169). The 1,476 patients with AIS surveyed in Montreal had more frequent and more severe back pain than did 1,755 control subjects (167). Disability rates have been higher (160,167) in some series and similar in others (162).

The social impact of scoliosis varies with the individual and the cultural setting. Many current patients have substantial concern about the appearance of their back and seek medical treatment for correction of their deformity (170). The rate of marriage for females with scoliosis is lower in some studies implying a psychosocial effect of the deformity (159,160). Many modern parents are unwilling to accept significant deformity of any type in their child whether it be dental, dermatologic, or orthopedic, particularly if there is a reasonable and safe way to correct the condition.

School Screening for Scoliosis

School screening programs to detect scoliosis at an early stage have been instituted in many countries, with a goal of detecting childhood scoliosis early enough to allow brace treatment, rather than in its late stages, when surgical correction and fusion would be needed (171,172 and 173). Screening programs for any disease are indicated if effective early treatment methods exist, and if the disorder is frequent enough to justify the cost. Although screening programs for scoliosis are widespread in North America, the variable sensitivity and specificity of the screening exam, and the borderline efficacy of brace treatment, have caused some to suggest that school screening is not justified (137,172,174,175,176 and 177).

Despite these concerns, scoliosis screening is commonly performed on school children between the fifth and sixth grades (age 10 to 12 years) (178). The Adams forward-bend test is employed in combination with scoliometer (179) measurement of the maximum angle of trunk rotation (ATR) (Fig. 18-9). A referral and radiograph are recommended when the ATR is >7 degrees (93,94,179,180). The 7-degrees ATR standard detects nearly all curves greater than 30 degrees, yet leads to a large number of patient referrals (2 to 3 per 100 children screened) (93,179) for radiographs in adolescents who have only spinal asymmetry (Cobb <10 degrees) or mild scoliosis (Cobb <25 degrees) not needing treatment. Overall, in screening programs the incidence of curves of >10 degrees (Cobb angle) is approximately 3%, and of curves >25 degrees, about 0.3%.

Both the Adams forward-bend test and measurement of the ATR with a scoliometer have been shown to have reasonable intraexaminer agreement (95,180,181 and 182). Although there is an overall linear correlation between the ATR and Cobb angles (95,183), precise prediction of the magnitude of deformity is not possible without a radiograph. The positive predictive value (the probability of having scoliosis with an abnormal screening test) of the forward-bend test is highly variable (94,134,174,176,184) and thought by many to be too low to warrant current scoliosis screening practices.

Despite the criticism leveled at school screening (cost and over-referral), many experts believe that the emphasis placed on screening for early diagnosis has greatly increased awareness of scoliosis, not only in the lay public, but also among primary care physicians. It appears that the combination of increased awareness plus the efficacy of screening programs has reduced the number of patients who do not see a physician until they have marked deformity (171,173,185,186). This remains controversial, and others have presented longitudinal data following the institution of a screening program which reject this idea (135,176).

Treatment of Idiopathic Scoliosis

Analysis of idiopathic scoliosis treatment is dependent on understanding the natural history of the condition in the untreated state compared to the outcome with intervention. As in many pediatric conditions, the short-term outcomes of treatment are reasonably well known; however, the long-term results are less well defined. Due to this lack of knowledge, controversy continues regarding treatment choices in any individual patient.

Nonoperative Treatment of Idiopathic Scoliosis

Because most patients with idiopathic scoliosis have curves of less than 20 degrees, and only a few progress to require treatment, most patients are simply monitored. Idiopathic curves of less than 25 degrees should be monitored every 4 to 12 months (depending on the age and growth rate of the patient) with clinical and radiographic examination. Those in the rapid phases of growth are seen at more frequent intervals (every 4 to 6 months). Curves of greater than 30 degrees should be monitored for progression after skeletal maturity with radiographs obtained approximately every 5 years. Curve progression in the mature patient (when it occurs) is slow enough (approximately 1 degree per year) that more frequent follow-up is not indicated.

Indications for Orthotic (Brace) Treatment. In growing children, a spinal orthosis (brace) is generally indicated when a curve progresses to 25 to 30 degrees (187,188 and 189). Scoliosis braces of many different styles and corrective mechanical principles have been developed with each having in common the goal of modifying spinal growth by applying an external force. Because brace treatment depends on spinal growth modulation, treatment is prescribed only for patients with substantial spinal growth remaining (Risser 2–3 or less). The upper limit of curve magnitude amenable to brace treatment is approximately 45 degrees. Most studies have confirmed that, even in the most cooperative patients, the final result of brace treatment is maintenance of the curve at the degree of severity present at the onset of bracing. Correction may occur while in the brace, but when the brace is discontinued, the curve will generally settle to its pre-treatment severity (190,191 and 192). Scoliosis patients and their parents should be advised of this, because most anticipate that the brace will provide permanent correction, as is seen in orthodontic correction, a common point of reference for the layperson. In more severe curves with trunk deformity already present, this information may cause some patients and their parents to select surgical correction rather than brace maintenance.

In general, a brace is indicated for growing adolescents with a curve between 25 and 45 degrees. Most surgeons insist that curve progression of more than 5 degrees be documented before bracing curves of less than 30 degrees. These indications may need to be altered depending on the clinical circumstance; for example, a 10-year-old premenarchal female, with a curve that has increased from 14 to 22 degrees in the prior 6 months, should probably be braced before reaching 25 degrees. Early bracing may also be considered when a strong positive family history for progressive scoliosis exists (mother or sibling required treatment).

Brace Types. The Milwaukee brace, developed by Walter Blount at Milwaukee Children's Hospital in the 1940s, became the standard to which other designs were compared (193). This brace remained popular into the 1980s (194), and remains an option in selected situations. The original design provided longitudinal traction between the skull and pelvis with lateral translational forces directed through pads on the chest wall (Fig. 18-22). The brace uprights can be adjusted in length to accommodate growth—a feature useful in treating infantile and juvenile patients. In addition, it remains one of the few designs that has the potential to maintain upper thoracic curves.

FIGURE 18-22. Milwaukee brace.

Underarm braces (e.g., Boston (195,196) and Wilmington (197,198)) (Fig. 18-23) have replaced the Milwaukee brace in most centers due to increased acceptance by the patients. Because no upright or neckpiece is used, the brace is less conspicuous, a feature highly important to the adolescent. The stigma of wearing a visible scoliosis brace produces a negative self-image in many teenagers (199,200). Despite improvements in brace appearance (brace worn under clothes—no visible neckpiece), many teenagers will not cooperate with brace wear. Factors for failure include pain (201), poor fit, heat, family environment, and concerns about self-esteem. The brace must be acceptable to the patient if it is to be worn and have any chance of limiting curve progression.

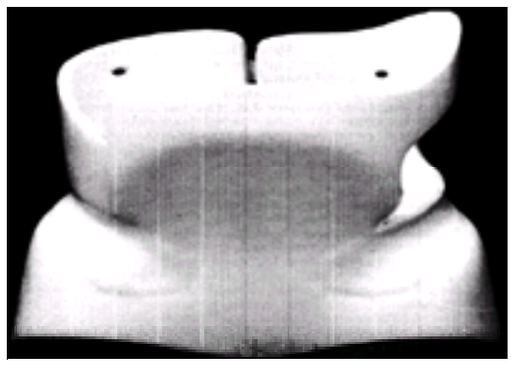

FIGURE 18-23. Boston brace.

The Charleston nighttime bending brace (202), an alternative that attempts to create a more complete correction of the curve (Fig. 18-24), requires a trunk bend so severe that it precludes walking. This brace is therefore only prescribed for nighttime wear and is best suited for single curves that are more distal (thoracolumbar and lumbar curves).

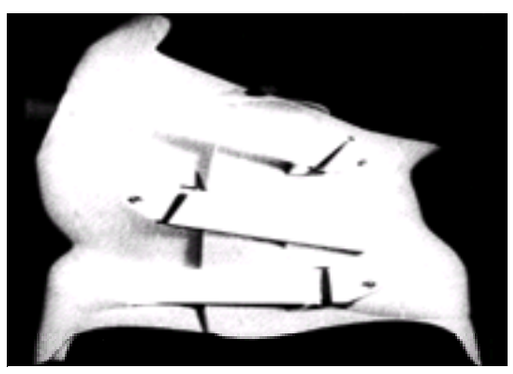

FIGURE 18-24. Charleston brace (nighttime bending brace).

Wearing Schedule. Correction by a brace is thought to be due to the constant corrective molding of the trunk and spine during growth. As such, full-time (23 h per day) brace wear was first advised by Blount, and continues to be recommended by many who prescribe scoliosis braces. About 15 years ago, certain centers began to treat patients for only 16 h per day, allowing the child to go to school without the brace, hoping that the abbreviated schedule would lead to greater patient compliance (197,203). This schedule is popular with many surgeons (and patients); however, one must question the biomechanical validity of the concept since the preponderance of brace wear is at night when the curve is least severe (patient supine). Alternatively, during daytime hours, when the curve is at its greatest (upright, forces of gravity), the curve is uncorrected. A metaanalysis performed by the Scoliosis Research Society Prevalence and Natural History Committee found a dose dependent relationship between the time per day in brace and success in preventing curve progression (204), suggesting that more hours of brace wear per day provides more effective correction. This contradicted a study of the Wilmington brace, which did not demonstrate a difference in efficacy between part-time and full-time bracing (197).

This recommendation for full-time brace wear is in sharp contrast to the Charleston nighttime bending brace philosophy, which attempts to produce hypercorrection. In a series reported by Price et al., the average curve correction while in the brace was 73% (205), and they postulated that less time per day of wear was required because of the marked correction while in the brace.

Brace Efficacy. The effectiveness of bracing for idiopathic scoliosis has been presumed for many years, yet controlled treatment trials with and without bracing had not been completed until recently (187,206). Earlier studies reporting high success rates for brace treatment were subsequently noted to have included many patients who were at low risk for progression. Lonstein and Winter evaluated 1,020 patients treated with a Milwaukee brace, over half who were at substantial risk for progression, and for whom the natural history was known. In the group with an initial curve between 20 and 29 degrees, and at high risk for progression, the brace was found to be effective compared to natural history data (194). This is in contrast to the findings of Noonan et al. who have recently called into question the efficacy of the Milwaukee brace (207).

In 1995 the results of a prospective controlled study of bracing by the Scoliosis Research Society was published. The results in 286 patients age 10 to 15 years, with an initial curve of 25 to 35 degrees, treated with either observation alone (129 patients), an underarm brace (111 patients), or nighttime electrical stimulation (46 patients) were compared. Curve progression at the end of bracing (skeletal maturity) was limited to less than 5 degrees in 74% of those treated with a brace, compared to 34% of those followed without treatment. The group treated with electrical stimulation had a success rate of only 33% (187). Although critics (137) site flaws in this and other studies, most centers have accepted the results, and continue to advise brace treatment for progressive curves in skeletally immature adolescents.

Data regarding the efficacy of various brace designs are mixed with differing inclusion criteria making direct comparisons impossible (203,204). However, in two recent studies a full-time underarm brace was more successful than a nighttime Charleston bending brace both in preventing curve progression and in preventing surgery (188,208). Both of these studies were retrospective with potential biases, and no prospective comparison of various braces has been performed to confirm these conclusions. In the series from Dallas, the nighttime Charleston brace equaled the efficacy of a Boston brace for single lumbar and thoracolumbar curves (188).

For each of these braces correction of the curve should be maximized in the brace with careful fitting, and adjustment of the pads by an experienced orthotist with an interest in scoliosis treatment. Efficacy is increased when the in-brace radiographic Cobb angle is reduced by 20% or more, compared to the pre-brace Cobb measurement (207).

In summary, although brace treatment for progressive curves provide the standard of care in most of the developed world, the scientific basis for brace efficacy is not powerful. When to intervene remains problematic, because very mild curves are easier to control with a brace, yet wholesale adoption of this policy leads to many children being braced unnecessarily. Waiting until the curve reaches 30 degrees allows one to brace the least number of patients, yet the margin between a curve of 30 degrees (brace instituted) and 40 to 45 degrees (surgery required) is distressingly small. Finally, many adolescents strongly resist brace wear, and their resistance is understandable (209,210), particularly in teenage boys with scoliosis, who might have to wear a brace for as long as 5 years (skeletal maturity often age >18 years). Each of these factors make the brace treatment of scoliosis a continuing challenge.

Surgical Correction of Idiopathic Scoliosis

Introduction and Indications. Goals for surgical treatment of idiopathic scoliosis include improved spinal alignment/balance and prevention of subsequent curve progression. Corrective instrumentation plus arthrodesis (fusion) provides the best method for achieving lasting correction, and can be used either anteriorly or posteriorly to restore spinal alignment, as well as to provide postoperative stabilization while the fusion mass progressively solidifies. All current methods rely on the development of a stable bony fusion mass to maintain the correction over time with the rods serving as internal struts while fusion occurs. Application of a rod system without a bony fusion predictably leads to rod fracture and loss of correction.

The indications for surgical correction of scoliosis are based on curve magnitude, clinical deformity, risk for progression, skeletal maturity, and curve pattern. In general, thoracic curves of greater than 40 to 50 degrees (Cobb angle) in skeletally immature patients should have surgical correction, while in mature patients (i.e., risk of progression decreased), surgical correction is reserved for curves of 50 degrees or more. These Cobb angle ranges are meant as guidelines rather than absolute indications and are based on the natural history of untreated scoliosis in immature and mature patients. Factors other than Cobb angle should be considered when deciding between operative and nonoperative treatment. Trunk deformity (rotation), as well as trunk balance, are important factors in deciding when to advise surgical correction. A patient with a lumbar curve of 35 degrees may have such a severe lateral trunk shift that surgical correction is indicated. The curve pattern has a great impact on the cosmetic deformity associated with the scoliosis, with single curves producing a more noticeable unbalanced trunk, compared to double or triple curves (Fig. 18-25).

FIGURE 18-25. This classic series of photographs from J.I.P. James demonstrates the clinical appearance of four patients, each with a 70-degrees magnitude curvature, although with different curve patterns. The clinical deformity is greater in single curves, particularly in the thoracic curve. (From ref. 141, with permission.)

When recommending surgical treatment of scoliosis, it is implied that both early and long-term outcome will be improved compared to the nonoperative treatment. The short-term results of surgical treatment are well known with a variety of surgical techniques having been studied for most curve types. Midterm (5 to 10 years) outcomes for modern corrective surgery are becoming available (211,212), but like all advancing technologies, the surgical methods tend to change faster than the results can be collected. The study by Dickson et al. of Harrington's surgically treated patients, with 20-year follow-up, showed good long-term results. Although the methods of Harrington (single distraction rod) have been replaced in many parts of the world, the fusion of patients with scoliosis in that era led to lasting stabilization in most cases (213).

Posterior Spinal Instrumentation. Paul Harrington of Houston introduced posterior spinal instrumentation in the early 1960s to make spine fusions more predictable (214). Prior to this, *in situ* fusions with body cast correction were performed (215) to correct the deformity and immobilize the spine while the fusion occurred. The addition of Harrington instrumentation improved scoliosis correction and greatly reduced the incidence of pseudarthrosis following scoliosis surgery.

Harrington Instrumentation. The Harrington instrumentation system consists of a ratcheted concave distraction rod with hooks at either end and a threaded compression rod attached to the transverse processes on the convex side of the curve **[➥2.2]**. Coronal plane improvement provided by the Harrington distraction rod was often gained at the expense of decreased thoracic kyphosis and flattening of the lumbar spine (so-called “flat-back deformity”), as noted in the sagittal plane (Fig. 18-26). Subsequent modifications of the Harrington concept included the use of sublaminar wires or a square-ended rod to allow rod contouring (in an attempt to maintain thoracic kyphosis and lumbar lordosis) while preventing rod rotation with distraction **[➥2.3]** (216).

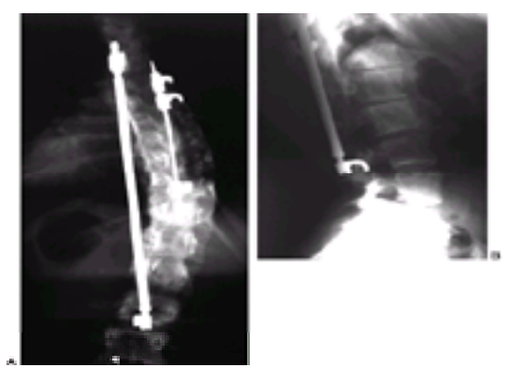

FIGURE 18-26. A: Harrington distraction rod can be seen on the left with the smaller threaded compression rod on the right. **B:** Distraction into the lumbar spine reduces lumbar lordosis creating a “flat-back” deformity.

The trend toward protecting normal lumbar contour was greatly advanced by Moe's clarification that most scoliosis (with apparent double curves) requiring surgical correction did *not* require fusion of the lumbar curve. He clarified that the lumbar curve is very often secondary, and does not require fusion (the so-called King-Moe type 2 curve). Application of the King-Moe curve classification is emphasized later in this chapter (217).

Cotrel-Dubousset and Other Double Rod, Multiple Hook Systems. Nearly 20 years after the Harrington method was introduced, Cotrel and Dubousset (France) introduced a multi-hook system that allowed distraction and compression on the same rod (218). Sagittal plane contouring of the rods and segmental hook fixation improved curve correction, as well as postoperative stability. Many additional segmental fixation posterior instrumentation systems utilizing similar concepts are now available for surgical correction of scoliosis. Current options for attachment to the posterior spine include hooks (for attachment to the transverse processes, laminae, and pedicles), sublaminar wires (Luque), and pedicle screws **[➥2.9]**.

The introduction of pedicle screw fixation into posterior scoliosis constructs distally, allows greater correction compared to distal hook constructs, and allows fewer levels to be instrumented caudally (219,220). The utility of pedicle screw attachment to vertebra was first recognized in Europe (221), and was initially quite controversial in North America because of an increased potential for neurologic injury associated with screw insertion. Pedicle screw attachment is highly effective, but the surgeon must have appropriate training and skill when using them to safely improve the stability of corrective scoliosis constructs. In North America they are generally used only in the lower thoracic and upper lumbar spine when used at all for scoliosis correction. The use of pedicle screws in mid and even upper thoracic vertebrae in scoliosis has been advocated by Suk et al., but this more demanding technique has not been widely adopted (222,223).

It must be emphasized that with all of these procedures the goal is to obtain fusion, and one must first perform careful subperiosteal exposure of the spine as well as meticulous facet excision **[➥2.1]**. The spine must also be decorticated prior to adding bone graft. The complexity of modern instrumentation sometimes causes surgeons to pay too little attention to the details required to obtain a successful fusion.

Mechanisms of Correction. Several strategies can be utilized when implanting posterior instrumentation systems. Frontal plane realignment of the spine can be

accomplished by translating the vertebra to the concave rod. This translational movement may be performed by connecting the concave rod, precontoured to the desired sagittal profile to each fixation site along the spine, then rotating the rod into the sagittal plane. This rod rotation maneuver, popularized by Dubousset, remains an effective method for translating the apex of the curve into a more normal position (Fig. 18-27). Another method for translating the apex in space involves locking the concave rod into the position of anticipated correction, then sequentially (with hooks) or incrementally (with sublaminar wires) drawing the spine to the rod. Compression and distraction forces are then added to enhance both frontal and sagittal plane correction.

FIGURE 18-27. Example of the rod derotation maneuver popularized by Dubousset. The rod, first contoured to match the scoliosis, is then secured to the hooks and rotated 90 degrees to recreate thoracic kyphosis and lumbar lordosis.

Distraction on the concave (usually left sided) rod in the thoracic spine increases thoracic kyphosis and decreases a right-sided scoliosis. Both are generally desired, given the frequent loss of normal thoracic kyphosis noted in idiopathic scoliosis. Similarly, *compression* applied on the same left-sided rod in the lumbar spine (of a double curve) corrects scoliosis and allows restoration/maintenance of lumbar lordosis. In most posterior instrumentation systems used to correct a right thoracic curve, the left-sided (concave) thoracic rod that is placed first provides the majority of the deformity correction. The second rod, placed on the right side, primarily adds stability and resistance to fatigue failure. In most modern systems, the two rods are then cross-linked to improve stability.

Anterior Release and Fusion. Indications for a combined anterior and posterior approach in idiopathic scoliosis include patients with large (greater than 75 degrees), rigid (bend correction less than 50 degrees) curves, and those at risk for post-fusion crankshaft deformity. Curve flexibility is increased by anterior disc excision, allowing greater correction with posterior instrumentation, and the bone graft used anteriorly leads to a very stable fusion (anterior and posterior). The procedure involves anterior disc excision with release of the anterior longitudinal ligament, removal of the annulus fibrosis and nucleus pulposus, excision of the vertebral endplate cartilage, and occasionally (in severe cases), excision of the rib head (at the costovertebral joint) (Fig. 18-28).

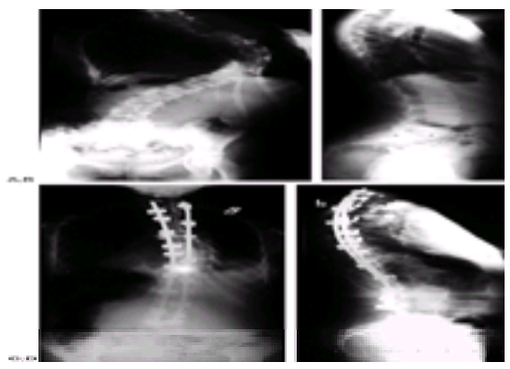

FIGURE 18-28. A: This adolescent female presented with a 90-degrees right thoracic scoliosis with marked trunk shift to the right. She corrected to 60 degrees on bending to the right. **B:** Preoperative lateral radiograph. **C:** Following thoracoscopic release and fusion the patient underwent a posterior spinal instrumentation and fusion, with correction of her deformity. A distraction was used through the concavity of the thoracic curve on the left rod with lumbar compression to restore trunk balance and maintain sagittal alignment through the lumbar spine. **D:** Postoperative lateral radiograph demonstrates maintenance of appropriate sagittal alignment.

The term “crankshaft deformity” (117,224,225,226 and 227) identifies a circumstance in which anterior spinal growth continues despite successful posterior fusion, resulting in worsening rotational deformity even after successful posterior fusion (Fig. 18-29). The problem occurs only in skeletally immature patients (Risser 1 or less, triradiate cartilage open). Defining and measuring crankshaft growth is difficult, and has been defined as an increase in the Cobb measurement of >10 degrees, or an increase in apical rotation despite successful posterior fusion. This largely axial rotational deformity is difficult to measure with routine radiography. Recent reports suggest that anterior fusion arrests the anterior growth center and limits the development of this late deformity (228).

FIGURE 18-29. A: This 8-year, 9-month-old female (clearly skeletally immature) presented with a 60-degree right thoracic scoliosis. **B:** She underwent an isolated posterior instrumentation and fusion with correction to 22 degrees. **C:** Due to continued anterior spinal growth, a crankshaft deformity developed with curve progression, and the trunk decompensated despite a successful posterior fusion. One year postoperatively her curve measured 34 degrees. In this illustration (taken two years postoperatively), her curve has progressed to 43 degrees.

An additional advantage of anterior release and fusion is the increased area for the arthrodesis (vertebral end plates) presumably reducing the risk of pseudarthrosis. The thoracoscopic approach is being developed as a means of accomplishing anterior disc excision and fusion with minimally invasive methods (229,230 and 231).

Anterior Spinal Instrumentation. At the time of anterior disc excision and fusion, anterior corrective instrumentation with vertebral body screw fixation and a single or double anterolateral rod construct can be considered for some curve patterns **[➥2.11]**. The first anterior instrumentation systems, introduced by Dwyer (232) and then Zielke (233), were both flexible rod compression systems that generated kyphosis within the instrumented segments. This production of kyphosis may be desirable in the scoliotic thoracic spine (that has become relatively lordotic), but is generally undesirable in the lumbar region.

Subsequently, more rigid solid-rod anterior systems were developed in an attempt to improve the sagittal alignment, particularly when used for thoracolumbar and

lumbar curves. Scoliotic curve patterns that are amenable to corrective anterior instrumentation and fusion generally include those with a single structural deformity (thoracic, thoracolumbar, or lumbar).

The greatest experience with anterior scoliosis correction has been gained in the treatment of thoracolumbar and lumbar scoliosis (234,235,236 and 237). Direct access to the vertebral bodies and intervertebral discs is possible via an open anterior thoracoabdominal approach. Anterior disc excision creates mobility, which enhances correction in the frontal and axial planes, but decreases sagittal plane lordosis. Special attention to the sagittal plane is required when anterior compression instrumentation is used distal to the thoracolumbar junction to avoid production of an iatrogenic flat-back deformity (due to loss of desired lordosis). Structural interbody support, by use of a structural bone graft or an interbody "cage," has been advocated as a means of maintaining sagittal alignment (238). Double-rod, double-screw anterior systems have also been introduced as a means of providing additional sagittal plane control (239,240). In most cases, anterior instrumentation can achieve similar or greater correction (than posterior instrumentation for the same curve) with fewer levels instrumented (241,242).

The selection of the most appropriate approach for correction of idiopathic scoliosis (anterior versus posterior) is dependent on the curve pattern, sagittal deformity, age of the patient, and experience of the surgeon. The selection of the fusion levels for any given patient is also dependent on several factors and remains a topic of much controversy. The fusion should be as short as possible, minimizing the changes in spinal mobility, yet be long enough to ensure optimal correction and lasting spinal balance (both coronal and sagittal).

Instrumentation without Fusion. Instrumentation without fusion, a technique utilized in young children with curves that progress relentlessly despite aggressive brace treatment, includes a subcutaneously positioned distraction construct that spans the deformity (243). At the proximal and distal hook sites, a limited fusion is performed to decrease the incidence of hook dislodgment. In the intervening segments, the spine is *not* stripped subperiosteally, since exposure alone may lead to spontaneous fusion in a young child (thus the concept of a "subcutaneous" rod). Sequential distraction is performed every 6 to 12 months during growth, until no further correction can be obtained. The height gained with these procedures is usually modest, and complications are common (243) (hook dislodgement, spontaneous fusion (244), and infection); therefore, these systems are presently used in children less than 5 to 6 years of age in whom there are few other options. The internal splint (spinal rods) requires external protection with a brace throughout the period of sequential rod distraction. Eventually, a formal instrumentation and fusion are performed. A short convex hemiepiphysiodesis (anterior and posterior) over the apical levels may also be included in the subcutaneous rod technique (224,245) (Fig. 18-30).

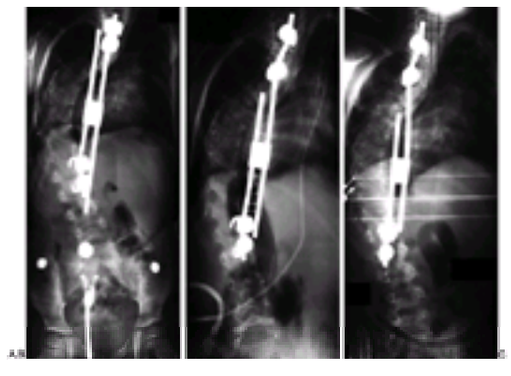

FIGURE 18-30. A: This patient with infantile idiopathic scoliosis (seen also in Fig. 18-17) underwent apical anterior and posterior hemiepiphysiodesis with posterior instrumentation at age 4 years. **B, C:** At the first repeat lengthening procedure, he achieved an increase in spine length of 2.5 cm. Additional lengthening procedures were performed every 6 months with a total length gain of 6 cm (some from deformity correction, some from growth of the spine) achieved 2½ years following the initial procedure.

Surgical Correction According to Curve Pattern

Idiopathic scoliosis takes on several typical and distinct curve patterns with the most common being a right thoracic curve. To surgically correct scoliosis one must understand these curve patterns. The most widely used classification, developed by Moe as reported by King et al. (King-Moe Classification) (Table 18-3, Fig. 18-31), was designed primarily to decide when to instrument the thoracic curve alone (in patients with apparent double curves), and when to instrument both the thoracic and lumbar curves. Despite the common use of this classification when planning surgery, the system was not designed as a comprehensive classification of idiopathic scoliosis curve patterns.

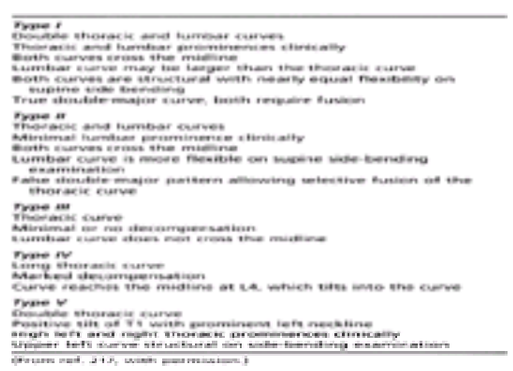

TABLE 18-3. CURVE PATTERNS OF THORACIC CURVES

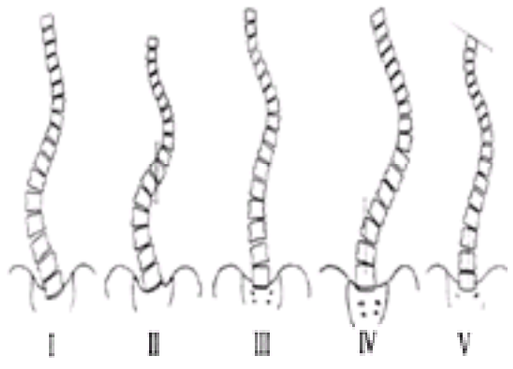

FIGURE 18-31. Diagrammatic representation of the King-Moe classification system for thoracic idiopathic scoliosis. (From ref. 217, with permission.)

Primary lumbar and thoracolumbar curves, as well as triple curves, are not included in the King-Moe classification. Others have designed classification systems that are more comprehensive (246,247). The system proposed by Lenke et al. considers both frontal and sagittal plane deformity and is designed to guide surgical treatment decision- making for all curve patterns. This classification system is currently being evaluated at several scoliosis centers around the world with the

practicality and usefulness of such a classification system yet to be proven (Fig. 18-32).

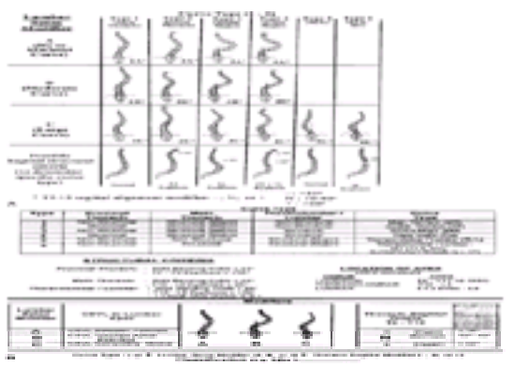

FIGURE 18-32. A, B: This comprehensive scoliosis classification scheme has been proposed by Lenke et al. to classify all forms of adolescent idiopathic scoliosis. Each curve is given a type 1 to 6, as well as a lumbar spine modifier A to C, and a thoracic sagittal profile modifier -, N, +.

Right Thoracic Curve Pattern. The common idiopathic right thoracic curve pattern is most often corrected with posterior spinal instrumentation and fusion of the thoracic curve. Selection of the best cranial and caudal vertebrae to attach to is critical, with the goal to fuse as short as possible, yet long enough to minimize residual trunk imbalance or late curve progression. For typical correction of a thoracic curve the most distal hook is attached to the vertebra that is one level proximal to the stable vertebra (vertebra bisected by the central sacral vertical line). Multiple hooks or sublaminar wires on the concave side of the spine are used to draw up the apex of the curve from its lordoscoliotic position into a more normal kyphotic alignment. The concave (left-sided) rod is placed first; setting the hooks in distraction on the concavity provides both scoliosis correction and also aids in restoration of more normal kyphosis with posterior distraction. The convex (right-sided) rod is then added, and the two rods are connected with a cross-link (Fig. 18-33).

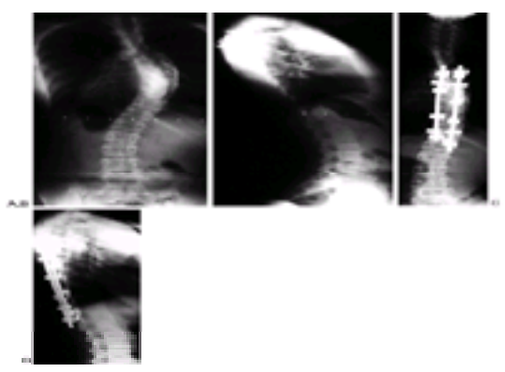

FIGURE 18-33. A, B: Preoperative radiographs (PA and lateral) of this 12-year-old female demonstrate a 45-degree right thoracic scoliosis. The stable vertebra (best bisected by a central vertical sacral line) is L2. The surgeon elected to perform a fusion extending distally only to T12 because of curve flexibility noted on bend films. **C, D:** PA and lateral views following posterior spinal instrumentation and fusion from T4 to T12. The trunk remains well balanced.

Thoracic curves can also be corrected by anterior instrumentation. This concept, more commonly used for thoracolumbar and lumbar curves in North America, has been regularly employed to also correct thoracic curves in multiple European centers for at least two decades. Advantages include greater correction, a shorter fusion, and ease of recreating normal kyphosis in the hypokyphotic thoracic spine. Most recently, several American centers have begun to correct thoracic cases with anterior instrumentation (241,248). The levels selected for fusion in anterior instrumentation to correct thoracic scoliosis include all vertebrae within the measured Cobb angle. The thoracotomy required for this approach, which results in at least a temporary decrease of pulmonary function, is a disadvantage of the method (Fig. 18-34). Also, in most systems only a single rod is used with the vertebral screw attached to the vertebral body, which is relatively more cancellous in nature compared to posterior fixation sites. This may increase the risk for screw–bone separation, especially at the cranial end of a thoracic curve, where the vertebral bodies are smaller.

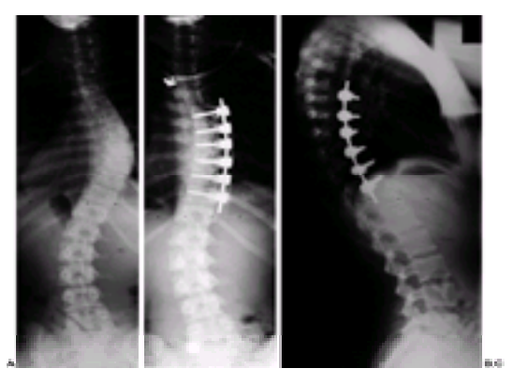

FIGURE 18-34. A: This 13-year-old female presented with a typical right thoracic curve. **B, C:** Postoperative PA and lateral radiographs demonstrate correction with limited anterior thoracic instrumentation and fusion from T6 to T11.

Anterior thoracic corrective instrumentation is being developed for thoracoscopic implantation, and may be a future option for correction of thoracic scoliosis in patients with only moderately severe curves.

Right Thoracic, Left Lumbar Curve Pattern. The lumbar curve (usually convex to the left) that often presents in association with a right thoracic curve, may vary substantially in both magnitude (Cobb angle) and severity of rotation. Either the thoracic or lumbar curve may dominate such a double-curve pattern, although the thoracic curve is more often primary. In deciding on surgical treatment, one must determine which of the curves requires instrumentation and fusion (thoracic, lumbar, or both). When the thoracic curve is larger and/or more rigid than the lumbar curve (King II), selective fusion of the thoracic curve only should be considered (217,249) (Fig. 18-35). There are situations, however, in which the lumbar curve is large enough to require fusion if a well-balanced spine is to be achieved after correction.

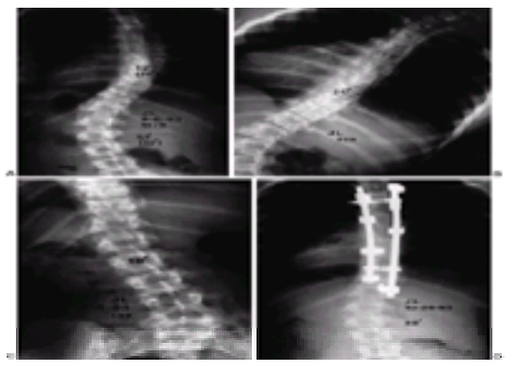

FIGURE 18-35. A: This 14-year-old female presented with idiopathic scoliosis and a right thoracic curve of 52 degrees and a left lumbar curve of 53 degrees. Clinically, she was balanced with level shoulders, and primarily a thoracic prominence on forward-bending. **B:** Supine-side bending to the right demonstrated correction of the right thoracic curve to 20 degrees. **C:** Supine side-bending to the left demonstrated lumbar curve correction to 10 degrees. Selective fusion of the thoracic curve alone is possible in this case, as long as there is not overcorrection of the right thoracic curve. The lower end vertebra of the curve (T11) is neutrally rotated and stable (bisected by the center sacral vertical line). **D:** Instrumentation and fusion were performed from T4 to T11. The thoracic curve was corrected to 20 degrees, and the lumbar curve spontaneously corrected to 22 degrees.

Several authors have provided criteria for selective fusion of the thoracic curve alone (249,250 and 251). Although universal agreement has not been reached, several factors should be understood. The instrumentation should not end inferiorly just above a “junctional kyphosis” (as noted on the lateral view). The junction between the thoracic and lumbar curves (approximately T12) may be focally kyphotic in the sagittal plane. A selective fusion of the thoracic spine in such a case will exaggerate the kyphosis at the thoracolumbar junction. When the lateral view demonstrates junctional kyphosis, the corrective instrumentation should extend distal to the kyphosis. If the lumbar curve is greater than 45 to 50 degrees, vigorous correction of only the thoracic curve with a posterior instrumentation system may result in postoperative truncal decompensation to the left (252,253). If selective fusion is elected in these cases, correction of the thoracic curve should be modest to minimize the chance of residual trunk imbalance (251).

When instrumentation of both the thoracic and the lumbar curves is required, the distal extent is usually to the L3 or L4 level (Fig. 18-36). Ideally, the distal extent of the fusion should be as proximal as possible to preserve lumbar motion segments, yet long enough to avoid creating trunk imbalance. Choosing between L3 and L4 can be difficult. The most predictable spinal balance occurs when the fusion/instrumentation extends distally to the stable vertebra (the vertebra best bisected by the central sacral vertical line). In patients with limited remaining growth and a left-sided lumbar curve, fusion to L3 may be considered, if there is minimal axial rotation of L3 as noted on the bend film to the left, and L3 levels above the pelvis with side bending to the right. With posterior instrumentation, laminar hook, or pedicle screw, fixation can be used to attach to lumbar vertebrae. When required to achieve thoracic and lumbar curve balance, pedicle screws provide an option that allows greater control and correction of a lumbar curve. Again, the surgical goal is to achieve improved spinal alignment with global truncal balance, with both C7 and the trunk well-centered over the pelvis in both the sagittal and coronal planes (Fig. 18-37).

FIGURE 18-36. A: This 12-year-old female with a 43-degree right thoracic and 53-degree left lumbar curve pattern is seen. **B:** The lateral radiograph demonstrates relative loss of thoracic kyphosis. **C:** Side-bending radiograph to the right demonstrates L4 leveling above the pelvis with flexibility of the thoracic curve to 15 degrees. L3 remains with substantial rotational deformity on the side-bending radiograph as seen by the asymmetry of the pedicles. **D:** Side-bending to the left demonstrates flexibility of the lumbar curve. **E:** Given the magnitude of the lumbar curve relative to the thoracic curve, both curves required instrumentation and fusion. The standing PA radiograph 2 years postoperatively demonstrates correction of the thoracic curve to 10 degrees and the lumbar curve to 15 degrees. **F:** Standing lateral radiograph demonstrates maintenance of lumbar lordosis and slight improvement in the thoracic kyphosis

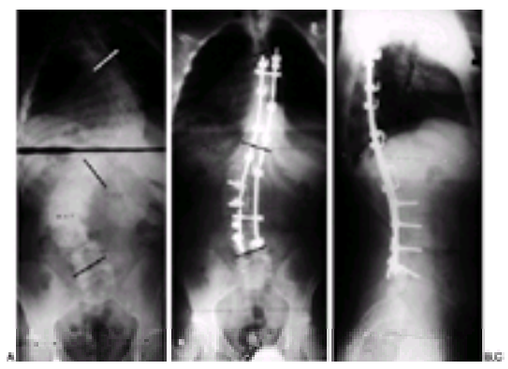

FIGURE 18-37. A: This 16-year-old male presented with severe double major scoliosis, with a right thoracic curve of 93 degrees and a left lumbar curve of 85 degrees. On side-bending radiographs to the right, the thoracic curve decreased to 68 degrees. On side-bending to the left the lumbar curve corrected to 52 degrees. **B:** The patient underwent a thoracoscopic anterior spinal release from T5 to T12, followed by a posterior spinal instrumentation and fusion of both curves. The lumbar curve was corrected to 36 degrees with pedicle screw fixation on the convex side of the curve. Coronal balance was maintained with correction of the thoracic curve to 42 degrees. **C:** The lateral radiograph demonstrates restoration of alignment in the sagittal plane.

Double Thoracic Curve Pattern. The double thoracic curve is recognized by the presence of an elevated left shoulder, whereas an isolated right thoracic curve is typically associated with an elevated right shoulder. If the left shoulder is higher, an upper thoracic curve to the left should be suspected. A left upper thoracic curve that is relatively rigid (reduces to >20 to 25 degrees on bend film) generally requires instrumentation beginning proximally at T1 or T2 (254). If the double pattern is not recognized, and the right thoracic curve alone is straightened, the left shoulder elevation is often worse following the surgery (255).

Left Lumbar or Thoracolumbar Curve Pattern. A primary lumbar or thoracolumbar curve pattern does not have a significant thoracic component and is usually convex to the left with a trunk shift to the left. In these cases, isolated fusion of a lumbar or thoracolumbar curve is appropriate, and can be accomplished by either anterior or posterior methods. Correction with posterior hook constructs has not been as successful in achieving derotation of the lumbar curve, compared to anterior instrumentation. Limited anterior instrumentation of the apical 3 or 4 vertebrae has been proposed by Bernstein and Hall with satisfactory early outcomes in the majority of patients **[➥2.11]** (242). Longer anterior constructs (256) some with the use of bone graft or a structural cage in the disc space, have become popular in the treatment of these curves (Fig. 18-38). Pedicle screw fixation has allowed better control and correction of these curves when corrected with posterior instrumentation

(Fig. 18-39). In severe cases, both anterior and posterior instrumentation may be indicated (Fig. 18-40).

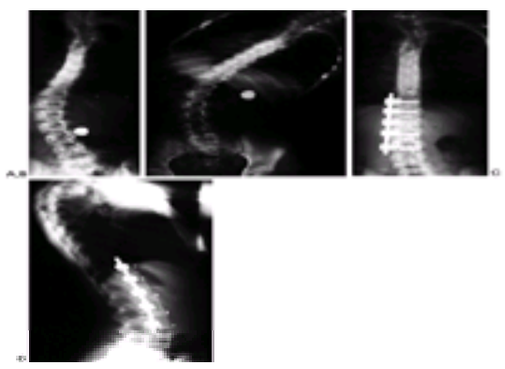

FIGURE 18-38. A: 12-year-old female who presented with a left lumbar scoliosis and trunk shift to the left. Of note, she also had a minor well-balanced congenital deformity of the upper thoracic spine. **B:** On side-bending to the right L3 leveled over the pelvis. Because this was the end vertebra of the curvature and it leveled on side-bending to the right, it was selected as the end-instrumented vertebra. **C:** The patient underwent anterior instrumentation and fusion with correction of the thoracolumbar curve. **D:** A lateral radiograph obtained 2 years postoperatively demonstrates solid arthrodesis and reasonable maintenance of lumbar lordosis.

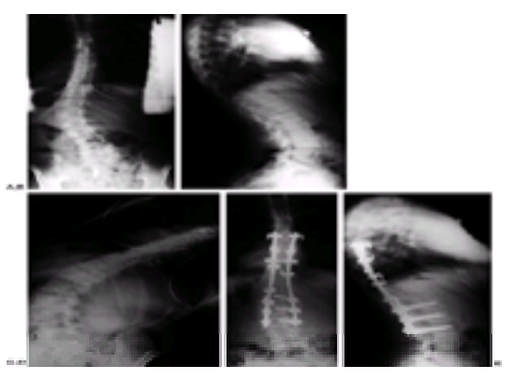

FIGURE 18-39. A: This 13-year-old female presented with a progressive left thoracolumbar scoliosis associated with trunk shift to the left. **B:** The lateral radiograph demonstrates maintenance of relatively normal sagittal alignment. **C:** Side-bending to the right demonstrates that L3 is level with the top of the pelvis. **D:** Posterior instrumentation and fusion were performed utilizing pedicle screw fixation through the apex of the lumbar spine at L1, L2, and L3 bilaterally. This provided correction of her lumbar deformity and improved her trunk shift, resulting in a balanced spine. **E:** Postoperative lateral radiograph demonstrates maintenance of lumbar lordosis in the instrumented segments.

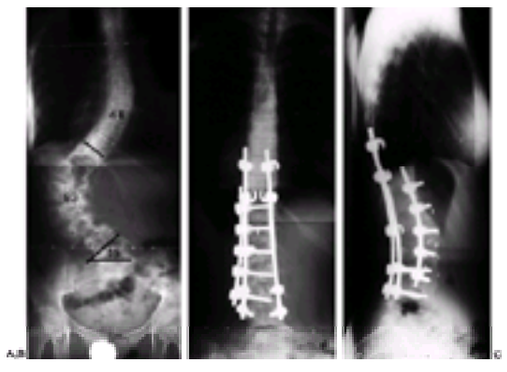

FIGURE 18-40. A: This 13-year-old female presented with previously untreated severe left lumbar scoliosis measuring 83 degrees. She had a flexible compensatory right thoracic deformity. **B:** Due to the severity of the lumbar curvature, an anterior disc excision with instrumentation was performed from T12 to L4. Following this procedure an additional posterior instrumentation was performed from T10 to L5, further correcting the inferior aspect of the lumbar spine with pedicle screw fixation. The patient has a sixth lumbar vertebra below the lowest instrumented level. **C:** Sagittal alignment has been restored and maintained with solid anterior and posterior arthrodesis seen 2 years postoperatively.

Triple Curve Pattern. Not infrequently, a combined curve pattern includes curves in all three locations: left upper thoracic, right thoracic, left lumbar/thoracolumbar. Although it may not be necessary to surgically treat all three curves, each should be considered individually to determine if they are structural (relatively rigid), and treated accordingly (Fig. 18-41). In these triple curves the lower thoracic curve, if dominant, is certainly included in the arthrodesis. The inclusion criteria for the upper thoracic and lumbar curves are the same as those used for the corresponding double-curve patterns. For example, elevation of the left shoulder, in an upper thoracic curve with a curve that remains greater than 20 to 25 degrees on side-bending, should be considered for inclusion within the levels of fusion. Similarly, the lumbar curve should be instrumented when its Cobb angle magnitude is equal to or greater than the thoracic curve. The greater the difference in magnitude and rotation between the thoracic and lumbar curves (i.e., thoracic greater than lumbar), the more likely the lumbar curve can be spared from fusion (249,251).

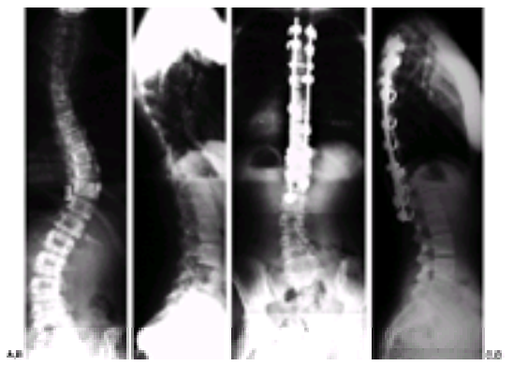

FIGURE 18-41. A: This premenarchal female had progressive scoliosis with a triple curve pattern. The left upper thoracic curve is seen with tilt of T1 and a 35-degree left upper thoracic deformity. The main right thoracic scoliosis measures 60 degrees and the left lumbar deformity 50 degrees. **B:** The lateral radiograph demonstrates hypokyphosis without a thoracolumbar junction kyphosis. The side-bending radiographs for this patient can be seen in FIGURE 29-12B and FIGURE 29-12C. **C:** Given the clinical elevation of the left shoulder, it was elected to include the left upper thoracic curve in the instrumented segment to prevent further elevation of this shoulder. The main right thoracic deformity was larger than the left lumbar curve; therefore, the lumbar curve was not included in the instrumentation. Postoperative radiograph demonstrates spontaneous improvement of the lumbar curve with balance of C7 over the pelvis. The shoulders are now more level. **D:** The lateral radiograph demonstrates restoration of a more normal sagittal profile. Hook reversal at L1 on the left rod was used to initiate lumbar lordosis, as well as limit the risk of significant trunk decompensation.

Outcomes of Surgical Treatment

Given the relatively new methods used for surgical correction of adolescent idiopathic scoliosis (Harrington instrumentation in the 1960s, Cotrel-Dubousset instrumentation in the 1980s), very long-term outcome data are not yet available. Spinal instrumentation techniques continue to undergo modification and improvement almost faster than outcome studies can be performed. The Scoliosis Research Society has recently developed an outcomes instrument which will allow more careful functional outcomes analysis of patients treated with scoliosis (257).

Outcome after Posterior Surgery. The longest follow-up exists for patients treated with Harrington instrumentation and fusion. An average coronal plane improvement of 48% of the Cobb angle has been reported (258). The long-term functional results of long posterior fusions have focused on the prevalence of late-onset low back pain. Conflicting results regarding the prevalence of pain and the correlation of pain with the caudal level of instrumentation have been reported. Moskowitz et al. (259) found no increase in pain or any correlation with the caudal level of arthrodesis. In contrast, Dickson et al. (168) found an increased incidence of back pain an average of 21 years after Harrington instrumentation compared with a control population. Cochran et al. (260) noted an increased frequency of pain in patients fused to L4 or L5 compared to those fused to L3 or above. Dickson et al. and Connolly et al. however, found no statistical correlation between the level of fusion and back pain (168,261).

Despite conflicting results regarding the increased potential for low back pain with more caudal levels of instrumentation and fusion, it seems intuitive that one should minimize the caudal extent of a fusion. Winter et al. demonstrated a significant loss of spinal motion when an arthrodesis included L4 compared to those only fused inferiorly to upper or midlumbar levels (262). Fusion to more caudal levels has also been associated with higher rates of radiographic degenerative changes in the unfused distal levels (spondylolisthesis, lateral olisthesis, disc narrowing, facet sclerosis) (261) (Fig. 18-42).

FIGURE 18-42. A: This 10-year-old female underwent posterior distraction instrumentation with a Harrington rod to L3. **B:** Eleven years postoperatively the degenerative changes in the remaining unfused lumbar spine has begun to be symptomatic. The facets have degenerated and become sclerotic, particularly at L5-S1 on the right side.

In addition to minimizing the caudal extent of the fusion, alignment in both the coronal and sagittal planes of the unfused segments should be optimized. It remains unclear whether the long-term functional results are better if the spine is fused to L4, with maintenance of lordosis and improved coronal position, compared to fusion to L3, with slightly greater residual deformity of the remaining caudal levels. The relationship of alignment and degenerative changes to the development of low back pain requires additional follow-up and analysis.

The early (253,263) and midterm (212) (5 to 10-year follow-up) results of CD instrumentation suggest improved coronal and sagittal plane correction, compared to Harrington instrumentation (264). An average correction of 61% can be expected when considering all curve types (258). The segmental hook constructs have provided clear improvement in postoperative sagittal alignment (265), although little improvement in the axial rotation deformity has been appreciated despite the early promise that systems such as the CD type would greatly derotate the spine by an intraoperative rotational maneuver as the instrumentation is applied (266,267,268 and 269). Postoperative immobilization has been minimal at most centers using the CD system, compared to Harrington instrumentation, yet the incidence of pseudarthrosis and loss of correction has been less with the newer system (212,264).

Early in the experience with CD instrumentation, truncal decompensation to the left was commonly noted in King type II curves when selective thoracic fusion was performed (250,253,270). Several techniques have been suggested to avoid this difficulty (249,252). The most important is to avoid over-correction of the thoracic spine beyond a degree that the unfused lumbar curve can adapt to. Also, hook reversal at the lower-most hook of the concave rod (most inferior hook upgoing) initiates coronal plane balance and lumbar lordosis, minimizing the risk for trunk decompensation (250,251,253) (Fig. 18-43).

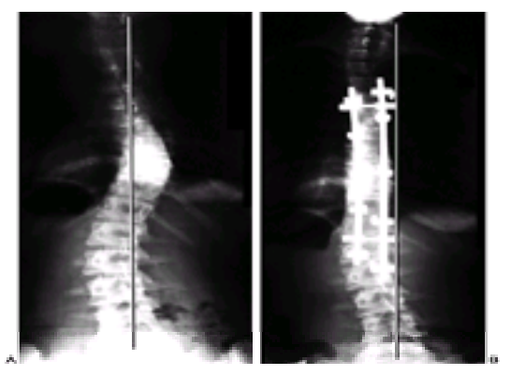

FIGURE 18-43. A: The preoperative PA radiograph demonstrates the stable vertebra to be at T12. **B:** The patient was instrumented posteriorly to L1 with a down-going hook at the distal end on the left side, resulting in decompensation to the left. This could have been prevented by either stopping the instrumentation at T12 or reversing the direction of the left-sided L1 hook to up-going.

Outcome after Anterior Surgery. Until recently, anterior correction of scoliosis has been primarily used for the correction of lumbar and thoracolumbar scoliosis. The percentage of frontal plane correction, with either Dwyer, Zielke, TSRH (Texas Scottish Rite Hospital) or Kaneda instrumentation, has been reported between 67 and 98% (234,235,236,237 and 238,242,271). Some authors have noticed a loss of sagittal plane lumbar lordosis with anterior compressive systems (272,273). Even solid ¼“ rod systems, such as the TSRH system have not been able to entirely preserve normal lordosis when used without anterior interbody structural support (234). Sweet et al. have reported that sagittal alignment in the lumbar spine can be maintained if interbody structural support is added (238); however, even with this interbody support, if a pseudarthrosis develops eventual rod breakage and collapse into increased scoliosis and kyphosis will occur (Fig. 18-44). Two rod anterior systems also provide an option that may allow better maintenance of lumbar lordosis (240,256), although reported follow-up remains limited.

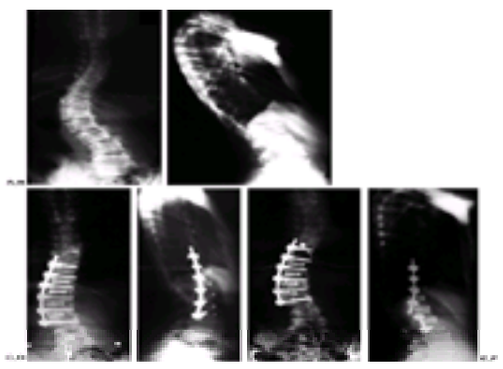

FIGURE 18-44. A: This 13-year-old female presented with a lumbar curve and trunk shift to the left. **B:** The preoperative lateral view demonstrates decreased lumbar lordosis. **C, D:** This was addressed with an anterior approach utilizing a single rod with interbody support to increase lumbar lordosis. **E, F:** She returned 1 year after the surgery asymptomatic but with loss of correction and fracture of the rod. This demonstrates that a single-rod anterior system may not always be strong enough to maintain correction while the bone graft is maturing, particularly in a very active patient.

The results of anterior instrumentation in the thoracic spine are beginning to be reported with Betz et al. having made a nonrandomized comparison of anterior versus posterior thoracic instrumentation for thoracic idiopathic scoliosis. The anterior 3.2- or 4.0-mm threaded rods resulted in comparable coronal plane scoliosis correction, compared to posterior hook systems, but were associated with a 31% incidence of rod breakage. The distal level of fusion in the anterior fusion group was on average two segments proximal to the those in the posterior group (241). Lenke et al. have also reported a greater spontaneous improvement of the uninstrumented portion of the lumbar spine when the thoracic instrumentation was anterior (and shorter), as compared to posterior in treating thoracic curves that had a compensatory lumbar curve pattern. At 2-year follow-up the thoracic curves were corrected 58% and the lumbar curves (uninstrumented) 56% in the anterior instrumentation group, compared to 38 and 37%, respectively, for the posterior instrumentation group (248). The rate of pseudarthrosis and rod breakage appears to be greatly reduced with the introduction of solid (nonthreaded) rods for thoracic curves, although proximal screw pull out can be more problematic as the rod stiffness is increased.

Complications

The complications of scoliosis surgery can be serious, although over the last 20 years these procedures have become much safer due to advances in anesthesia, blood loss management, instrumentation systems, and neurologic monitoring.

The remarkable corrective power of the new instrumentation methods, coupled with better surgical skills, spinal cord monitoring, and methods to minimize blood loss have changed how one advises patients regarding possible complications following scoliosis surgery. In the past, the surgeon focused on blood loss, hook dislodgment, infections, and paraplegia or other neurologic deficits. Although all potential complications must be mentioned in the current era, patients are more likely to experience problems such as postoperative trunk imbalance or a need for subsequent metal removal. Due to the size, complexity, and modularity of the implants, they are more likely to produce muscle irritation, bursitis, or even a late low-grade infection in the bursitic area (274,275 and 276).

Neurologic Injury

The risk for neurologic injury during idiopathic scoliosis surgery is not well documented in a large series, although data from the membership of the Scoliosis Research Society is collected annually. In 1995 the reported incidence of neurologic injury after surgery was 1% in all types of scoliosis surgery in all ages. One of the 1,643 patients undergoing surgery for idiopathic scoliosis developed a complete spinal cord injury. The incidence of partial spinal cord and nerve root injury was 10 of 1,643 for the idiopathic scoliosis group, compared to 7 of 211 for the congenital scoliosis group. More than one-half of these patients had subsequent recovery of normal neurologic function. In a series of 1,090 patients undergoing spinal deformity correction by Bridwell et al., four patients developed a neurologic deficit postoperatively. However, only one of these patients had idiopathic scoliosis, and the total number of idiopathic scoliosis cases is not reported (277).

The etiology of spinal cord dysfunction can be classified as a result of direct trauma (contusion) to the cord, excessive traction to the neural elements produced by corrective instrumentation, and vascular insufficiency to the cord. The blood supply to the spinal cord is segmental and enters via the neural foramina. There has been some controversy as to the risk of vascular insufficiency to the cord associated with ligation of the anterior segmental blood vessels in anterior spine surgery. Winter et al. reported 1,197 cases in which segmental vessels were divided with no neurologic sequelae noted (278). There have, however, been other reports suggesting a possible vascular cause of spinal cord dysfunction postoperatively after segmental vessel ligation (279). Those at greatest risk appear to be patients with congenital malformations and hyperkyphosis (279,280 and 281). If an anterior procedure requires division of the segmental vessels, they should be ligated in the midvertebral body area rather than near the neural foramen. In high risk cases (congenital, kyphosis, revision surgery), temporary clamping of the vessels with concomitant spinal cord monitoring has been suggested by some as a means of detecting a potentially critical source of spinal cord blood supply (280).

Induced hypotension is a well-accepted standard in scoliosis to minimize operative blood loss; however, the mean arterial pressure must be maintained at a safe level to assure adequate blood flow to the spinal cord. In extremely complex corrections (kyphosis, osteotomies, revision surgery) in which the risk for cord ischemia is greater, the surgeon may elect to keep the blood pressure higher (even though blood loss will be greater) to assure cord perfusion (279).

Spinal Cord Monitoring

The wake-up test described by Stagnara was the first widely used method for monitoring spinal cord function after deformity correction. This technique includes decreasing the level of anesthesia intraoperatively to a level that allows the patient to follow commands. The patient is instructed to move their feet/toes, confirming the competency of the spinal cord motor tracts (282).

Subsequently, continuous electrical spinal cord monitoring has become almost standard in surgical correction of spine deformity. Monitoring of sensory and motor pathways is possible; however, from a technical standpoint sensory monitoring is simpler and more widely accepted. Somatosensory evoked potentials (SSEPs) are obtained by stimulating distally (legs) and measuring the response proximally (brain), and have been very reliable in detecting changes in spinal cord function, providing the surgeon relatively rapid feedback about any effect that deformity correction is having on neurologic function (283). The lag time between the insult to the spinal cord and the resulting monitoring changes may be 10 to 20 min. Other factors (besides injury to the cord that have been found to affect spinal cord monitoring) resulting in false-positive indications of injury include hypotension, hypothermia, and dislodgment of the monitoring leads, as well as other technical malfunctions in the system. If changes are noted these factors should be evaluated and corrected, and if the monitoring abnormalities persist, a wake-up test should be performed to confirm the findings. Loosening of the implants to remove any corrective forces, or complete removal of the implants, should be performed as soon as a deficit is confirmed. Institution of the methylprednisolone steroid spinal cord injury protocol (284) also seems warranted, although the efficacy in this specific group of spinal cord injury patients has not been carefully studied.

Blood Loss and Transfusion

Scoliosis surgery may be associated with blood loss requiring transfusion. This requires appropriate anticipation by the surgeon based on the type of deformity and the extent of the planned surgery. Preoperative autologous donation may be the most reliable way to avoid exposure to allogenic blood products, although this is not possible in all patients (too small, psychologic stress of donating too great, long distance to the blood bank, preoperative anemia, congenital heart disease, and/or expense). Alternatives to minimize allogenic blood exposure include intraoperative blood salvage, preoperative erythropoietin administration (285), intraoperative hemodilution (286), and (used with the precautions noted above) controlled hypotensive anesthesia (287).

Early Postoperative—In-hospital Complications

Complications in the early postoperative period include respiratory compromise, wound infection, and delayed neurologic injury. The incidence of respiratory complications in idiopathic scoliosis is approximately 1%, whereas wound infection occurs in approximately 2% of cases (childhood and adult surgery). The incidence

for infection in childhood and adolescent surgery is probably lower (288). Delayed neurologic injury has been recognized with increasing frequency, and the importance of careful neurologic monitoring of lower-extremity function for the 48 h following corrective surgery must be emphasized. Cases have been reported that confirmed intact neurologic function after the surgery with loss of motor and sensory function in the days following surgery (277,289,290). The etiology of delayed-onset paraplegia is unclear, and may be vascular due to post-operative hypotension, or mechanical resulting from a compressive hematoma.

Implant–Hardware Complications

Complications related to the hardware may present early or late in the postoperative period. Despite greatly improved implant systems, there is still a potential for early failure of the bone–hardware interface by either implant dislodgment or bony fracture. If a pseudarthrosis develops, late hardware failure can be anticipated. The time to hardware failure depends to some degree on the size and number of the rods used (Fig. 18-44). Small single-rod systems may fatigue and fracture in less than a year, compared to a double-rod system that may not fail for up to 5 years, if a pseudarthrosis is present. Rod fracture is diagnostic of pseudarthrosis; however, pseudarthrosis and rod failure may not be associated with any clinical problems. If pain or curve progression are noted revision surgery may be necessary.

Due to their prominence, the newer instrumentation systems have increased the need for late hardware removal, compared to the experience with Harrington rods. Another problem with new systems has been the development of delayed infection and/or metal reaction (274,275 and 276). The cause of these problems likely relates to the bulk of the systems and their modularity. Loosening of any one component of the complex system can lead to formation of a bursa, which can then eventually become infected.

Late Alignment Problems

Postoperative spinal alignment may not match what was anticipated preoperatively. The problems and causes of trunk decompensation have been discussed above. The correction of spinal deformities should result in a harmonious transition from the instrumented to the noninstrumented regions of the spine. Abrupt changes in sagittal or coronal alignment may result in junctional problems (Fig. 18-45). Levels adjacent to a fused segment of spine are subjected to increased mechanical stresses, and this is likely increased if malalignment exists. The use of new multisegmental, powerfully corrective instrumentation has the potential for increasing the incidence of postsurgical trunk imbalance.

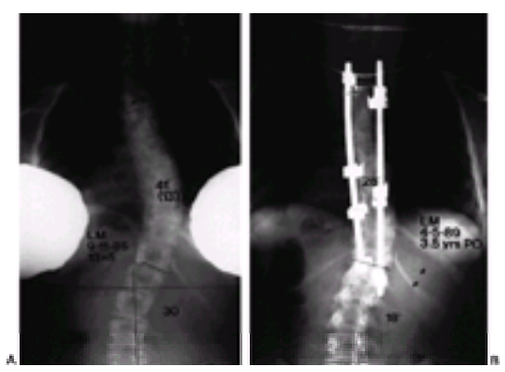

FIGURE 18-45. A: This 13-year-old female presented with a 41-degree right thoracic idiopathic scoliosis. The stable vertebra is probably L2. **B:** The patient was fused from T5 to T12. This radiograph 1 year postoperatively shows correction of the deformity to 13 degrees, but with acute angulation at T12-L1 and a 2-cm decompensation to the right. This case demonstrates the pitfalls of fusing too short.

CONGENITAL SCOLIOSIS—DETAILS OF DIAGNOSIS AND TREATMENT

Definition

Congenital scoliosis is the result of abnormally formed vertebral elements with the altered vertebral shape producing deviations in spinal alignment. These deficiencies occur in the embryonic period of intrauterine development (before 48 days gestation), and are commonly associated with cardiac and urologic abnormalities that develop during the same period (126,127). The etiology is unknown in humans; however, in animal studies congenital scoliosis has been produced by transient exposure to toxic elements during the fetal period (291). Congenital deformities are classified broadly into failures of vertebral formation and failures of segmentation between the vertebrae. Congenital scoliosis, by definition, involves anomalous vertebral elements, and when these anomalies are identified, the curve should be classified as congenital, even if the scoliosis is not diagnosed until adolescence. Similarly, patients noted early in life to have scoliosis without abnormally formed vertebrae should not be diagnosed as having congenital scoliosis. Occasionally, in infants with significant curves with the vertebrae not yet fully ossified, differentiation between an idiopathic and a congenital curve can be difficult.

Classification

Congenital scoliosis classification (based on the developmental anomaly of the spine) includes deficiencies in vertebral formation, segmentation, or a combination of the two (mixed) (Fig. 18-46). Failures of formation and segmentation may occur on either the right or left side of the body resulting in “pure” scoliosis, or in the anterior and posterior elements resulting in “pure” kyphosis or lordosis, respectively. Combined deficiencies are common, and associated sagittal plane deformity is important to recognize (292) (Fig. 18-47).

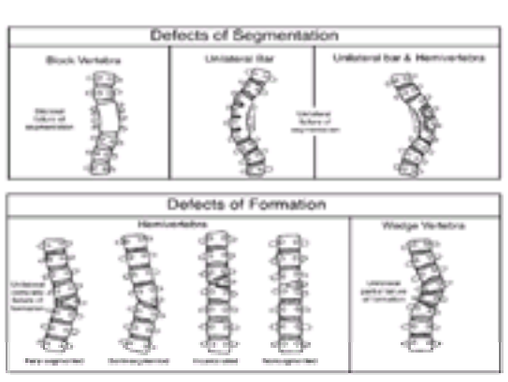

FIGURE 18-46. Diagrammatic representation of classification system of congenital scoliosis. (From ref. 294, with permission.)

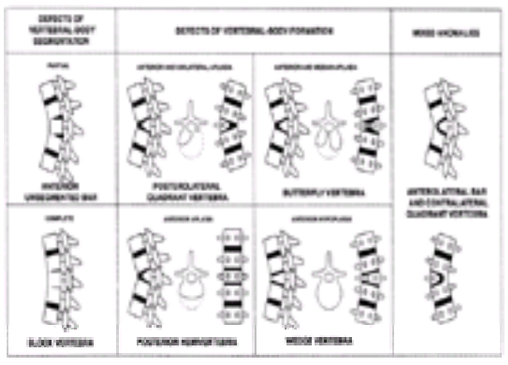

FIGURE 18-47. Diagrammatic representation of the failure of formation and segmentation in congenital kyphosis. (From ref. 292, with permission.)

In the classic failure of formation anomaly, hemivertebra (a triangular-shaped vertebra) forms on only one side, and can be subclassified into those that have disc and growth potential on: a) both the superior and inferior ends of the vertebra— *fully segmented*, b) either the superior or inferior end only— *semi-segmented*, or c) those that are fused to the vertebrae above and below—*nonsegmented* (Fig. 18-48). The degree of deficiency in unilateral formation is variable, and in the mildest form, a "wedge" vertebra develops. The vertebral width is normal, although the height of the vertebra is asymmetric on the right and left side. Rib deficiencies tend to match the vertebral deficiencies, and when the number of ribs on the right and left sides do not match, a hemivertebra or other congenital anomalies should be suspected.

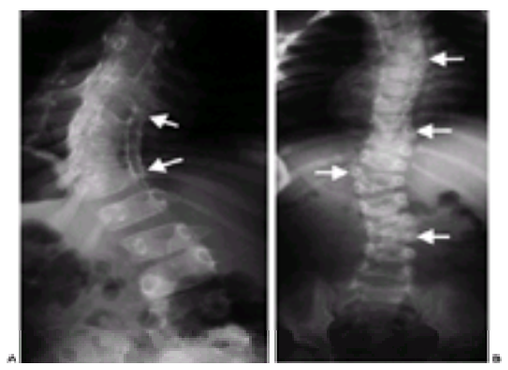

FIGURE 18-48. A: This radiograph demonstrates a long unilateral unsegmented bar (*arrows*). **B:** This radiograph demonstrates multiple hemivertebrae, both fully segmented and semi-segmented, as well as incarcerated and non-incarcerated varieties.

Failure of normal segmentation of the vertebral column may occur on both sides of the spine symmetrically or unilaterally. Segmentation deficiencies result in inhibition of longitudinal growth, and result in little deformity if they occur circumferentially around the spine (block vertebra). A unilateral unsegmented bar, however, produces a growth tether that often results in marked scoliosis due to growth only on one side of the spine. Mixed deformities are common, and at times exact classification of congenital scoliosis is difficult.

Identifying a congenital malformation on the spinal radiographs requires careful assessment of the films. Asymmetry of the size or number of the pedicles may suggest a failure of formation, and an absent rib is often associated with a deficiency of the vertebral elements. An unsegmented bar is suggested when the corresponding ribs and/or pedicles are conjoined. Segmentation defects can also be presumed when the disc space is narrowed. A three-dimensional CT study often helps to clarify the diagnosis in an older child with a complex deformity (293) (see Fig. 18-16).

Natural History

The likelihood of any single case of congenital scoliosis developing progressive deformity is difficult to state with certainty. There are, however, known anomalies and curve locations that make some generalizations possible. McMaster and Ohtsuka reviewed 251 patients with congenital scoliosis, documenting curve progression during growth (292,294). Three-fourths of the patients' curves progressed substantially, and they were able to relate this to curve location and type. Those with a thoracic location progressed the greatest, and the curve types with the poorest prognosis were those with multiple hemivertebrae and a convex unilateral bar (failure of segmentation) opposite the hemivertebrae.

A summary of the median annual rate of curve progression is seen in Figure 18-49. Block and wedge vertebrae progressed <1 degree per year and generally did not require treatment. Hemivertebrae, however, increased between 1 degree and 2.5 degrees per year. Double hemivertebrae increased at roughly twice that rate. Unilateral unsegmented bars progressed at rates up to 6 to 9 degrees per year in the thoracolumbar junction, whereas the unilateral unsegmented bars with a contralateral hemivertebra were at the greatest risk of progression, at times exceeding 10 degrees per year (294) (Fig. 18-50).

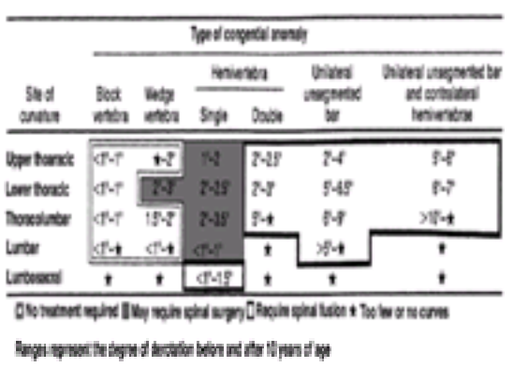

FIGURE 18-49. The annual rates of curve progression for each of the congenital anomalies are shown. The shaded areas represent the likelihood of spinal fusion based on the predicted increase in deformity. (From ref. 294, with permission.)

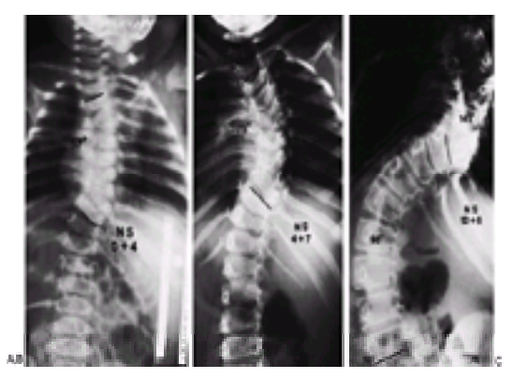

FIGURE 18-50. A: Four-month-old female presented with a 57-degree congenital right thoracic scoliosis. There is a hemivertebra on the right and a segmentation defect on the left (*unsegmented bar*). She did not receive treatment. **B:** At 4 years of age, the curve had progressed to 75 degrees. The congenital bar on the left is more easily seen, as well as the fusion between the ribs. **C:** By 12 years of age her curve progressed to 141 degrees with a 98-degree compensatory lumbar curve developing. (From ref. 295, with permission.)

Despite the information gained from the review of these patients, the growth potential of a curve may be difficult to classify and/or predict in any single case. Careful monitoring of radiographs is required to document and detect progression. The most likely times of increasing deformity match the phases of normally rapid spinal growth (the first 2 to 3 years of life and the adolescent years). Cobb angle measurement remains the method of following curves for progression, yet it is more difficult to apply in complex congenital curves (296), and the use of patient photographs can at times be helpful in addition.

Treatment

Nonoperative Treatment—Observation

The presence of a congenital spinal anomaly requires close monitoring of spinal growth until maturity. Initially, most curves are simply monitored, with radiographic assessment performed every 4 to 12 months, depending on the age of the patient and the suspicion (based on curve type) that progression is likely. Early in life, supine radiographs are the most reproducible; however, when old enough to cooperate (approximately age 2 years), upright radiographs should be taken. The landmarks used for Cobb angle determination are often difficult to mark, and Loder et al. found the interobserver error in Cobb angle measurement of congenital scoliosis curves to be as high as 10 degrees (296). Sequential analysis of trunk shift and Cobb measurement of the compensatory curves are also useful in determining if progression is occurring. Often, the compensatory curve which has no vertebral anomalies is easier to measure than is the congenital curve, and serves as an accurate “biomechanical indicator” about what is happening in the primary congenital curve.

In general, brace treatment has not been shown to be very effective in managing the primary curve in congenital scoliosis, because the curves tend to be short with little flexibility. Certain curves with a long flexible component may be amenable to orthotic management. On occasion, the compensatory curves which develop above or below a congenital deformity become problematic, and bracing to aid trunk balance may be helpful in these circumstances (297).

Surgical Treatment

Operative management is the standard treatment for progressive congenital scoliosis; however, because of the relative inflexibility of these curves, correction with instrumentation is less feasible than in idiopathic deformities. Because significant correction can usually not be obtained within the anomalous segments of the spine, surgical intervention is required earlier in the development of the curve (compared to surgery for idiopathic scoliosis). Surgical treatment options include: posterior fusion (*in situ* or with instrumentation), combined anterior and posterior fusion, convex hemiepiphysiodesis (anterior and/or posterior hemiarthrodesis), and hemivertebra excision. Each of these methods has its own indications, risks, and benefits, and the principles of each must be understood in order to optimize the outcome.

Preoperative Assessment. The most important aspect of preoperative documentation is sequential radiographs confirming progressive deformity. An exception is an unsegmented bar with a contralateral hemivertebra that has been suggested as an indication for surgery at the time of initial diagnosis (298). As discussed previously, the genitourinary system should be screened with an ultrasound examination, looking for a treatable cause of urinary tract outflow obstruction. Prior to undertaking surgical treatment of a congenital spinal deformity, an MRI of the entire spinal cord should be considered, especially if distraction instrumentation is planned. Associated intraspinal malformations, such as a diastematomyelia or a tethered cord, have been noted in cases of congenital scoliosis (298,299) (Fig. 18-51). A detethering procedure should be performed before a corrective spinal fusion procedure if neurologic symptoms are present. The treatment of asymptomatic patients with MRI findings only is more controversial. If there is a large compensatory curve (with normal motion segments) that will be straightened with instrumentation and included in the fusion, a prophylactic detethering procedure is indicated.

FIGURE 18-51. A: This patient presented with right thoracic scoliosis with a prominent right scapula and hair patch in the lumbar area. One foot was smaller than the other, and the ankle reflex was absent on that side. **B:** A myelogram demonstrates a diastematomyelia. **C:** Magnetic resonance imaging (MRI) scan also shows a diastematomyelia with a split in the spinal cord. **D:** On the sagittal MRI the cord extended to the sacral area with a tight filum terminale for each hemicord.

Goals of Surgery in Congenital Scoliosis. The goal for the variety of surgical procedures used in congenital scoliosis is to limit progression of a deformity that has been documented to be increasing with growth. Removing or modifying this growth potential in a young patient will limit curve progression, but may also affect ultimate spinal length. A recent study by Goldberg et al. has shown that children with congenital scoliosis are usually both small for their age and remain very small (compared to their peers) into adulthood, even if they do not require surgery. Discussion of surgical methods and their potential effect on final height must be tempered with the knowledge that final height may be limited by these poorly understood constitutional factors that are associated with congenital scoliosis (300). In addition, the surgeon and the parents must accept that growth of abnormally shaped vertebrae does not generate increased trunk height if deformity is allowed to progress. Trunk height will be greatest if a progressive curve is fused early, and the adjacent segments allowed to grow straight, rather than becoming part of a large compensatory curve.

Although the goal for most cases is limiting curve progression with the use of instrumentation or vertebral excision, one can surgically *reduce* the degree of deformity in some cases. These procedures carry somewhat greater risk for neurologic injury, the degree of which varies with the procedure, the curve pattern, flexibility, the location within the spine (cervical, thoracic, and lumbar), and the experience of the surgeon. It is for this reason that many patients with congenital scoliosis are treated with *in situ* fusion.

Posterior Fusion. Posterior *in situ* arthrodesis is the simplest approach to the surgical treatment of congenital scoliosis with the resultant large posterior fusion mass designed to limit progression of congenital curves (298,301,302). The fusion must include all of the vertebrae of the measured Cobb angle, and extend laterally to the transverse processes. Without instrumentation, a postoperative cast or vigorously worn rigid plastic jacket is required for 4 to 6 months after the procedure. The expected correction, by placement of a molded Risser cast, is generally modest in most congenital deformities; thus, the method is referred to as an *in situ* fusion. The neurologic risks associated with the technique are minimal.

The success of this procedure in preventing further deformity (increase in the Cobb angle or increase in the rotational deformity) depends on the nature of the malformation and the growth potential of the remaining unfused anterior vertebral bodies. Increased rotational deformity after a posterior spinal fusion (the “crankshaft phenomenon”) (225), first described in idiopathic scoliosis, has also been documented to occur in skeletally immature patients with congenital (301,303) and neuromuscular scoliosis (227,303,304). Predicting which curves are likely to develop late crankshaft deformity is difficult, and relates to the curve pattern and anterior

growth potential; however, understanding that congenital curves—fused posteriorly only— are at risk for it has led many surgeons to also perform anterior fusion in cases in which the risk for progression is perceived to be high.

Use of Posterior Instrumentation. The addition of instrumentation to a posterior arthrodesis can be considered in older children. Pediatric-sized instrumentation systems are available for children older than approximately age 3 years, which makes limited deformity correction possible in selected cases. Postoperative immobilization may be avoided in cases with secure internal fixation (juvenile and adolescent patients), whereas in the younger group, extended immobilization may be required to protect the instrumentation from dislodgment. The risk of neurologic injury increases with more aggressive attempts at instrumented deformity correction (302). The dimension of the spinal canal, as well as the blood supply to the spinal cord may also be congenitally deficient, both of which make the placement of hooks and distraction rods somewhat more dangerous than in typical idiopathic deformities. Careful spinal cord monitoring is required (see Idiopathic Scoliosis section).

Anterior Fusion. Anterior *in situ* arthrodesis may be required when substantial anterior vertebral growth is expected. Anterior growth potential in congenital deformities appears dependent both on the age of the patient (as in idiopathic scoliosis) and on the presence and orientation of anterior growth cartilage. The width of the disc space can be used to make inferences regarding growth potential. For example, a hemivertebra that is semisegmented (fused to one of the adjacent vertebra anteriorly) has less growth potential than one that is fully segmented with growth cartilage on both the superior and inferior end plates. Anterior fusion is usually combined with a posterior procedure (posterior fusion with or without instrumentation), and is most commonly used for young patients with highly progressive deformities (e.g., hemivertebra and a contralateral bar). This gives the best chance for limiting growth in the circumstances known to be at greatest risk for rapid progressive deformity (305).

A fully segmented hemivertebra also may require an anterior fusion, because the additional growth centers of an anterior and laterally placed hemivertebra may generate substantial rotational deformity in the presence of a posterior fusion alone. The age at the time of surgery also plays a roll in this decision. Block vertebrae, semisegmented hemivertebrae, and wedge vertebrae are less likely to be progressive from the outset, and if they do progress, can often be treated with a posterior fusion alone.

Anterior procedures are designed primarily to limit growth of the vertebrae; however, some degree of flexibility may be obtained following discectomies in deformities which do not have a segmentation deficiency. The surgical exposure must allow for complete removal of the disc and end plate growth cartilage of the levels involved. The disc spaces are filled with autogenous rib or cancellous allograft bone to ensure an arthrodesis between the vertebrae. The risk of surgically related paralysis due to vascular insufficiency seems greatest in congenital scoliosis surgery (280) as compared to surgery on other curve types.

Partial Fusion, Growth Modulation, and Hemiepiphysiodesis. Methods for obtaining correction of a congenital deformity by modifying the growth of the involved levels have been proposed by many authors (306,307,308,309 and 310), with the principal of a Blount-type hemiepiphysiodesis (used to correct a long-bone deformity) applied to the spine. Convex hemiarthrodesis (hemiepiphysiodesis), a technique that includes performing a fusion only on the convex side of the curve, both anteriorly and posteriorly, has led to mixed results. Depending on the growth potential of the concave vertebral elements, the hemiarthrodesis may need to be extended one level above and below the measured curve. This technique has been most useful when utilized early in life (before age 5 years). Additionally, it should be employed when curves have proven to be progressive yet remain less than 50 degrees (Fig. 18-52). Beyond these levels, the results are less predictable. This procedure should not be used if a significant kyphotic component to the deformity exists, because the anterior fusion may lead to worsening of the kyphosis. It is similarly important to be certain that the anterior hemiarthrodesis component is extended posteriorly to the posterior longitudinal ligament. If not, growth in the posterior remainder of the vertebral end plates may result in a progressive kyphotic deformity.

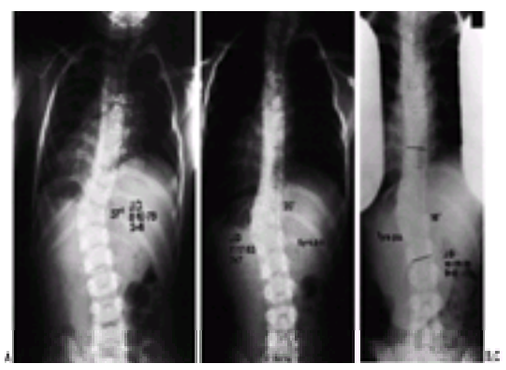

FIGURE 18-52. A: A 2-year, 6-month-old girl presented with progressive congenital thoracolumbar scoliosis caused by a hemivertebra. Treatment options included anterior and posterior fusion, epiphysiodesis, posterior fusion only, and hemivertebra excision. She underwent a convex anterior and posterior growth arrest (hemiepiphysiodesis). **B:** Five years after surgery the curve was 20 degrees. **C:** Seven years after surgery the curve was 16 degrees. Nine years after her surgery the curve was 10 degrees.

Hemivertebra Excision. Hemivertebra excision, **[➥2.12]** a procedure that allows for acute deformity correction as well as stabilization with arthrodesis, is associated with greater neurologic risk and is technically much more demanding than the options discussed above. Resection of a hemivertebra is safest (neurologically) when performed below the tip of the cord (conus), and has the greatest impact on trunk balance when applied to lower lumbar or lumbosacral deformities. Thus, the procedure is most commonly used for lower lumbar hemivertebrae associated with truncal decompensation (311), although it has also been effectively applied to severe deformities of the thoracic and thoracolumbar spine (298,312) (Fig. 18-53).

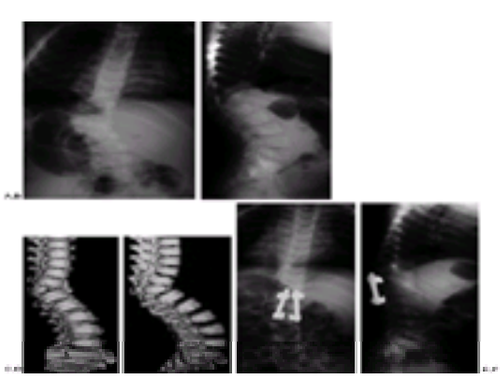

FIGURE 18-53. A: Preoperative radiograph in a 6-year-old male with progressive congenital scoliosis due to an apparent T12 hemivertebra. **B:** Lateral view demonstrates focal kyphosis centered at the T12 level. **C:** Anterior view on a three-dimensional CT study demonstrates that the hemivertebra may have a small “butterfly” component (small residual of body on the opposite side). The absence of body anteriorly is leading to severe kyphosis. **D:** Sagittal view on three-dimensional CT study. The cause of the kyphosis is clear. **E:** PA radiograph after vertebral body excision and corrective instrumentation. **F:** Lateral view after vertebral body excision and corrective instrumentation.

Surgical exposure may be either by simultaneous anterior and posterior exposure or by staged anterior and posterior procedures. The combined approach allows removal under direct vision of all the bony components of the hemivertebra, with anterior and posterior grafting between the remaining superior and inferior vertebrae and is preferred. If an unsegmented bony bar exists an osteotomy may be required. When possible, compression instrumentation is used on the convex side of the curve to close down the wedge resection. A Risser cast may be used for immobilization in the corrected position, and is also generally required even when instrumentation is used to prevent hook dislodgment. Unrecognized compression of neural elements can occur with hemivertebra excision, and reliable spinal cord

monitoring or a wake-up test is mandatory. The results of several series suggest that in experienced hands this is a safe and effective approach to the deformity caused by a hemivertebra (309,312,313 and 314).

CHAPTER 19

KYPHOSIS

WILLIAM C. WARNER, JR.

W. C. Warner, Jr.: Department of Orthopaedics, University of Tennessee, Memphis, Tennessee 38163; Campbell Clinic, Germantown, Tennessee 38138.

Kyphosis is a curvature of the spine in the sagittal plane, in which the convexity of the curve is directed posteriorly. Lordosis is a curvature of the spine in the sagittal plane, in which the convexity of the curve is directed anteriorly. The thoracic spine and the sacrum normally are kyphotic, and the cervical spine and the lumbar spine normally are lordotic (1). Although several authors have tried to define normal kyphosis of the thoracic spine and normal lordosis of the lumbar spine, these studies have shown much variability in what is considered normal (2,3,4,5,6,7 and 8). The ranges of normal kyphosis and lordosis change with increasing age, and vary according to gender and the area of the spine involved (2,3,4 and 5). The degree of kyphosis or lordosis that is considered normal or abnormal depends on the location of the curvature and the age of the patient. For example, 30 degrees of kyphosis is normal in the thoracic spine, but abnormal at the thoracolumbar junction.

For the purposes of this chapter, the guidelines established by the Scoliosis Research Society for normal thoracic kyphosis and lordosis are used. The normal range of thoracic kyphosis is defined as 20 to 40 degrees, and that of lumbar lordosis as 30 to 60 degrees (9). The thoracolumbar junction should have no kyphosis or lordosis (10). Lumbar lordosis begins at L1–L2 and increases gradually until the L3-L4 disc space. The apex of normal thoracic kyphosis is the T6-T7 disc space (10,11).

Initially during fetal and intrauterine development the entire spine is kyphotic. During the neonatal period the thoracic, lumbar, and sacral portions of the spine remain in a kyphotic posture. Cervical lordosis begins to develop when a child starts holding the head up. When an upright posture is assumed, the primary and secondary curves begin to develop. The primary curves are thoracic and sacral kyphosis, and the secondary or compensatory curves in the sagittal plane are cervical and lumbar lordosis. These curves balance each other so that the head is centered over the pelvis (2,12,13).

Cutler et al. (14) and Fon et al. (15) showed that the ranges of normal thoracic kyphosis and lumbar lordosis are dynamic, progressing gradually with growth. During the juvenile and adolescent growth periods thoracic kyphosis and lumbar lordosis become more pronounced and take on a more adult appearance. Differences also exist between male and female spines (6). Thoracic kyphosis and spine mobility are different in boys and girls. Mellin and others (3,11) have shown that during the juvenile and adolescent periods (ages 8 to 16 years) girls have less thoracic kyphosis and thoracic spinal mobility than do boys of the same age. Thoracic kyphosis also tends to progress with age. Fon et al. (15) showed that from 30 to 70 years of age women have a progressive increase in kyphosis, from a mean of 25 to 40 degrees. Men also show a definite progression with age, but at a lower rate.

Normal sagittal balance is defined as a plumb line dropping from C7 and intersecting the posterosuperior corner of the S1 vertebral body (Fig. 19-1). Positive sagittal balance occurs when the plumb line falls in front of the sacrum, and negative sagittal balance occurs when the plumb line falls behind the sacrum (16).

FIGURE 19-1. A plumb line is made from the middle of the C7 vertebral body to the posterosuperior corner of the S1 vertebral body. (From ref. 16, with permission.)

Different forces are exerted on the spine, depending on the presence of kyphosis or lordosis. In the upright position the spine is subjected to the forces of gravity, and several structures maintain its stability: the disc complex (nucleus pulposus and annulus), the ligaments (anterior longitudinal ligament, posterior longitudinal ligament, ligamentum flavum, apophyseal joint ligaments, and interspinous ligament), and the muscles (the long spinal muscles, the short intrinsic spinal muscles, and the abdominal muscles). Alteration in function resulting from paralysis, surgery, tumor, or infection, or alteration in growth potentials, can cause a progressive kyphotic deformity in a child (17). Both compressive and tensile forces are produced by the action of gravity on an upright spine (Fig. 19-2). With normal thoracic kyphosis, the compressive forces borne by the anterior element are balanced by the tensile forces borne by the posterior element. In a lordotic spine, the compressive forces are posterior and the tensile forces are anterior. These forces of compression and tension on the spinal physes can cause changes in normal growth, and a growth deformity can be added to a biomechanical deformity to cause a pathologic kyphosis (17,18).

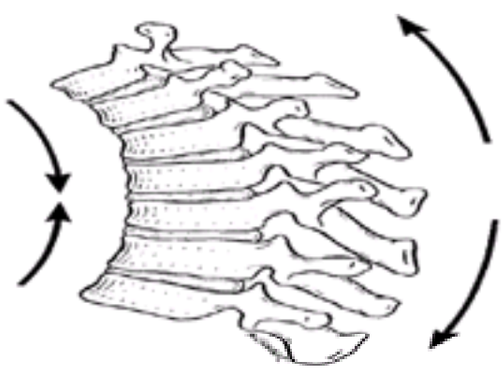

FIGURE 19-2. Forces that contribute to kyphotic deformity of the thoracic spine. The anterior vertebral bodies are in compression, and the posterior vertebral elements are in tension. (From ref. 17, with permission.)

Voutsinas and MacEwen (19) believe that relative differences in forces applied to the spine are reflected more accurately by the length and width of a kyphotic curve than by just the degree of the curve. For example, curves that are longer and wider (farther from the center of gravity) are more likely to cause deformity in an immature spine (Fig. 19-3). Winter and Hall (20) classified disorders that result in kyphosis of the spine. Only the more common causes are presented in this chapter; the other causes are discussed elsewhere in this text (Table 19-1).

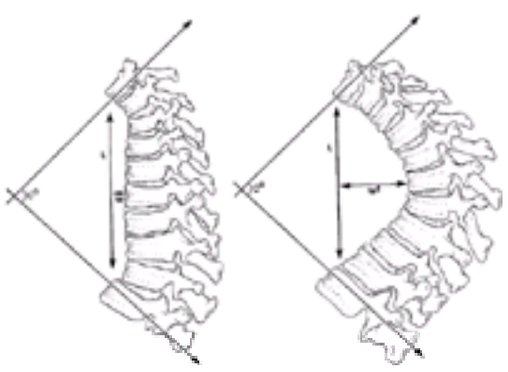

FIGURE 19-3. The two spinal curvatures represented by these drawings are different in magnitude; however, using Cobb's method to measure the deformities, the degrees of curvature are identical. The differences in the curves are more accurately reflected when the length of the curves (*L*) and their respective widths (*W* and W^1) are taken into consideration. (From ref. 19, with permission.)

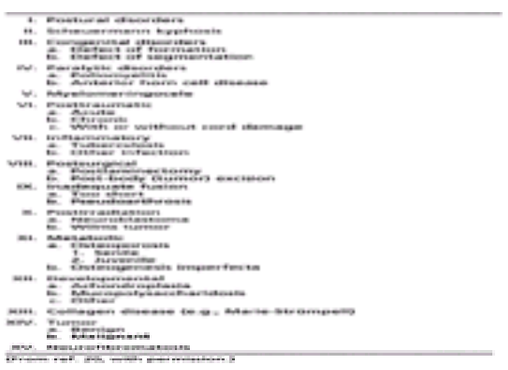

TABLE 19-1. DISORDERS AFFECTING THE SPINE THAT RESULT IN KYPHOSIS

POSTURAL KYPHOSIS

Postural kyphosis is a flexible deformity of the spine, and is a common complaint of juvenile and adolescent patients. Usually, the parents are more concerned about the postural roundback deformity than the adolescent is, and these parental concerns typically are what bring the patient to the physician's office. The physician's role in this situation is to rule out more serious causes of kyphosis. Postural kyphosis should be differentiated from pathologic types of kyphosis, such as Scheuermann disease or congenital kyphosis. When observed from the side, patients with postural roundback have a gentle rounding of the back while bending forward (Fig. 19-4). Patients with Scheuermann disease and congenital kyphosis have a sharp angular kyphosis or gibbus on forward bending when observed from the side. Radiographs usually are necessary to rule out pathologic types of kyphosis. Patients with postural kyphosis do not have radiographic vertebral body changes, and the deformity is completely correctable by changes in position or posture. This deformity is common in patients who are taller than their peers, and in young adolescent girls undergoing early breast development who tend to stoop because they are self-conscious about their bodies (21).

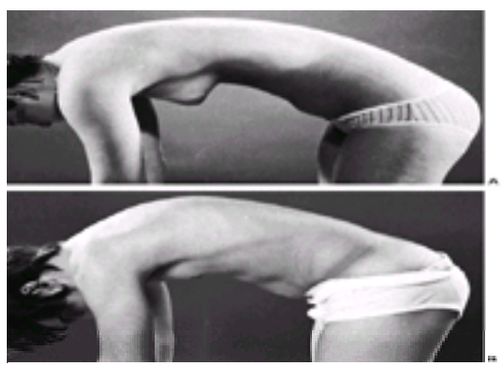

FIGURE 19-4. A: Lateral view of normal spinal contour on forward bending. **B:** Lateral view of a patient with Scheuermann disease on forward bending. Note the break in the normal contour of the spine. (Courtesy of Robert Winter, M.D., Minneapolis.)

No active medical treatment is necessary. Bracing is not indicated. Exercises have been suggested and may help maintain better posture, but adherence to such a therapy program is difficult for juveniles and young adolescents. This problem is treated best by patient and, more important, parent education and observation (22).

CONGENITAL KYPHOSIS

Congenital kyphosis is an uncommon deformity, but despite its rare occurrence, neurologic deficits as a result of this deformity are frequent.

Congenital kyphosis occurs because of abnormal development of the vertebrae, including a failure of developing segments of the spine to form or to separate properly (23). The spine can be stable or unstable, or it can become unstable with growth (24). Spinal deformity in congenital kyphosis usually progresses with growth, and the amount of progression is directly proportional to the number of vertebrae involved, the type of involvement, and the amount of remaining normal growth in the affected vertebrae (24,25).

Van Schrick in 1932 (26) and Lombard and LeGenissel in 1938 (27) initially described two basic types of congenital kyphosis: a failure of formation of part or all of the vertebral body, and a failure of segmentation of part or all of the vertebral body. Winter and associates (23,28) developed the most useful classification of congenital kyphosis, which divides the deformity into three types (Table 19-2). Type I is failure of formation of all or part of the vertebral body (Fig. 19-5 A); type II is failure of segmentation of one or multiple vertebral levels (Fig. 19-5 B); and type III is a mixed form, with elements of both failure of formation and failure of segmentation.

Type I	Failure of formation of all or part of the vertebral body
Type II	Failure of segmentation of one or multiple vertebral levels
Type III	Mixed form, with elements of both failure of formation and failure of segmentation

TABLE 19-2. WINTER'S CLASSIFICATION OF CONGENITAL DEFORMITY

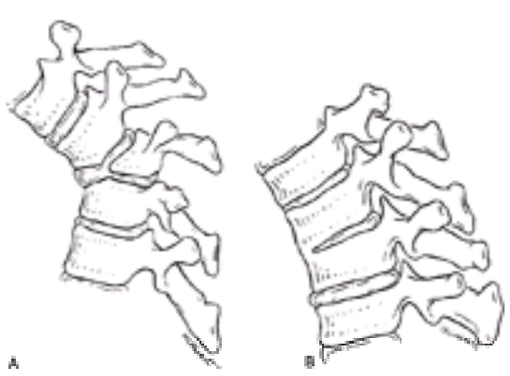

FIGURE 19-5. A: Congenital kyphosis caused by failure of formation of the vertebral body (type I). **B:** Congenital kyphosis caused by failure of segmentation (type II). (Courtesy of Robert Winter, M.D., Minneapolis.)

Dubousset and Zeller et al. (29,30) also classified congenital kyphosis. Their classification is similar to that of Winter, except that their type III includes rotary dislocation of the spine. Shapiro and Herring (31) also described a type III congenital kyphosis, but further divided the displacement into type A (sagittal plane only) and type B (rotary, transverse, and sagittal plane). Either classification can be subdivided further into deformities with and without neurologic compromise. Both classifications and the presence or absence of neurologic compromise are useful for making treatment decisions, because each type of congenital kyphosis has a distinct natural history and risk of progression. The presence of neurologic compromise also affects the type of treatment recommended.

Most vertebral malformations that cause spinal deformity occur between the twentieth and thirtieth days of fetal development (24,28,32). The somatic mesoderm, which is devoted to the formation of the vertebral column and rib cage, undergoes segmentation into discrete, bilateral, 38 to 44 paired somites. Formation of a vertebra depends on contributions of cells from two separate and successive pairs of sclerotomes. This condensation of the paired sclerotomes occurs around 5 weeks of gestation. If one side of the pair of sclerotomes fails to develop, this will cause a hemivertebra to be formed, and result in congenital scoliosis (33,34). Tsou (35) concluded that congenital kyphosis and congenital scoliosis occur during different periods of spinal development. He divided the development of the spine into an embryonic period (the first 56 days) and a fetal period (from 57 days to birth). During the embryonic period, hemivertebra formation from aplasia of part of the vertebrae, and failure of segmentation, caused scoliosis.

Tsou (35) believes that the causes of congenital kyphosis occur in the fetal period, during the cartilaginous phase of development. Failure of formation occurs in this cartilaginous phase when the cartilaginous centrum of the vertebral body forms a functionally inadequate growth cartilage.

Failure of formation varies from complete aplasia, which involves the pars and the facet joints, and makes the spine unstable to involvement of only the anterior one-third to one-half of the vertebral body. This abnormal development is thought to be the result of inadequate vascularization of the vertebral body during the fetal period, leading to hypoplasia or aplasia of the anterior vertebral body. If one side of the vertebra is involved more than the other side, scoliosis also may occur (Fig. 19-6). Unlike hemivertebral anomalies that occur in the embryonic period as a result of maldevelopment of corresponding pairs of somites, causing congenital scoliosis, posterior arch anomalies are almost universally absent in pure congenital kyphosis.

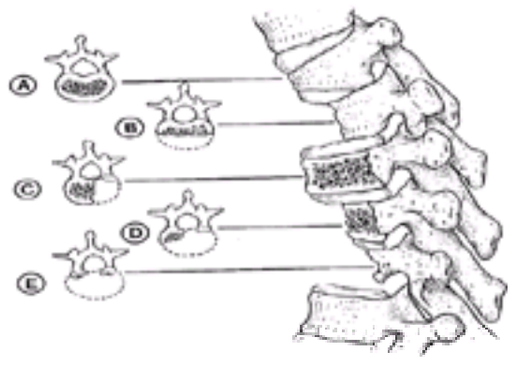

FIGURE 19-6. The five most common patterns of congenital vertebral hypoplasia and aplasia are illustrated in lateral and transverse views. Types *B* and *E* tend to produce pure congenital kyphosis. (From ref. 35, with permission.)

Failure of segmentation is believed by Tsou (35) to be an osseous metaplasia of the annulus fibrosus (35,36), which acts as a tether against normal growth and causes spinal deformity. The height of the vertebral bodies is relatively normal, but the depth of the ossification of the annulus fibrosus varies. Ossification also may be delayed, with a period of normal growth followed by spontaneous ossification. Morin et al. (37) believes that kyphosis caused by a "segmentation defect" represents a developmental defect of the perivertebral structures (the annulus fibrosis, the ring apophysis, and the anterior longitudinal ligament), rather than a true intervertebral bar.

The natural history of congenital kyphosis is well known, and based on the type of congenital kyphosis: failure of formation (type I), or failure of segmentation (type II). The natural history of type III congenital kyphosis is less well understood. Both type I and type II deformities tend to be progressive, with the greatest rate of progression occurring during the adolescent growth spurt. Failure of formation (type I deformity) produces a much more malignant kyphosis, with a rate of progression that averages 7 degrees a year (28). Type I deformities have a much higher incidence of neurologic involvement and paraplegia than do type II deformities (28). Neurologic problems are increased in patients with these types of deformity because they tend to have an acute angular kyphosis over a short segment, which places the spinal cord at high risk for compression at the level of acute angulation. Type II deformities generally progress an average of 5 degrees per year and rarely result in neurologic problems because involvement of several segments produces a more gradual kyphosis, and vertebral body height usually is maintained with little or no vertebral body wedging. The most frequent location of congenital kyphosis is from T10 to L1 (28).

Patients with congenital kyphosis can have other anomalies. Intraspinal abnormalities have been reported to occur in 5 to 18% of patients with congenital kyphosis and congenital scoliosis (38). A study by Bradford et al. (39) indicates that this incidence may be greater. They found that six of eight patients with congenital kyphosis had spinal cord abnormalities visible on magnetic resonance imaging (MRI). Even though the proposed time of development of deformity may be different from that of congenital scoliosis other nonskeletal anomalies, such as cardiac, pulmonary, renal, and auditory disorders, or Klippel-Feil syndrome (40,41) can be associated with congenital kyphosis. Dubousset (29) has suggested that certain forms of type II congenital kyphosis (failure of segmentation) may be inherited. The patients have a failure of segmentation, with delayed fusion of the anterior vertebral elements, which is not visible on radiographs until 8 or 10 years of age. Dubousset (29) described one family in which three individuals had delayed ossification and congenital kyphosis, and another family in which the grandmother, mother, and two sisters had the deformity. Progression of congenital kyphosis can be significant during the adolescent growth spurt.

Patient Presentation

The diagnosis of a congenital spine problem usually is made by a pediatrician before the patient is seen by an orthopaedist. The deformity may be detected before birth on prenatal ultrasonography (42), or noted as a clinical deformity in the newborn nursery. If the deformity is mild, congenital kyphosis can be overlooked until a rapid growth spurt makes the condition more obvious. Some mild deformities are found by chance on radiographs that are obtained for other reasons. Physical examination usually reveals a kyphotic deformity at the thoracolumbar junction or in the lower thoracic spine. An attempt should be made to determine the rigidity of the deformity by flexion and extension of the spine. A detailed neurologic examination should be done, looking for any subtle signs of neurologic compromise. Associated musculoskeletal and nonmusculoskeletal anomalies should be sought on physical examination.

High-quality, detailed anteroposterior and lateral radiographs provide the most information in the evaluation of congenital kyphosis (Fig. 19-7). Failure of segmentation and the true extent of failure of formation may be difficult to detect on early films because of incomplete ossification. Flexion and extension lateral radiographs are helpful to determine the rigidity of the kyphosis and possible instability of the spine. Computed tomographic (CT) scans with three-dimensional reconstructions have replaced tomography in most cases, and can identify the amount of vertebral body involvement as well as determine whether more kyphosis or scoliosis might be expected. CT scans can only identify the nature of the bony deformity and the size cartilage anlage. They do not show the amount of growth potential in the cartilage anlage, and therefore only an estimate of possible progression can be made. MRI should be obtained in most cases because of the significant incidence of intraspinal abnormalities. In addition, the location of the spinal cord and any areas of spinal cord compression caused by the kyphosis can be seen on MRI. The cartilage anlage will be well defined by MRI in patients with failure of formation (Fig. 19-8); however, as with CT scans and plain radiographs, MRI cannot reveal how much growth potential is present in the cartilage anlage, and can only help to estimate the probability of a progressive deformity.

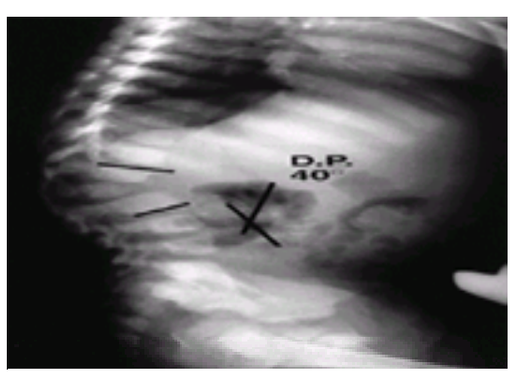

FIGURE 19-7. A 2-year-old child with type I congenital kyphosis measuring 40 degrees. Radiograph demonstrates failure of formation of the anterior portion of the first lumbar vertebra.

FIGURE 19-8. Magnetic resonance image of type I congenital kyphosis. Failure of formation of the anterior vertebral body is demonstrated, but the growth potential of

the involved vertebra cannot be determined. Note the pressure on the dural sac.

Ultrasonography has been used in the early prenatal (20 weeks of gestation) diagnosis of this condition, and is helpful for evaluating the renal system for any occult abnormalities (42). Myelograms have been used to document spinal cord compression, but have been mostly replaced by MRI. If myelography is used, images should be taken in the prone and supine positions. Myelograms obtained in only the prone position may miss information about spinal cord compression because of pooling of dye around the apex of the deformity. Myelography can be used in conjunction with CT scanning to add to the diagnostic information obtained.

Treatment

Because the natural history of this condition is continued progression with an increased risk of neurologic compromise, surgery usually is the preferred method of treatment (23). If the deformity is mild or if the diagnosis is uncertain close observation may be a treatment option. However, observation of a congenital kyphotic deformity must be used with caution, and the physician must not be lulled into a false sense of security if the deformity progresses only 3 to 5 degrees over a 6-month period. If the deformity is observed over 2 to 3 years, it will have progressed 20 to 30 degrees and cannot be easily corrected. Bracing has no role in the treatment of congenital kyphosis, unless compensatory curves are being treated above or below the congenital kyphosis (23,40,43). Bracing a rigid structural deformity, such as congenital kyphosis, neither corrects the deformity nor stops the progression of kyphosis.

Surgery is the recommended treatment for congenital kyphosis. The type of surgery depends on the type of deformity, the size of the deformity, the age of the patient, and the presence of neurologic deficits. Procedures can include posterior fusion, anterior fusion, both anterior and posterior fusions, and anterior osteotomy and posterior fusion. Fusion can be performed with or without instrumentation.

Treatment of Type I Deformities

Treatment of type I deformities can be divided into three stages: early with mild deformity, late with moderate or severe deformity, and late with severe deformity and spinal cord compression.

Early Treatment of Mild Deformities. For type I deformities, with a known average progression rate of 7 degrees a year, the best treatment is early posterior fusion. If the deformity is less than 50 or 55 degrees and the patient is younger than 5 years of age, posterior fusion alone, extending from one level above the kyphotic deformity to one level below, is recommended (23,28,40,44). Winter and Moe (44,45) recommend that a hyperextension cast be worn for 6 months. At 6 months from the initial fusion a second procedure with exploration of the fusion mass and a possible second fusion may be needed, followed by another 6 months of casting. Winter and Moe (44,45) found that this predictably controlled the progressive kyphotic deformity and that the deformity improved, with growth in many cases. The improvement seen with growth probably is due to normal growth from the anterior end plates of the vertebrae one level above and below the congenital kyphotic vertebrae that are included in the posterior fusion. Anterior and posterior fusion predictably halts the progression of the kyphotic deformity, but does not allow for the possibility of some correction of the deformity with growth because of ablation of the anterior physes. (30,44).

Late Treatment of Moderate to Severe Deformities. In older patients with type I kyphotic deformities posterior arthrodesis alone may be successful if the kyphosis is less than 50 to 55 degrees (28,46). If the deformity is more than 55 degrees (which usually is the case in deformities detected late), anterior and posterior fusion produces more reliable results (28,46). Anterior arthrodesis alone will not correct the deformity. Any correction of the deformity requires anterior strut grafting with temporary distraction and posterior fusion, with or without posterior compression instrumentation. The posterior instrumentation should be regarded more as an internal stabilizer than as a correction device (23). Correction by instrumentation should be avoided in rigid, angular curves because of the high incidence of neurologic complications. If anterior strut grafting is performed the strut graft should be placed anteriorly under compression. When an associated scoliosis is present the kyphosis should be approached from the concave side of the scoliosis to place the strut grafts under compression. If no correction is attempted and the goal of surgery is just to stop progression of the kyphosis, a simple anterior interbody fusion combined with a posterior fusion can be performed. The use of skeletal traction (halo-pelvic, halo-femoral, or halo-gravity) to correct the deformity is tempting but is not recommended because of the risk of paraplegia (47). In a patient with a rigid gibbus deformity traction pulls the spinal cord against the apex of the rigid kyphosis, which can result in neurologic compromise (Fig. 19-9).

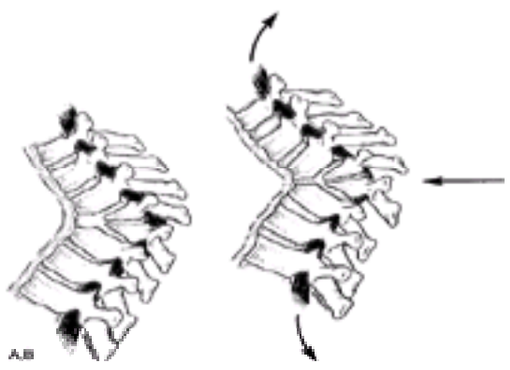

FIGURE 19-9. The effect of traction on a rigid congenital kyphosis. **A:** The apical area does not change with traction, but the adjacent spine is lengthened. **B:** The spine, and thus the spinal cord, lengthen, producing increased tension in the spinal cord and aggravation of any neurologic deficits. (From ref. 262, with permission.)

Late Treatment of Severe Deformities with Cord Compression. Late treatment of a severe congenital kyphotic deformity with spinal cord compression is difficult. If congenital kyphosis causes spinal cord compression, anterior decompression is indicated. The compression is created by bone or disc material pressing into the front of the spinal cord, and this can be decompressed only by an anterior procedure; laminectomy has no role in the treatment of this condition (20). For associated scoliosis the anterior approach should be on the concavity of the scoliosis, to allow the spinal cord to move both forward and into the midline after decompression **[➥ 2.12]**. After adequate decompression has been achieved the involved vertebrae are fused with an anterior strut graft. This is followed by a posterior fusion, with or without posterior stabilizing, instrumentation. Postoperative support with a cast, brace, or halo cast, usually is required.

Treatment of Type II Deformities

Treatment of type II deformities can be divided into early treatment of mild deformities and late treatment of severe deformities as outlined by Mayfield et al. (48). If a type II kyphosis is mild and detected early, posterior fusion with compression instrumentation can be performed. The kyphosis must be less than 50 degrees for a posterior fusion alone to have a good chance of success. The posterior fusion should include all the involved vertebrae, plus one vertebra above and one vertebra below the congenital kyphosis.

Compression instrumentation can be used more safely in type II deformities because the kyphosis is more rounded and over several segments, instead of sharply angular, as in type I deformities **[➥ 2.13, 2.14]**. If the deformity is severe and detected late correction can be obtained only by performing anterior osteotomies and fusion, followed by posterior fusion and compression instrumentation (48).

Complications of Treatment

Some of the more frequent complications of treatment of congenital kyphosis are pseudarthrosis, progression of kyphosis, and paralysis. Pseudarthrosis and progression of the kyphotic deformity can be minimized by performing anterior and posterior fusions for deformities of more than 50 degrees. The posterior fusion should extend from one level above to one level below the involved vertebrae. This may allow for some correction with growth.

Paralysis is perhaps the most feared complication of spinal surgery. The risk of this complication can be lessened by not attempting to correct the deformity with

instrumentation. Instrumentation should just be used for stabilization of rigid deformities. The use of halo traction in rigid congenital kyphotic deformities, has been associated with an increased risk of neurologic compromise (47). Another long-term problem is low back pain that occurs in 38% of patients, because of increased lumbar lordosis which is needed to compensate for the kyphotic deformity (49).

SEGMENTAL SPINAL DYSGENESIS

Segmental spinal dysgenesis is a congenital anomaly of the lumbar or thoracolumbar spine, consisting of focal agenesis or dysgenesis of the spine that results in severe spinal stenosis and instability (50). A progressive kyphosis occurs at the site of segmental spinal dysgenesis. This condition often is confused with other spinal anomalies, such as type I congenital kyphosis, sacral agenesis, lumbosacral agenesis, or lumbar agenesis. Faciszewski et al. (51) have described detailed radiographic and clinical definitions of this condition. Segmental spinal dysgenesis is characterized by severe focal stenosis of the spinal canal at the involved segment, and is associated with significant narrowing of the thecal sac and absence of adjacent nerve roots. At the involved level, a ring of bone encircles the posteriorly positioned spinal canal, causing stenosis. The spinal canal has limited potential for enlargement with growth because of the absence of neurocentral junctions, where growth occurs. No pedicles or spinous or transverse processes are present at this level. Anterior to the bony ring is a fat-filled space. The distal bony anatomy and spinal canal usually are normal, although spina bifida has been noted in a few cases (52). Neurologic function can range from normal to complete paraplegia. Associated anomalies are common, and there is a high incidence of a neurogenic bladder.

The etiology of segmental spinal dysgenesis is unknown. The diagnosis can be made on the basis of plain radiographs, but MRI and CT scans and three-dimensional reconstructions usually are needed to fully show the extent of this condition. A progressive kyphosis will occur with this condition. Progressive neurologic deterioration has been noted by Flynn et al. (53) and Faciszewski et al. (51). Early anterior and posterior fusion, with or without decompression, is recommended. The use of spinal instrumentation is controversial because of the small size of the patient. Hughes et al. (52) believe that treatment should be directed toward the establishment and maintenance of spinal stability first, and toward decompression of the cord secondarily.

SACRAL AGENESIS

Sacral agenesis consists of a complete or partial absence of the sacrum (54,55,56 and 57). Rarely is it associated with absence of the most caudal segment of the lumbar spine. The association with maternal diabetes has been well documented (54,55,56 and 57). Kyphosis may occur with this condition, although it is usually not progressive and does not require treatment (58,59).

PROGRESSIVE ANTERIOR VERTEBRAL FUSION

Progressive anterior vertebral fusion (PAVF) is rare and an uncommon cause of kyphosis in pediatric patients; however, if discovered late it may be confused with type II congenital kyphosis. Knutsson (60), in 1949, was the first to describe PAVF in the English literature, and a total of 80 cases have since been reported. This condition is distinguishable from type II congenital kyphosis because the disc spaces and vertebral bodies are normal at birth and later become affected with an anterior fusion. Although the etiology is unknown, PAVF is probably a distinct clinical condition, even though consideration has been given to the possibility that it may represent a delayed type II congenital kyphosis. Kharrat and Dubousset (61) found this condition to be familial in 6 of 15 patients, and Van Buskirk et al. (62) reported associated anomalies in 46% of 15 patients, including heart defects, tibial agenesis, foot deformities, Klippel-Feil syndrome, Ito syndrome, pulmonary artery stenosis, and hemisacralization of L5.

Neurologic deficits usually are not seen in PAVF, but Smith (63) reported one case of spinal cord compression resulting from an acutely angled kyphosis. Van Buskirk et al. (62) and Dubousett (24,29) described five stages of PAVF: stage 1 is disc space narrowing, which occurs to a greater extent anteriorly than posteriorly; stage 2 is increased sclerosis of the vertebral end plates of the anterior and middle columns; stage 3 is fragmentation of the anterior vertebral end plates; stage 4 is fusion of the anterior and sometimes the middle columns; and stage 5 is development of a kyphotic deformity.

Kyphosis is the last stage in PAVF, and is caused by the anterior disc space fusing while part of the posterior disc space remains open, allowing for continued growth in the posterior disc space and the posterior column. Bollini et al. (64) found that patients with thoracic PAVF had a relatively good prognosis, while those with lumbar involvement had a poor prognosis. Involvement of the thoracic spine is better tolerated by patients than is involvement of the lumbar area because of the normal kyphotic posture of the thoracic spine. Therefore, nonoperative treatment for most thoracic PAVF deformities is recommended. For PAVF in the lumbar spine a posterior spinal fusion is indicated in stages 1, 2, and 3. In stages 4 and 5 lumbar PAVF, the kyphotic deformity has already occurred in a normally lordotic lumbar spine. Posterior fusion will only stop progression of kyphotic deformity. If normal sagittal alignment is to be obtained an anterior osteotomy, followed by posterior fusion and instrumentation, is recommended (60,61,62,63,64,65,66 and 67).

SCHEUERMANN DISEASE

Scheuermann disease is a common cause of structural kyphosis in the thoracic, thoracolumbar, and lumbar spine. Scheuermann originally described this rigid juvenile kyphosis in 1920; it is characterized by vertebral body wedging that is believed to be caused by a growth disturbance of the vertebral end plates (68,69) (Fig. 19-10).

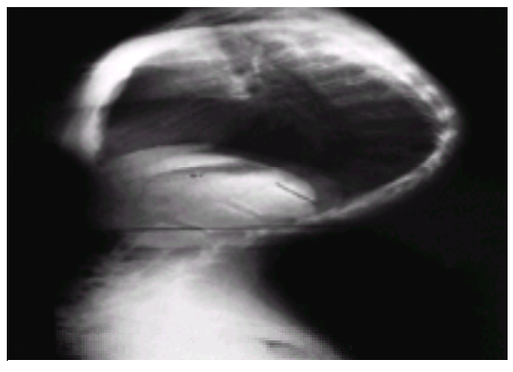

FIGURE 19-10. Lateral radiograph of a patient with Scheuermann disease and an 81-degree kyphotic deformity. Note the narrowing of the intervertebral disc spaces and the irregularity of the vertebral end plates. There is an associated increase in lumbar lordosis below the kyphotic deformity.

Classification

Scheuermann disease can be divided into two distinct groups: a typical form and an atypical form. These two types are determined by the location and natural history of the kyphosis, including symptoms occurring during adolescence and after growth is completed. Typical Scheuermann disease usually involves the thoracic spine, with a well-established natural history during adolescence and after skeletal maturity (70). This classic form of Scheuermann kyphosis will have three or more consecutive vertebrae, each wedged 5 degrees or more, producing a structural kyphosis. In contrast, atypical Scheuermann disease usually is located in the thoracolumbar junction or in the lumbar spine, and its natural history is less well understood. The atypical type is characterized by vertebral end plate changes, disc space narrowing, and anterior Schmorl nodes, but does not necessarily fulfill Sorenson's criteria of three consecutively wedged vertebrae of 5 degrees. Thoracic Scheurmann is the most common form, with the atypical form less frequently seen.

Epidemiology

Typical Scheuermann disease consists of a rigid thoracic kyphosis in a juvenile or adolescent spine. The apex of kyphosis is located between T7 and T9 (10). The reported incidence of Scheuermann deformities in the general population ranges from 0.4 to 8.3% (71,72,73 and 74). Reported male-to-female ratios vary in the literature. Scheuermann originally reported a male preponderance of 88% (68). Most reports in the literature note either a slight male preponderance or an equal

male-to-female ratio (34,73,74,75,76 and 77). Bradford et al. (72) has been the only one to report an increased incidence of Scheuermann disease in women.

The age at onset of Scheuermann kyphosis is difficult to establish. Sorensen (74) described a Scheuermann prodrome in patients who have a lax, asthenic posture from the age of approximately 4 to 8 years, and in whom, within a few years, a fixed kyphosis developed. The clinical detection of Scheuermann disease occurs at about 10–12 years of age. Radiographic evidence of Scheuermann disease usually is not detectable in patients younger than 10 years of age because the ring apophysis is not yet ossified. Until the ring apophysis ossifies, vertebral body wedging and irregularity of the end plate are difficult to measure on radiographs.

Etiology

Many possible etiologies have been suggested for Scheuermann disease, but the true cause remains unknown. Etiologic factors that have been suggested as causes of Scheuermann kyphosis include genetic, vascular, hormonal, metabolic, and mechanical. Sorensen (74) noted a high familial predilection, and Halal et al. (78), in a study of 5 families, and McKenzie and Sillence (79), in a study of 12 families, suggested that the disease may be inherited in an autosomal dominant fashion with a high degree of penetrance. Additional support for a genetic basis for this condition is provided in a report by Carr et al. (80,81) of Scheuermann disease occurring in identical twins. Halal et al. (78), McKenzie et al. (79), and Carr et al. (81) have reported on possible autosomal dominant inheritance of Scheuermann kyphosis.

Scheuermann believed that the kyphosis was caused by a form of avascular necrosis of the ring apophysis, which led to a growth disturbance resulting in a progressive kyphosis with growth (68,69). The problem with this theory is that the ring apophysis contributes little to the longitudinal growth of the vertebrae (81,82). Bick and Copel (83) demonstrated that the ring apophysis lies outside the true cartilaginous physis and contributes nothing to the longitudinal growth of the vertebral body. Therefore, a disturbance in the ring apophysis should not affect growth of the vertebrae or cause vertebral wedging.

Schmorl (84) described a herniation of disc material through the cartilaginous end plate, known as Schmorl nodes. He believed that the herniation of disc material occurred because of a weakened end plate. The disc herniation was thought to damage the anterior end plate, resulting in abnormal growth, which in turn caused the kyphosis. There is a definite increased incidence of Schmorl nodes in patients with Scheuermann kyphosis, but the problem with this theory is that Schmorl nodes were found outside the area of kyphosis, and in patients who had asymptomatic normal spines and did not have a kyphotic deformity.

Ferguson (85) suggested that persistence of an anterior vascular groove altered the anterior growth of the vertebral body, but Aufdermaur and Spycher (86,87) and Ippolito and Ponseti (88) were unable to document growth disturbances around the anterior vascular groove, and concluded that persistence of an anterior vascular groove was a sign of immaturity of the spine. Lambrinudi (89) postulated that Scheuermann disease resulted from upright posture and a tight anterior longitudinal ligament. The fact that no cases of Scheuermann disease have been found in quadruped animals lends support to this theory (90). This has led to the more popular belief that the anterior end plate changes are caused by mechanical forces in response to Wolff's law or the Heuter-Volkmann principle. Compression forces in the anterior growth plate cause a decrease in growth in the area of kyphosis. Indirect support for this argument can be found in the changes in the wedging of the involved vertebral bodies and the reversal of these changes when bracing or casting is used in the immature spine. Scoles et al. (90) also support this theory by demonstrating disorganized endochondral ossification in involved vertebrae, similar to that seen in Blount disease. They conclude that the changes in endochondral ossification are the result of increased pressure on the vertebral growth plate.

Ascani et al. (91,92) found that patients with Scheuermann disease tended to be taller than normal for their chronologic and skeletal ages, and that their bone age tended to be more advanced than their chronologic age. Because they found increased growth hormone levels in these patients they suggested that the increased height and the advanced skeletal age could be caused by the increased growth hormone (91,92). The increased height and more rapid growth may make the vertebral end plates more susceptible to increased pressure and result in the changes seen in Scheuermann disease. The increased growth hormone levels noted by Ascani et al. also may lead to a relative osteoporosis of the spine, which may predispose the spine to the development of Scheuermann disease.

Bradford et al. (71,93), Burner et al. (94), and Lopez et al. (95) reported that Scheuermann kyphosis may be caused by a form of juvenile osteoporosis. Lopez et al. noted a similar association between osteoporosis and Scheuermann disease, on dual photon absorptiometry (95). Gilsanz et al. (96), on quantitative CT scans, found no evidence of osteoporosis in patients with Scheuermann kyphosis, when compared to normal research subjects. They suggested that the differences in his report, and reports showing osteoporosis, could be related to the technique used to determine osteoporosis. Scoles et al. (90), on single-photon absorptiometric analysis, in a study of cadaver vertebrae from patients with Scheuermann kyphosis, also found no evidence of osteoporosis.

What is shown by the histologic studies of Ascani et al. (91), Ippolito et al. (88,97), and Scoles et al. (90) is that an alteration in endochondral ossification occurs. Whether this altered endochondral ossification is the cause or the result of kyphosis is not known. Ippolito and Ponseti (88) found a decrease in the number of collagen fibers and an increase in proteoglycan content, and the collagen fibers were thinner than normal. Some areas of the altered end plate showed direct bone formation from cartilage instead of the normal growth plate sequences for ossification. These studies help support the belief that Scheuermann kyphosis is an underlying growth problem of the anterior vertebral end plates, which results in kyphosis.

Natural History

Many early studies suggested a poor natural history for Scheuermann disease, and recommended early treatment to prevent severe deformity, pain, impaired social functioning, embarrassment about physical appearance, myelopathy, degeneration of the disc spaces, spondylolisthesis, and cardiopulmonary failure. Despite these reports, few long-term follow-up studies of Scheuermann disease were performed until that of Murray et al. (73). Findings by Travaglini and Conti (34,98), Murray et al. (73), and Lowe (99) suggest that the natural history of the disease tends to be benign.

The kyphotic deformity progresses rapidly during the adolescent growth spurt. Bradford et al. (100) noted that more than half of his patients who required brace treatment had progression of their deformities during this growth spurt before brace treatment was begun. Little is known about progression of the kyphosis after growth is completed, and whether it is similar to that in scoliosis. Whether the kyphosis will continue to progress during adulthood, after a certain degree of kyphosis has been reached, is not well documented. Tragvaglini and Conte (34) found that the kyphosis did progress during adulthood, but few patients developed severe deformities. What is known is that patients with Scheuermann kyphosis have more intense back pain, jobs that require relatively little physical activity, less range of motion of the trunk in extension, and different localization of back pain than the general population that does not have Scheuermann kyphosis (73). Even with these findings, when compared with normal individuals patients with Scheuermann kyphosis have no significant differences in self-esteem, social limitations, or level of recreational activities. The number of days they miss from work because of back pain also is similar. The data regarding the natural history of Scheuermann disease suggest that, although patients may have some functional limitations, their lives are not seriously restricted, and they have few clinical or functional problems. Pulmonary function actually increases in these patients, probably because of the increased diameter of the chest cavity, until their kyphosis is more than 100 degrees. Patients with kyphosis of more than 100 degrees had restrictive pulmonary function. Another finding in patients with Scheuermann kyphosis was that disc degeneration was five times more likely to be seen on MRI in patients with Scheuermann, compared with controls (101). The clinical significance of this finding is not known (73).

Associated Conditions

Mild to moderate scoliosis is present in about one-third of patients with Scheuermann disease (99), but the curves tend to be small, about 10 to 20 degrees. Scoliosis associated with Scheuermann disease usually has a benign natural history. The scoliotic curve rarely is progressive, and usually does not require treatment. Deacon et al. (102,103) divided scoliotic curves found in patients with Scheuermann disease into two types, based on the location of the curve and the rotation of the vertebrae into or away from the concavity of the scoliotic curve. In the first type of curves, the apices of scoliosis and kyphosis are the same, and the curve is rotated toward the convexity. The rotation of the scoliotic curve is opposite that normally seen in idiopathic scoliosis. Deacon et al. (102,103) suggested that the difference in direction of rotation is caused by scoliosis occurring in a kyphotic spine, instead of the hypokyphotic or lordotic spine that is common in idiopathic scoliosis. In the second type of curves, the apex of scoliosis is above or below the apex of kyphosis, and the scoliotic curve is rotated into the concavity of the scoliosis, more like idiopathic scoliosis. This type of scoliosis seen with Scheuermann kyphosis is the most common, and rarely progresses or requires treatment.

Lumbar spondylolysis is a frequent associated finding in Scheuermann kyphosis. The suggested reason for the increased incidence of spondylolysis is that increased stress is placed on the pars interarticularis as a result of the associated compensatory hyperlordosis of the lumbar spine in Scheuermann disease. This increased stress causes a fatigue fracture at the pars interarticularis, resulting in spondylolysis. Ogilvie and Sherman (104) found a 50% incidence of spondylolysis in the 18 patients he reviewed. Stoddard and Osborn reported a 54% incidence of spondylolysis in their patients with Scheuermann kyphosis (105).

Other conditions reported in patients with Scheuermann disease include endocrine abnormalities (106), hypovitaminosis (107), inflammatory disorders (105,106), and

dural cysts (90,108).

Clinical Presentation

Clinical signs of Scheuermann disease occur around the time of puberty. The clinical feature that distinguishes postural kyphosis from Scheuermann kyphosis is rigidity. Often, mild Scheuermann disease is believed to be postural because the kyphosis may be more flexible in the early stages than in later stages. Usually the patient seeks treatment because of a parent's concern about poor posture. Sometimes, the poor posture has been present for several months or longer, or the parents may have noticed a recent change during a growth spurt. Attributing kyphotic deformity in a child to poor posture often causes a delay in diagnosis and treatment.

Pain may be the predominant clinical complaint rather than deformity. The pain generally is located over the area of the kyphotic deformity, but also occurs in the lower lumbar spine if compensatory lumbar lordosis is severe. Back pain usually is aggravated by standing, sitting, or physical activity. The distribution and intensity of the pain vary according to the age of the patient, the stage of the disease, the site of the kyphosis, and the severity of the deformity. Pain usually subsides with the cessation of growth, although pain in the thoracic spine can sometimes continue, even though the patient is skeletally mature (73,109). More commonly, after growth is completed patients complain of low back pain caused by the compensatory or exaggerated lumbar lordosis.

Most symptoms related to Scheuermann disease occur during the rapid growth phase. During the growth spurt, pain is reported by 22% of patients, but as the end of the adolescent growth spurt approaches, this figure reaches 60%. Some authors believe that when growth is complete the pain recedes completely, except for well-circumscribed perispinal discomfort (110,111 and 112). In adult patients with Scheuermann disease, pain may be located in and around the posterior iliac crest. This pain is thought to result from arthritic changes at T11 and T12, because the posterior crest is supplied by this dermatome. Stagnara (113) believes that the mobile areas above and below the rigid segment are the source of pain.

Symptoms also depend on the apex of kyphosis. Murray et al. (73) noted that if the apex of kyphosis was in the upper thoracic spine patients had more pain with everyday activities. The degree of kyphosis also has been correlated with symptoms. It seems logical that the larger the kyphosis, the more likely it is to be symptomatic, but Murray et al. (73) found that curves between 65 and 85 degrees produced the most symptoms, whereas curves of more than 85 degrees and less than 65 degrees produced fewer symptoms. However, in patients with thoracolumbar or lumbar kyphosis (atypical Scheuermann disease), activity decreased as the degree of kyphosis increased.

Lumbar Scheuermann

Patients with lumbar Scheuermann disease differ from those with thoracic deformity. These patients usually have low back pain, but, unlike patients with the more common form of Scheuermann disease, their kyphotic deformity is not as noticeable. Pain is associated with spinal movement. Lumbar Scheuermann is especially common in males involved in competitive sports, and in farm laborers, suggesting that this may be an injury to the vertebral physes from repeated trauma (114).

Physical Examination

In a patient with Scheuermann disease, a thorough examination of the back and a complete neurologic evaluation are essential. With the patient standing the shoulders appear to be rounded and the head protrudes forward. The anterior bowing of the shoulders is caused by tight pectoralis muscles. Angular kyphosis is seen best when the patient is viewed from a lateral position and is asked to bend forward. Normally, the back exhibits a gradual rounding with forward bending, but in patients with Scheuermann disease an acute increase in the kyphosis of the thoracic spine, or at the thoracolumbar junction, is evident. Stagnara et al. (115) found cutaneous pigmentation to be common at the most protruding spinous process at the apex of the kyphosis, probably the result of friction exerted by the backs of chairs and clothing. Compensatory lumbar and cervical lordosis, with forward protrusion of the head, further increases the anterior flexion of the trunk. Associated hamstring and hip flexor muscle tightness often are present.

The kyphotic deformity has some form of rigidity, and will not correct completely with hyperextension. Larger degrees of kyphosis are not necessarily more rigid, and the amount of rigidity will vary with the age of the patient (73).

The neurologic evaluation usually is normal, but must not be overlooked. Spinal cord compression has been reported occasionally in patients with Scheuermann disease (116,117,118,119 and 120). Three types of neural compression have been reported: ruptured thoracic disc (121), intraspinal extradural cyst, and mechanical cord compression at the apex of kyphosis. However, spinal cord compression and neurologic compromise are rare (122). Bouchez et al. (66) found that only 1% of patients with a paralyzing disc herniation had Scheuermann disease. In patients with spinal cord compression caused by the kyphosis alone, Ryan and Taylor (119) suggest that the factors influencing the onset of cord compression are the angle of kyphosis, the number of segments involved, and the rate of change of the angle of kyphosis. This may be why neurologic findings are rare in Scheuermann kyphosis—the kyphosis occurs gradually over several segments, without acute angulation.

Radiographic Examination

The most important radiographic views are standing anteroposterior and lateral views of the spine. The amount of kyphosis present is determined by the Cobb method on a lateral radiograph of the spine. This is accomplished by selecting the cranial- and caudal-most tilted vertebrae in the kyphotic deformity. A line is drawn along the superior end plate of the most cranial vertebra and the inferior end plate of the most caudal vertebra. Lines are drawn perpendicular to the lines along the end plates, and the angle they form is the degree of kyphosis (123). Normal kyphosis is between 20 and 40 degrees (9).

The criterion for diagnosis of Scheuermann disease on a lateral radiograph is more than 5 degrees of wedging of at least three adjacent vertebrae (74). The degree of wedging is determined by drawing one line parallel to the superior end plate and another line parallel to the inferior end plate of the vertebra, and measuring the angle formed by their intersection. Bradford believes that three wedged vertebrae are not necessary for the diagnosis, but rather an abnormal, rigid kyphosis is indicative of Scheuermann disease (124).

The vertebral end plates are irregular, and the disc spaces are narrowed. The anteroposterior diameter of the apical vertebra frequently is increased (90) (Fig. 19-11). Associated Schmorl nodes often are seen in the vertebrae in the kyphosis. Flexibility is determined by taking a lateral radiograph with the patient lying over a bolster placed at the apex of the deformity, to hyperextend the spine. The bolster should be placed at the apex of the deformity to maximize the amount of correction seen on a hyperextension radiograph. On the lateral radiographs, most patients will be in negative sagittal balance (125). Sagittal balance is measured radiographically by dropping a plumb line from the center of the C7 vertebral body and measuring the distance from this line to the sacral promontory, with a positive value indicating the plumb line lies anterior to the promontory of the sacrum. Normal sagittal balance values are ±2 cm to the sacral promontory. On a lateral radiograph of lumbar Scheuermann kyphosis irregular end plates, Schmorl nodes, and disc-space narrowing will be seen, but rarely vertebral-body wedging. MRI and CT scans are necessary only if the patient has unusual symptoms or positive neurologic findings. An anteroposterior or posteroanterior radiograph of the spine should be obtained to look for associated scoliosis or vertebral anomalies. The patient's skeletal maturity can be estimated from a radiograph of the left hand and wrist, or from the Risser sign on the anteroposterior radiograph of the spine.

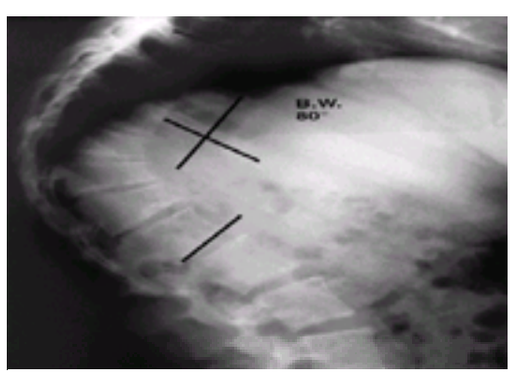

FIGURE 19-11. Lateral radiograph of a patient with Scheuermann disease demonstrates the kyphotic deformity seen in this disorder. Note the irregularity of the vertebral end plates and the anterior vertebral wedging.

Treatment

The indications for the treatment of patients with Scheuermann kyphosis can be grouped into five general categories: pain, progression of deformity, neurologic compromise, cardiopulmonary compromise, and cosmesis.

Treatment options include observation, nonoperative methods, and surgery. Observation is an active form of treatment. If the deformity is mild and nonprogressive, the kyphosis can be observed every 6 months with lateral radiographs. The parents and patient must understand the need for regular follow-up visits. If the deformity begins to progress another form of treatment, such as bracing, casting, or surgery, may be indicated.

Nonoperative methods include exercise, physical therapy, electrical stimulation, bracing, and casting. Exercise and physical therapy alone will not permanently improve kyphosis that is caused by skeletal changes. The improvement seen with these methods is due to improved muscle tone and correction of bad posture. The goals of physical therapy are to increase flexibility of the spine, correct lumbar hyperlordosis, strengthen extensor muscles of the spine, and stretch tight hamstring and pectoralis muscles. The efficacy of this treatment method has not been proven, and although it may improve the postural component of Scheuermann disease, its effect on a rigid kyphosis is questionable.

Although electrical stimulation has been reported in a small number of patients with scoliosis or kyphosis, (126). its use has not been reported in patients with Scheuermann disease. The general consensus at this time is that electrical stimulation is of no benefit in these patients (99).

Other nonoperative treatment methods can be divided into active correction systems (braces) and passive correction systems (casts). For either a brace or a cast to be effective, the kyphotic curve must be flexible enough to allow correction of at least 40% (92,127).

The Milwaukee brace is the brace recommended for the treatment of Scheuermann disease (128) (Fig. 19-12). The Milwaukee brace functions as a dynamic three-point orthosis that promotes extension of the thoracic spine. The neck ring maintains proper alignment of the upper thoracic spine, and the padded poster uprights apply pressure over the apex of the kyphosis. The pelvic girdle stabilizes the lumbar spine by flattening the lumbar lordosis. A low-profile brace, without a chin ring and with anterior shoulder pads, can be used for curves, with an apex at the level of T9 or lower. The indications for brace treatment are spine immaturity and kyphosis of 50 to 70 degrees, with radiologic evidence of Scheuermann disease. The brace initially is worn full-time for an average of 12 to 18 months. If the curve is stabilized and no progression is noted after this time, a part-time brace program can be started. If no progression is noted with part-time bracing, a nighttime bracing program is used until skeletal maturity is reached. However, Gutowski and Renshaw (129) reported that part-time bracing (16 h/day) is as effective as full-time bracing, and is associated with improved patient compliance. In this study, a Boston lumbar kyphosis orthosis was used. The rationale for correction in this orthosis was reduction of the lumbar lordosis, which caused the patient to dynamically straighten the thoracic kyphosis to maintain an upright posture. This presupposes a flexible thoracic kyphosis, a normal neurovestibular axis, and the absence of hip flexion contractures.

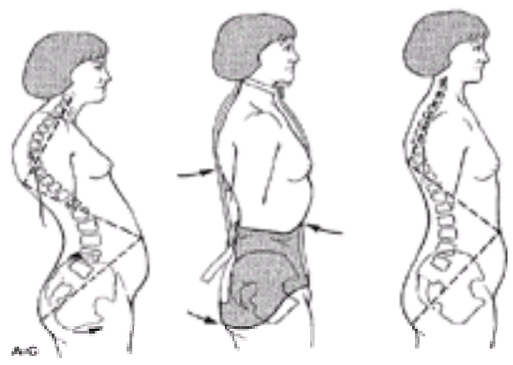

FIGURE 19-12. A: Patient with Scheuermann kyphosis has thoracic kyphosis, compensatory lumbar lordosis, anterior protrusion of the head, and rotation of the pelvis. **B:** Patient with Scheuermann kyphosis in a Milwaukee brace. The placement of the pelvic girdle, posterior thoracic pads, occipital pads, and neck ring encourage correction of the kyphosis. **C:** Correction of kyphosis after Milwaukee brace treatment. (Courtesy of Robert Winter, M.D., Minneapolis.)

Despite initial improvement, several authors have noted a significant loss of correction after the discontinuation of brace treatment (46,130). Montgomery and Erwin (77) believe that if permanent correction of kyphosis is possible, a change in vertebral body wedging should be seen before bracing is discontinued. Even though some loss of correction can occur after bracing is discontinued, it still is effective in obtaining some correction of the kyphosis, and possibly reversing vertebral body wedging, or at least preventing any progression of the kyphotic deformity (77) (Fig. 19-13). Poor brace results were noted by Bradford in patients in whom the kyphosis exceeded 75 degrees, the wedging of the vertebral bodies was more than 10 degrees, or the patient was near or past skeletal maturity (124).

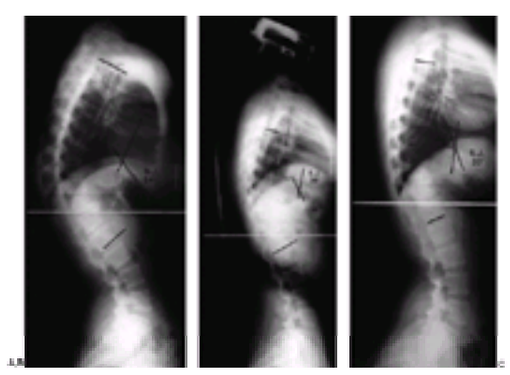

FIGURE 19-13. A: A 15-year-old girl with a 64-degree thoracic kyphosis secondary to Scheuermann disease. **B:** Lateral radiograph of the patient in a Milwaukee brace with the kyphotic deformity improved to 39 degrees. **C:** Lateral radiograph obtained after the patient completed brace treatment; the kyphotic deformity has improved to 33 degrees.

De Mauroy and Stagnara (131) developed a therapeutic regimen for patients with Scheuermann disease that uses serial casts for correction. This method consists of three stages. First, a physical therapy program is started in preparation for the casts. Next, three antigravity casts are applied on separate occasions. The casts are changed at 45-day intervals, to obtain gradual correction of the deformity at each cast change. The third stage involves the use of a plastic maintenance brace that is worn until skeletal maturity is reached. Although the reported results of this method of treatment have been good (131), the Milwaukee brace is still the preferred nonoperative treatment method in North America.

Surgical correction of kyphosis may be a posterior approach, an anterior approach, or a combined anterior and posterior approach. The combined anterior and posterior approach is the most frequently recommended and reliable procedure for surgical correction of kyphosis (132,133,134 and 135) (Fig. 19-14). A posterior procedure alone can be considered if the kyphosis can be corrected to, and maintained at, less than 50 degrees, while a posterior fusion occurs (136,137 and 138). The spine can be instrumented with Harrington compression rods (73,139) or a posterior Cotrel-Dubousset type of instrumentation system (140). If Harrington compression rods are used for posterior instrumentation, the ¼-inch rods are used. Even when ¼-inch Harrington compression rods are used, a brace or cast should be applied after surgery to prevent rod breakage until a solid fusion is obtained. Prolonged immobilization is necessary, however, and there are potential

complications. When a Cotrel-Dubousset or similar type of instrumentation system is used, postoperative immobilization may not be required. Anterior instrumentation for Scheuermann disease has been reported by Kostuik (141), consisting of an anterior interbody fusion and anterior instrumentation, with a Harrington distraction system augmented by postoperative bracing. A single rod and multiple bone screws, available in the present-day spine instrumentation systems, may be used instead of the Harrington distraction system. Although Kostuik has reported good results with this technique, the anterior instrumentation approach for treatment of Scheuermann kyphosis is not widely used (141).

FIGURE 19-14. A: A 19-year-old man with a 70-degree lower thoracic Scheuermann kyphosis was treated by anterior ligament release and interbody fusion, followed by posterior instrumentation and fusion. **B:** Two years after surgery the kyphosis is 37 degrees. **C:** Standing photographs before and 2 years after surgery. **D:** Forward-bending photographs before and 2 years after surgery. (Courtesy of Robert Winter, M.D., Minneapolis.)

When anterior and posterior surgery is performed for Scheuermann disease, the anterior release and fusion are performed first, followed by the posterior fusion and instrumentation. The posterior fusion and instrumentation can be done on the same day as the anterior release and fusion, or they can be done as a staged procedure. Harrington compression rods can be used for posterior instrumentation, but usually rods with multiple hooks are used. Lowe (134) and Coscia et al. (142) have reported a high complication rate after using Luque rods and wires for posterior fixation, because this system does not allow for any compression. The posterior instrumentation should include at least three sets of hooks above the apex and at least two sets of hooks below the apex of the kyphosis. The fusion and instrumentation should include the proximal vertebra in the measured kyphotic deformity and the first lordotic disc distally. If the fusion and instrumentation end in the kyphotic deformity, a junctional kyphosis at the end of the instrumentation is likely to develop.

Lowe emphasized that overcorrection of the deformity should be avoided to prevent proximal junctional kyphosis (134). He recommended that no more than 50% of the preoperative kyphosis be corrected, and that the final kyphosis should never be less than 40 degrees. He also found that patients with Scheuermann disease tend to be in negative sagittal balance and become further negatively balanced after surgery, which may predispose them to the development of junctional kyphosis. Reinhardt and Bassett (143) recommended fusion to the first square vertebra distally if the end vertebra distally was wedged to prevent junctional kyphosis. The type of instrumentation used will determine whether postoperative immobilization is needed. This immobilization can consist of a brace or a Risser body cast.

POSTLAMINECTOMY KYPHOSIS

A laminectomy or multiple laminectomies are needed most often in children for the diagnosis and treatment of spinal cord tumors, but also may be needed for other conditions, such as neurofibromatosis, Arnold Chiari malformation, and syringomyelia (144,145). Although deformity after laminectomy is unusual in adults, it is common in children because of the unique and dynamic nature of the growing spine (121,146,147,148,149 and 150). Postlaminectomy deformities usually result in kyphotic deformity, but a scoliotic deformity also may occur (147).

The pathophysiology of postlaminectomy kyphotic deformity can be multifactorial. Deformity of the spine after multiple laminectomies can be caused by (i) skeletal deficiencies (anterior column, facet joint, laminae), (ii) ligamentous deficiencies, (iii) neuromuscular imbalance, (iv) effects of gravity, and (v) progressive osseous deformity resulting from growth disturbances (144,151). Panjabi and colleagues (152) showed that with loss of posterior stabilizing structures caused by removal of the interspinous ligaments, spinous processes, and laminae, the normal flexion forces placed on the spine will produce kyphosis. Gravity places a flexion moment on the spine, producing compression force on the anterior vertebrae and discs, and a tensile force on the remaining posterior structures. This may explain why postlaminectomy deformities occur most often in the cervical and thoracic spine, and rarely in the lumbar spine. Gravity tends to cause a kyphosis in the cervical and thoracic spine, whereas it accentuates the usual lordosis of the lumbar spine.

Skeletal deficiencies also can produce deformity. The most important factor noted to influence the development of postlaminectomy deformity is the integrity of the facet joint (147,152,153 and 154). If the facet joint is removed or damaged during surgery, deformity is likely to develop. In addition, any secondary involvement of the anterior column, by tumor or surgical resection, adds to the risk of instability and deformity after laminectomy. Also, multiple laminectomies increase the risk of deformity (155).

Paralysis of muscles that help stabilize the spine also can add to a postlaminectomy deformity, because these muscles are unable to resist the normal flexion forces placed on the spine by gravity and by the normal flexor muscles of the spine. Yasuoka et al. (156) noted increased wedging of the vertebrae and excessive motion after laminectomy in children, but not in adults. This increased wedging is caused by increased pressure on the cartilaginous end plates of the vertebral bodies. With time the increased pressure will cause a decrease in growth of the anterior portion of the vertebrae, according to the Heuter-Volkman principle (Fig. 19-15). Excessive spinal motion in children after laminectomy can be attributed to the facet joint anatomy in the cervical spine and the increased ligamentous laxity of growing children. Orientation of the cervical joint in a child is more horizontal than that seen in an adult. This horizontal orientation offers less resistance to forces that tend to cause kyphosis in the cervical spine.

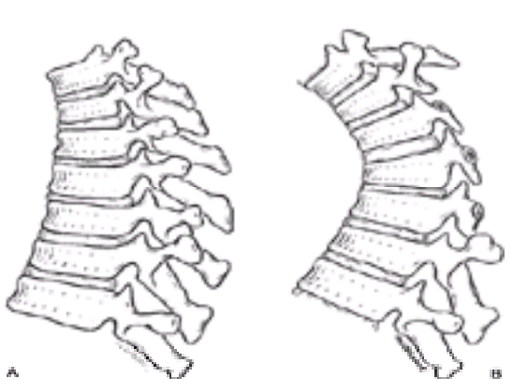

FIGURE 19-15. Drawings of the thoracic spine before and after repeated laminectomy demonstrate the effects on growth of the vertebral bodies. **A:** Before laminectomy, the anterior vertebral bodies are rectangular in configuration. **B:** The spine that has had multiple laminectomies will have increased compression anteriorly because of loss of posterior supporting structures. This compression results in less growth in the anterior potion of the vertebral body than in the posterior portion. In time, this will result in wedging of the vertebral bodies, causing a kyphotic deformity. (From ref. 157, with permission.)

Kyphosis is the most common deformity, although scoliosis also can occur, either as the primary deformity or in association with kyphosis. The incidence of postlaminectomy kyphotic deformity ranges from 33 to 100% (157), and depends on the age of the patient and the level of the laminectomy. Generally, the deformity is more likely in younger patients, and after more cephalad laminectomy. For example, Yasuoka et al. (156) found that spinal deformity occurred in 46% of patients younger than 15 years of age, but in only 6% of patients 15 to 24 years of age. All the patients between 15 and 24 years of age in whom deformity developed were 18

years of age or younger. Yasuoka et al. (156) and Fraser et al. (158) found that higher levels of laminectomy were associated with a greater chance of deformity. Deformity occurred after 100% of cervical spine laminectomies, in 36% of thoracic laminectomies, and in none of the lumbar laminectomies, in their study.

Kyphosis in the cervical and thoracic spine is the most common postlaminectomy deformity. The lumbar spine is normally in lordosis, and this may protect the lumbar spine from developing kyphosis after multiple lumbar laminectomies. Papagelopoulos et al. (159) reported that hyperlordosis occurred in children who had lumbar laminectomies for intraspinal tumors. If the laminectomies extended into the thoracolumbar junction, kyphosis at the thoracolumbar junction occurred in 33% of his patients. Peter et al. (160) found that most of his patient did not develop a significant deformity after multiple lumbar laminectomies for selective posterior dorsal root rhizotomy, but he did find that 9% developed spondylolysis. This may be the result of increased lordosis in this patient population (161).

Postlaminectomy deformity can occur early in the postoperative period or gradually over time. Kyphotic deformities have been reported to occur as late as 6 years after surgery (146,161). Progression also can be sudden or gradual, or the deformity may progress significantly only during the adolescent growth spurt.

The natural history of postlaminectomy spinal deformity is varied, and depends on the age of the patient at the time of surgery, the location of the laminectomy or laminectomies, and the integrity of the facet joint. Three types of postlaminectomy kyphosis have been described in children: (i) instability after facetectomy, (ii) hypermobility between vertebral bodies associated with gradual rounding of the spine, and (iii) wedging of vertebral bodies caused by growth disturbances (157).

Kyphosis from instability after facetectomy tends to be sharp and angular, and usually occurs in the immediate or early postoperative period, causing associated loss of neurologic function (Fig. 19-16). Gradual rounding of the kyphotic deformity is seen more often when the facet joints are preserved. Kyphosis increases gradually over time because of the stress placed on the remaining posterior structures. If the spine is immature when the laminectomy is performed, the resulting kyphosis can inhibit the growth of the anterior growth plates of the involved vertebrae. Unequal growth results in wedging of the vertebrae and a progressive kyphotic deformity that is accelerated during the adolescent growth spurt.

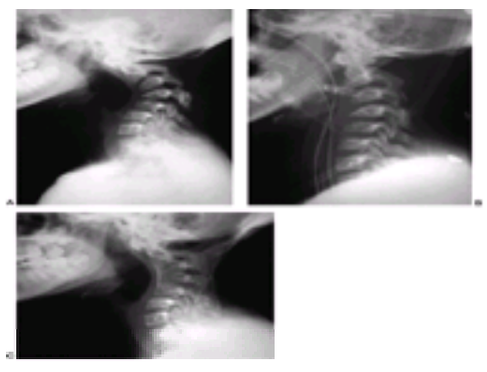

FIGURE 19-16. Radiographs of a 13-year-old girl treated for a low-grade astrocytoma. She underwent resection of the tumor and a portion of the occiput and the laminae of C1-C4, followed by radiotherapy of 5400 cGy. **A:** A progressive cervical kyphosis developed. Note wedging of the anterior vertebral body. **B:** Radiograph in halo traction demonstrates partial reduction of the kyphosis. **C:** Postoperative radiograph after anterior and posterior fusion.

Other associated conditions also can add to or cause kyphotic deformities, including persistence of spinal cord tumors, neurologic deficits, intraspinal pathology (hydromyelia), and radiation therapy (162,163).

Evaluation

The evaluation of a postlaminectomy deformity should focus on (i) the flexibility of the deformity, (ii) loss of spinal structures, and (iii) determination of future deformity with growth. The flexibility of a deformity can be estimated by flexion and extension lateral radiographs. If these cannot be obtained then a lateral traction film can be used. CT scans and three-dimensional reconstruction views may better delineate which bony elements are missing. MRI may be used, but gives more information about the spinal cord, disc, and surrounding soft tissue. To aid in preoperative planning, Lonstein recommends drawing the spine preoperatively (144). The lines should represent the spinous processes and intact laminae and facet joints. This may aid in predicting progression of a postlaminectomy deformity.

Treatment

Treatment of postlaminectomy kyphosis is difficult, and it is best to prevent the deformity from occurring (164). The facet joints should be preserved whenever possible during laminectomy. Localized fusion at the time of facetectomy or laminectomy may help prevent progressive deformity (165). Because of the loss of bone mass posteriorly, however, localized fusion may not produce a large enough fusion mass to prevent kyphosis. Even so, this approach is advocated, because it may produce enough bone mass posteriorly to stabilize what otherwise would be a severe progressive deformity.

After surgery in which the laminae have been removed, bracing has been suggested to prevent deformity (166,167), although no studies have documented the efficacy of this form of treatment. After the deformity has occurred and started to progress, bracing is ineffective in preventing further progression (144,147).

For progressive or marked deformity, spinal fusion is recommended, although the patient's long-term prognosis should be considered before making definitive treatment plans. If the prognosis for survival is poor, spinal fusion may not be appropriate. However, given the availability of effective treatment protocols for tumors and the improved survival rates, fusion usually is indicated for progressive deformity. Combined anterior and posterior spinal fusion is preferred in most patients, because of the frequency of pseudarthrosis after either procedure alone.

Lonstein (144) reported pseudarthrosis in 57% of patients after posterior fusion, and in 15% of patients after anterior fusion. Anterior and posterior fusion can be performed on the same day, or as staged procedures. When the anterior procedure is performed, care must be taken to remove all the physes back to the posterior longitudinal ligament. Leaving some of the physes in the vertebral body can cause an increase in the deformity. When the posterior procedure is performed, instrumentation of the involved spine is desirable, but not always possible, because of the absence of posterior elements. The development of pedicle screw fixation has been helpful in allowing the use of posterior instrumentation for postlaminectomy kyphosis **[➥2.8, 2.9]**. When it can be performed safely, this procedure provides secure fixation while the spinal fusion is maturing. Torpey et al. recommend a posterior fusion, using titanium rod instrumentation at the time of laminectomy. The instrumentation provides stability postoperatively, and the titanium rods allow for postoperative MRI to evaluate spinal cord tumors. In certain cases, anterior instrumentation with rod and bone screws or plates may be used to obtain stability and correction of the deformity (168). If the deformity is severe or long-standing, anterior release, followed by halo traction or a halo cast with an Ilizarov device, can be used to obtain gradual correction (169,170).

A technique known as “laminoplasty” may lessen the chance of progressive deformity. This approach involves suturing the laminae back in place after removal, or removing just one side of the laminae and allowing them to hinge open like a book to expose the spinal cord, then suturing that side of the laminae back in place (171,172 and 173). This may provide only a fibrous tether connecting the laminae to the spine, but reported results have been promising (174,175). Another technique is to hinge the laminae open in a lateral direction, after dividing the laminae in the midline. This provides a lateral trough for the placement of bone graft for a lateral fusion (176). Hopefully, the use of these techniques will decrease the incidence of postlaminectomy deformity.

RADIATION KYPHOSIS

The relative radiosensitivity of growing cartilage was discovered by investigators during the 1940s. Animal studies by Engel (177,178), Gall et al. (179), Hinkel (180), Barr et al. (181), and Reidy et al. (182) documented radiation-induced growth inhibition in growing cartilage and bone. The longitudinal growth of a vertebral body takes place through normal endochondral ossification, similar to the longitudinal growth of the metaphyses of long bones. Bick and Copel (82,83) demonstrated this on histologic sections in fresh autopsy specimens of vertebral bodies, taken from research subjects ranging in age from 14 weeks of fetal development to 23 years of age. This endochondral ossification at the physeal growth plate is radiosensitive (82,83,177,178,180,182,183). Engel (177,178) and Arkin and Simon (184) were able to produce spinal deformities in experimental animals, using radiation. Arkin et al. (185) were the first to report a case of spinal deformity caused by radiation in

humans. Since these reports, it has become clear that exposing an immature spine to radiation can produce spinal deformity, including scoliosis, kyphoscoliosis, lordoscoliosis, and kyphosis.

The three most common solid tumors of childhood in which radiation therapy is part of the treatment regimen, and in which the vertebral column is included in the radiation fields, are neuroblastoma, Wilms tumor, and medulloblastoma. Early in the history of radiation therapy, survival rates were poor and spinal deformities were not as prevalent. With improved treatment protocols and survival rates, the incidence of spinal deformities has increased. The degree of growth inhibition of the spine is related to the accumulated radiation dose and the age of the child when the spine is irradiated. Progression is directly dependent on the remaining growth potential in the irradiated vertebrae. The younger the child and the greater the accumulated radiation dose, the greater the chance of deformity (186,187,188,189,190 and 191). The most severe growth changes occur in patients who are 2 years of age or younger at the time of irradiation. Initial vertebral changes usually occur 6 months to 2 years after radiation exposure (192), but the deformity may not become apparent until years later, after a period of growth (187,190).

Reports of radiation involving the spinal column show that an accumulated dose less than 1,000 cGy does not produce a detectable inhibition of vertebral growth, whereas a dose of 1,000 to 2,000 cGy causes a temporary inhibiting effect on growth. Sometimes, this is manifested as a transverse growth arrest line in the vertebra, which gives the appearance of a bone within a bone. A dose of radiation between 2,000 and 3,000 cGy causes irregularity or scalloping of vertebral end plates, diminishing axial height, and sometimes leads to a flattened, beaked vertebra (187,188,190,192,193,194 and 195). A dose of 5,000 cGy causes bone necrosis (188). The effect that radiation has on soft tissue also affects the progression of spinal deformity. The soft tissue anterior to the spine and the abdominal muscle can become fibrotic and act as a tether with growth, adding to the deformity of the spine as the child grows (196).

The incidence of spinal deformity after irradiation of the spine has been reported to range from 10 to 100% (187,190,191,193,197,198,199 and 200). These rates are decreasing because of shielding of growth centers, symmetric field selection, and decreased total accumulated radiation doses. The last of these changes has resulted from an increase in the use and effectiveness of chemotherapeutic regimens that reduce the need for large doses of radiation. Early reports showed an increased incidence of scoliotic deformities with the use of asymmetric fields, but the incidence of kyphotic postirradiation deformities has increased with the use of symmetric radiation fields (201).

Any child who has received irradiation to the spine should be observed carefully for the development of spinal deformity. Because the development of deformity is related to the amount of disordered growth in the vertebral bodies that were affected by irradiation, it depends to a large extent on the amount of growth left in the spine, when irradiation was started, and the amount of damage to the physes caused by irradiation, which correlates directly with the accumulated radiation dose. If the dose of radiation is large enough to cause permanent damage to the physes the deformity will be progressive. Postirradiation scoliosis and kyphosis both progress more rapidly during the adolescent growth period (190,191,194,201). Before the adolescent growth spurt, the deformity may remain relatively stable or progress at a steady rate. Severe curves can continue to progress even after skeletal maturity, and these patients may require continued observation.

Radiographic evaluation of a postirradiation deformity should include standard posteroanterior and lateral radiographs of the spine. Occasionally, tomograms or CT scans with sagittal or coronal reconstruction, are needed for better delineation of the vertebral body deformities. The spinal cord is evaluated best with MRI. Neuhauser et al. (188) described the roentgenographic changes seen in irradiated spines. The earliest changes were alterations in the vertebral bodies within the irradiated section of the spine, caused by impairment of endochondral growth at the vertebral end plates. Growth arrest lines produced a bone-within-a-bone picture. This occurred in 28% of the 81 patients in the study by Riseborough et al. (190). Other radiographic changes were end plate irregularity with an altered trabecular pattern, and decreased vertebral body height. This pattern was the most common radiographic change reported by Riseborough et al. (83%) (190). Contour abnormalities, causing anterior narrowing and beaking of the vertebral bodies, much like those seen in patients with conditions that affect endochondral ossification (e.g., Morquio syndrome, achondroplasia), were the third type of radiographic change noted by Neuhauser et al. (188).

Treatment

Milwaukee brace treatment has been recommended for progressive curves, but generally has been ineffective for post- irradiation kyphosis (190,201), especially in patients with soft tissue contractures contributing to the deformity. The irradiated skin also may be of poor quality, making long-term brace wear difficult. If progression occurs, spinal fusion with or without instrumentation should be performed, regardless of the age of the patient. Because bone quality is poor, fusion can be difficult to obtain after a single attempt. Anterior and posterior fusion are recommended, and should extend at least one or two levels above and below the end of the kyphosis (157,190,201,202,203 and 204). The posterior fusion mass may require reexploration and repeated bone grafting at 6 months, and cast immobilization may need to be prolonged for 6 to 12 months. Posterior instrumentation should be used whenever feasible because it adds increased stability while the fusion mass is maturing, and may allow for some limited correction of the kyphotic deformity (Fig. 19-17) **[➥2.13, 2.14]**. Although anterior instrumentation can be used in certain cases, as a result of the radiation the vertebral bodies usually remain in an infantile form, and instrumentation with bone screws may be difficult.

FIGURE 19-17. A and **B:** Anteroposterior (AP) and lateral radiographs of a 16-year-old child with a suprasellar germinoma treated with resection and 3400 cGy of radiation to the base of the skull and the entire spine. Radiographs demonstrate a 67-degree kyphosis with associated scoliosis. **C:** The kyphosis progressed to 85 degrees over 18 months despite bracing. **D** and **E:** AP and lateral radiographs after anterior and posterior fusion with posterior instrumentation. The kyphosis has been corrected to 46 degrees.

Correction of postirradiation kyphosis is difficult. Typically, these curves are rigid, and soft tissue scarring and contractures often further hamper correction. Healing can be prolonged and pseudarthrosis is common. Infection is a frequent complication in these patients because of poor vascularity of the irradiated tissue (190). Riseborough et al. (190) reported a pseudarthrosis rate of 37% and an infection rate of 23% in his patients after surgery. King and Stowe (201) also reported a high complication rate in patients who were treated surgically. Because viscera also can be damaged by irradiation, bowel obstruction, perforation, and fistula formation may occur after spinal fusion. This can be difficult to differentiate from postoperative cast syndrome, and the treating physician should be aware of this complication (205). Radiation myelopathy also can occur in this patient population (206). King and Stowe (201) reported postoperative paraplegia in 2 of 7 patients after radiation treatment for neuroblastoma and correction of their kyphotic spine deformity. They believed that these two patients had a subclinical form of radiation myelopathy, and with spinal correction what little vascular supply was present to the cord was compromised. Therefore, the surgeon should be aware of this possibility and try to avoid overcorrection.

MISCELLANEOUS CAUSES OF KYPHOTIC DEFORMITIES

Spinal deformity in the sagittal plane can occur in patients with skeletal dysplasia (207,208). The natural history of spinal deformity varies with the type of deformity and the type of dysplasia. Some sagittal plane deformities that appear severe at birth or in infancy improve spontaneously with growth, whereas others continue to progress and eventually can cause paraplegia. A knowledge of the various skeletal dysplasias and the natural history of sagittal plane deformities in each is necessary to prevent overtreatment and undertreatment.

Achondroplasia

Treatment of spinal problems is required most often in patients with achondroplasia. The most common sagittal plane deformity in achondroplastic dwarfs is

thoracolumbar kyphosis (209,210,213). The kyphosis usually is detected at birth, and is accentuated when the child is sitting, because of the associated hypotonia in these infants (211). Ambulation is delayed until about 18 months of age, but after ambulation begins, the thoracolumbar kyphosis tends to improve. According to Lonstein (212), thoracolumbar kyphosis resolves in 70% of achondroplastic dwarfs, and persists in 30%. One-third of these patients, or 10% of achondroplastic dwarfs with thoracolumbar kyphosis, have progressive kyphosis (212) (Fig. 19-18).

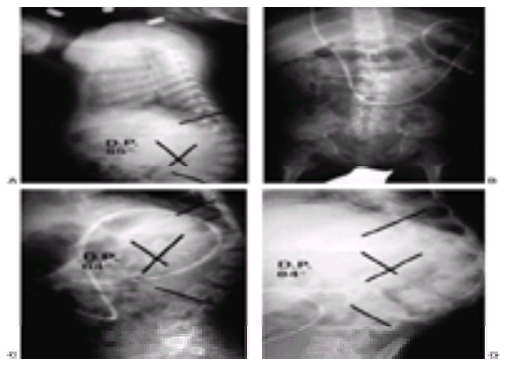

FIGURE 19-18. Achondroplastic dwarf with progressive thoracolumbar kyphosis. **A:** Lateral radiograph at 1 year of age shows a 55-degree thoracolumbar kyphosis. **B:** Anteroposterior radiograph at 5 years of age shows narrowing of the lumbar interpedicular distance characteristic of achondroplasia. **C:** Lateral radiograph at 5 years of age reveals a 64-degree kyphosis. **D:** Lateral radiograph at 9 years of age shows an 84-degree thoracolumbar kyphotic deformity.

A lateral radiograph of the thoracolumbar spine during infancy shows anterior wedging of the vertebrae at the apex of the kyphosis (213). In patients whose thoracolumbar kyphosis resolves, the anterior vertebral body wedging also improves. When the kyphosis is progressive, anterior vertebral body wedging persists.

If no improvement in the thoracolumbar kyphosis is evident by 3 years of age, a thoracolumbosacral orthosis (TLSO) is recommended, to try to prevent progression of the kyphosis (214,215,216 and 217). Early treatment to prevent the development of a progressive kyphosis has been recommended by Pauli et al. (218). They developed an algorithm for treatment in the young achondroplastic patient, first counseling the parents against unsupported sitting and for close follow-up. If kyphosis develops, and is less than 30 degrees, TLSO bracing is begun and continued until the child is walking independently and there is evidence of improvement of vertebral body wedging and kyphosis. Using this form of early intervention, Pauli et al. (218) reported no occurrences of progressive kyphosis.

Indications for surgery are documented progression of a kyphotic deformity, kyphosis of more than 40 degrees in a child older than 5 or 6 years of age, or neurologic deficits related to the spinal deformity (210,211,219). Distinguishing between neurologic deficits that result from a kyphotic deformity and those associated with lumbar stenosis, which is common in achondroplastic dwarfs, can be difficult. A thorough physical examination and diagnostic studies, such as myelography, CT, and MRI, are necessary to determine appropriate treatment. Most patients with progressive thoracolumbar kyphosis require combined anterior and posterior fusion. Instrumentation is not recommended in these patients because of the small size of the spinal canal and the lack of epidural fat, which make instrumentation hazardous.

Pseudoachondroplasia

Kyphotic deformities also can occur in children with pseudoachondroplasia, and are caused by multiple vertebral body wedging in the thoracolumbar and thoracic spine. The kyphotic deformity in patients with pseudoachondroplasia differs from that in patients with achondroplasia. In patients with pseudoachondroplasia, the kyphosis involves multiple levels, and is less acutely angular than the deformity in patients with achondroplasia, which involves only one or two levels. Bracing may prevent progression of this deformity, but surgery is indicated if progression occurs. Spinal fusion with instrumentation can be performed safely in patients with pseudoachondroplasia, because there is no associated stenosis of the spinal canal as in patients with achondroplasia (211,220,221).

Spondyloepiphyseal Dysplasia Congenita

Thoracolumbar kyphotic deformities in patients with spondyloepiphyseal dysplasia congenita usually are mild and nonprogressive, and seldom require treatment (211,221).

Diastrophic Dwarfism

Midcervical kyphosis frequently occurs in patients with diastrophic dwarfism. Progressive cervical kyphosis can be stabilized with a spinal fusion (211,221,222). There are in- sufficient data to recommend posterior fusion alone or combined anterior and posterior fusion. If a posterior fusion is performed, the increased incidence of cervical spina bifida in diastrophic dwarfism must be considered during dissection.

Mucopolysaccharidosis

Patients with any of the mucopolysaccharidoses can develop kyphotic spine deformities at the thoracolumbar junction. In patients with Hurler syndrome (type I), the vertebral bodies have an anterior beaking at the level of the kyphotic deformity. This kyphosis usually is not progressive and rarely requires treatment, because most children with Hurler syndrome die before 10 years of age. Kyphotic deformities in patients with Hunter syndrome (type II) also rarely require treatment, because the kyphosis rarely is progressive, and patients do not often survive past 20 years of age (223). Thoracolumbar kyphosis in patients with Morquio syndrome (type IV) is associated with anterior vertebral body defects in the form of anterior beaking of the vertebrae. This kyphosis remains constant with growth, and rarely progresses. Patients with Maroteaux-Lamy syndrome (type VI) have a longer life span, and can develop progressive kyphosis, which should be treated with bracing. If progression is not halted with bracing, anterior and posterior fusion may be indicated (211,221).

Marfan Syndrome

Marfan syndrome is a generalized disorder of connective tissue that affects the supporting structures of the body, especially those in the musculoskeletal system. This syndrome is caused by mutations in coding of the genes for the glycoprotein fibrillin (224,225). Spinal deformity is the most common skeletal abnormality in Marfan syndrome, and scoliosis is the most common spinal deformity in patients with Marfan syndrome (112,226,227,228,229,230 and 231). Thoracic lordosis has been traditionally reported as the most common sagittal plane deformity (232,233). In some patients, the thoracic lordosis becomes severe enough to compromise respiration. With the lordotic posture of the thoracic spine, an associated kyphosis or relative kyphosis may develop in the lumbar spine. A third common spinal deformity associated with Marfan syndrome is thoracolumbar kyphosis, which affects about 10% of patients (Fig. 19-19). These spinal deformities usually occur during the juvenile growth period, before the adolescent growth spurt (233). Sponseller et al. found that 41% of his patients with Marfan syndrome had a kyphotic deformity of more than 50 degrees, with a tendency for longer kyphoses extending through the thoracolumbar junction (234).

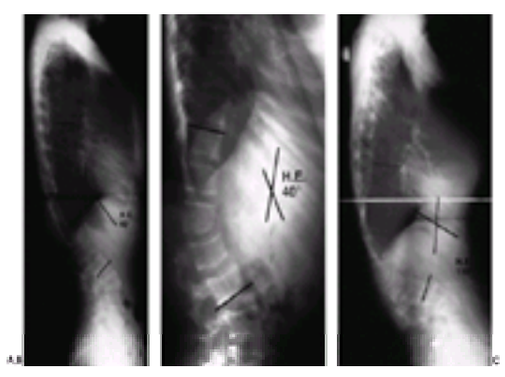

FIGURE 19-19. A and **B:** Lateral radiographs of a 17-year-old child with Marfan syndrome and a 40-degree progressive thoracolumbar kyphosis. **C:** Lateral radiograph of the same patient 3 years later shows that the thoracolumbar kyphosis has progressed to 110 degrees.

Brace treatment has been recommended to try to halt the progression of spinal deformity, but Birch and Herring (235) found this approach to be ineffective in their patients. Correction of kyphotic deformities requires anterior and posterior spinal fusion with segmental instrumentation (235). Thoracic lordosis is corrected by posterior segmental instrumentation to correct the lordotic deformity, followed by posterior fusion (236). Complications are more frequent after surgical correction of spinal deformity in patients with Marfan syndrome than after spinal surgery in other patients (235).

Cervical spinal abnormalities also are common in patients with Marfan syndrome, but clinical problems from these abnormalities are rare. Basilar impression and focal cervical kyphosis are the most frequently reported cervical spine abnormalities. Focal cervical kyphosis usually is associated with a lordotic thoracic spine (237).

Because of the increased incidence of cervical spine abnormalities, Hobbs et al. (237) has recommended that patients with Marfan syndrome avoid sports with risks of high-impact loading of the cervical spine.

Larsen Syndrome

Larsen et al. (238), in 1950, described a congenital malformation syndrome (239) consisting of facial dysmorphism and hyperelasticity of the joints, with congenital dislocation of the knees and frequent dislocation of the hips and elbows (112,240,241,242 and 243). Equinovarus or valgus foot deformities and ancillary calcaneal nuclei also are characteristic features of this syndrome. Abnormalities of the cervical spine, specifically cervical kyphosis, were not emphasized in the original description, and often this life-threatening finding is overlooked (169,240,244). Johnston et al. (239) reported cervical kyphosis and vertebral body anomalies in 5 of 9 patients with Larsen syndrome. The apex of the kyphosis usually occurs at the fourth or fifth cervical vertebra, with marked hypoplasia of one or two of the vertebral bodies (Fig. 19-20). Cervical kyphosis is present in infants with Larsen syndrome. Developmental delay may be attributed to hypotonia and dislocation of the knees or hips, but the underlying cause for developmental delay may be a chronic myelopathy from the cervical kyphosis. Cervical kyphosis and vertebral hypoplasia are easily demonstrated on lateral C-spine radiographs. Flexion and extension views usually are not needed, and may be difficult to obtain safely in an infant. MRI scans will demonstrate spinal cord compression or compromise.

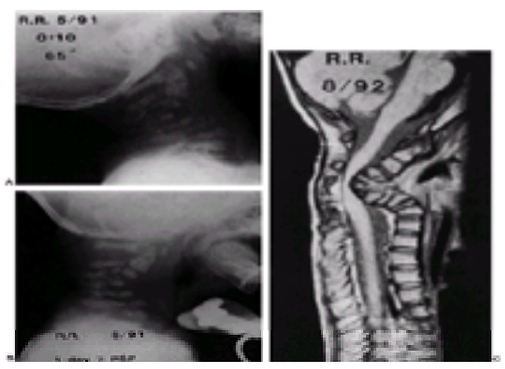

FIGURE 19-20. Larsen syndrome. **A:** Lateral radiograph of a 10-month-old patient showing kyphosis of 65 degrees, with correction to only 48 degrees in extension. **B:** Lateral radiograph immediately after posterior arthrodesis, showing patient with orthosis and correction of kyphosis to 39 degrees. **C:** T2-weighted magnetic resonance image 15 months postoperatively shows severe impingement on spinal cord. Kyphosis had progressed to 110 degrees, and patient was quadriplegic after a fall. (From ref. 239, with permission.)

Treatment recommendations for cervical kyphosis in Larsen syndrome is an early posterior arthrodesis to stabilize the spine. An *in situ* posterior arthrodesis, with autogenous iliac crest bone graft, followed by immobilization in either a halo or Minerva cast or custom orthosis, is recommended. The only reduction of the kyphosis is that obtained in the postoperative halo or Minerva cast or orthosis. Johnston et al. (239) found that over time, after a solid posterior arthrodesis a gradual correction of the kyphosis occurs because of continued anterior vertebral body growth. Because the posterior arthrodesis is performed at a young age, the patient must be followed for potential complications from continued anterior growth, resulting in lordosis. Johnston and Schoenecker (245) reported a patient who developed neurologic symptoms from this growth-related lordosis.

Posttraumatic Deformities

Kyphosis can occur as a direct result of trauma to the spinal column or the spinal cord. Deformity can occur at the fracture site, or as a result of paralysis after spinal cord injury or anterior growth arrest at the fracture site (246,247,248,249 and 250). Kyphosis at the fracture site is acute and spans a short segment of vertebrae. Paralytic kyphosis is a long, C-shaped deformity that spans many vertebral segments.

Kyphosis at a fracture site requires surgical intervention for correction. Anterior, posterior, and combined anterior and posterior procedures have been described for correction of posttraumatic kyphosis (251,252,253,254 and 255). Brace treatment has been ineffective for progressive paralytic kyphosis (246), and surgery is indicated for paralytic kyphosis of more than 60 degrees. If the kyphosis is flexible, and can be reduced to less than 50 degrees, posterior fusion with segmental instrumentation can be performed. If the kyphosis is rigid and cannot be reduced to less than 50 degrees on preoperative bending x-ray films, anterior release and fusion should be followed by posterior fusion and segmental instrumentation (246,250).

Neurofibromatosis

Kyphoscoliosis is common in patients with neurofibromatosis, although kyphosis may be the predominant deformity (256). Funasaki et al. (257) found that 50% of their patients with neurofibromatosis and spinal deformity had an abnormal sagittal curve. The vertebral bodies frequently are deformed and attenuated at the apex of the kyphosis. Dystrophic vertebral body changes may develop over time (258,259). Crawford (258) described this as modulation of the deformity, from a nondystrophic curve to a dystrophic curve. The kyphosis typically is sharp and angular over a relatively small number of vertebral segments. Severely angular kyphosis can cause neurologic compromise (260,261). Lonstein et al. (262) found cord compression, due to spinal curvature from neurofibromatosis, to be second only to congenital kyphosis as a cause of spinal cord compression. The kyphosis in patients with neurofibromatosis typically involves the thoracic spine or upper thoracic spine. Involvement of the cervical and cervicothoracic vertebrae also have been reported (260,263,264,265,266 and 267).

Kyphotic deformities with dystrophic changes tend to be progressive, and more commonly lead to neurologic compromise.

Treatment of kyphoscoliosis in patients with neurofibromatosis begins with a thorough physical examination for neurologic abnormalities. MRI scans should be obtained to demonstrate any intraspinal lesions, such as pseudomeningocele, dural ectasia, or neurofibroma, which may cause impingement on the spinal cord (268). Any intraspinal lesions should be treated as necessary before spinal fusion and instrumentation are undertaken. Because posterior fusion alone has resulted in a high rate of pseudarthrosis (65%) (269), anterior and posterior spinal fusion, combined with posterior instrumentation, is recommended. Abundant autogenous bone graft and prolonged immobilization may be required to obtain a solid fusion in these patients, and repeated bone grafting 6 months after the initial surgery may be required. Vascularized fibular or rib grafts also may be used for anterior fusion and structural support (93,258,263,266,270,271 and 272).

Tuberculosis

Spinal tuberculosis is the most dangerous form of skeletal tuberculosis, because of its ability to cause bone destruction, deformity, and paraplegia. In childhood spinal

tuberculosis, the extent and degree of abscess formation is greater than that seen in adult tuberculosis, but paraplegia is less common in children than adults with spinal tuberculosis (273). The most frequent site of spinal tuberculosis in children is the thoracolumbar junction and its adjacent segments. Tuberculosis infection usually destroys the anterior elements of the spine, and results in a significant angular kyphosis at the infected site. With differential growth of the intact posterior elements, kyphosis may increase with growth (273).

All forms of active spinal tuberculosis are treated with a complete course of chemotherapy. First-line drugs are streptomycin, isoniazid, and rifampicin, and second-line drugs are ethambutol and pyrazinamide (274). Even with adequate medical treatment of spinal tuberculosis, problems arising from bone destruction, such as spinal deformity or paraplegia, must be treated surgically. Chemotherapy alone can be used when there is little bone destruction or risk of deformity, or in medically high-risk patients. Several different surgical approaches have been used in the treatment of spinal tuberculosis (275,276,277,278 and 279). The surgery with most consistent long-term results is anterior debridement and strut grafting, with or without a posterior fusion and instrumentation (274,280,281,282,283,284,285,286,287,288,289,290 and 291). Some correction of the kyphosis may be obtained at the time of surgery. Kyphosis also can be a problem in patients with healed spinal tuberculosis (292). The infected area of the anterior spine usually fuses, and continued growth posteriorly causes progressive kyphosis that can result in paraplegia. The presence of neurologic symptoms is an indication for anterior decompression and fusion, which can be followed by posterior fusion and instrumentation.

Juvenile Osteoporosis

Idiopathic juvenile osteoporosis is an acquired systemic condition that consists of generalized osteoporosis in otherwise normal prepubertal children (293). Although idiopathic juvenile osteoporosis is uncommon, associated kyphosis and back pain are common in patients with this condition.

Schippers (294) first described this condition in 1939, and since that time, other authors have described its clinical findings and natural history (134,295,296,297,298,299,300 and 301). The etiology of idiopathic juvenile osteoporosis is unknown. Laboratory values of serum calcium, phosphorus, alkaline phosphatase, parathyroid hormone, and osteocalcin are normal. The collagen type and ratios from skin biopsy samples also are normal. There have been some reports of a slight decrease in 1,25-dihydroxyvitamin D (299,302,303), but the significance of this finding is not known. Low serum calcitonin levels also have been reported, but treatment with calcitonin has not proven to be beneficial (297,304). In contrast, Saggese et al. (300) noted normal serum calcitonin levels in their patients. Green (305) believes that a mild deficiency of 1,25-dihydroxyvitamin D can explain most of the findings in idiopathic juvenile osteoporosis. During rapid growth phases the deficiency is discovered because growth requirements cannot keep pace, causing a relative osteoporosis. When puberty occurs, the increase in sex hormone overcomes the deficit in 1,25-dihydroxyvitamin D, and the relative osteoporosis improves. This theory has yet to be proved.

Clinically, these patients complain of insidious onset of low back pain (306), lower-extremity pain or fractures, and difficulty walking (63,224,307,308). Difficulty walking may sometimes be the only finding. This condition occurs during the prepubertal period, and is slightly more common in boys than girls. Vertebral collapse or wedging, with resulting kyphosis, is common. Brenton and Dent (304) classified idiopathic juvenile osteoporosis into mild, moderate, and severe types. Patients with the mild type had only back pain and vertebral fractures; those with the moderate type had back and lower-extremity pain and fractures, with some limitation of activities, but eventual return to normal function; and those with the severe form had back and lower-extremity pain and fractures. Both metaphyseal and diaphyseal fractures can occur in the lower extremities. Patients with severe disease improve clinically, but do not return to normal activity after puberty.

Plain radiographs show wedging or collapse of the vertebral bodies. A “codfish” appearance of the vertebral bodies can occur, with the superior and inferior borders of the vertebrae becoming biconcave (Fig. 19-21). Because of the osteoporosis, tomograms may be necessary to better delineate the spinal deformity. Other studies that can be useful for following the progress of this disease are single-photon absorptiometry, dual-photon absorptiometry, and quantitative CT scanning (297,299,300). The problems with these tests are that normal ranges for adolescents and children are variable and have not been standardized.

FIGURE 19-21. Standing lateral radiograph of a 10-year-old girl with idiopathic juvenile osteoporosis shows diffuse osteopenia, multiple “codfish” vertebrae in the thoracic and lumbar spine, and “coin” vertebrae in the upper thoracic spine secondary to extreme collapse. (From ref. 305, with permission.)

Idiopathic juvenile osteoporosis is a diagnosis of exclusion. Other diseases that must be considered include metabolic bone diseases, leukemia, Cushing syndrome, lysinuric protein intolerance, type I homocystinuria, and osteogenesis imperfecta. The natural history of this condition is spontaneous improvement or remission at the onset of puberty. Associated kyphosis tends to improve after the onset of puberty.

Treatment of idiopathic juvenile osteoporosis involves modification of activities, possible calcium supplementation and vitamin D supplementation, and supportive treatment of spinal deformities. A balance must be obtained between restriction of activities to prevent fractures and excessive restriction of activities that will increase osteoporosis. If a significant progressive kyphosis develops, the Milwaukee brace is the treatment of choice (298). The brace is worn until there is evidence of improvement of the osteoporosis. Operative therapy for this condition has been associated with a high complication rate, because the poor bone quality makes instrumentation and fusion difficult (309).

CHAPTER 20

SPONDYLOLYSIS AND SPONDYLOLISTHESIS

JOHN E. LONSTEIN

J. E. Lonstein: Department of Orthopaedic Surgery, University of Minnesota, Minneapolis, Minnestoa 55455; Twin Cities Spine Center, Minneapolis, Minnesota 55404.

“Spondylolysis” is the term used to refer to a defect in the pars interarticularis of the vertebra, being most common at L5 in the child or adolescent. The term is from the Greek *spondylos*, or vertebra, and *lysis*, or break or defect. Spondylolisthesis is from the Greek words *spondylos*, or vertebra, and *olisthesis*, meaning “movement” or “slipping,” and refers to the slipping forward of one vertebra on the next caudal vertebra, being first described by a Belgium obstetrician, Herbiniaux, in 1782 (1). Because the defect is most common at L5, the resultant slip is most common at this level, with L5 slipping forward on S1.

CLASSIFICATION

The most well-known classification of spondylolisthesis is that of Wiltse, who divided it into five types (2):

Type I—Dysplastic or congenital. This type of spondylolisthesis is due to a congenital abnormality of the L5-S1 facet joints, consisting of a more transverse orientation of the facets than normal. This allows forward slipping of the vertebrae with the intact neural arch.

Type II—Isthmic. There is a defect of the pars interarticularis that permits the forward slippage, the articular facets being normal. There are three subtypes that describe the nature of the defect in the pars:

1. Lytic fracture of the pars
2. Elongated but intact pars
3. Acute pars fracture

Type III—Degenerative. Degenerative arthritis of the facet joints, as well as degeneration of the disc.

Type IV—Traumatic. An acute fracture in an area of the vertebra other than the pars.

Type V—Pathologic. A lesion of the pars or pedicle due to generalized bone disease that allows forward slippage.

Only two of these types, Types I and II, occur in children and adolescents, and these are discussed in this chapter (Fig. 20-1).

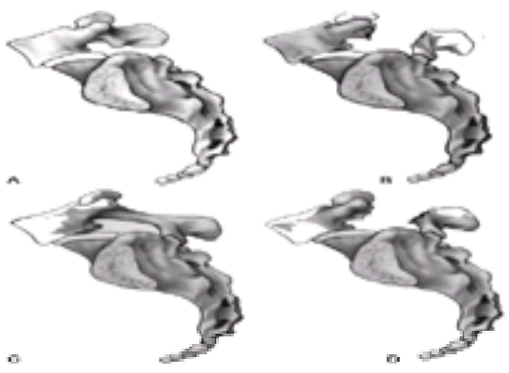

FIGURE 20-1. In type I, or dysplastic spondylolisthesis, there is a congenital deficiency of the L5-S1 facet joints that allows forward slippage of L5 on S1 (**A**). In type II, or isthmic spondylolisthesis, there is a lesion of the pars interarticularis that permits the forward slippage. This condition is divided into three groups: (**B**) a lytic lesion of the pars, (**C**) an elongated but intact pars, or (**D**) an acute fracture of the pars.

NATURAL HISTORY

With one exception (3), a defect in the pars has never been found at birth (4,5,6,7 and 8). The incidence of spondylolysis is 4.4% at age 6 years, rising to the adult rate of 5.5 to 6% by the age of 14 years (4,9). There have been cases reported in the first year of life with scattered cases reported under age 2 years (6,7,10). The incidence is higher in males, with a lower incidence in blacks (4,11). The highest incidence is in Alaskan Eskimos, with a rate of 26%, with the highest rate being in Eskimos from north of the Yukon River (12).

Of the two types of spondylolisthesis seen in children and adolescents, dysplastic or congenital is the least common. This type of spondylolisthesis has a 2:1 female:male ratio (13,14) and makes up between 14 and 21% of the cases in various series (13,15). Most do not progress beyond 50% slippage because of the

severe symptoms produced by the intact neural arch impinging on the neural elements. These children are at higher risk for neurologic injury, e.g., cauda equina syndrome, than those with isthmic spondylolisthesis.

Isthmic spondylolisthesis is much more common, and although most authors mix both types of spondylolisthesis with spondylolysis in their reports, most of the data in the literature refer to this type of spondylolisthesis. The percentage of cases with spondylolysis that develop spondylolisthesis is documented in only one longitudinal study, that of Fredrickson et al. (4). In a radiographic study of school children, they reported the incidence of spondylolysis to be 4.4% at 6 years of age, increasing to 6% in adulthood. This agrees with other studies (9,10 and 11). They also found that 68% of the 5-year-old children had an associated slip or spondylolisthesis, increasing slightly to 74% in adulthood (4). This would indicate that the number of children with spondylolysis who will develop spondylolisthesis after 6 years of age is small.

Saraste, in her 20-year follow-up review of 255 patients with spondylolysis and spondylolisthesis, reported that 40% of adults showed no progression of the slip, 40% slipped an additional 1 to 5 mm, and 15% 11 to 15 mm (16). Her data also suggest that spondylolisthesis is more common than spondylolysis, with approximately 22% of patients having only spondylolysis at initial presentation.

Osterman et al. noted in their report the following severity of slipping in those with spondylolisthesis: grade I, 79%; grade II, 20%; grade III, 1% (17). Others report a slightly higher incidence of more severe slips (18).

Rowe and Roche report a difference in the incidence of spondylolisthesis between the races and sexes: 6.4% in white males, 2.8% in black males, 2.3% in white females, and 1.1% in black females (11). The difference in natural history between the sexes is illustrated by the fact that, although the incidence is twice as high in males, high-grade slips are four more times as common in females.

There are two questions related to the natural history of spondylolysis and spondylolisthesis, the answers to which have a major impact on clinical decision-making: How frequently does the slip in spondylolisthesis progress? and How often does pain or other symptoms become a problem?

Progression

Progression occurs in a low percentage of cases, occurring in 4% of Frennered et al.'s series, and 5% of Saraste's cases (16,19). In the series of Fredrickson et al. it appeared that progression was unlikely after adolescence (4), whereas other authors reported progression in adolescence, often related to disc degeneration (20,21 and 22). In adolescence, progression is most likely to occur during the growth spurt, and is more common in females, and in dysplastic spondylolisthesis (4).

Some radiographic features have related to a greater chance of progression. The degree of slip on presentation has been found to be associated with chance of progression by some authors (9,23,24), and not by others (16,19). The amount of lumbosacral kyphosis, or the slip angle, especially when severe, is associated with progression in the growing child. Other changes are found with high-grade slips, e.g., dome-shaped sacrum and trapezoidal L5, these being secondary to the slip, and not prognostic for slip progression (19).

Pain

Because pain is the most common presenting symptom, are there any prognostic features for this? Saraste found that there were radiographic features that correlated with low back symptoms. These were a slip of greater than 25%, L4 spondylolysis or spondylolisthesis, or early disc degeneration at the level of the slip (16).

ETIOLOGY

The exact etiology of this condition is unknown, theories being related to hereditary factors, a congenital predisposition, trauma, posture, growth, and biomechanical factors.

Hereditary Factors

Family studies have shown a high incidence of spondylolysis and spondylolisthesis in first-degree relatives of children with these conditions, the incidence varying from 19 to 69% (7,25,26,27 and 28). Wynne-Davies and Scott noted an increased incidence of dysplastic lesions in affected relatives, in addition to a higher incidence of spina bifida of S1 (28).

Trauma

Trauma is considered to be a factor in etiology of spondylolysis and spondylolisthesis. Acute trauma is obviously the cause of the acute traumatic type of spondylolysis. In addition, many cases present after a traumatic episode. Is the trauma the cause of the lesion, or does it make an asymptomatic defect symptomatic? Wiltse et al. theorized that spondylolysis is a stress fracture in the pars, so that repetitive microtrauma or microstresses are generally considered to be the factor in the etiology (29). Repetitive hyperextension motion, in which the caudal edge of the inferior articular facet makes contact with the pars interarticularis, is considered to be the causative trauma. This is confirmed by the higher incidence of spondylolysis in certain sports (female gymnasts [30], college football linemen [31,32], weight lifters [33]), and in Scheuermann disease (34). In addition, spondylolysis has not been reported in adults who have never walked (35), pointing to the mechanical effects of the upright posture.

Growth

Growth definitely plays a role in the etiology of spondylolysis, as evidenced by the fact that defects do not occur in the newborn, and reach an incidence of 4% at age 6 years, rising to the adult incidence by age 14 years. This increase is more marked during the adolescent growth spurt (4).

The etiology is thus multifactorial, with an inherited predisposition that leads to the defect occurring with repeated microtrauma. This predisposition may be an inherent weakening of the pars itself, or may result in a certain structure of the facets that creates the stress fracture with repetitive hyperextension. The dysplastic variety, with an elongated pars, has a strong familial pattern with abnormal facet orientation and spina bifida of S1.

PATIENT EVALUATION

History

Spondylolysis and spondylolisthesis, when asymptomatic, are usually detected as an incidental finding on a pelvis or spine radiograph. However, they are frequently found as the cause of low back pain in children and adolescents. The most common time for this is the adolescent growth spurt, ages 10 to 15 years. The pain may be of a chronic nature, generally being exacerbated by sports or other physical activity, and relieved by rest or restriction of activities. The pain may also follow an acute traumatic episode, often involving hyperextension during sports participation. The pain is a dull, aching, low back discomfort, either localized to the low back, or with some radiation into the buttock and posterior thighs. This pain is probably due to the instability due to the pars defect. Radicular pain is unusual in the adolescent and more common in the adult, and is usually in the L5 distribution due to nerve compression by the hypertrophic callus at the pars defect, or due to the foraminal stenosis accompanying the spondylolisthesis.

The child can present with parents noting a change in posture or gait, with or without accompanying pain. This is usually with spondylolisthesis, especially with more marked degrees of slip. The postural changes noted are a flattening of the buttocks, increased lumbar lordosis, and gait alterations, described as a waddling gait.

Occasionally, these cases present with scoliosis. This can be as adolescent idiopathic scoliosis, with the spondylolysis or spondylolisthesis detected incidentally on radiographic assessment of the scoliosis. On the other hand, the curve pattern may be atypical, and may be spasm scoliosis associated with the spondylolisthesis or an olisthetic curve due to asymmetric slip at the lumbosacral area.

Physical Examination

The physical findings depend on whether pain is part of the presenting symptoms, as well as on the degree of slip in spondylolisthesis. Back and gait examination may be completely normal with no hamstring tightness. With spondylolisthesis there is usually some degree of hamstring tightness with restriction of forward bending. The cause of this hamstring tightness is unknown. It usually resolves with a solid fusion. When it does not, decompression of the roots and sacroplasty may also be curative (36).

With spondylolisthesis and associated pain, there is usually a restriction of spine motion in addition to restriction of forward bending. With greater degrees of slip there is shortening of the waistline, with a flattening of the buttocks. In addition, a step-off at the lumbosacral area may be visible as well as palpable (Fig. 20-2). A localized area of tenderness to deep palpation may also be elicited in the lumbosacral area. In addition, in these severe slips the child stands with hips and knees flexed due to the anterior rotation of the pelvis, and the gait is one of short steps due to inability to extend the hips.

FIGURE 20-2. The typical findings of spondylolisthesis include flattening of the buttocks, lumbosacral kyphosis, a step-off in the lower lumbar area, and the lumbar lordosis.

Straight-leg raising is severely restricted due to the tight hamstrings. Neurologic examination is usually completely normal, but may show diminished or absent ankle deep-tendon reflex, and weakness of the extensor hallucis longus. Sphincter dysfunction is very rare.

Scoliosis may be a part of the presentation, either a typical idiopathic type, or with more decompensation and spasm, indicative of a spasm or olisthetic scoliosis. It is important to recognize that the pain complaints and/or the neurologic findings may be due to some pathology other than the spondylolysis or spondylolisthesis, e.g., bone, spinal cord, conus or cauda tumor, disc herniation, or disc-space infection. It is thus incumbent on the physician to rule out other causes of the back pain with a detailed history, physical examination, radiographs, and adjunctive tests.

RADIOLOGIC EVALUATION

Routine Views

The initial radiographic evaluation consists of standing posteroanterior and lateral lumbosacral spine films. Full-length views are taken in addition in the presence of scoliosis, and a full-length lateral is taken with larger degrees of slip to evaluate the sagittal spine alignment. The spot lateral film usually shows the defect, especially with bilateral pars defects, and the degree of slip in spondylolisthesis is appreciated. It is important to recognize that the degree of slip differs in the supine and standing position, and that the standing view shows a greater slip, and should always be taken (37). In cases of a unilateral defect there may be sclerosis of the facet, lamina, or pars on the intact side opposite the defect.

To better visualize the pars defect oblique views of the lumbosacral area are often necessary. The view is an oblique of the lumbosacral area and not of the lumbosacral spine, so the central x-ray beam must be in the lumbosacral area and not in the midlumbar spine. The defect is seen as the well known “collar” on the “Scotty dog” (Fig. 20-3). In cases in which the defect is strongly suspected but is not seen on the oblique views, a CT scan may be used to visualize the defect.

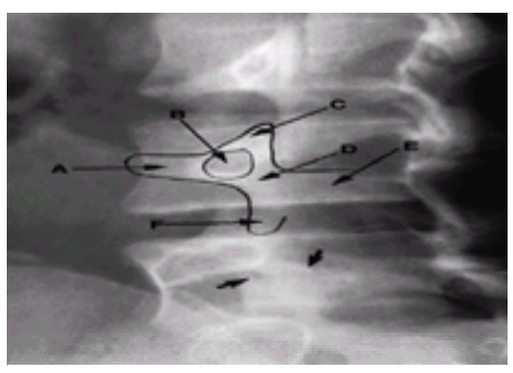

FIGURE 20-3. Oblique lumbosacral radiograph showing the “Scotty dog,” which is made up of the following anatomic structures: the nose is the transverse process (*A*), the eye is the pedicle (*B*), the ear is the superior articular process (*C*), the neck is the pars (*D*), the back is the lamina (*E*), and the front leg is the inferior articular process (*F*). At L5, there is a “collar” on the dog (*arrows*), which is the isthmic defect in the pars.

Supine flexion and extension views are useful in demonstrating the mobility of the spondylolisthesis—both of the amount of slip and of the reduction of the lumbosacral kyphosis. This is useful information for assessing the instability and in planning treatment.

Bone Scan

A bone scan is used in cases with a recent onset of pain or with a distinct history of trauma, to detect an acute fracture of the pars or exclude a bony tumor. This is best performed using single photon emission computed tomography (SPECT) scan because of the greater detail.

CT or MRI Scan

Additional imaging is occasionally necessary. A CT scan is the method of choice when a defect in the pars is strongly suspected on clinical grounds, but cannot be identified on the oblique radiographs. This should be done with fine cuts 1.5-mm apart. When there is a neurologic deficit, or the symptoms suggest a diagnosis other than spondylolysis or spondylolisthesis, imaging of the neural elements should be performed. Today this is best done with an MRI, although special circumstances may call for CT myelography. The area assessed must extend from the lower thoracic area to the sacrum. Cases with spondylolisthesis and a neurologic deficit due to a tumor of the conus or cauda equina have occurred. In these cases elimination of this possibility, with imaging studies of the spinal canal, is essential.

MRI done for low back pain should be carefully assessed for changes of spondylolysis or spondylolisthesis.

Measurement

The deformity in spondylolisthesis, usually at the lumbosacral junction, consists of forward slippage of L5 on S1, usually accompanied by rotation of L5 on S1 into lumbosacral kyphosis. The degrees of slip, kyphosis, and other changes in the lumbosacral anatomy are evaluated on the standing spot lateral of the lumbosacral area (38).

Slip Percentage

The amount of anterior translation is most commonly described using the Meyerding grading system (39). This classifies the slip into five grades: grade I is a slip of 1 to 25%, grade II a slip of 26 to 50%, grade III a slip of 51 to 75%, grade IV a slip of 76 to 100%, and grade V, or spondyloptosis, slippage past the anterior border of the sacrum.

The slip can be expressed as a percentage following the description of Talliard (40). A line is drawn along the posterior border of the sacrum, and a perpendicular line is drawn at the upper end of the sacrum. The displacement of the posteroinferior corner of L5 from the line along the posterior border of the sacrum is measured. The width of S1 forms the denominator of the calculation, the slip being expressed as a percentage (Fig. 20-4A). In many cases the upper end of the sacrum is rounded, and the measurement of the width of S1 is inaccurate, so the anteroposterior width of L5 is used instead.

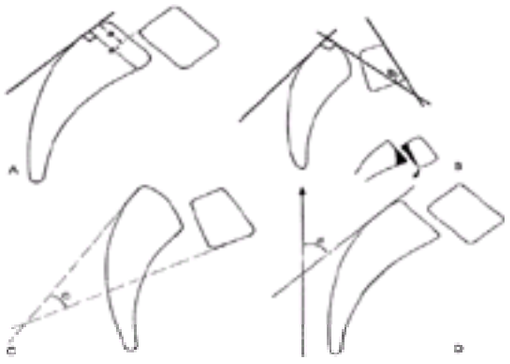

FIGURE 20-4. Measurement of spondylolisthesis. **A:** Measurement of the amount of forward displacement (*a*) and of the sagittal diameter of S1 (a^1) allows calculation of the percent slip. **B:** Measurement of the slip angle (*b*), which is the kyphosis at the area of the slip (i.e., the L5-S1 kyphosis). As the slip increases, there is a growth inhibition of the anterior lip of S1 and the posterior lip of L5. Because of this, the vertebra becomes trapezoidal, and using the bottom of L5 does not accurately measure the angular deformity. **C:** Measurement of the sagittal rotation angle (*c*), which also represents the L5-S1 kyphosis and equals the slip angle. **D:** Measurement of the sacral inclination (*d*).

Slip Angle

The slip angle measures the amount of lumbosacral kyphosis or sagittal rotation. The kyphosis is measured using the relationship of L5 to S1. A perpendicular to the line at the back of the sacrum, as drawn above, forms the sacral measuring line. A line is drawn along the upper end plate of L5, and the angle formed by these two lines is the slip angle, which normally is in lordosis and expressed by a negative sign (38) (Fig. 20-4B). Boxall et al. (15) have used the line along the inferior edge of L5 for their measurement, but this edge is often difficult to visualize accurately. In addition, with more marked slips L5 is often trapezoidal in shape, and using the lower edge gives the additive measurement of the kyphosis and the wedging of L5.

Sagital Rotation

The amount of sagittal rotation can also be measured as the angle between the lines drawn along the back of the sacrum and along the back of L5. This sagittal rotation angle (SRA) should equal the slip angle measured above (Fig. 20-4C).

In larger degrees of slip (either translation or angulation), it is seen that L4 shows retrolisthesis on L5. In these severe slips (more than 50%), the slip angle of L4, in relation to the sacrum is also measured, because, after an L4-to-sacrum fusion this is the effective lumbosacral slip angle.

Sacral Inclination

The inclination of the sacrum to the vertical is measured by the angle of a line along the posterior edge of the sacrum and the vertical (a line drawn parallel to the edge of the x-ray film) (Fig. 20-4D).

Anatomic Changes

There are changes in the shape of L5 and S1 that are noted. The contour of S1 is altered, in that it is rounded and dome-shaped. The fifth lumbar vertebra becomes trapezoidal in shape, being narrower posteriorly and wider anteriorly.

TREATMENT

There are a large number of treatment choices for the child with spondylolysis or spondylolisthesis. These include doing nothing, observation, limitation of activities, exercises, bracing, casting, repair of a pars defect, fusion, decompression, and reduction of the slip. The problem is selecting the specific treatment for the child. In making this choice, the following factors are considered: the presenting complaint, age, growth potential, and physical findings, especially neurologic signs and the amount of displacement and slip (slip percentage and slip angle). The different treatment choices in spondylolysis and spondylolisthesis are discussed, along with the indications for each treatment method.

Spondylolysis

Nonoperative

Observation. As noted above, many cases of spondylolysis are asymptomatic. The follow-up depends on the child's growth potential. In a child who has completed growth no follow-up is necessary. In the growing child, on the other hand, regular annual visits with radiographs taken are necessary until the end of growth. The child is allowed to participate in all sports without restriction (Fig. 20-5).

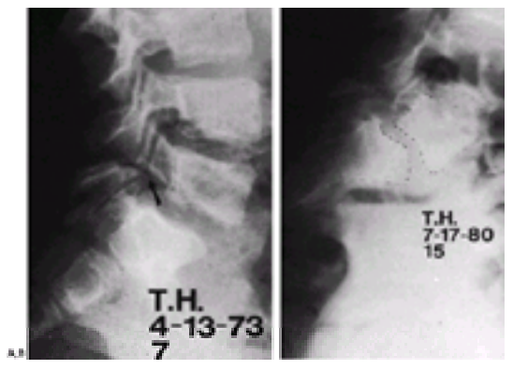

FIGURE 20-5. A: This 7-year-old boy was seen for lordosis. He was completely asymptomatic, and the radiograph showed a pars defect. He was treated with periodic observation. **B:** At 15 years of age, he was still asymptomatic, and was an outstanding high school athlete.

Bracing. When the child presents with pain the question is whether the symptoms are of recent origin, following an acute injury, or whether they are chronic and of long duration. In the cases with pain following a definite injury a SPECT bone scan is performed to determine whether the pars defect is of recent origin, and is an acute fracture. In cases in which the scan is positive, immobilization in a cast or brace is used to aid in healing of the pars defect. The best method to immobilize this area is with a body cast with a leg extension. Healing of the defect has been described with varying success, with healing taking 3 to 4 months, and being documented with oblique views or repeat bone scans, but seldom with CT scans (41,42,43 and 44) (Fig. 20-6).

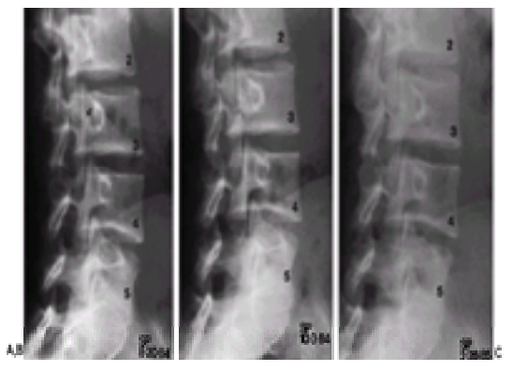

FIGURE 20-6. A: This high school soccer player was seen for mild, generalized low back pain. Physical examination and radiographs, including this oblique view, were normal. **B:** Two months later, 10 days after an acute back injury suffered during a soccer game, a pars defect at L3 is clearly visible. **C:** The patient was placed in an orthosis for 3 months, and 1 month later the lesion had healed, the symptoms had resolved, and the patient had returned to playing sports. (From ref. 45, with permission.)

Following healing of the defect, or when the child becomes asymptomatic with immobilization, even with a persistent pars defect, resumption of all activities is allowed. This includes participation in all sporting or athletic activities with no restriction.

Reduction of Activities. In general, when symptomatic the child with spondylolysis presents with a long history of pain with activity. These cases are treated with restriction of activity and abdominal and spinal muscle-strengthening exercises, with rest being used in the rare case that is very symptomatic. This restriction continues until the child is asymptomatic, at which time gradual resumption of activities is initiated. This treatment plan is also used in the case of spondylolysis with a history of a recent injury in which the bone scan is negative or cold.

If there is no relief with reduction of activities, the use of an orthosis may be suggested to the child and family. Only a very symptomatic child may agree to this treatment alternative. In cases that do not respond to nonoperative treatment, surgery should be offered as an alternative.

Operative

Arthrodesis. A one-level L5 to S1 posterolateral lumbosacral arthrodesis is performed for cases not responsive to nonoperative treatment. This is performed through a midline skin incision with approach to the transverse process and sacral ala via a muscle-splitting incision, as described by Wiltse and Jackson (14) **[➥2.15]**, with the addition of autologous iliac bone graft. Postoperative immobilization may or may not be used depending on the surgeon's preference and the patient's symptomatology. Many reports recommend spica casting for 3 months based on their results (15,36,46,47,48,49 and 50). Others report good results with no immobilization (44), immobilization in a corset (51), or immobilization in a Boston brace (52). I prefer immobilizing these children with a thoracolumbosacral orthosis (TLSO) or body cast with a leg extension, the latter being used in the more painful case, or when the child is very active (Fig. 20-7). Although the rate of success for fusion in spondylolisthesis is superior when a cast with a leg extension is used, no such data exist for fusion for spondylolysis.

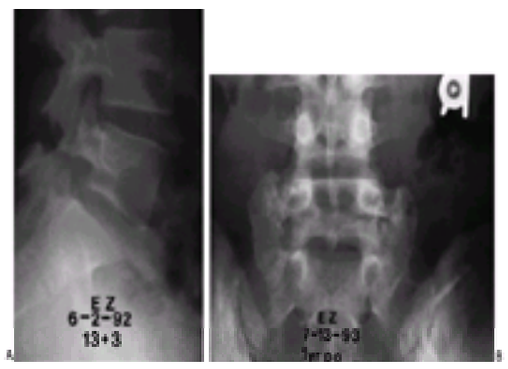

FIGURE 20-7. A patient was seen at the age of 13 years 3 months, with a 1-year history of low back pain. She was a competitive figure skater, and initially reduction in the amount of time spent skating reduced her symptoms. On this presentation, however, the pain interfered with her daily life. **A:** The spot lateral lumbosacral radiograph showed an L5 spondylolysis. **B:** The patient underwent a one-level posterolateral lumbosacral arthrodesis, with postoperative immobilization in a one-leg spica cast for 3 months. One year later, she was free of pain and had returned to figure skating, and the radiograph showed a solid posterolateral fusion.

Repair of Defect. In cases in which the pars defect is at L4 or higher the preferred technique is direct repair of the pars defect to maintain normal lumbar motion. This technique is used only in those cases of spondylolysis without any slippage. This technique was first described by Buck (53) and popularized by Scott, Johnson and Thompson (54). Several techniques have been described (55,56,57 and 58). These authors emphasize the careful selection of patients and the learning curve associated with this procedure. The defect is first cleaned of all soft tissue and, if necessary, the nerve root is decompressed with a laminotomy. Then the defect is grafted, and some form of fixation is used to compress the proximal pedicle portion of the pars to the caudal laminar portion (Fig. 20-8).

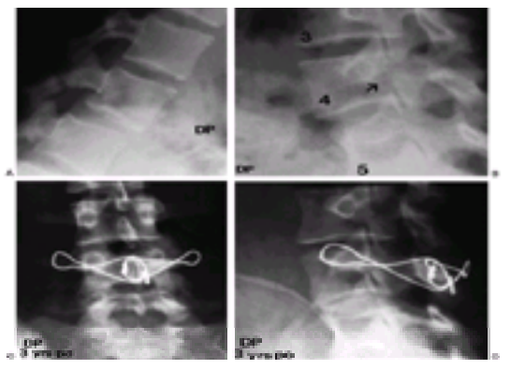

FIGURE 20-8. A 14-year-old girl was seen for chronic low back pain. She had bilateral pars fractures at L4, as seen on (**A**) lateral and (**B**) oblique radiographs (*arrow*, pars defect). The patient underwent bone grafting, with wiring of the defect with a spinous process transverse process wire. The wire position is seen on the posteroanterior view (**C**), and the solid fusion is seen on the oblique view (**D**). She was rendered free of pain and returned to full activity.

Good results, with healing in all cases, have been described by Bradford and Iza, who reported good or excellent results in 17 of 21 patients using the Scott technique (59). Others have reported similar results, but follow-up for most patients is short and a large number of these procedures were done for L5 spondylolysis (60,61 and 62).

Spondylolisthesis

Nonoperative

Nonoperative treatment is indicated for slips of less than 30 to 50% in the growing child, and for some larger slips in the mature adolescent.

Observation. An asymptomatic slip of less than 30 to 50% in an actively growing child is observed for progression with standing lateral lumbosacral radiographs. This is also the treatment of an asymptomatic mature adolescent with a slip of less than 50%. If there is no change in the slip angle or the amount of the slip, the observation continues. With an increase in the spondylolisthesis, surgical stabilization is indicated.

Reduction of Activities. A growing child who presents with low back pain and a slip of less than 30 to 50% is advised to limit exercise and sporting activities. After the symptoms subside these activities are resumed.

Bracing. If with restricting the activities the pain does not resolve, the use of a TLSO may be beneficial (43,63,64). This usually requires a period of 6 to 12 weeks in a brace. Once the symptoms are relieved, gradual resumption of activities occurs.

Operative Treatment

Surgical stabilization of the spondylolisthesis should be considered for the symptomatic child who does not respond to nonoperative management, and the pain prevents full participation in normal activities. In addition, the growing child with a slip of more than 30 to 50%, or the mature adolescent with a slip of more than 75%, should be treated surgically even if there are no symptoms.

Arthrodesis. The surgical procedure used to treat spondylolisthesis is a posterolateral arthrodesis. The approach is with a midline skin incision, and a midline or paramedian approach to the spine. The midline approach is used when decompression is performed **[➥2.15]**. When no decompression is necessary the approach is paraspinal, with an incision through the fascia midway between the posterior iliac crest and the midline. The transverse processes and sacral ala are approached either through or around the paraspinal musculature. Iliac bone graft is placed in this prepared bed on the decorticated transverse process and adjacent lateral aspect of the superior articular process, and on the decorticated sacral ala. In decorticating the sacral ala, it has been found best to create a cavity in the ala to place the strips of cancellous graft in this cavity, as described by Hensinger et al. (48). This places the bone graft more vertically, and there is a larger surface area for fusion to the sacrum.

Decision-making. In the surgical treatment of spondylolisthesis, decisions have to be made regarding the levels to be fused, the role of decompression, the role of reduction, the need for an anterior fusion, the use of instrumentation, and decisions regarding immobilization and bed rest. These decisions depend on the degree of the deformity (slip percentage and kyphosis), neurologic symptoms and signs, and on the mobility of the spondylolisthesis shown on flexion and extension radiographs.

Levels to Be Fused. The basic procedure is a posterolateral one-level L5-S1 fusion. The fusion is extended to L4 with greater degrees of slip (i.e., more than 50%) for two reasons. With this degree of slip the transverse process of L5 is displaced anterior to the sacral ala, and it is impossible to expose the transverse process of L5 without exposing the L4 transverse process. In addition, bone graft placed from L5 to the ala will be horizontal and under shear forces, whereas graft from the ala to the L4 transverse process will lie more vertically. A two-level arthrodesis will be necessary in a slip of less than 50%, where the transverse process of L5 is very small, and thus provides an insufficient bed for the fusion.

Decompression. True nerve root compression is evidenced by motor weakness and a sensory deficit, and is confirmed with further imaging studies, which also eliminate other possible causes of the neurologic changes, e.g., a spinal cord or cauda tumor. Usually the L5 root is involved, being compressed at the foraminal level by the proximal part of the pars as it slips forward with the vertebral body, or by the fibrocartilaginous tissue at the pars defect. In rare cases with a more marked slip the nerve root can be trapped between the transverse process of L5 and the sacral ala. These cases with true root compression are an indication for nerve root decompression. Tight hamstrings are not a sign of root compression, and no correlation has been found between tight hamstrings and the objective neurologic findings of weakness, sensory deficit, or reflex changes (15). Cases with tight hamstrings alone require a fusion without decompression, and after the fusion is solid the tightness resolves with time in the majority of cases.

The basis of decompression is the Gill procedure, with removal of the loose lamina (65). This alone does not decompress the nerve root, additional dissection and a formal root decompression being necessary. Nerve root decompression alone is contraindicated in the growing child and should always be accompanied by a spinal fusion (65,66). Wiltse believes that root decompression is rarely necessary, and that tight hamstrings, abnormal reflexes, and motor weakness recover after a posterior fusion alone (14). The author believes that a formal decompression of the nerve gives the nerve the best chance of recovery. This must be weighed against the chance of increased slip, which follows a decompression and fusion (see below).

Reduction. When treating spondylolisthesis the question of reduction is always brought up. Reasons given for reduction, rather than *in situ* fusion, are reduced pseudarthrosis rate, elimination of the risk for postoperative slip progression, saved motion segments, and reduced clinical deformity. A large number of articles have been written about different techniques for reduction, without in fact demonstrating that the results in these areas are improved following reduction; the majority of these articles include adolescents as well as adults. Muschik et al. compared anterior fusion with anterior and posterior fusion, and reduction with transpedicular screws in 59 children (67). In addition to the expected radiographic improvement, they reported a lower rate of pseudarthrosis (7 versus 24%). However, the complication rate was the same, and there was no difference subjectively for the patient or objectively on clinical examination. This highlights the dilemma for the surgeon in recommending a bigger operation.

Many different techniques have been described to reduce spondylolisthesis, following the initial description of Jenkins in 1936 (68). The techniques include halo-femoral traction (6,40,69), cast reduction (70), instrumentation (71,72), and the combined anterior and posterior approach (33,73,74 and 75).

Distraction instrumentation across the lumbar spine has been shown to be bad because it reduces the lumbar lordosis and has a major deleterious effect on sagittal balance. Of the two deformities in spondylolisthesis (translation and kyphosis), the kyphosis is the more important problem and should be focused on. In addition, the

degree of instability as shown on flexion/extension x-rays is important, as well as the magnitude of the symptoms.

Minor degrees of slip (less than 25%) are treated with fusion *in situ*, unless there is instability on flexion/extension views **[➥2.15]** (Fig. 20-9). In those with demonstrated instability, in larger degrees of slip translation, or with kyphosis, cast reduction can be used. The cast is a single leg spica that is applied 5 to 7 days postoperatively on a Risser frame, with the child in traction and a support under the sacrum, and the thigh (and pelvis) in extension (70) (Fig. 20-10). In these greater degrees of slip, even with slips over 75%, the relationship of L4 to the sacrum is important as the fusion extends to L4. This includes the sagittal relationship, and slip angle of L4 to the sacrum, because this becomes the effective lumbosacral joint after fusion (77).

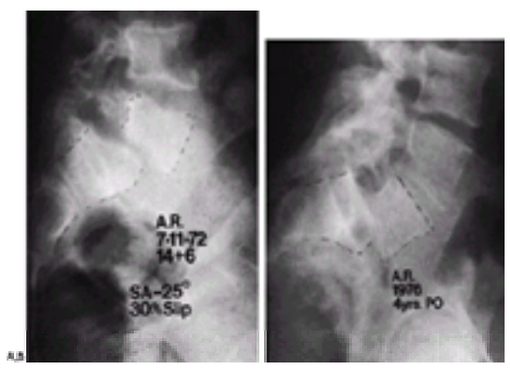

FIGURE 20-9. A patient was seen at the age of 14 years 6 months with chronic low back pain. **A:** The lateral lumbosacral view showed spondylolisthesis with a 30% slip and a –25-degree slip angle. An L4-to-sacrum fusion was performed, followed by postoperative immobilization in a cast. **B:** Four years after operation, a radiograph shows a solid fusion with no alteration in displacement or slip: a fusion *in situ*. The patient had complete pain relief.

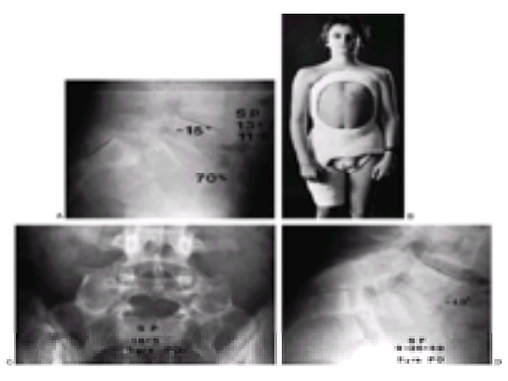

FIGURE 20-10. A patient was seen at the age of 13 years 7 months with severe low back and leg pain and inability to bend forward. **A:** The spot lateral lumbosacral view showed a 70% spondylolisthesis with an L5 slip angle of 15 degrees, but an L4 slip angle of –15 degrees. He underwent a posterolateral L4-to-sacrum fusion, and 5 days after operation had reduction on a Risser frame, and was placed in a single-leg spica cast (**B**). He wore the leg extension for 4 months and a body cast for an additional 3 months. (From ref. 76, with permission.) **C:** Five years after the operation, he was free of pain, and his fusion was solid. **D:** The lateral view showed reduction of the displacement and slip angle, with improvement of the L4-to-sacrum slip angle. Note the retrolisthesis of L4 on L5.

With more marked deformity, especially increased lumbosacral kyphosis and spondyloptosis, some degree of reduction may be necessary to realign the lumbar spine over the sacrum in a position to achieve a solid fusion. Closed reduction with halo-femoral traction or spinous process wiring can result in some reduction, with the reduction held with a posterior fusion; and some authors describe the addition of an anterior fusion (73,74,78,79 and 80). An L5 vertebral body resection, or vertebrectomy, has been described for spondyloptosis. This shortens the lumbar spine, allowing reduction of L4 onto the sacrum, where it is fused (81,82). All these more complex reduction techniques have as a complication a significant incidence of radiculopathy, which must be borne in mind in the decision-making process (79,83,84 and 85).

The role of the combined techniques for the treatment of these severe grades of spondylolisthesis is small, as the majority of cases of spondylolisthesis in children and adolescents are of lesser grades, and can be adequately treated with a posterior fusion and cast reduction alone. The posture in children with severe slips is due in part to the spasm associated with the slip and to pain. When the fusion is solid, the pain disappears and the posture improves.

The need to resort to more complex reduction techniques with instrumentation in children and adolescents is thus rare. In those children in whom it is necessary to reduce the kyphosis or the amount of slipping to restore the balance of L3 over the sacrum, combined anterior and posterior arthrodesis with instrumentation may be necessary. However, it remains controversial as to whether this approach improves the ultimate clinical outcome.

Anterior Fusion. The role of an anterior fusion in the treatment of spondylolisthesis is reserved for the more severe grades. This can be part of a two-staged approach, with the anterior fusion being via the trans- or retroperitoneal approach (86,87,88 and 89). A useful method of anterior arthrodesis, which is becoming more popular for *in situ* fusion of severe or partially reduced slips, is with a fibular graft inserted posteriorly through the sacrum into the body of L5 (90,91) **[➥2.16]**. This technique requires mobilization of the thecal sac so that the graft can be inserted from the midline, and thus some neurologic complications, usually temporary, can be expected (92).

Instrumentation. The initial use of instrumentation in the treatment of spondylolisthesis was with Harrington distraction instrumentation to reduce the slip. This use has disappeared due to the effect of distraction on reducing the lumbar lordosis. Transpedicular fixation is commonly used in the lumbar spine in adults for lumbar fusions for various conditions, including spondylolisthesis **[➥2.8 & 2.9]**. The use in adolescents can be for stabilization of the lumbosacral spine, taking the place of the spica cast. Reduction of the spondylolisthesis is possible with positioning on the operative table, and the lumbosacral relationship being maintained internally with the instrumentation (93) (Fig. 20-11). The use of transpedicular instrumentation to maintain the reduced position is becoming more commonly used because it replaces a spica cast and is more acceptable to adolescents.

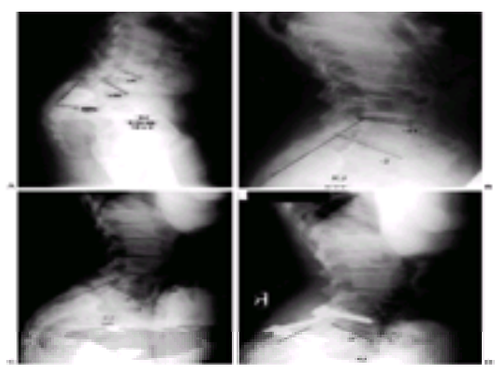

FIGURE 20-11. A patient presented at the age of 13 years 3 months with increasing lumbosacral pain that was restricting her activities. **A:** A standing spot lateral of the lumbosacral area showed a 60% L5-S1 spondylolisthesis with an L5 slip angle of +20 degrees and an L4 slip angle of +l4 degrees. **B:** An extension radiograph showed that this was very mobile, correcting to a slip angle of L4 of –21 degrees. **C:** She was positioned on the operating table with supports under her thighs, which extended her hips and spine, reducing the L4 slip angle to –26 degrees. **D:** She underwent a L4 to S1 posterolateral fusion with transpedicular instrumentation, and

the postoperative radiograph shows maintenance of the correction with a L4 slip angle of –23 degrees.

Amundson et al. have described a technique of intraoperative reduction of spondylolisthesis using the instrumentation on grades I to IV. This is time-consuming, has a high incidence of radiculopathy, and the need for these complete reductions has never been proven (83).

Immobilization and Bed Rest. The possible immobilization following fusion varies from no immobilization (8,94) or a brace, to a single or bilateral spica cast (7,48), with the patient ambulatory or on a period of bed rest postoperatively. As fusion is performed for symptoms, the author prefers to use some immobilization postoperatively, both to slow the patient down and to improve the fusion rate. For a routine fusion there is usually cast reduction, with the patient ambulatory in a single leg spica cast, and immobilization being continued for 4 months. The patient who is in a great deal of pain, with marked spasm, or who has a larger degree of slip (more than 50 to 75%) with significant kyphosis, requires a period of bed rest following the fusion, which is usually performed posteriorly, or may be used with a combined approach. Five to seven days after the fusion, a spica cast is applied with cast reduction, with the patient being nonambulatory for 3 to 4 months. After this, the patient is ambulatory in a body cast or brace without a leg extension. After fusion with instrumentation the author prefers to use a body brace (TLSO) with a thigh extension and hinge hip joint for 3 to 4 months until the fusion is solid.

Scoliosis Associated with Spondylolisthesis

Scoliosis may be associated with spondylolisthesis in two scenarios—it may be spondylolisthesis with adolescent idiopathic scoliosis, two common conditions that may coexist, or the scoliosis may be due to the spondylolisthesis. The latter may be a spasm curve or may be due to an asymmetric slip, the so-called olisthetic scoliosis. In a study of 500 consecutive cases with adolescent idiopathic scoliosis, Fisk et al. found the incidence of pars defects was 6.2%, the same as the incidence in the general population (95). In this case, the scoliosis and the spondylolysis or spondylolisthesis are assessed separately and treated independently. If the scoliosis needs fusion it should be treated accordingly; the same holds true for the spondylolisthesis. There is no current evidence that a long fusion to L4 results in increased stress on spondylolisthesis with an increase in the slip. Whenever possible, the caudal extent of the fusion should be to L3 to preserve motion segments, even though no concrete scientific evidence exists for possible problems with a fusion to L4. Careful observation of the spondylolisthesis below a fusion is necessary till the end of growth. The possible occurrence of scoliosis requiring fusion to L4 and an asymptomatic slip requiring fusion to L4 is very rare, and the author knows of no such occurrence. If this does occur all attempts must be made to fuse the scoliosis to the upper lumbar spine, with an anterior fusion and instrumentation for the lumbar curve, and a posterior fusion for both curves and the spondylolisthesis.

A spasm scoliosis consists of a long, sweeping curve with a curve pattern atypical for adolescent idiopathic scoliosis. It is usually due to spasm, or rarely due to an unequal slip with rotation at the lumbosacral junction. The curve reduces or disappears when the patient is supine. These cases benefit from a period of being supine in a cast postoperatively, and the curve disappears with a solid fusion (Fig. 20-12).

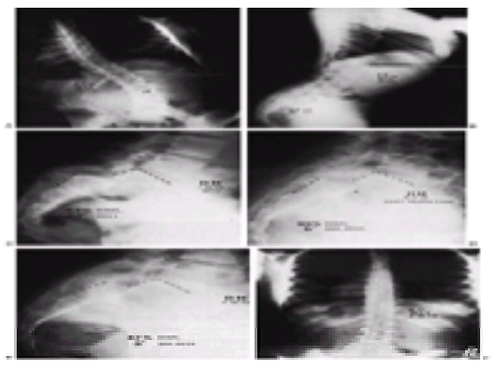

FIGURE 20-12. A patient was seen at the age of 12 years 3 months with a “spasm” scoliosis, lumbosacral pain, and sciatica. **B:** The lateral standing radiograph showed a relatively vertical sacrum, 67% displacement, a 26-degree slip angle, and total lordosis from T1 to L5. Note how the torso is displaced forward in relation to the pelvis. **C:** The spot lateral lumbosacral view shows an elongated pars of L5, with a pars defect near the pedicle. **D:** The patient was treated by nerve root decompression, L4-S1 transverse process fusion, and partial reduction by double pantaloon cast application in a hyperextended position. The percentage of slip was reduced from 67 to 53%, but, more importantly, the slip angle was reduced from 23 to 6 degrees. The patient was nonambulatory for 3 months, then was ambulatory in a body cast for an additional 3 months. **E:** At a 2-year follow-up visit the patient's fusion was solid, she was free of pain, and there was no loss of correction. **F:** An anteroposterior view 3 years after surgery shows the solid lumbosacral fusion and total disappearance of the scoliosis.

COMPLICATIONS

Pseudarthrosis

The pseudarthrosis rate in the literature varies from 0 to 25% (15,18,36,46,48,96,97), the majority being under 15%, with the higher rate attributed to severe spondylolisthesis (15). Most of the studies in the literature are small, and no statistical correlation was found between the degree of slip and the pseudarthrosis rate, although the studies suggest a higher pseudarthrosis rate with higher grades of slip.

Increased Slippage

Increased slip, as measured by the amount of displacement or kyphosis, can increase in the presence of a solid fusion (14,15,23,47,49,96). However, it should be noted that these fusions were assessed with radiographs, and not CT scans, which may demonstrate that at least some cases of increased slipping are due to the fact that the fusion was not solid. This further slip following surgery is more common following a posterior dissection, especially after decompression, all tending to remove the midline-stabilizing structures and thus increase lumbosacral instability. This is also more common with higher degrees of spondylolisthesis, with more displacement or kyphosis (Fig. 20-13). Burkus et al. have shown that slippage is less common following cast reduction, compared to the cases with lesser immobilization postoperatively (46).

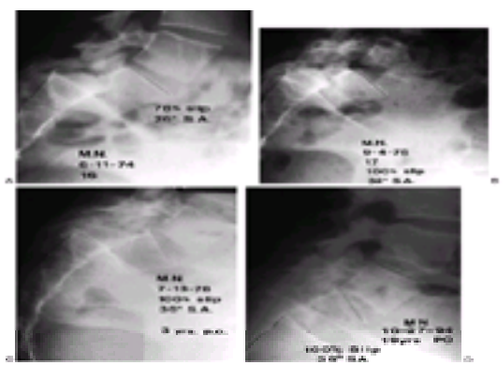

FIGURE 20-13. A: A patient was seen at the age of 16 years with low back pain and sciatica. **A:** The spot lateral lumbosacral radiograph showed a 78% displacement and a slip angle of 26 degrees. The patient was treated with decompression and L4-to-S1 posterolateral fusion, and after operation was ambulatory in a brace. **B:** Two months later, a standing radiograph in the brace showed an increase in the displacement to 100% and a slight increase in the slip angle to 32 degrees. **C:** Three years after operation the fusion was solid, the patient was free of pain, and the lumbosacral relation was unchanged. **D:** Nineteen years after operation the patient

remains free of pain, without a single degree of change detectable in her radiographs.

Neurologic Complications

Radiculopathy has been described following the reduction of spondylolisthesis, and this complication must be appreciated if this treatment plan is used (79,83,84 and 85). This is usually an L5 lesion with varying recovery rates.

In addition, acute postoperative cauda equina syndrome has been reported after a simple posterolateral fusion, without decompression or reduction (98,99). All but three of the patients in the multicenter report of Schoenecker et al. had severe slips of grade III or IV, and preoperative neurologic symptoms or signs implicating the L5 root or cauda. This complication can occur through a midline or lateral muscle-splitting incision, and with the patient prone or lateral (36,99). The cause of this significant complication is not definitely known.

It has been found that in these severe slips the MRI scan shows a lumbosacral disc that is split, with the posterior half indenting the dural sac. The occurrence of the cauda equina syndrome is thus probably due to acute neural compression due to this disc segment in a patient with a marked slip and neural elements that are already compressed, and thus at risk. During anesthesia, with the relaxation of muscle tone, an acute change occurs in the lumbosacral relationship with acute cauda equina compression. This may explain at least some of the cases that develop cauda equina syndrome, and suggests that MRI should be performed on all severe slips prior to surgery. It must be noted that this complication can occur in the absence of presenting neurologic signs or symptoms (98,99).

Even with immediate decompression in these cases, permanent neurologic deficits may still remain. If possible, this complication should be prevented. Any neurologic deficit in a case of spondylolisthesis should be investigated with further imaging studies. Any root compression in a case of severe spondylolisthesis should be decompressed; any of these cases may be an ideal indication for stabilization with pedicle fixation. Careful neurologic follow-up is essential in all cases postoperatively, and prompt evaluation and appropriate decompression following imaging studies, follow. Only with knowledge and vigilance can this rare complication be minimized.

CHAPTER 21

THE CERVICAL SPINE

RANDALL T. LODER

R. T. Loder: Department of Orthopaedics, University of Minnesota, Minneapolis, Minnesota 55455; Shriners Hospital, Minneapolis, Minnesota 55414.

Many of the diseases and congenital anomalies affecting the pediatric cervical spine are simply a reflection of aberrant growth and developmental processes. This chapter discusses these diseases and anomalies in this framework. A basic knowledge of the normal embryology, growth, and development of the pediatric cervical spine is helpful to understand these conditions. Most of the anomalies and diseases involving the pediatric cervical spine are easily divided into those of the upper (occiput, C1, C2) and lower (C3-C7) segments.

NORMAL EMBRYOLOGY, GROWTH, AND DEVELOPMENT

Embryology

Occipitoaxioatlas Complex

The occiput is formed from at least four or five somites. All definitive vertebrae develop from the caudal sclerotome half of one segment and the cranial sclerotome half of the succeeding segment (1). These areas of primitive mesenchyme separate from each other during fetal growth, then undergo chondrification and subsequent ossification. This chondrification and ossification is a passive process that follows the blueprint laid down by the mesenchymal anlage. Because of this sequencing the cranial half of the first cervical sclerotome remains as a half segment between the occipital and atlantal rudiments, and is known as the proatlas. The primitive centrum of this proatlas becomes the tip of the odontoid process, whereas its arch rudiments assist in the formation of the occipital condyles (2). The vertebral arch of the atlas separates from its respective centrum, becoming the ring of C1; the separated centrum fuses with the proatlas above and the centrum of C2 below, to become the odontoid process and body of C2. The axis forms from the second definitive cervical vertebral mesenchymal segment. The odontoid process is the fusion of the primitive centra of the atlas and the proatlas half segment. The posterior arches of C2 form from only the second definitive cervical segment.

Thus, the atlas is made up of three main components: the body and the two neural arches. The axis is made up of four main components: the body, the two neural arches, and the odontoid (or five components, if the proatlas rudiment is considered).

Vertebrae C3-C7

These vertebrae follow the normal formation scheme of all vertebrae (3). A portion of the mesenchyme from the sclerotomal centrum creates two neural arches that migrate posteriorly and around the neural tube. This eventually forms the pedicles, the laminae, the spinous processes, and a very small portion of the body. The majority of the body is formed by the centrum. An ossification center develops in each of the two neural arches and one in the vertebral center, with a synchondrosis formed by the cartilage between the ossification centers.

Growth and Development

Atlas

Ossification is present only in the two neural arches at birth (4). These ossification centers extend posteriorly toward the rudimentary spinous process to form the posterior synchondrosis, and anteriorly into the articular facet region to form all of the bone present in the facets. Anteromedial to each facet the neurocentral synchondroses form, joining the neural arches and the body; this occurs on each side of the expanding anterior ossification center. The body starts to ossify between 6 months and 2 years, usually in a single center. By 4 to 6 years the posterior synchondrosis fuses, followed by the anterior synchondroses slightly thereafter. The final internal diameter of the pediatric C1 spinal canal is determined by 6 to 7 years of age. Further growth is obtained only by periosteal appositional growth on the external surface, which leads to thickening and increased height, but without changing the size of the spinal canal.

Axis

The odontoid develops two primary ossification centers that usually coalesce within the first 3 months of life; these centers are separated from the C2 centrum by the dentocentral synchondrosis (5,6). This synchondrosis is below the level of the C1-C2 facets, and contributes to the overall height of the odontoid, as well as to the body of C2. It is continuous with the vertebral body and facets, and it coalesces with the anterior neurocentral synchondroses. These synchondroses progressively close, starting first in the regions of the facets, next at the neurocentral synchondroses, and finally at the dentocentral synchondrosis. This closure occurs between 3 and 6 years of age. The tip of the dens is composed of a cartilaginous region similar to an epiphysis, the chondrum terminale, which develops an ossification center between 5 and 8 years of age, becoming the ossiculum terminale. The ossiculum terminale fuses to the remainder of the odontoid between 10 and 13 years of age.

The posterior neural arches are partially ossified at birth, joined by the posterior synchondrosis. By 3 months of age these arches, growing more posteriorly, form the rudimentary spinous process. By 1 year of age, ossification fills the spinous process, and by 3 years of age, the posterior synchondrosis has fused. Thus, both the posterior and the anterior synchondroses are closed by 6 years of age, and there is no further increase in spinal canal size after this age.

C3-C7

At birth all three ossification centers are present. The anterior synchondrosis (i.e., neurocentral synchondrosis) is slightly anterior to the base of the pedicles; it usually closes between 3 and 6 years of age. The posterior synchondrosis is at the junction of the two neural arches; it usually closes by 2 to 4 years of age. In the neonate and young child the articular facets are horizontal; they become more vertically oriented as the child ages and reaches the normal adult configuration. They are also more horizontal in the upper cervical spine than in the lower cervical spine. The vertebral bodies enlarge circumferentially by periosteal appositional growth, whereas they grow vertically by endochondral ossification. Secondary ossification centers develop at the tips of the spinous processes and the cartilaginous ring apophyses of the bodies around the time of puberty. These ring apophyses are involved in the vertical growth of the body. These secondary ossification centers fuse with the vertebral body around age 25 years.

Normal Radiographic Parameters

Certain radiographic parameters that indicate pathology of the cervical spine in adults represent normal developmental processes in children. These parameters are the atlantooccipital motion and atlanto-dens interval (ADI), pseudosubluxation and pseudoinstability, variations in the curvature of the cervical spine that may resemble spasm and ligamentous injury, variations in the presence of skeletal growth and growth centers that may resemble fractures, and anterior soft tissue widening. Normal cervical spine motion in children, is also discussed.

Atlanto-dens Interval and Atlantooccipital Motion

These intervals are determined on lateral flexion and extension radiographs, which should be made voluntarily with the patient awake. The ADI is the space between the anterior aspect of the dens and the posterior aspect of the anterior ring of the atlas (Fig. 21-1). An ADI of more than 5 mm on flexion and extension lateral radiographs indicates instability (7,8). This is more than the 3-mm adult value because of the increased cartilage content of the odontoid and ring of the atlas in children, as well as the increased ligamentous laxity in children. In extension, overriding of the anterior arch of the atlas on top of the odontoid also can be seen in up to 20% of children (9).

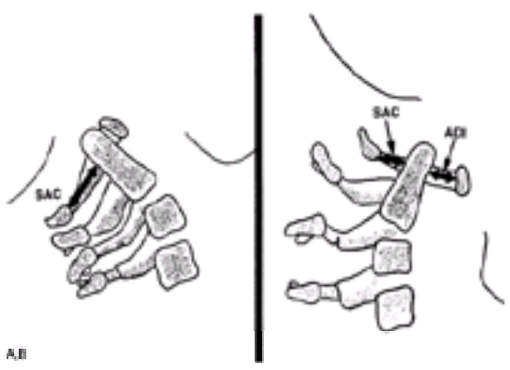

FIGURE 21.1. Lateral view of the atlantoaxial joint. The atlanto-dens interval (*ADI*) is the distance between the anterior aspect of the dens and the posterior aspect of the anterior portion of the ring of the atlas. The space available for the cord (*SAC*) is the distance between the posterior aspect of the dens and the anterior aspect of the posterior portion of the ring of the atlas. In children, an ADI of 5 mm or larger is abnormal. In teenagers and adults, a SAC of 13 mm or smaller may be associated with canal compromise. In younger children, spinal cord impingement is imminent if the SAC is equal to or less than the transverse diameter of the odontoid. **A:** The relations in extension. **B:** The relations in flexion.

A mild increase in the ADI may indicate a subtle disruption of the transverse atlantal ligament. In adults, this ligament ruptures around an interval of 5 mm (10). In chronic atlantoaxial conditions (e.g., rheumatoid arthritis, Down syndrome, congenital anomalies), the ADI is less useful. In children with these disorders who are frequently hypermobile but do not have ruptured transverse atlantal ligaments, the ADI is increased beyond the 3- to 5-mm range. The complement of the ADI, the space available for the cord (SAC), is a more useful measure in this situation. This space is the distance between the posterior aspect of the dens and the anterior aspect of the posterior ring of the atlas or the foramen magnum. A SAC of less than 13 mm may be associated with neurologic problems (11).

In patients in whom there is an attenuation of the transverse atlantal ligament without rupture, the alar ligament provides some stability. It acts like a checkrein (12), first tightening up in rotation, then becoming completely taut as the odontoid process continues to move posteriorly for a distance equivalent to its full transverse diameter. This safety zone between the anterior wall of the spinal canal of the atlas, the axis, and the neural structures is an anatomic constant equal to the transverse diameter of the odontoid. This constant defines Steel's rule of thirds: one-third cord, one-third odontoid, and one-third space (12). This rule remains constant throughout the growth of the cervical spine (13). The cord can move into this space (safe zone) when the odontoid moves posteriorly because of an attenuated transverse atlantal ligament. It is here that the alar ligament becomes taut, acting as a checkrein and secondary restraint, preventing further movement of the odontoid into the cord. In the chronic situation, it is important to recognize when this safe zone has been exceeded and the child enters the region of impending spinal cord compression. In the case of trauma, the alar ligament is insufficient to prevent a fatal cord injury in the event of another neck injury similar to the one that caused the initial interruption of the transverse atlantal ligament.

Normal ranges of motion at the atlantooccipital joint are not well defined. In a series of 40 normal college freshmen, the tip of the odontoid remained directly below the basion of the skull in both flexion and extension (14). Thus, the joint should not allow any horizontal translation during flexion and extension. Tredwell and colleagues (15) believe that a posterior subluxation of the atlantooccipital relation in extension of more than 4 mm indicates instability (Fig. 21-2). This can be measured as the distance between the anterior margin of the condyles at the base of the skull and the sharp contour of the anterior aspect of the concave joint of the atlas anteriorly, or as the distance between the occipital protuberance and the superior arch of the atlas posteriorly. Another method to measure posterior subluxation of the atlantooccipital joint is that of Wiesel and Rothman (16) (Fig. 21-3). With this technique, occiput–C1 translation from maximum flexion to maximum extension should be no more than 1 mm in normal adults. These norms in children have not yet been established.

FIGURE 21.2. Lateral flexion (**A**) and extension (**B**) radiographs of an 11-year-old boy with Down syndrome. The child presented with loss of hand control when flexing his neck. Using the method of Tredwell and colleagues (15), the atlantooccipital distance is measured as the distance between the anterior margin of the condyles at the base of the skull and the sharp contour of the anterior aspect of the concave joint of the atlas. More than 4 mm of posterior translation is abnormal. The atlantooccipital distance (*arrows*) measured 10 mm in extension and 1 mm in flexion. The atlantodens interval was 1 mm in extension and 6 mm in flexion, for a total of 5 mm of motion (*arrowheads*). The space available for the cord was 17 mm in flexion and 20 mm in extension. Both occipitoatlantal instability (more than 4 mm of posterior translation) and atlantodens hypermobility (5-mm atlantodens interval in flexion) were present.

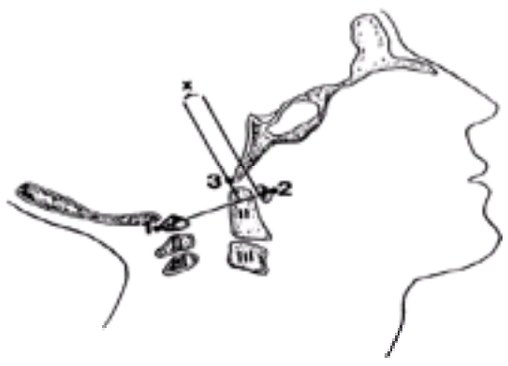

FIGURE 21.3. The method of measuring atlantooccipital instability, according to Wiesel and Rothman (16). The atlantal line joins points *1* and *2*. A perpendicular line to the atlantal line is made at the posterior margin of the anterior arch of the atlas. The distance (*x*) from the basion (*3*) to the perpendicular line is measured in flexion and extension. The difference between flexion and extension represents the anteroposterior translation at the occipitoatlantal joint; in normal adults, this translation should be no more than 1 mm. (From ref. 17, with permission.)

Pseudosubluxation

The C2-C3 interspace, and, to a lesser extent the C3-C4 [tbinterspace in children, have a normal physiologic displacement. In a study of 161 children (9), marked anterior displacement of C2 on C3 was observed in 9% of children between 1 and 7 years old. In some children, the anterior physiologic displacement of C2 on C3 is so pronounced that it appears pathologic (pseudosubluxation). To differentiate this from pathologic subluxation, Swischuk (18) has used the posterior cervical line (Fig. 21-4) drawn from the anterior cortex of the posterior arch of C1 to the anterior cortex of the [nbposterior arch of C3. In physiologic displacement of C2 on C3, the posterior cervical line may pass through the cortex of the posterior arch of C2, touch the anterior aspect of the cortex of the posterior arch of C2, or come within 1 mm of the anterior cortex of the posterior arch of C2. In pathologic dislocation of C2 on C3, the posterior cervical line misses the posterior arch of C2 by 2 mm or more.

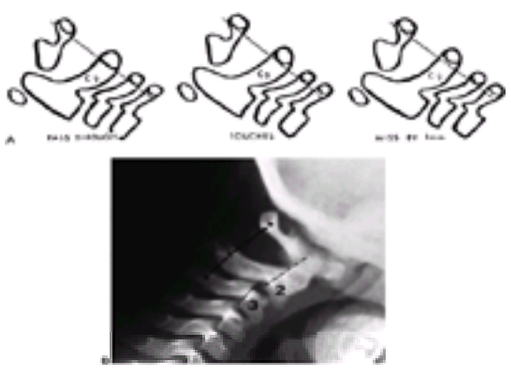

FIGURE 21.4. A: The posterior line of Swischuk showing the normal limits: passing through or just behind the anterior cortex of C2 (**left**); touching the anterior aspect of the cortex of C2 (**center**); coming within 1 mm of the anterior aspect of the cortex of C2 (**right**). (From ref. 18, with permission.) **B:** Lateral cervical radiograph of a child with pseudosubluxation at C2-C3, shown by a stepoff at C2-C3 (*dashed line*), but with a normal posterior cervical line (*asterisk line*). Also note the anterior wedging of the C3 vertebral body. (From ref. 19, with permission.)

The planes of the articular facets change with growth. The lower cervical spine facets change from 55 to 70 degrees, whereas the upper facets (i.e., C2-C4) may have initial angles as low as 30 degrees, which gradually increase to 60 to 70 degrees. This variation in facet angulation, along with normal looseness of the soft tissues, intervertebral discs, and the relative increase in the size and weight of the skull compared with the trunk, are the major factors responsible for this pseudosubluxation. No treatment is needed for this normal physiologic subluxation.

Variations in the Curvature and Growth of the Cervical Spine That Can Resemble Injury

In the classic study of Catell and Filtzer (9), 16% of normal children showed a marked angulation at a single interspace, suggestive of injury to the interspinous or posterior longitudinal ligament; 14% showed an absence of the normal lordosis in the neutral position; and 16% showed an absence of the flexion curvature between the second and seventh cervical vertebrae, which could be erroneously interpreted as splinting secondary to injury.

Spina bifida of the posterior arch, or multiple ossification centers of the ring of C1, may mimic fractures. They can be delineated from fractures by their smooth cortical margins. In some children, the posterior ring of C1 remains cartilaginous, which is usually of no clinical significance (20). Spina bifida also may occur at other cervical levels, and the overlapping lucent areas on anteroposterior radiographs, when crossing a vertebral body, may mimic a vertical fracture of the body.

The dentocentral synchondrosis of C2 begins to close between 5 to 7 years of age (5). However, it may be visible in vestigial forms up to 11 years of age (9), and may be erroneously interpreted as an undisplaced fracture. Similarly, the apical odontoid epiphysis (i.e., ossiculum terminale) may appear by 5 years of age, although it most typically appears around 8 years of age. This also can be misinterpreted as an odontoid tip fracture.

Wedging of the C3 vertebral body is a normal radiographic finding in 7% of younger children (21) (Fig. 21-4B). If it is not known whether the wedging is a normal variation or a true compression fracture in the face of a traumatic history, a computed tomography (CT) scan will demonstrate fracture lines through the body if a fracture is present. In the lower cervical levels, secondary centers of ossification of the spinous processes may resemble avulsion fractures (9).

Normal Lower Cervical Spine Motion

Generally, the interspinous distances increase with increasing age, being the smallest at C4–C5 and the largest at C6–C7, until 15 years of age, when this distance is largest at C5–C6 (8). The anteroposterior displacement, from hyperflexion to hyperextension, decreases from C2–C3 to C6–C7. The angular displacement is greatest (15 degrees) at C3–C4 and C4–C5 for children 3 to 8 years of age; is greatest (17 degrees) at C4–C5 for children 9 to 11 years of age; and is greatest (15 degrees) at C5–C6 for children 12 to 15 years of age.

CONGENITAL AND DEVELOPMENTAL PROBLEMS

Torticollis

Torticollis is a combined head tilt and rotatory deformity. Torticollis indicates a problem at C1-C2, because 50% of the cervical spine rotation occurs at this joint. A head tilt alone indicates a more generalized problem in the cervical spine. The differential diagnosis of torticollis is large, and can be divided into osseous and nonosseous types. In a recent large series from a tertiary care pediatric orthopaedic center (22), a nonmuscular cause of torticollis was found in 18% of patients, most frequently the Klippel-Feil syndrome or a neurologic disorder (ocular pathology, obstetric palsy, or central nervous system lesion).

Osseous Types

Occipitocervical synostosis, basilar impression, and odontoid anomalies are the most common congenital/developmental malformations of the occipitovertebral junction, with an incidence of 1.4 to 2.5 per 100 children (23). These lesions arise from a malformation of the mesenchymal anlages at the occipitovertebral junction.

Basilar Impression. Basilar impression is an indentation of the skull floor by the upper cervical spine. The tip of the dens is more cephalad, and sometimes protrudes into the opening of the foramen magnum. This may encroach on the brainstem, risking neurologic damage from direct injury, vascular compromise, or alterations in cerebrospinal fluid flow (24).

Basilar impression can be primary or secondary. Primary basilar impression, the most common type, is a congenital abnormality often associated with other vertebral defects (e.g., Klippel-Feil syndrome, odontoid abnormalities, atlantooccipital fusion, atlas hypoplasia). The incidence of primary basilar impression in the general population is 1% (25).

Secondary basilar impression is a developmental condition attributed to softening of the osseous structures at the base of the skull. Any disorder of osseous softening can lead to secondary basilar impression. These include metabolic bone diseases (e.g., Paget disease [26], renal osteodystrophy, rickets, osteomalacia [27]), bone dysplasias and mesenchymal syndromes (e.g., osteogenesis imperfecta [28], achondroplasia [29], hypochondroplasia [30], neurofibromatosis [31]), and rheumatologic disorders (e.g., rheumatoid arthritis, ankylosing spondylitis). The softening allows the odontoid to migrate cephalad and into the foramen magnum.

These patients typically present with a short neck (78% in one series) (32). This shortening is only an apparent deformity because of the basilar impression. Asymmetry of the skull and face (68%), painful cervical motion (53%), and torticollis (15%) can also occur. Neurologic signs and symptoms are often present (33). Many children will have acute onset of symptoms precipitated by minor trauma (34). In cases of isolated basilar impression, the neurologic involvement is primarily a pyramidal syndrome associated with proprioceptive sensory disturbances (motor weakness, 85%; limb paresthesias, 85%). In cases of basilar impression associated with Arnold-Chiari malformations, the neurologic involvement is usually cerebellar, and symptoms include motor incoordination with ataxia, dizziness, and nystagmus. In both types the patients may complain of neck pain and headache in the distribution of the greater occipital nerve and the involvement of cranial nerves, particularly those that emerge from the medulla oblongata (trigeminal [V], glossopharyngeal [IX], vagus [X], and hypoglossal [XII]). Ataxia is a very common finding in children with basilar impression (34). Hydrocephalus may develop as a result of obstruction of the cerebrospinal fluid flow by obstruction of the foramen magnum from the odontoid.

Basilar impression is difficult to assess radiographically. The most commonly used lines are Chamberlain's (35), McRae's (36), and McGregor's (37) (Fig. 21-5). McGregor's line is the best line for screening because the landmarks can be clearly defined at all ages on a routine lateral radiograph. McRae's line is helpful in assessing the clinical significance of basilar impression because it defines the opening of the foramen magnum; in patients who are symptomatic, the odontoid projects above this line. At present, CT with sagittal plane reconstructions can show the osseous relations at the occipitocervical junction more clearly, and magnetic resonance imaging (MRI) clearly delineates the neural anatomy. Occasionally, vertebral angiography is needed (38).

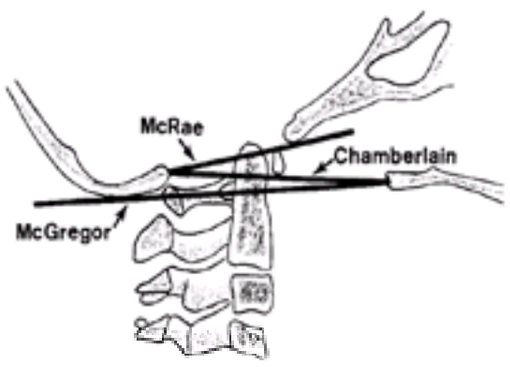

FIGURE 21.5. These landmarks on a lateral radiograph of the skull and upper cervical spine are used to assess basilar impression. McRae's line defines the opening of the foramen magnum. Chamberlain's line is drawn from the posterior lip of the foramen magnum to the dorsal margin of the hard palate. McGregor's line is drawn from the upper surface of the posterior edge of the hard palate to the most caudad point of the occipital curve of the skull. McGregor's line is the best line for screening because of the clarity of the radiographic landmarks in children of all ages.

Treatment of basilar impression can be difficult, and requires a multidisciplinary approach (orthopaedic, neurosurgical, and neuroradiologic) (39). The symptoms rarely can be relieved with customized orthoses (40); the primary treatment is surgical. If the symptoms are caused by a hypermobile odontoid, surgical stabilization in extension at the occipitocervical junction is needed **[➥2.18]**. Anterior excision of the odontoid is needed, if it cannot be reduced (41), but this should be preceded by posterior stabilization and fusion. If the symptoms are from posterior impingement, suboccipital decompression and often, upper cervical laminectomy are needed. The dura often needs to be opened to look for a tight posterior band (32,42). Posterior stabilization also should be performed. These are general statements, and each case should be considered individually.

Atlantooccipital Anomalies. Children with congenital bony anomalies of the atlantooccipital junction present with a wide spectrum of deformities. The anterior arch of C1 is commonly assimilated to the occiput, usually in association with a hypoplastic ring posteriorly (Fig. 21-6), as well as condylar hypoplasia. The height of C1 is variably decreased, allowing the odontoid to project upward into the foramen magnum (i.e., the primary basilar impression). More distal cervical anomalies can also occur in association with the atlantooccipital anomaly. The odontoid may be misshapen, or directed posteriorly more than normal. Up to 70% of children with this condition have a congenital fusion of C2-C3 (Fig. 21-6). (Posterior congenital fusion of C2-C3 is a clue that occiput–C1 anomalies, or other more distal cervical fusions, may be present. These may be cartilaginous initially, and not appear on plain radiographs until the child becomes more mature.)

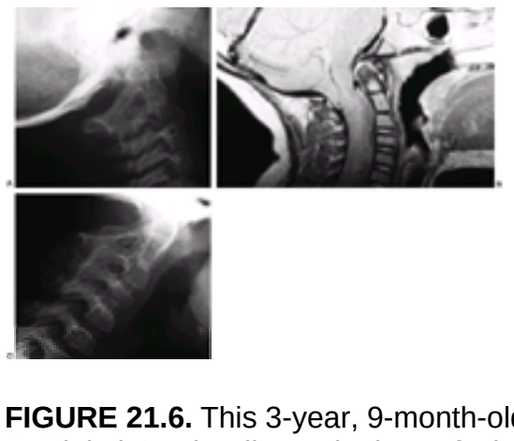

FIGURE 21.6. This 3-year, 9-month-old girl had a history of vertex headaches for 1 year. One month before presentation she developed a painful, left-sided torticollis. **A:** Plain lateral radiograph shows fusion of C2-C3 and absence of the ring of C1 with occipitalization. **B:** The magnetic resonance image shows an Arnold-Chiari malformation, with herniation of the cerebellar tonsils into the foramen magnum (*arrow*). Also note the cordal edema (*arrowhead*). **C:** The child underwent occipital decompression and laminectomy to C3, posterior cervical fusion from the occiput to C4, and halo cast immobilization for 4 months. Flexion and extension lateral radiographs 1 year after treatment show solid incorporation of the fusion from C2 to C4, with dissolution of the graft from the occiput to C2. However, there is no atlantooccipital instability. The child's symptoms resolved.

Clinically, these children resemble those with Klippel-Feil syndrome: short, broad necks; restricted neck motion; low hairline; high scapula; and torticollis (42,43). The

skull may be deformed and shaped like a “tower skull.” They also may have other associated anomalies, including dwarfism, funnel chest, jaw anomalies, cleft palate, congenital ear deformities, hypospadias, genitourinary tract defects, and syndactyly. They can present with neurologic symptoms during childhood, but more symptoms appear between 40 and 50 years of age. These symptoms can be initiated by traumatic or inflammatory processes, and they progress slowly and relentlessly. Rarely do they present suddenly or dramatically, although they have been reported as a cause of sudden death. The most common signs and symptoms, in decreasing order of frequency, are neck and occipital pain, vertigo, ataxia, limb paresis, paresthesias, speech disturbances, hoarseness, diplopia, syncope, auditory malfunction, and dysphagia (44,45).

Standard radiographs are difficult to obtain, because of fixed bony deformities and overlapping shadows from the mandible, occiput, and foramen magnum. An x-ray beam, directed 90 degrees perpendicular to the skull (rather than to the cervical spine), usually gives a satisfactory view of the occipitocervical junction. The anomaly usually is studied further with CT. In young children, the head-wag autotomography technique can be quite useful (46). This technique involves side-to-side rotation of the child's head, while a slow anteroposterior radiographic exposure of the upper cervical spine is performed. This rotation blurs the overlying head and mandibular structures, allowing for improved visualization of the occiput–C1-2 complex.

The position of the odontoid, relative to the opening of the foramen magnum, has been described by measuring the distance from the posterior aspect of the odontoid to the posterior ring of C1 or the posterior lip of the foramen magnum, whichever is closer (43,47). This should be determined in flexion, because this position maximizes the reduction in the SAC. If this distance is less than 19 mm, a neurologic deficit is usually present. Lateral flexion and extension views of the upper cervical spine often show up to 12 mm of space between the odontoid and the C1 ring anteriorly (43); associated C1-C2 instability has been reported to develop eventually in 50% of these patients.

MRI is used to visualize the neural structures. Flexion–extension MRI is often necessary to fully evaluate the pathology (48). Compression of the brainstem or upper cervical cord anteriorly occurs from the backward-projecting odontoid. This produces a range of findings and symptoms, depending on the location and degree of compression. Pyramidal tract signs and symptoms (e.g., spasticity, hyperreflexia, muscle weakness, gait disturbances) are most common, although signs of cranial nerve involvement (e.g., diplopia, tinnitus, dysphagia, auditory disturbances) can be seen. Compression from the posterior lip of the foramen magnum or dural constricting band can disturb the posterior columns, with a loss of proprioception, vibration, and tactile senses. Nystagmus also occurs frequently as a result of posterior cerebellar compression. Vascular disturbances from vertebral artery involvement can result in brainstem ischemia, manifested by syncope, seizures, vertigo, and unsteady gait. Cerebellar tonsil herniation can occur. The altered mechanics of the cervical spine may result in a dull, aching pain in the posterior occiput and neck, with intermittent stiffness and torticollis. Irritation of the greater occipital nerve may cause tenderness in the posterior scalp.

The natural history of atlantooccipital anomalies is unknown. The neurologic symptoms may develop so late, and progress so slowly, because the frequently associated C1-C2 instability progresses with age, and the increased demands placed on the C1-C2 interval produce gradual spinal cord or vertebral artery compromise.

Treatment is difficult. Surgery for atlantooccipital anomalies is more risky than with isolated anomalies of the odontoid (42,45). For this reason, nonoperative methods should be attempted, initially. Cervical collars, braces, and traction often help for persistent complaints of head and neck pain, especially after minor trauma or infection. Immobilization may achieve only temporary relief if neurologic deficits are present. Patients with evidence of a compromised upper cervical area should take precautions not to expose themselves to undue trauma.

When symptoms and signs of C1-C2 instability are present, a posterior C1-C2 fusion is indicated **[➥2.17]**. Preliminary traction to attempt reduction is used if necessary. If reduction is possible and there are no neurologic signs, surgery has an improved prognosis (42,44,45). Posterior signs and symptoms may be an indication for posterior decompression, depending on the evidence of dural or osseous compression. Results vary from complete resolution to increased deficits and death (42,49). In the instance of no instability but only compressive pathology, the role of concomitant posterior fusion has not yet been determined. However, if decompression (whether anterior or posterior) can destabilize the spine, concomitant posterior fusion should be considered.

Unilateral Absence of C1. This congenital malformation of the first cervical vertebra is, in essence, a hemiatlas or a congenital scoliosis of C1. Doubousset (50) has described 17 patients with this absence. No definite population incidence is known. The problem often is associated with other anomalies common to children with congenital spine deformities (e.g., tracheoesophageal fistula).

Two-thirds of the children present at birth; the others develop torticollis and are noticed later. A lateral translation of the head on the trunk, with variable degrees of lateral tilt and rotation (best appreciated from the back) is the typical finding. There also may be severe tilting of the eye line. The sternocleidomastoid muscle is not tight, although regional aplasia of the muscles in the nuchal concavity of the tilted side is noted. Neck flexibility is variable and decreases with age. The condition is not painful. Plagiocephaly can occur, and increases as the deformity increases. Neurologic signs (e.g., headache, vertigo, myelopathy) are present in about one-fourth of the patients. The natural history is unknown.

Standard anteroposterior and lateral radiographs rarely give the diagnosis, although the open-mouth odontoid view may suggest it. Tomograms or CT scans usually are needed to visualize the anomaly (Fig. 21-7). The defect can range from a hypoplasia of the lateral mass to a complete hemiatlas with rotational instability and basilar impression. Occasionally the atlas is occipitalized. There are three types of this disorder. Type I is an isolated hemiatlas. Type II is a partial or complete aplasia of one hemiatlas, with other associated anomalies of the cervical spine (e.g., fusion of C3-C4, congenital bars in the lower cervical vertebrae). Type III is a partial or complete atlantooccipital fusion and symmetric or asymmetric hemiatlas aplasia, with or without anomalies of the odontoid and the lower cervical vertebrae.

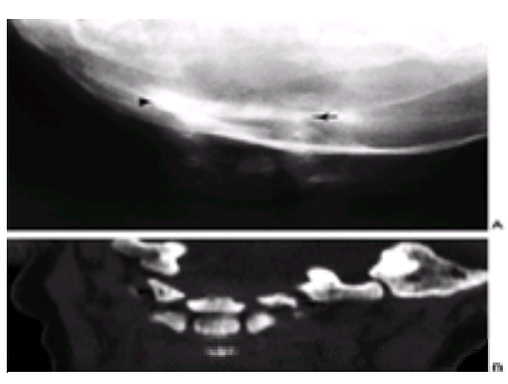

FIGURE 21.7. This 2-month-old girl presented with left-sided torticollis. Physical examination revealed no tightness in the sternocleidomastoid muscle, but reduced right lateral extension was present. **A:** An anteroposterior radiograph of the cervical spine demonstrates the head tilt and suggests a hypoplastic lateral mass on the patient's left at C1 (*arrow*) compared with that on the patient's right (*arrowhead*). **B:** A computed tomography scan with frontal reconstruction clearly demonstrates the left hypoplastic lateral mass of C1 (*arrow*), with a normal right lateral mass (*arrowhead*). Further workup of this child demonstrated nearly complete tracheal stenosis, which required reconstructive surgery. The lateral tilt of the neck has been slowly resolving with gentle physiotherapy and improvement of normal cervical muscle motor tone.

Once this malformation is diagnosed entire spinal radiographs should be taken to rule out other congenital vertebral anomalies. Other imaging studies that may be needed are vertebral angiography and MRI. Angiography should be performed if operative intervention is undertaken, because arterial anomalies (e.g., multiple loops, vessels smaller than normal, abnormal routes between C1 and C2) often are found on the aplastic side. MRI also should be performed if operative intervention is undertaken, because many of these children will have stenosis of the foramen magnum, and occasionally an Arnold-Chiari malformation.

The deformity should be observed to document the presence or absence of progression. This observation is primarily clinical (e.g., photographic), because radiographic measurements are difficult if not impossible to obtain. Bracing does not halt the progression of the deformity. Surgical intervention is recommended in those patients with severe deformities. A preoperative halo cast is used for gradual traction correction over 6 to 8 days. An ambulatory method of gradual cervical spine deformity correction has been described using the halo-Ilizarov technique (51). A posterior fusion from the occiput–C2 or occiput–C3 is then performed, **[➥2.18]** depending on the extent of the anomaly. Decompression of the spinal canal is necessary when the canal size is not ample, either at that time or if it is projected not to

be able to fully accommodate the developed spinal cord. The ideal age for posterior fusion is between 5 and 8 years, corresponding to the age at which the canal size reaches adult proportions.

Familial Cervical Dysplasia. The epidemiology of this atlas deformity (52) is not known. Clinical presentation varies from an incidental finding to a passively correctable head tilt, suboccipital pain, decreased cervical motion, or a clunking of the upper cervical spine.

Plain radiographs are difficult to interpret. Various anomalies of C1, most commonly a partial absence of the posterior ring of C1, typically are seen. Various anomalies of C2 also commonly exist, e.g., a shallow hypoplastic left facet. Other dysplasias of the lateral masses, facets, and posterior elements, and occasionally spondylolisthesis, are seen. Occiput–C1 instability is frequently seen; C1-C2 instability rarely is seen. The delineation of this complex anatomy often is seen best with a CT scan and three-dimensional reconstruction (Fig. 21-8). When symptoms of instability are present, MRI in flexion and extension is recommended to assess the presence and magnitude of neural compression. Occipitocervical junction instability attributable to the malformation may lead to neural compromise.

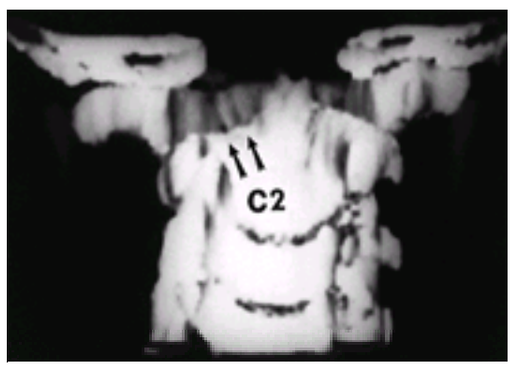

FIGURE 21.8. A three-dimensional computed tomography scan of the upper cervical spine in a child with familial cervical dysplasia. The left superior facet of C2 is shallow and hypoplastic (*arrows*). (From ref. 52, with permission.)

Nonsurgical treatment consists of observation every 6 to 12 months to ensure that instability does not develop, either clinically (e.g., progressive weakness and fatigue or objective signs of myelopathy) or radiographically, with lateral flexion and extension radiographs. Surgical intervention is recommended for persistent pain, torticollis, and neurologic symptoms. A posterior fusion from the occiput to C2 usually is required **[➥2.18]**, with gradual preoperative reduction using an adjustable halo cast (51).

Atlantoaxial Rotary Displacement. Atlantoaxial rotary displacement is one of the most common causes of childhood torticollis. Rotary displacements are characteristically a pediatric problem, but they may occur in adults. There are several causes. Because the resultant radiographic findings and treatment regimens are the same for all pediatric causes, they are discussed as a unit, and individual exceptions are noted where necessary.

The confusing terminology includes rotary dislocation, rotary deformity, rotational subluxation, rotary fixation, and spontaneous hyperemic dislocation (53,54). "Atlantoaxial rotary subluxation" is probably the most accepted term used in describing the common childhood torticollis. "Subluxation" is misleading, however, because cases of subluxation usually present within the normal range of motion of the atlantoaxial joint. "Rotary displacement" is a more appropriate and descriptive term because it includes the entire range of pathology, from mild subluxation to complete dislocation. If the deformity persists, the child presents with a resistant and unresolving torticollis that is best termed "atlantoaxial rotary fixation or fixed atlantoaxial displacement." Gradations exist between the very mild, easily correctable rotary displacement and the rigid fixation. Complete atlantoaxial rotary dislocation rarely has been reported in surviving patients.

The radiographic findings of rotary displacement are difficult to demonstrate (55). With rotary torticollis the lateral mass of C1 that has rotated anteriorly appears wider and closer to the midline (medial offset), whereas the opposite lateral mass is narrower and away from the midline (lateral offset). The facet joints may be obscured because of apparent overlapping. The lateral view shows the wedge-shaped lateral mass of the atlas lying anteriorly where the oval arch of the atlas normally lies, and the posterior arches fail to superimpose because of the head tilt (Fig. 21-9). These findings may suggest occipitalization of C1 because with the neck tilt the skull may obscure C1. The normal relation between the occiput and C1 is believed to be maintained in children with atlantoaxial rotary displacement. A lateral radiograph of the skull may demonstrate the relative positions of C1 and C2 more clearly than a lateral radiograph of the cervical spine. This is because tilting of the head also tilts C1, which creates overlapping shadows and makes interpretation of a lateral spinal radiograph difficult.

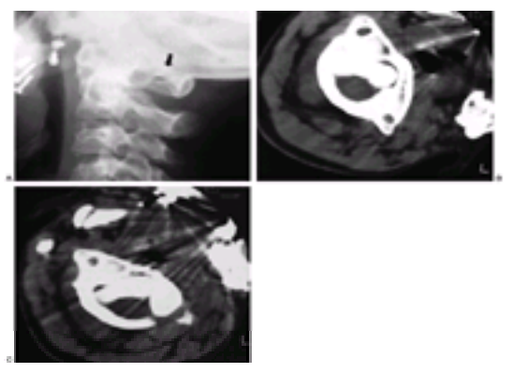

FIGURE 21.9. Radiographic findings in atlantoaxial rotary subluxation. **A:** The lateral cervical spinal radiograph. The posterior arches fail to superimpose because of the head tilt (*arrow*). **B** and **C:** Dynamic computed tomography scans in a 9-year-old girl with a fixed atlantoaxial rotary displacement, with the head maximally rotated to the left (**B**), and the head maximally rotated to the right (**C**), which, in this case, does not reach the midline. The ring of C1 is still in the exact relation to the odontoid as in **B**, indicating a fixed displacement.

The difficulty with plain radiographs is differentiating the position of C1-C2 in a child with subluxation from that in a normal child whose head is rotated, because both give the same picture. Open-mouth views are difficult to obtain and interpret, and the lack of cooperation and diminished motion on the part of the child often make it impossible to obtain these special views. Cineradiography has been recommended, but the radiation dose is high and patient cooperation may be difficult because of muscle spasms (55,56). CT is helpful in this situation if it is done properly (57). A CT scan, when taken with the head in the torticollic position, may be interpreted by the casual observer as showing rotation of C1 on C2. If the rotation of C1 on C2 is within the normal range, as it usually is early in this condition, the observer may attribute this rotation to patient positioning. A dynamic-rotation CT scan is helpful here. Views with the head maximally rotated to the right, then to the left, will demonstrate atlantoaxial rotary fixation when there is a loss of normal rotation (Fig. 21-9).

Rotary displacement can be classified into four types (53) (Fig. 21-10): type I is a simple rotary displacement without an anterior shift; type II is rotary displacement with an anterior shift of 5 mm or less; type III is rotary displacement with an anterior shift greater than 5 mm; and type IV is rotary displacement with a posterior shift. The amount of anterior displacement considered to be pathologic is greater than 3 mm in older children and adults, and greater than 4 mm in younger children (7). Flexion and extension lateral-stress radiographs are suggested to rule out the possibility of anterior displacement.

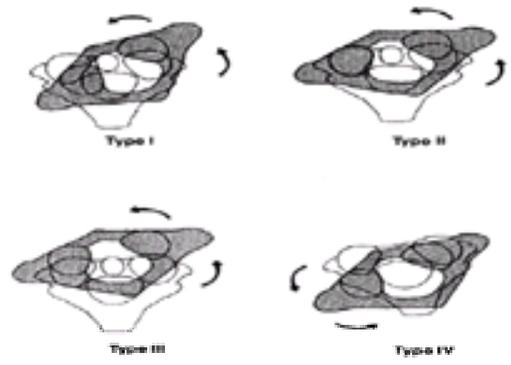

FIGURE 21.10. The four types of atlantoaxial rotary displacement. (From ref. 53, with permission.)

Type I is the most common pediatric type. It is usually benign and frequently resolves by itself. Type II deformity is potentially more dangerous. Types III and IV are very rare, but because of the potential for neurologic involvement and even instant death, management must be approached with great caution.

The cause and pathoanatomy are not known completely (58). Several etiologic mechanisms are possible. Fracture is a rare cause. More commonly, atlantoaxial rotary displacement occurs after minor trauma, after head and neck surgery, or after an upper respiratory infection. The child presents with a “cocked-robin” torticollis, and resists any attempt to move the head because of pain. The associated muscle spasm is noted on the side of the long sternocleidomastoid muscle because the muscle is attempting to correct the deformity, unlike congenital muscular torticollis, in which the muscle causes the torticollis. If the deformity becomes fixed, the pain subsides but the torticollis persists, along with decreased neck motion. In long-standing cases, plagiocephaly and facial flattening may develop on the side of the tilt.

Spontaneous atlantoaxial subluxation with inflammation of adjacent neck tissues, also known as Grisel syndrome, is commonly seen in children after upper respiratory infections (Fig. 21-11). A direct connection exists between the pharyngovertebral veins and the periodontal venous plexus and suboccipital epidural sinuses (59). This may provide a route for hematogenous transport of peripharyngeal septic exudates to the upper cervical spine and an anatomic explanation for the atlantoaxial hyperemia of Grisel syndrome. Regional lymphadenitis is known to cause spastic contracture of the cervical muscles. This muscular spasm, in the presence of abnormally loose ligaments (hypothetically caused by the hyperemia of the pharyngovertebral vein drainage), could produce locking of the overlapping lateral joint edges of the articular facets. This prevents easy repositioning, resulting in atlantoaxial rotary displacement. The hyperemia after surgery of the oral pharynx, most frequently tonsillectomy and adenoidectomy, enhances the passage of the inflammatory products into the pharyngovertebral veins. Kawabe and colleagues (60) have demonstrated meniscus-like synovial folds in the atlantooccipital and lateral atlantoaxial joints of children, but not in those of adults, and have found that the dens–facet angle of the axis is steeper in children than in adults. They postulate that excessive C1-C2 rotation, caused by the steeper angle, compounded by ligament laxity from an underlying hyperemia, allows the meniscus-like synovial folds to become impinged in the lateral atlantoaxial joint, leading to rotary fixation. The predominance of this syndrome in childhood correlates with the predilection for the adenoids to be maximally hypertrophied and inflamed at this same time, and located in the area drained by the pharyngovertebral veins.

FIGURE 21.11. A 5-year-old boy developed an atlantoaxial rotary subluxation after an upper respiratory viral infection (Grisel syndrome). It rapidly resolved after treatment with a soft collar and mild doses of diazepam.

Most atlantoaxial rotary displacements resolve spontaneously. Rarely, however, the pain subsides and the torticollis becomes fixed. The duration of symptoms and deformity dictates the recommended treatment (61).

Patients with rotary subluxation of less than 1 week can be treated with immobilization in a soft cervical collar and rest for about 1 week. Close follow-up is mandatory. If spontaneous reduction does not occur with this initial treatment, hospitalization and the use of halter traction, muscle relaxants (e.g., diazepam), and analgesics are recommended next. Patients with rotary subluxation of greater than 1 week but less than 1 month should be hospitalized immediately for cervical traction, relaxants, and analgesics. A halo cast occasionally is needed to achieve reduction. The reduction is noted clinically and confirmed with a dynamic CT scan. If no anterior displacement is noted after reduction, cervical support should be continued only as long as symptoms persist. If there is anterior displacement, immobilization should be continued for 6 weeks to allow ligamentous healing to occur. In patients with rotary subluxation for more than 1 month cervical traction (usually halo skeletal) can be tried for up to 3 weeks, but the prognosis is guarded. These children usually fall into two groups: those whose rotary subluxation can be reduced with halo traction but, despite a prolonged period of immobilization, resubluxate when the immobilization is stopped, and those whose subluxation cannot be reduced, and is fixed.

When the deformity is fixed, especially when anterior C1 displacement is present the transverse atlantal ligament is compromised, with a potential for catastrophe. In this situation, posterior C1-C2 fusion should be performed. The indications for fusion are neurologic involvement, anterior displacement, failure to achieve and maintain correction, a deformity that has been present for more than 3 months, and recurrence of deformity after an adequate trial of conservative management (at least 6 weeks of immobilization after reduction). Before surgical fusion halo traction for several days is used to obtain as much straightening of the head and neck as possible; a forceful or manipulative reduction should not be performed. Postoperatively, the child is simply positioned in a halo cast or vest in the straightened position obtained preoperatively; this usually results in satisfactory alignment. A Gallie-type fusion, with sublaminar wiring at the ring of C1 and through the spinous process of C2, is preferred to a Brooks-type fusion in which the wire is sublaminar at both C1 and C2. This is because of the decreased SAC at C2 with a higher risk of neurologic injury. This wiring does not reduce the displacement, but simply provides some internal stability for the arthrodesis. The overall results with a Gallie fusion are very good (62) (Fig. 21-12).

FIGURE 21.12. The child in Figure 21-9 had a fixed deformity that occurred 6 months earlier, immediately after reconstructive maxillofacial surgery for Goldenhar

syndrome. It did not respond to traction, including halo traction. She underwent posterior C1-C2 (Gallie-type) fusion. A solid fusion was present 9 months later; clinically, the patient achieved 80 degrees of rotation to the left and 45 degrees of rotation to the right.

Nonosseous Types

Congenital Muscular Torticollis. Congenital muscular torticollis, or congenital wry neck, is the most common cause of torticollis in the infant and young child. The deformity is caused by contracture of the sternocleidomastoid muscle, with the head tilted toward the involved side and the chin rotated toward the opposite shoulder. A disproportionate number of children with this deformity have a history of a primiparous birth or a breech or difficult delivery. However, it has been reported in children with normal births and in children born by cesarean section (63,64).

The exact cause is not known, and there are several theories. Because of the birth history, one theory is that of a compartment syndrome occurring from soft tissue compression of the neck at the time of delivery (65). Surgical histopathologic sections suggest venous occlusion of the sternocleidomastoid muscle (66). This occlusion may result in a compartment syndrome, as manifested by edema, degeneration of muscle fibers, and muscle fibrosis. This fibrosis is variable, ranging from small amounts to the entire muscle. It has been suggested that the clinical deformity is related to the ratio of fibrosis to remaining functional muscle. If ample muscle remains the sternocleidomastoid will probably stretch with growth and the child will not develop torticollis; if fibrosis predominates there is little elastic potential and torticollis will develop. Another theory is *in utero* crowding, because three of four children have the lesion on the right side (67) and up to 20% have developmental hip dysplasia (68). The fact that this condition can occur in children with normal birth histories or in children born by cesarean section challenges the perinatal compartment syndrome theory, and supports the *in utero* crowding theory. The fact that it can occur in families (supporting a genetic predisposition) (69) also raises doubts about the compartment syndrome theory. A third theory is primarily neurogenic (70), supported by histopathologic evidence of denervation and reinnervation. The primary myopathy initially may be attributable to trauma, ischemia, or both, and unequally involves the two heads of the sternocleidomastoid muscle. With continuing fibrosis of the sternal head the branch of the spinal accessory nerve to the clavicular head of the muscle can be trapped, leading to a later progressive deformity (70).

The final theory concerns mesenchymal cells remaining in the sternocleidomastoid from fetal embryogenesis. Recent histopathologic studies have demonstrated the presence of both myoblasts and fibroblasts in the sternocleidomastoid tumor in varying stages of differentiation and degeneration (71). The source of these myoblasts and fibroblasts is unknown. After birth environmental changes stimulate these cells to differentiate, and the sternocleidomastoid tumor develops. Hemorrhagic and inflammatory reactions would be expected if the tumor was a result of perinatal birth trauma or intrauterine positioning, yet these cells were not seen in the sternocleidomastoid histopathologic studies. The occurrence of torticollis depends on the fate of the myoblasts in the mass. If the myoblasts undergo normal development and differentiation no persistent torticollis will occur, and conservative treatment will likely succeed. If the myoblasts mainly undergo degeneration, the remaining fibroblasts produce large amounts of collagen, with a scar-like contraction of the sternocleidomastoid muscle and the typical torticollis.

The clinical features of congenital muscular torticollis depend on the age of the child. It is often discovered in the first 6 to 8 weeks of life. If the child is examined during the first 4 weeks of life a mass or “tumor” may be palpable in the neck (63). Although the mass may be palpable, it is unrecognized up to 80% of the time (72). Characteristically, it is a nontender, soft enlargement beneath the skin, and is located within the sternocleidomastoid muscle belly. This tumor reaches its maximum size within the first 4 weeks of life then gradually regresses. After 4 to 6 months of life the contracture and the torticollis are the only clinical findings. In some children the deformity is not noticed until after 1 year of life, which raises questions about both the congenital nature of this entity and the perinatal compartment syndrome theory. Recent studies (73) indicate that the rate of associated hip dysplasia in children with congenital muscular torticollis is 8%, lower than the previously cited 20% (68).

If the deformity is progressive, skull and face deformities can develop (plagiocephaly), often within the first year of life. The facial flattening occurs on the side of the contracted muscle, and is probably caused by the sleeping position of the child (74). In the United States children usually sleep prone, and in this position, it is more comfortable for them to lie with the affected side down. The face, therefore, remodels to conform to the bed. If the child sleeps supine reverse modeling of the contralateral skull occurs. In the child who is untreated for many years the level of the eyes and ears becomes unequal and can result in considerable cosmetic deformity.

Radiographs of the cervical spine should be obtained to rule out associated congenital anomalies. Plain radiographs of the cervical spine in children with muscular torticollis are always normal, aside from the head tilt and rotation. If any suspicion exists about the status of the hips appropriate imaging (e.g., ultrasonography, radiography) should be performed, depending on the age of the child and the expertise of the sonographer.

Research MRI studies demonstrate abnormal signals in the sternocleidomastoid muscle but no discrete masses within the muscle (65). The muscle diameter is increased to two to four times that of the contralateral muscle. In older patients the signals are consistent with atrophy and fibrosis, similar to those encountered in compartment syndromes of the leg and forearm.

As the deficit in cervical rotation increases the incidence of a previous sternocleidomastoid tumor and hip dysplasia, and the likelihood of needing surgery, increase (75). Treatment initially consists of conservative measures (63,64,72,76,77). Good results can be expected with stretching exercises alone, with one series reporting 90% success (76). These results also may reflect, in part, the favorable natural history of many of these children. The exercises are performed by the caregivers and guided by the physiotherapist. The ear opposite the contracted muscle should be positioned to the shoulder, and the chin should be positioned to touch the shoulder on the same side as the contracted muscle. When adequate stretching has occurred in the neutral position, the exercises should be graduated up to the extended position, which achieves maximum stretching and prevents residual contractures. Treatment measures to be used along with stretching consist of modifying the child's toys and crib so that the neck is stretched when the infant is reaching for or looking at objects of interest. The exact role of the efficacy of these stretching measures, versus a natural history of spontaneous resolution, is not known; there are many anecdotal cases of spontaneous resolution.

Stretching measures are usually unsuccessful after 1 year of age (77,78), and surgery is recommended. The child's neck and anatomic structures are larger, making surgery easier. Established facial deformity or a limitation of more than 30 degrees of motion usually precludes a good result, and surgery is required to prevent further facial flattening and cosmetic deterioration (77). Asymmetry of the face and skull can improve as long as adequate growth potential remains after the deforming pull of the sternocleidomastoid is removed; good but not perfect results can be obtained as late as 12 years of life (72). The best time for surgical release is between the ages of 1 and 4 years (63,79).

Surgical treatments include unipolar release at either the sternoclavicular or the mastoid pole, bipolar release, middle-third transection, and even complete resection. Bipolar release, combined with Z-plasty of the sternal attachment (Fig. 21-13), yielded 92% satisfactory results in one series, whereas only 15% satisfactory results were obtained with other procedures (78). Middle-third transection has also been reported to give 90% satisfactory results (80). Z-plasty lengthening maintains the V contour of the neck and cosmesis, which middle-third transection does not. Structures that can be injured during surgery are the spinal accessory nerve, the anterior and external jugular veins, the carotid vessels and sheath, and the facial nerve. Skin incisions should never be located directly over the clavicle because of cosmetically unacceptable scar spreading; rather, they should be made one finger-breadth proximal to the medial end of the clavicle and sternal notch, and in line with the cervical skin creases. The postoperative protocol can vary from simple stretching exercises to cast immobilization. Some type of bracing device to maintain alignment of the head and neck is probably desirable as part of the postoperative protocol.

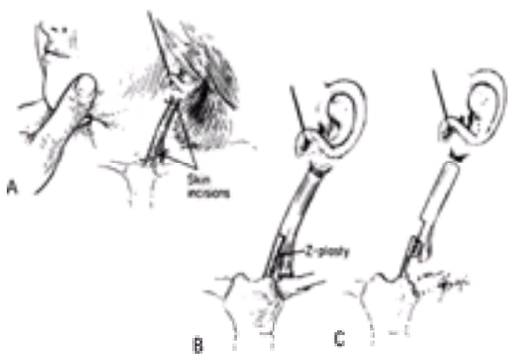

FIGURE 21.13. The Z-plasty procedure for torticollis. **A:** The location of the skin incisions. **B:** The clavicular and mastoid attachments of the sternocleidomastoid muscle are cut, and a Z-plasty is performed. Note that the medial aspect of the sternal attachment is preserved. **C:** The completed procedure after release of the proximal muscle insertion. (From ref. 78, with permission.)

Neurogenic Types

Although rare, these causes should be considered in the differential diagnosis of any atypical torticollis, especially when the condition is unresponsive or progressive in the face of therapy believed to be appropriate. The major neurogenic causes are central nervous system tumors (i.e., of the posterior fossa or spinal cord), syringomyelia with or without cord tumor, Arnold-Chiari malformation, ocular dysfunction, and paroxysmal torticollis of infancy.

Posterior fossa tumors can present with torticollis (81). The ophthalmologic literature (82) has described three children with torticollis, photophobia, and epiphora (tearing). In all three children the diagnosis was delayed, with an initial diagnosis of a local ocular inflammatory condition. The age at presentation ranged from 1 to 23 months. The delay in diagnosis ranged from 5 months to 4 years. The neoplastic diagnosis was not considered initially by the ophthalmologists because the primary signs of posterior fossa tumors are extraocular muscle paresis, nystagmus, and papilledema.

Cervical cord tumors can present with torticollis, often early in their course (83,84). Frequently, the initial diagnosis is congenital torticollis, obstetric birth palsy, muscular dystrophy, or cerebral palsy (83). The peculiar, often overlooked signs of the tumor are spinal rigidity, early spinal deformity, and spontaneous or induced vertebral pain. In young children pain may be expressed as irritability and restlessness.

Imaging of a child with a potential central nervous system tumor should consist of plain radiographs of the skull and cervical spine, followed by CT and MRI scans. Vertebral angiography also may be needed, both diagnostically and in neurosurgical planning.

The Arnold-Chiari malformation (Fig. 21-6) is caudal displacement of the hindbrain, often with other congenital deformities of the brainstem and cerebellum (85,86). It may be associated with myelomeningocele (i.e., type II malformation). The Chiari type I malformation is a downward displacement of the medulla oblongata with extrusion of the cerebellar tonsils through the foramen magnum, and is encountered in older children. Dure and colleagues (85) described 11 children with Chiari type I malformations; torticollis was the presenting complaint at 5 years of age in 1 of the 11 children. It also was associated with headaches and paracervical muscle spasm; the torticollis was left-sided. As with tumors, the workup of a child with the potential for a Chiari malformation consists of plain radiographs of the skull and cervical spine, followed by an MRI scan (85). The treatment is neurosurgical.

Ocular pathology accounts for up to one-third of children with no obvious orthopaedic cause of torticollis (87). The torticollis is usually atypical (88). These children typically present around 1 year of age. The face can be turned about a vertical axis, the head can be tilted to one shoulder with the frontal plane of the face remaining coronal, the chin can be elevated or depressed, or a combination of any of these positions can occur. These abnormal head positions optimize visual acuity and maintain binocularity. An ocular cause is likely if the head is tilted but not rotated, or if the tilt changes when the child is lying versus sitting or standing. Children with ocular torticollis have a full range of cervical motion without the fibrotic sternocleidomastoid muscle seen in congenital muscular torticollis. Ophthalmologic evaluation is usually positive for paralytic squint or nystagmus. Detailed tests conducted by an experienced ophthalmologist are diagnostic. Treatment of ocular torticollis is usually surgical.

Paroxysmal torticollis of infancy is a rare episodic torticollis lasting for minutes to days with spontaneous recovery (89,90). The attacks usually occur in the morning, with a frequency from less than one episode per month to three to four episodes per month. The attacks can be associated with lateral trunk curvature, eye movements or deviations, and alternating sides of torticollis. The children are usually girls (71%), the average age of onset is 3 months (range, 1 week to 30 months), and the recovery period is 24 months (range, 6 months to 5 years). It has been suggested that paroxysmal torticollis of infancy is equivalent to migraine headache because of positive family histories for migraines in 29% of patients, or that it is a forerunner of benign paroxysmal vertigo of childhood (90). Whatever the cause, it is usually self-limiting and does not require therapy.

Sandifer Syndrome

This is a syndrome of gastroesophageal reflux, often from a hiatal hernia, and abnormal posturing of the neck and trunk, usually torticollis (91,92). The torticollis is likely an attempt by the child to decrease esophageal discomfort resulting from the reflux. The abnormal posturing also may present as opisthotonos or neural tics and often mimics central nervous system disorders. The majority of patients present in infancy. The incidence of gastroesophageal reflux is high (up to 40% of infants) (93), with the principal symptoms being vomiting, failure to thrive, recurrent respiratory disease, dysphagia, various neural signs, torticollis, and respiratory arrest. The diagnosis of symptom-causing gastroesophageal reflux frequently is overlooked. On careful examination of these infants the tight and short sternocleidomastoid muscle or its tumor is not seen, eliminating congenital muscular torticollis. Further workup excludes dysplasias and congenital anomalies of the cervical spine and central nervous system disorders. In these situations, the physician should consider Sandifer syndrome in the differential diagnosis.

Plain radiographs of the cervical spine eliminate congenital anomalies or dysplasias; contrast studies of the upper gastrointestinal tract usually demonstrate the hiatal hernia and gastroesophageal reflux (94). Esophageal pH studies may be necessary; many children, both asymptomatic and symptomatic, show evidence of gastroesophageal reflux (95). Treatment begins with medical therapy. When this fails, fundoplication can be considered, which is usually curative (96).

Klippel-Feil Syndrome

Klippel-Feil syndrome consists of congenital fusions of the cervical vertebrae clinically exhibited by the triad of a low posterior hairline, a short neck, and variably limited neck motion (97). Its incidence is approximately 0.7% (98). Other associated anomalies are often present in both the musculoskeletal and other organ systems. The congenital fusions result from abnormal embryologic formation of the cervical vertebral mesenchymal anlages. This unknown embryologic insult is not limited to the cervical vertebrae, and explains the other anomalies associated with Klippel-Feil syndrome.

Approximately one-third of these children have an associated Sprengel deformity. Other anomalies associated with the syndrome are scoliosis (both congenital and idiopathic like) (97), renal anomalies (99), deafness (100), synkinesis (mirror movements) (101), pulmonary dysfunction (102), and congenital heart disease (103).

Radiographs demonstrate a wide range of deformity, ranging from simple block vertebrae to multiple and bizarre anomalies. Associated scoliosis makes interpretation of the radiographs even more difficult. Flexion and extension lateral radiographs are used to assess for instability, and should always be made before any general anesthetic is administered. Any segment adjacent to unfused segments may develop hypermobility and neurologic symptoms (104). A common pattern is fusion of C1-C2 and C3-C4, leading to a high risk of instability at the unfused C2-C3 level (105). If the flexion and extension radiographs are difficult to interpret, flexion and extension CT or MRI scans can be useful. CT is especially helpful at the C1-C2 level in assessing the SAC; sagittal MRI is more helpful at other levels.

All children with Klippel-Feil syndrome should be further evaluated for other organ system problems. A general pediatric evaluation should be undertaken by a qualified pediatrician to ensure that no congenital cardiac or other neurologic abnormalities exist. Renal imaging should be performed in all children; simple renal ultrasonography is usually adequate for the initial evaluation (106). MRI should be performed whenever any concern for neurologic involvement exists on a clinical basis, and before any orthopaedic spinal procedure (107).

The natural history depends on the presence of renal or cardiac problems with the potential for organ system failure and death. Cervical spine instability (108) can develop with neurologic involvement, especially in the upper segments or in segments with iniencephaly (108,109). Degenerative joint and disc disease develops in patients with lower-segment instabilities. In adulthood, many patients with Klippel-Feil syndrome will complain of headaches, upper-extremity weakness, or numbness and tingling. Subtle findings on neurologic examination can be seen in up to half of these adults. Degenerative disc disease, as seen on MRI scans, occurs in nearly 100% of these patients (110).

Because children with large fusion areas are at high risk for developing instabilities, strenuous activities should be avoided, especially contact sports. Other nonsurgical methods of treatment are the use of cervical traction, collars, and analgesics when mechanical symptoms appear, usually in the adolescent or adult patient. Arthrodesis is needed for neurologic symptoms because of instability. Asymptomatic hypermobile segments pose a dilemma with regard to stabilization.

Unfortunately, no guidelines exist for this problem. The need for decompression at the time of stabilization depends on the exact anatomic circumstance, as will the need for combined anterior and posterior fusions versus simple posterior fusion alone. Surgery for cosmesis alone is usually unwarranted and risky.

Os Odontoideum

Os odontoideum is a rare anomaly in which the tip of the odontoid process is divided by a wide transverse gap, leaving the apical segment without its basilar support (111). The exact incidence is not known. It most likely represents an unrecognized fracture at the base of the odontoid, or damage to the epiphyseal plate during the first few years of life, although a congenital cause has also been proposed. Either of these conditions can compromise the blood supply to the developing odontoid, resulting in the os odontoideum. MRI scans have further documented the presence of nuchal cord changes consistent with trauma (112).

Local neck pain is the usual presentation; transitory episodes of paresis, myelopathy, or cerebral brainstem ischemia, attributable to vertebral artery compression from the upper cervical instability, is less common. Sudden death rarely occurs.

Radiographs demonstrate an oval or round ossicle with a smooth sclerotic border of variable size, located in the position of the normal odontoid tip. It is occasionally located near the basioccipital bone in the foramen magnum area. The base of the dens is usually hypoplastic. The gap between the os and the hypoplastic dens is wider than in a fracture, usually well above the level of the facets. However, it may be difficult to differentiate an os odontoideum from nonunion after a fracture. Tomograms and CT scans are useful to further delineate the bony anatomy, and flexion and extension lateral radiographs are useful to assess instability. The instability index and the sagittal plane rotation angle can be measured (113). The presence of myelopathy is highly correlated with a sagittal plane rotation angle of greater than 20 degrees and an instability index of greater than 40%.

The neurologic symptoms are caused by cord compression from posterior translation of the os into the cord in extension or from translation of the odontoid into the cord in flexion. Hypermobility at the C1-C2 level may cause vertebral artery occlusion with ischemia of the brainstem and posterior fossa structures; this will result in seizures, syncope, vertigo, and visual disturbances.

Patients with local pain or transient myelopathies often recover with immobilization. Subsequently, only nonstrenuous activities should be allowed, but the curtailment of activities in the pediatric age group can be difficult. The risk of a small insult leading to catastrophic quadriplegia and death must be weighed. The long-term natural history is unknown.

Surgery is indicated when there is 10 mm or more of ADI, an SAC of 13 mm or less (11), neurologic involvement, progressive instability, or persistent neck pain. Surgery should also be strongly considered in asymptomatic patients with an instability index of greater than 40% and/or a sagittal plane rotation angle of greater than 20 degrees. A Gallie fusion is recommended. The surgeon must be careful when tightening the wire so that the os is not pulled back posteriorly into the canal and cord with disastrous consequences. In small children the wire may be eliminated. In all children a Minerva or halo cast or vest also is used for at least 6 weeks, and often for 12 weeks.

Developmental and Acquired Stenoses and Instabilities

Down Syndrome

Because of underlying collagen defects in these children, cervical instabilities can develop at both the occiput–C1 and C1-C2 levels. The instability may occur at more than one level, and in more than one plane (e.g., sagittal and rotary planes). With the advent of the Special Olympics, there has been much concern regarding the participation of children with Down syndrome, and much confusion regarding the appropriate approach to the problem of upper cervical instability in these children. Outlined below are the most recent recommendations regarding this problem.

Atlantooccipital hypermobility recently has been described in Down syndrome children. The incidence of occiput–C1 instability has been reported to be as high as 60% in children (15) and 69% in adults (114). The vast majority are asymptomatic (115,116). Measurement reproducibility is poor (117), but a Powers ratio of less than 0.55 is more likely to be associated with neurologic symptoms (118). No guidelines exist regarding the frequency of periodic screening or the indications for surgery, with the exception of those for atlantooccipital fusion in the symptomatic child. Tredwell and colleagues (15) believe that treatment plans for these children should depend on the amount of room available for the cord, rather than on absolute values of displacement for both atlantoaxial and atlantooccipital instability. This area requires further investigation.

Atlantoaxial instability in children with Down syndrome was first reported by Spitzer and colleagues (114) in 1961. Subsequently, there have been many reports on this instability. Despite these reports, there is no documentation of the true incidence of atlantoaxial dislocation (in contrast to instability), and there are no long-term studies regarding the natural history of this problem.

The incidence of atlantoaxial instability in children with Down syndrome has been estimated to range from 9 to 22% (15,119,120 and 121). The incidence of symptomatic atlantoaxial instability is much less; it was reported to be 2.6% (119) in a series of 236 Down syndrome patients. Progressive instability and neurologic deficits are more likely to develop in male patients older than 10 years (121). Children with Down syndrome have a significantly greater incidence of cervical skeletal anomalies, especially persistent synchondrosis and spina bifida occulta of C1, than do normal children (122). Also, children with both Down syndrome and atlantoaxial instability have an increased frequency of cervical spine anomalies, compared with other Down syndrome children without atlantoaxial instability (122). These spinal anomalies may be a contributing factor in the cause of atlantoaxial instability in these children.

The majority of children with atlantoaxial or occipitoatlantal hypermobility are asymptomatic. When symptoms occur they are usually pyramidal tract symptoms, such as gait abnormalities, hyperreflexia, easy fatigability, and quadriparesis. Occasionally, local symptoms exist, such as head tilt, torticollis, neck pain, or limited neck mobility. The neurologic deficits are not necessarily attributable to hypermobility of the atlantoaxial or occipitoatlantal joints. Neurologic symptoms in one series of adult Down syndrome patients were equally as common in those with an increased ADI as in those with a normal ADI (123). Further evaluation with flexion/extension CT or MRI scans to assess for cord compression is needed in this situation.

Rarely does sudden catastrophic death occur. Nearly all of the individuals who have experienced catastrophic injury to the spinal cord have had weeks to years of preceding, less severe neurologic abnormalities. In a recent review by the American Academy of Pediatrics, 41 cases of symptomatic atlantoaxial instability were compiled. In only 3 of these 41 children did the initiation or worsening of symptoms of atlantoaxial instability occur after trauma during organized sports activities (120).

In the past, screening of Down syndrome patients with lateral flexion/extension radiographs was recommended (124). However, symptomatic atlantoaxial instability is very rare, and the chances of a sports-related catastrophic injury are even rarer. The reproducibility of radiographic screening for atlantoaxial and occipitoatlantal mobility is poor (116,117). Furthermore, the radiologic picture can change over time, most frequently from abnormal to normal (121). Because of all these factors, and the absence of any evidence that a screening program is effective in preventing symptomatic atlantoaxial and occipitoatlantal mobility, lateral cervical radiographs are of unproven value, and the previous recommendations for screening radiographs by the American Academy of Pediatrics have been retired (120).

The identification of patients with symptoms or signs consistent with symptomatic spinal cord injury is thus more important than radiographs. Neurologic examination is often difficult to perform and interpret in these children (15). Parental education regarding the early signs of myelopathy is extremely important (e.g., increasing clumsiness and falling, worsening of upper-extremity function). A thorough history and neurologic examination are more important before participation in sports than are screening radiographs. However, further research is needed in this confusing matter, and because of persistent concerns, the Special Olympics does not plan to remove its requirement that all Down syndrome athletes have radiographs of the cervical spine before athletic participation.

Because of this requirement, spinal radiographs are often obtained without neurologic symptoms. When these are available, they should be reviewed to determine if there are any other associated anomalies, such as persistent synchondrosis of C2, spina bifida occulta of C1, ossiculum terminale, os odontoideum, or other less common anomalies. When the plain radiographs indicate atlantoaxial or atlantooccipital instability of 6 mm or more in an asymptomatic patient, CT and MRI scans in flexion and extension can determine the extent of neural encroachment and cord compression.

Once a Down syndrome patient presents with radiographic instability, what treatment should be instituted? Those with asymptomatic atlantoaxial or occipitoatlantal hypermobility should probably be followed up with repeat neurologic examinations; the role of repeat radiographs is more clouded, as noted in the previous

discussion. Because the risk of a catastrophic spinal cord injury is extremely low with organized sports in Down syndrome children without any neurologic findings, the avoidance of high-risk activities must be individualized. For those children with sudden onset or recent progression of neurologic symptoms, immediate fusion should be undertaken if appropriate imaging confirms cord compromise. The most difficult question concerns the patient with upper cervical hypermobility with minimal or nonprogressive chronic symptoms. Before embarking on arthrodesis, imaging with flexion/extension MRI (48) or CT should be undertaken to confirm cord compression from the hypermobility, and to eliminate other central nervous system causes of neurologic symptoms. CT is faster, reducing the need for sedation, which is potentially dangerous in these children. CT also easily visualizes the C1-C2 relationships necessary to measure the SAC. MRI is more useful for evaluating other central nervous system lesions. Even if successfully stabilized, patients with chronic symptoms often show little symptomatic improvement after arthrodesis (125).

Posterior cervical fusion at the levels involved is the recommended surgical treatment. The classic technique for posterior C1-C2 fusion uses autogenous iliac crest bone grafting, with wiring and postoperative halo cast immobilization. Internal fixation with wiring provides protection against displacement, shortens the time of postoperative immobilization, permits the consideration of using less-rigid forms of external immobilization, and is reported to aid in obtaining fusion. However, internal fixation with sublaminar wiring poses added risk. If the instability does not reduce on routine extension films the patient is at high risk for development of iatrogenic quadriplegia with sublaminar wiring and acute manipulative reduction (126,127). For this reason, it has been recommended that preoperative traction be used to effect the reduction. If reduction does not occur with traction, then only onlay bone grafting should be performed without sublaminar wiring (126). Sublaminar wiring at C2 is not recommended, regardless of the success of reduction, because it was associated with the only death in a recent series at the author's institution (128). If wiring is to be performed, pliable, smaller-caliber wires should be used. Satisfactory results can be obtained with onlay bone grafting and rigid external immobilization without internal fixation (129).

The Down syndrome patient is at higher risk for postoperative complications (neurologic and other) after fusion (130,131 and 132). Neurologic complications can range from complete quadriplegia and death to Brown-Séquard syndrome (128). Another potential cause of neurologic impairment is overreduction, if an unstable os odontoideum is present (128). A posterior translation of the ring of C1 and the os fragment into the SAC can occur from this overreduction. In a study of the results of surgical fusion in 35 symptomatic Down syndrome children, 8 made a complete recovery, 14 showed improvement, 7 did not improve, 4 died, and the outcome for 2 is unknown (119). Patients with long-standing symptoms and marked neural damage showed no or little postoperative improvement, whereas patients with more recent onset of symptoms usually made an excellent recovery. Other complications are loss of reduction despite halo cast immobilization, and resorption of the bone graft with a stable fibrous union or unstable nonunion (129,130) (Fig. 21-14).

FIGURE 21.14. A: The child in Figure 21-2 underwent posterior cervical fusion from the occiput to C2 with internal fixation and an autogenous iliac crest bone graft. **B** and **C:** Halo vest immobilization was maintained for 4 months postoperatively, and was followed by a Philadelphia collar. Despite this the boy progressed to nonunion, as indicated by graft resorption, wire breakage, and subsidence of the Luque rectangle, although flexion and extension radiographs 1.5 years postoperatively showed a marked decrease in hypermobility. The atlantooccipital distance was 4 mm, with only a 1-mm change of the atlanto-dens interval; the space available for the cord measured 18 mm in flexion and 19 mm in extension. The child's neurologic symptoms also disappeared.

The long-term results after cervical fusion are not yet known. Individuals with Down syndrome who undergo short cervical fusions are at risk for developing instability above the level of fusion, such as occiput–C1 after a C1-C2 fusion, or C1-C2 after lower-level fusions (133). This later instability occurred in four of five children between 6 months and 7 years after surgery.

Nontraumatic Occipitoatlantal Instability

Nontraumatic occipitoatlantal instability is rare in the absence of any underlying syndrome (e.g., Down syndrome). Georgopoulos and colleagues (134) have described pediatric nontraumatic atlantooccipital instability. Congenital enlargement of the occipital condyles may have been the cause by increasing motion at this joint. The presenting symptoms were severe vertigo in one 14-year-old boy and nausea with projectile vomiting in one 6-year-old girl. These symptoms are postulated to be a result of vertebrobasilar arterial insufficiency resulting from the hypermobility at the occiput–C1 junction. The diagnosis of instability was suggested by plain radiographs initially, and confirmed by cineradiography. Both children were treated with a posterior occiput–C1 fusion with resolution of symptoms.

Cerebral Palsy

Cervical radiculopathy and myelopathy in cerebral palsy (135,136,137 and 138) were first described in the athetoid types, and subsequently in the spastic types. Athetoid cerebral palsy patients, compared with the normal population, develop cervical disc degeneration at a younger age. This degeneration progresses more rapidly and involves more levels. Angular and listhetic instabilities also are more frequent and appear at a younger age (139). The combination of disc degeneration and listhetic instability predisposes these patients to a relatively rapid, progressive neurologic deficit.

The symptoms are brachialgia and weakness of the upper extremity, with decreased functional use or increased paraparesis or tetraparesis (136,137 and 138). In ambulatory patients, a loss of ambulatory ability is often a sign of presentation. Occasional loss of bowel and bladder control also occurs.

Radiographic findings (Fig. 21-15) are narrowing of the spinal canal and premature development of cervical spondylosis; malalignment of the cervical spine with localized kyphosis, increased lordosis, or both; and instability of the cervical spine manifested as spondylolisthesis. Flattening of the anterosuperior margins of the vertebral bodies and beak-like projections of the anteroinferior margins are radiographic findings of the spondylosis. Myelography demonstrates stenosis, disc protrusion, osteophyte projection, and blocks in dye flow, most commonly at the C3-C4 and C4-C5 levels.

FIGURE 21.15. A 14-year-old girl with spastic quadriparesis showed progressive loss of upper-extremity function, with loss of the ability to control her wheelchair and feed herself. She also complained of some mild neck pain. **A:** The lateral radiograph shows marked stenosis from C3 to C6, as indicated by a spinal canal-to-vertebral body ratio (Torg ratio) of less than 0.8. **B:** The myelogram shows nearly complete block of the dye column from C3 to C5. This stenosis was treated by posterior laminectomy from C3 to C7, and posterior cervical fusion from C2 to T1, using Luque rectangle fixation with spinous process and facet wiring. **C:** Eight months

postoperatively there is stable fixation and solid facet joint fusion. The girl's upper-extremity strength is improved, and she is able to feed herself. (From ref. 19, with permission.)

The kyphosis, herniated discs, and osteophytes result in nerve root and cord compression. It is believed that the exaggerated flexion and extension of the neck in these young adults with cerebral palsy cause accelerated cervical degeneration and cervical stenosis earlier than in unaffected people, who develop stenosis in the late fourth and fifth decades of life. Exaggerated flexion and extension occur in patients with athetosis and writhing movements. Difficulty with head control also can cause exaggerated flexion and extension in the spastic cerebral palsy patient.

Treatment is primarily surgical. Anterior discectomy, resection of osteophytes, and interbody fusion have been the most effective methods. A halo cast is best and is well tolerated in some patients with athetosis (137). However, postoperative immobilization can be a problem for some patients, and thus some authors also recommend posterior wiring of the facets to minimize the amount of time that postoperative immobilization is needed (136). Posterior laminectomy alone (137) is contraindicated in cerebral palsy patients with developmental cervical stenosis because this increases the instability.

Postlaminectomy Deformity

Cervical kyphosis is common after cervical laminectomy in children (140,141,142,143,144,145 and 146). This phenomenon is more likely in immature, growing children. It has been duplicated in animal models; a C3-C6 laminectomy in growing cats uniformly resulted in kyphosis, whereas normal cervical curves were maintained in adult cats (147). The natural history of postlaminectomy kyphosis is unknown; however, the incidence of kyphosis when extensive cervical laminectomies are performed in childhood varies from 33 to 100%, with an overall average of 70% (145).

Postlaminectomy kyphosis is weakly age-dependent (mean age at laminectomy of 10.5 years), and is not dependent on the total number of levels decompressed or the location of these levels (145). Postlaminectomy lordosis is less common and is strongly correlated with a peak age at decompression of 4 years (145). In one study, 12 of 15 children who had undergone cervical or cervicothoracic laminectomy before 15 years of age, developed kyphosis (144). The normal posterior muscular attachments to the spinous processes and laminae, as well as facet capsules, the ligamentum nuchae, and the ligamentum flavum, are violated by the laminectomy. This loss of posterior supporting structures allows for a progressive deformity, which, if kyphotic in nature, can eventually result in neurologic symptoms and deficits. The early radiographic appearance is of a simple kyphosis; later, vertebral body wedging and anterior translations of one vertebral body on another can develop. A late, severe deformity is the swan-neck deformity (143). Neurologic problems result from cord stretching and compression from the anterior kyphotic vertebral bodies. MRI is useful to delineate the extent of cord attenuation and compression.

Nonsurgical treatment starts with frequent radiographic follow-up studies after laminectomy; the role of prophylactic bracing is not yet known. When kyphotic deformities develop, anterior vertebral body fusion with a halo cast or vest, or Minerva cast immobilization is recommended (142) (Fig. 21-16 and Fig. 21-17). The role of prophylactic posterior fusion at the time of laminectomy is not yet known (140), nor is the role of osteoplastic laminotomy, instead of laminectomy (148), although this approach might not always be amenable to the primary pathology.

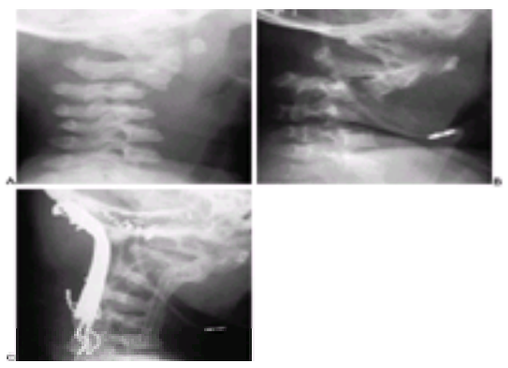

FIGURE 21.16. A: Lateral cervical spine radiograph of a 9-month-old boy with neurofibromatosis. Note the preexisting cervical kyphosis at C2-C3. At the age of 3 years he underwent a suboccipital craniectomy and cervical laminectomy from C1 to C4 for resection of neurofibromata. **B:** By the age of 3 years, 10 months, he had developed a 90-degree kyphosis. **C:** He underwent combined anterior cervical fusion from C2 to C6 with a fibular strut graft, and posterior cervical fusion from the occiput to C6 with internal fixation provided by a Luque U-rod. Three years postoperatively solid fusion, with a residual 70-degree kyphosis, is present.

FIGURE 21.17. This girl underwent a cervical laminectomy from C2 to C6 for a low-grade astrocytoma of the cervical cord. At 1 year, 7 months of age, she had a postlaminectomy kyphosis that was 45 degrees in extension (**A**) and 82 degrees in flexion (**B**). **C:** An anterior cervical discectomy and fusion from C2 to C6 was performed with an autogenous iliac crest strut graft. Immediately after the operation the kyphosis was corrected to 20 degrees. Halo vest immobilization was used for 3 months. **D:** Solid incorporation of the fusion occurred by 6 months postoperatively. At 4 years, 7 months of age, flexion (**E**) and extension (**F**) lateral radiographs show maintenance of the correction, solid fusion, and no instability at the remaining levels.

Other Syndromes

Fetal Alcohol Syndrome

Central nervous system dysfunctions, growth deficiencies, facial anomalies, and variable major and minor malformations are the characteristics of fetal alcohol syndrome. The children present with developmental delay, especially in motor milestones, failure to thrive, mild to moderate retardation, mild microcephaly, distinct facies (hypoplasia of the facial bones and circumoral tissues), and congenital cardio-vascular anomalies. The cervical findings are similar to those of Klippel-Feil syndrome. Radiographically, congenital fusion of two or more cervical vertebrae occurs in approximately one-half of these children, resembling Klippel-Feil syndrome (149). The major visceral anomaly in Klippel-Feil syndrome is in the genitourinary system, whereas in fetal alcohol syndrome, it is in the cardiovascular system (149).

The natural history is not known. Radiographic imaging and treatment recommendations regarding the cervical spine are the same as those for Klippel-Feil syndrome.

Craniofacial Syndromes

Cleft lip and palate is the most common craniofacial anomaly. It can be a solitary finding, but more often it is associated with other syndromes and anomalies. Children with cleft anomalies have a 13% incidence of cervical spinal anomalies, compared with the 0.8% incidence of children undergoing orthodontia care for other reasons (150). This incidence is highest in patients with soft palate and submucous clefts (45%). These anomalies, usually spina bifida and vertebral body hypoplasia, are predominantly in the upper cervical spine. The potential for instability is unknown, as is the natural history. No documented information regarding treatment is available; however, the clinician should be aware of this association and make sound clinical judgments as needed.

Craniosynostosis Syndromes

The craniosynostosis syndromes—Crouzon, Pfeiffer, Apert, and Goldenhar—exhibit cervical spine fusions, atlantooccipital fusions, and butterfly vertebrae (151,152 and 153). Fusions are more common in Apert syndrome (71%) than in Crouzon syndrome (38%) (151). Upper cervical fusions are most common in Crouzon and Pfeiffer syndromes (153), whereas in Apert syndrome the fusions are more likely to be complex and involve C5-C6 (151). However, this syndrome variation is not accurate enough for syndromic differentiation. Congenital cervicothoracic scoliosis with rib fusions is seen in Goldenhar syndrome, usually from hemivertebrae (153,154).

The cervical fusions are progressive with age; in younger children the vertebrae appear to be separated by intervertebral discs, but as the children grow older the vertebrae fuse together. There are no specific, standard recommendations for treatment. The author recommends following the same principles as in Klippel-Feil syndrome. The main concern is the potential difficulty with intubation in these children. Odontoid anomalies are rare; however, if any question exists regarding the stability of the cervical spine, lateral flexion and extension radiographs should be obtained.

Skeletal Dysplasias

Skeletal dysplasias are discussed in detail in Chapter 8.

Combined Soft Tissue and Skeletal Dysplasias

Neurofibromatosis. Neurofibromatosis is the most common single-gene disorder in humans. The proportion of patients with neurofibromatosis and cervical spine involvement is difficult to assess: 30% of patients in the series of Yong-Hing and colleagues (155) and 44% of patients with scoliosis or kyphosis had cervical spine lesions. The cervical lesions are often asymptomatic (155). Symptoms, when they do occur, are diminished or painful neck motion, torticollis, dysphagia, deformity, and neurologic signs ranging from mild pain and weakness to paraparesis and quadriparesis (31,156). Neck masses constituted 20% of presenting symptoms in one study of neurofibromatosis patients (157).

Radiographic features of neurofibromatosis in the cervical spine are vertebral body deficiencies and dysplasia or scalloping (155). This condition often is associated with kyphosis and foraminal enlargement. Lateral flexion and extension radiographs are recommended for all neurofibromatosis patients before general anesthesia or surgery (155). MRI is helpful for assessing the involvement of neural structures and dural ectasia. CT is useful for evaluating the upper cervical spine complex and the bony definition of the neural foramen. The natural history of neurofibromatosis in the cervical spine is unknown, but patients with severe kyphosis often develop neurologic deterioration.

Surgical indications are cord or nerve root compression, C1-C2 rotary subluxation, pain, and neurofibroma removal (155,156). A halo cast or vest is usually needed after fusion with or without internal fixation, and is usually achieved with simple interspinous wiring. Kyphosis requires both anterior and posterior fusion (Fig. 21-16). Pseudarthroses are frequent with isolated posterior fusions. Vascularized fibular grafts may be necessary to effect fusion in difficult cases (158,159). If there are no indications for surgical treatment the patient should be followed closely.

Fibrodysplasia Ossificans Progressiva. Fibrodysplasia ossificans progressiva is an inherited, autosomal dominant disorder (160) of connective tissue with progressive soft tissue ossification. The disorder itself is rare; most cases represent new spontaneous mutations. Eventually all patients with this disorder develop cervical spine changes (161), often starting in childhood. These patients usually present with neck stiffness (162) within the first 5 years of life. No cases of neurologic compromise have been reported. Other general clinical features are big-toe malformations, reduction defects of all digits, deafness, baldness, and mental retardation. Early in the course of the disease small vertebral bodies and large pedicles are seen radiographically. Occasionally, nuchal musculature ossification also is seen. Later, neural arch fusions are seen. This factor reflects the progressive ossification of the cervical spinal musculature, ligament ossification, and spontaneous fusion of the cervical discs and apophyseal joints. No effective medical treatment is known. Surgical treatment of the cervical spine has not been necessary.

TRAUMA

Injuries to the cervical spine are rare in children, and are more common in boys than in girls. In a recent study the age- and gender-adjusted incidence was 7.41 per 100,000 population per year (163); this incidence was much less in children (younger than 11 years of age, 1.19 per 100,000) than in adolescents (older than 11 years of age, 13.24 per 100,000). The cause of the injury in children is frequently a fall, whereas in adolescents it is frequently sports, recreational activities, or motor vehicle crashes. In general, children (younger than 11 years of age) are more likely to sustain ligamentous injuries and injuries to the upper cervical spine, whereas adolescents are more likely to sustain fractures and injuries to the lower cervical spine (163). By the age of 10 years the bony cervical spine has reached adult configurations, and the injuries it sustains are essentially those of the adult. Therefore, the author concentrates on those injuries sustained in the first decade of life.

Most children with potential cervical spine injuries have sustained polytrauma, and frequently arrive immobilized on backboards and wearing cervical collars. If the child is comatose or semiconscious, if there are external signs of head injury, or if the child complains of neck pain, cervical spine radiographs are needed. All children involved in motor vehicle crashes with head trauma and neck pain, or who have neurologic signs or symptoms, should have cervical spine radiographs (164,165). The views recommended for this initial screening are the cross-table lateral, open-mouth odontoid, and anteroposterior views. If the child is too critically ill to be positioned for all views, the cross-table lateral view is adequate until a complete evaluation can be performed. Cervical spine precautions must be maintained until a complete evaluation has demonstrated no injury. Once a cervical injury has been identified, close scrutiny must be undertaken to ensure that there are no other injuries in the remainder of the axial skeleton.

The child arriving in the emergency suite is often on a standard backboard. Young children have a disproportionately large head, and positioning them on a standard backboard leads to a flexed posture of the neck (166) (Fig. 21-18A). This flexion can lead to further anterior angulation or translation of an unstable cervical spine injury, and can also cause pseudosubluxation, which, in an injured child, can be difficult to interpret. To prevent this undesirable cervical flexion in young children during emergency transport and radiography, modifications must be made by either creating a recess for the occiput of the larger head or using a double mattress to raise the chest (Fig. 21-18B). A simple clinical guideline is to align the external auditory meatus with the shoulder.

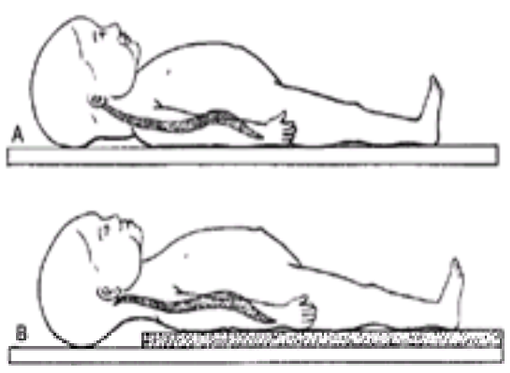

FIGURE 21.18. A: Positioning a young child on a standard backboard forces the neck into a kyphotic position because of the relatively large head. **B:** Positioning a young child on a double mattress, which raises the chest and torso and allows the head to translate posteriorly, compensates for the relatively large head. This creates a normal alignment of the cervical spine. (From ref. 166, with permission.)

Flexion and extension lateral radiographs may be necessary to determine the stability of the cervical spine; hyperflexion ligamentous injuries may not be seen immediately, and flexion and extension views a few weeks after the spasm has subsided may document instability. In one series of children with ligamentous injuries of the cervical spine 8 of 11 children with lower cervical instability were diagnosed between 2 weeks and 4 months after the trauma (167).

Secondary signs of spinal injury in children often are seen before the actual injury or fracture itself. Malalignment of the spinous processes on the anteroposterior radiograph should be regarded as highly suspicious for a jumped facet. Widening of the posterior interspinous distances should be regarded as highly suspicious for a posterior ligamentous injury. In adults, an increase in the retropharyngeal soft tissue space can indicate a hematoma in the setting of trauma, and increase the suspicion on the part of the clinician that an upper cervical fracture exists. In children, however, the pharyngeal wall is close to the spine in inspiration, whereas there may be a large increase in this space with forced expiration, as in a crying child (168). This should be remembered when considering the significance of prevertebral pharyngeal soft tissue in the cervical spine radiographs of a frightened, crying child.

CT is useful to further assess the upper cervical spine, especially the ring of the atlas, and occasionally the odontoid. As a rule, CT is not recommended for screening, but to further study suspicious areas on plain radiographs or for treatment planning. It should be used to study all fractures of C1. MRI is useful to assess the spinal cord and discs.

Fractures and Ligamentous Injuries of the Occipital Complex to the C1-C2 Complex

Atlantooccipital Dislocation

Atlantooccipital dislocation is rare (169), and most of the children do not survive (170). Deployment of air bags has been associated recently with this injury in children (171). With the present rapid response to trauma victims and more aggressive field care more of these children now survive. These children are usually polytrauma victims with severe head injuries, and present with a range of clinical neurologic pictures (169,170). In the past, those who survived had incomplete lesions, often demonstrating cranial nerve dysfunctions and varying degrees of quadriplegia. Many of the children have complete loss of neurologic function below the brainstem, and survive only because of outpatient ventilatory support. Other presentations may include a responsive child with hypotension or tachycardia, or a child in complete cardiac arrest. Occasionally, some patients present with normal neurologic examinations.

In severe cases the diagnosis is evident; however, some of the cases do not demonstrate marked radiographic displacement. In the past, a Powers ratio greater than 1.0 (Fig. 21-19A) was used to indicate the presence of atlantooccipital dislocation (172). This criterion can cause the practitioner to miss isolated distraction injuries, anterior atlantooccipital dislocations that have spontaneously reduced after injury, and posterior atlantooccipital injuries (169). For this reason, the distance between the tip of the dens and the basion (Fig. 21-19B) has been used, in which a distance of more than 12.5 mm indicates the potential for atlantooccipital dislocation.

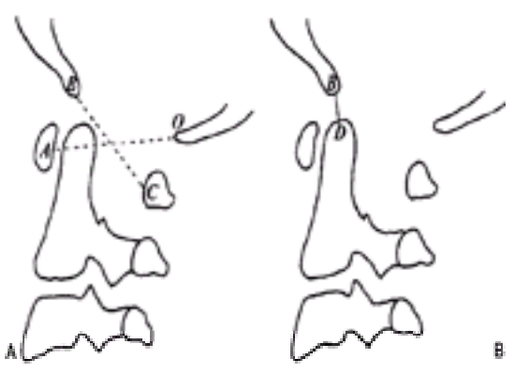

FIGURE 21.19. The *BC*:*OA* ratio (**A**) and the *DB* distance (**B**) are used to assess for traumatic atlantooccipital dislocation. (From ref. 169, with permission.)

The first obstacle in the treatment of this injury is its diagnosis. If the suspicion for craniocervical trauma is still present after inconclusive plain radiography, CT or MRI can be quite useful (Fig. 21-20). Subarachnoid hemorrhage at the craniocervical junction will be seen after atlantooccipital dislocation (173); CT can also assist in assessing osseous alignment (174). Once atlantooccipital dislocation is diagnosed, standard respiratory and other supporting measures are given. Early definitive immobilization of the dislocation should be undertaken. The immobilization can be with a halo cast alone, or with supplemental internal fixation and posterior fusion (173,175). Traction should be avoided because it can distract the joint and cause further neurologic injury. These children must be moved rapidly into an upright position to maximize pulmonary care. Late neurologic deterioration may indicate progressive hydrocephalus or retropharyngeal pseudomeningocele (176).

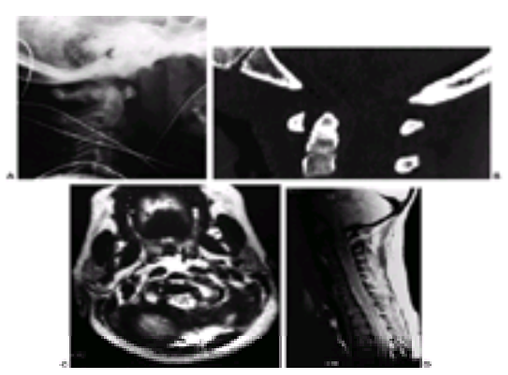

FIGURE 21.20. This 5-year, 6-month-old girl was hit by a van from behind, and presented with bilateral palsies of cranial nerve VI. **A:** The lateral radiograph of the upper cervical spine demonstrates a rotational malalignment. The basion hemishadows fail to overlap, whereas the C1 arches nearly superimpose on each other, raising the concern for atlantooccipital dislocation. **B:** A computed tomography scan with sagittal reconstruction demonstrates elevation of the periosteum at the caudal level of the clivus level (*arrows*) and hemorrhage (*arrowheads*). **C:** An axial image from the magnetic resonance imaging scan demonstrates abnormal fluid accumulation immediately anterior to the atlantooccipital junction (*arrow*). **D:** The magnetic resonance imaging scan sagittal view demonstrates subarachnoid space narrowing at the level of the foramen magnum and the atlantooccipital joint.

Fractures of the Atlas

The Jefferson fracture is rare in children (177,178). It is caused by an axial load from the head into the lateral masses. Unlike in adults, a single fracture through the ring in children may be isolated, hinging on the synchondrosis (178), instead of being a double break in the ring. A transverse atlantal ligament rupture may occur as the lateral masses separate, resulting in C1-C2 instability.

CT scans are useful in both the diagnosis of this injury and the assessment of healing. This injury in children is not commonly seen on plain radiographs, which usually show only an asymmetry between the odontoid and the lateral masses. If it is clearly seen on plain radiographs CT should also be performed to confirm the diagnosis and to rule out a transverse alar ligament rupture. Treatment is usually simple immobilization with a Minerva or halo cast. Rarely is surgery necessary unless rupture of the transverse alar ligament occurs, which renders the spine unstable. The timing of surgery needs to be individualized.

Transverse Atlantoaxial Ligament Ruptures

Transverse atlantoaxial ligament ruptures may occur from either severe or mild trauma (167). Radiographically the ADI is increased, usually well beyond the normal 5 mm. Adequate ligamentous healing and stability do not occur from simple immobilization. The recommended treatment is reduction in extension, posterior cervical C1-C2 fusion with autogenous bone graft **[➥2.17]**, and immobilization with a halo or Minerva cast. A solid arthrodesis is documented on flexion and extension lateral radiographs after 2 to 3 months of immobilization.

Odontoid Fractures

Odontoid fractures are a common pediatric cervical spine injury (179). They are usually physeal fractures of the dentocentral synchondrosis, usually Salter-Harris type I fractures. These may occur after major or minor trauma. Neurologic deficits are rare. These fractures usually displace anteriorly, with the dens posteriorly angulated (Fig. 21-21). This fracture usually is seen only on the lateral view. If there is confusion between the mild posterior angulation of the dens and a dens fracture with posterior angulation, which occurs in up to 4% of normal children (180), dynamic flexion and extension CT, with sagittal reconstruction, can be performed to evaluate for any motion or instability.

FIGURE 21.21. This 2-year, 9-month-old boy was brought to the emergency department unable to move his upper extremities, and withdrew his lower extremities only in response to noxious stimuli. He had a history of falling off a couch. On investigation it became clear that the child had been battered. **A:** A lateral radiograph demonstrates the odontoid fracture through the dentocentral synchondrosis, with anterior angulation and translation. A magnetic resonance imaging scan did not reveal any abnormalities in the cord. **B:** Simple positioning with a double mattress allowed for reduction of the fracture; the child was maintained on a double mattress for several days to allow for subsidence of cord edema and early healing. He was then placed into a Minerva cast 10 days after injury. The cast was removed 6 weeks after injury, followed by immobilization with a soft collar. Flexion (**C**) and extension (**D**) radiographs demonstrated no instability with the healed fracture. **E:** The child improved remarkably. By 2 months after injury he was running and walking without difficulty. There were some subtle upper-extremity changes, indicated by a change in hand dominance from right to left. Magnetic resonance imaging showed signal changes in the cord (*arrow*), which were interpreted as development of an early posttraumatic syrinx.

Displaced odontoid fractures in children reduce easily with mild extension and posterior translation. In most circumstances the simple double-mattress technique is all that is needed to obtain a reduction. After a few days of recumbency and early healing the fracture can be immobilized easily with the use of a Minerva or halo cast. As with all physeal fractures, healing is rapid, and immobilization usually can be stopped in 6 to 10 weeks. Flexion and extension lateral radiographs should be taken to confirm union with stability. These fractures, unlike those in adults, do not have a significant nonunion rate requiring subsequent C1-C2 fusion. The intact hinge of the anterior periosteum most likely aids in the ease of reduction and accounts for the stability of reduction and rapid healing.

Spondylolisthesis of C2

Spondylolisthesis of C2, also known as hangman fracture in adults, is rare in children. It most likely arises from hyperextension. Pizzutillo and colleagues (181) reported on a series of five cases in children. Care must be taken to not confuse this fracture with congenital anomalies that may mimic hangman fracture and lead to overtreatment. These fractures readily heal with immobilization in either a Minerva or halo cast after gentle positioning to obtain reduction. Traction alone, as with most cervical injuries in children, should be avoided because it overdistracts the spine with an increased potential for nonunion and more serious neurologic injury. Posterior cervical fusion of C1-C3 is indicated for the rare case of nonunion or instability.

Fractures and Ligamentous Injuries of C3-C7

These injuries are more common in older children and adolescents than in young children (163,182). The typical patterns of fracture usually are compression fractures of the vertebral body, or facet fractures and dislocations caused by hyperflexion. These injuries are adult patterns, and standard adult treatment should be used. Physeal fractures, usually of the inferior end plates, also can occur (183); these are caused by hyperextension. In older children they are usually ring apophyseal fractures with minimal instability or neurologic damage. In younger children they usually involve the entire end plate. Physeal fractures frequently are not recognized in severely injured children, or they may be noted for the first time at autopsy (183). They have a high incidence of neurologic damage (Fig. 21-22). In these children, simple positioning (e.g., double mattresses and rarely, traction followed by immobilization) is all that is needed for treatment. Because these are physeal injuries, healing is rapid.

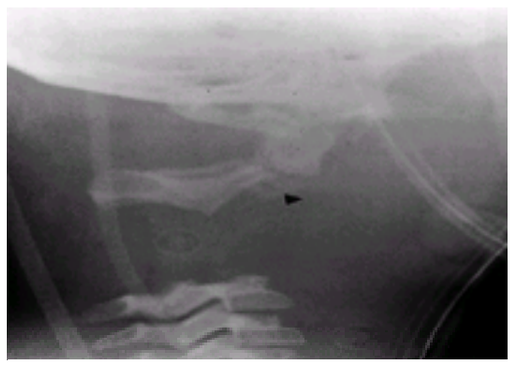

FIGURE 21.22. This 7-year, 2-month-old girl sustained polytrauma and presented in an agonal state. A lateral radiograph demonstrates complete separation at the C2-C3 level, along with an associated C2 hangman fracture. Also note the small fleck of bone (*arrowhead*) attached to the base of the C2 body; this likely represents an avulsion of the superior aspect of the body of C3 with the C2-C3 disc.

Traumatic ligamentous instability in children also can occur (167). The pivot point for younger children is in the upper cervical spine because of their large head size, weak cervical musculature, incompletely ossified wedge-shaped vertebrae, physiologic ligamentous laxity, and horizontal facet joints in this region. The upper cervical spine offers little resistance to traumatic shear forces, which often result in ligamentous instability. The goal is to differentiate this traumatic ligamentous instability from pseudosubluxation, using the posterior cervical line. In one study of ligamentous injuries of the cervical spine in children, 7 of 11 injuries occurred at the C2-C3 level (167). When instability exists, treatment should consist of posterior cervical fusion with Minerva or halo immobilization **[➥2.17]** (Fig. 21-23). Children undergoing cervical arthrodesis for cervical spine injury demonstrate decreased mobility and increased osteoarthritis at long-term follow-up (184). Treatment for a mild sprain is

immobilization for comfort followed by flexion and extension radiographs several weeks to a few months later to ensure that late instability does not occur.

FIGURE 21.23. This 4-year, 9-month-old boy was run over by a snowmobile trailer 2 weeks before these radiographs were taken. He had complained of some neck pain and had been treated by chiropractic manipulation during these 2 weeks. The flexion (**A**) and extension (**B**) radiographs demonstrate marked instability at the C3-C4 interspace, which does not completely reduce, even with extension (*arrow*). **C:** He was treated by posterior fusion with an iliac crest bone graft and interspinous wiring at C3-C4, as shown in this intraoperative radiograph. Halo vest immobilization was used for 3 months. **D** and **E:** One year postoperatively, there was no instability at the C3-C4 level, and there was solid fusion that had extended to C2 and C5, despite meticulous care not to expose the laminae of C2 and C5 or the interspinous ligaments of C2-C3 and C4-C5.

Spinal Cord Injury without Radiographic Abnormality

Spinal cord injury without radiographic abnormality (SCIWORA) occurs in 5 to 55% of all pediatric spinal cord injuries (185). By definition, no disruption, malalignment, or other abnormalities are seen on plain radiographs. The immature and elastic pediatric spine is more easily deformed than that of an adult. Momentary displacement from external forces endangers the spinal cord without disrupting bones or ligaments. The four major factors involved in this injury are hyperextension, flexion, distraction, and spinal cord ischemia. Ischemia may arise from cord contusion or direct vascular insult (186).

The neurologic deficit may range from complete cord transection to partial cord deficits. The physiologic disruption of the spinal cord is not necessarily associated with anatomic disruption. The majority of deficits (78%) are cervical; patients with upper cervical SCIWORA are more likely to have severe neurologic lesions than patients with lower cervical SCIWORA. An MRI is most useful to study the cord and disc/ligament complexes, and correlates with clinical outcome (187). The outcome usually is determined by the presenting neurologic status. Approximately one-fourth of these children have late deterioration in neurologic function.

Treatment is controversial. Immobilization in a Guilford brace for 3 months has been recommended by Pang and Pollack (185), with complete avoidance of all sports. However, in that series no instability was noted in any of the children at initial evaluation, and only one child later developed instability on flexion and extension radiographs. Without documented radiographic instability the biomechanical usefulness of brace immobilization is questionable. Pang and Pollack, however, denote this as treating “incipient instability” (185). Most ligamentous spine injuries, when allowed to heal with simple immobilization, do not return to the stability seen in the preinjury state; fusion usually is needed. It is atypical for SCIWORA to behave differently with regard to instability, incipient or otherwise. Regardless of whether the child is braced, close follow-up of neurologic function is needed. Flexion and extension radiographs should be taken after 3 months of bracing; any late development of instability requires surgical stabilization.

Transient Quadriparesis

Transient quadriparesis is a neuropraxia of the cervical cord with transient quadriplegia. It is seen most often in collegiate and professional athletes (188,189), although several cases in younger athletes have been reported (190). The incidence in the National Collegiate Athletic Association is 1.3 per 10,000 athletes per season (189).

The anteroposterior diameter of the spinal canal is decreased in these athletes. The spinal cord is compressed on forced hyperextension or hyperflexion, causing the transient quadriparesis. Sensory changes, such as burning pain, numbness, tingling, and loss of sensation, and motor changes, ranging from weakness to complete paralysis, are seen. These episodes are transient, and recovery occurs in 10 to 15 minutes; neck pain is not present at the time of injury. Transient quadriparesis needs to be differentiated from a brachial plexus stretch, or “burner.” Brachial plexus stretch presents with monoparesis of the upper extremity and often with neck pain.

No fractures or dislocations are present. The ratio of the spinal canal to the vertebral body is decreased, with a value of 0.8 used to indicate significant developmental cervical stenosis. Congenital fusions, cervical instability, and intervertebral disc disease also may exist. In children, this spinal canal–to-vertebral body ratio is not as accurate, and is inconsistent in predicting spinal cord concussion (190). An MRI may be necessary to assess the presence or absence of a herniated nucleus pulposus.

Symptom resolution is universal. The only nonsurgical treatments that are needed are the use of collars, analgesics, and antispasmodics. The role of fusions for coexistent instability, discectomy for herniated nucleus pulposus, or decompression for congenital cervical stenosis is not known.

The major concern is whether or not athletic participation should continue, and if so, what is the risk of permanent quadriplegia developing with a later episode. Torg and colleagues (191) believe that athletes with pure developmental spinal stenosis are not predisposed to more severe injuries if they return to sports, and that only those with instability or degenerative changes should be precluded from participation in contact sports. Odor and colleagues (192) found that one-third of professional and rookie football players have a spinal canal ratio of less than 0.8, and that it is difficult to make continued play decisions based on this ratio alone. Eismont and colleagues (193), however, have shown that smaller cervical canals are correlated with significant neurologic injury in routine trauma. Considering this finding, and the fact that narrowing of the spinal canal correlates even more poorly with spinal cord concussion in children (190), it is prudent to preclude any child who has had a cervical cord concussion from further contact sports until further epidemiologic data have been established.

Special Injury Mechanisms

Birth Injuries and Battered Children

Birth trauma is a common cause of pediatric spinal cord injury, and usually involves the cervical cord (194,195). As in SCIWORA, the vertebral column is more elastic than the cord, and during delivery with prolonged distraction it may be tethered by nerve ends and blood vessels, injuring the cord but not the chondroosseous structures. Damage to the vertebral artery with resultant ischemia of the cord also can occur (196). In battered children, the large head, poorly supported by the cervical musculature, makes the upper cervical spine vulnerable to repeated shaking, with either SCIWORA or fracture.

The diagnosis is difficult, especially with incomplete neurologic injury. Pure transection of the cord itself is rare (197). Temperature regulation dysfunction can cause fevers, reflex movements may be mistaken for voluntary movements, and respiratory distress can occur from paralyzed intercostal muscles. These children also may present with a cerebral palsy-like picture (198) or as victims of sudden infant death syndrome (199). In one study, the diagnosis was delayed in three of four children, and the delay averaged 4.4 years from birth (200). Typically, no fractures are seen radiographically; MRI is often helpful in assessing cord damage.

Some children without complete transection can improve neurologically. Treatment is usually nonsurgical because these are very young infants. Bed rest, respiratory support, and physical therapy, to prevent paralytic contractures, should be instituted. Older children with bony injuries may need Minerva casts (Fig. 21-21). Surgical fusion and stabilization rarely are needed.

Car Seat Injuries

Cervical fractures are described with the increased and recent use of infant car seats (201). When these devices, which clearly make automobile travel safer for children, are not adequately tightened serious and potentially fatal injuries can occur. The harness must be adjusted periodically to account for normal growth and seasonal changes in clothing thickness. Car seat styles that allow the main lock to be attached to the crotch strap (Fig. 21-24) prevent forward sliding movements which can apply hyperextension forces to the head, the neck, and the upper chest.

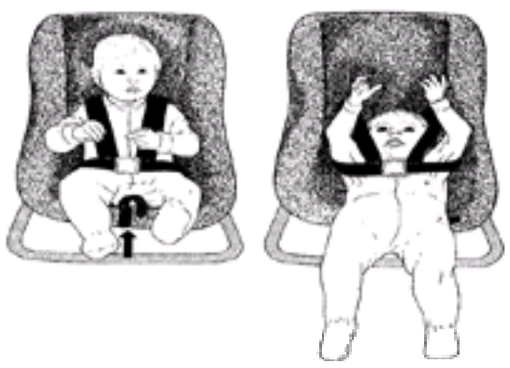

FIGURE 21.24. Placing a child in a car seat without locking the crotch strap (*arrow*) is a dangerous situation, and can allow serious injury in a collision. (From ref. 201, with permission.)

Gunshot Wounds

Spinal injuries from gunshot wounds (202) are increasing, and currently account for half of all adolescent spinal cord injuries (203). One-third of these injuries involve the cervical spine. Various degrees of neurologic loss are noted, with complete lesions in 75% in one series (202). Other body areas can be injured as well, which may cause more morbidity than the trauma to the neck itself.

Various degrees of fracture and intracanal bullets are seen radiographically. Other imaging studies, such as arteriography and esophagography, often are needed to look for other injuries. Panendoscopy is useful to assess injury to the trachea and esophagus. Spinal decompression is not indicated in either complete or incomplete lesions. For patients with complete injuries removal of retained bullet fragments from the canal does not improve neurologic outcome. Patients who undergo decompression have a higher risk of meningitis and spinal instability without any added benefit. Spinal instability is rare unless laminectomy is performed. Indications for neck exploration are a positive arteriogram, impending airway obstruction, tracheal deviation, widened mediastinum, expanding hematoma, and appropriate pathology on panendoscopy. Routine exploration of the neck and wound is not advised.

INFLAMMATORY AND SEPTIC CONDITIONS

Juvenile Rheumatoid Arthritis

Juvenile rheumatoid arthritis is a chronic synovitis that can affect the joints of the cervical spine as well. The subtypes that usually involve the cervical spine are the polyarticular and systemic onset types; only rarely does the pauciarticular type affect the cervical spine (204).

Cervical spine involvement usually occurs in the first 1 to 2 years from disease onset and presents with stiffness. Pain and torticollis are rare, and when they occur in a patient with juvenile rheumatoid arthritis other causes should be examined, such as fracture, infection, or tumor. Torticollis was present in only 4 of 92 children in the series of Fried and colleagues (205), and in only 1 of 121 children in the series of Hensinger and colleagues (204). Neurologic findings are also infrequent in these children.

The radiographic features consist of seven types (204):

1. Anterior erosion of the odontoid process
2. Anteroposterior erosion of the odontoid process (apple-core odontoid) (Fig. 21-25)

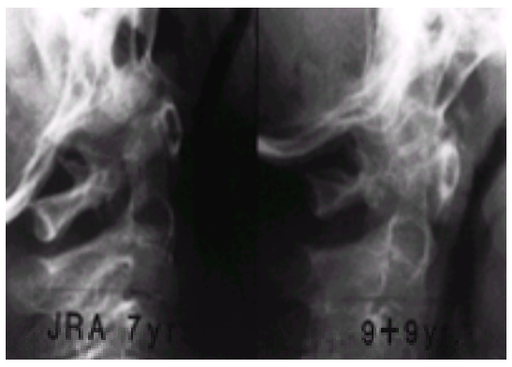

FIGURE 21.25. A boy with polyarticular juvenile rheumatoid arthritis. At 7 years of age there was only slight erosion of the anterior part of the odontoid but by 9 years of age there was an apple-core lesion exhibited by both marked anterior and posterior erosion of the odontoid. (From ref. 204, with permission.)

3. Subluxation of C1 on C2
4. Focal soft tissue calcification appearing adjacent to the ring of C1 anteriorly
5. Ankylosis of the apophyseal joints
6. Growth abnormalities
7. Subluxations between C2 and C7

The most common radiographic features in children with neck stiffness are soft tissue calcification at the leading edge of C1, anterior erosion of the odontoid process, and apophyseal joint ankylosis. Although there may be mild hypermobility at C1-C2 with flexion and extension, true instability or myelopathy is rare. Basilar invagination, which often occurs in adult rheumatoid arthritis, also is rare in juvenile rheumatoid arthritis (205). The radiographic findings of juvenile rheumatoid arthritis that differ most from those of adult rheumatoid arthritis are late destruction of articular cartilage and bone, growth disturbances, spondylitis with associated vertebral subluxation and apophyseal joint ankylosis, and micrognathia (206). In five patients who had long-standing disease (average age, 19 years), Hallah and colleagues (207) described a nonreducible head tilt attributable to collapse of an atlantoaxial lateral mass.

Other imaging studies are needed in the child with juvenile rheumatoid arthritis and neck pain. A bone scan is used to pinpoint the exact anatomic location of activity, and the anatomy is further studied by CT. These studies can be helpful in looking for occult fractures, infections, and bony tumors.

Odontoid erosion results from the inflammatory synovitis and the pannus of the synovial ring surrounding the odontoid process. The pannus erodes the odontoid anteriorly and posteriorly, but leaves the apical and alar ligament attachments free, creating the apple-core lesion. This lesion is more susceptible to fracture, both

from erosions and from vascular compromise to the odontoid, because the blood supply to the odontoid courses along its side (208), and may be disturbed by the invading pannus. Ankylosis of the apophyseal joints is most common in the systemic-onset subtype. In these young children posterior ankylosis of the immature spine creates a tether, preventing further anterior growth. Decreased disc-space height and smaller vertebral bodies, both longitudinally and circumferentially, result.

The treatment is generally nonsurgical, in conjunction with good rheumatologic care. Patients rarely develop flexion deformities; early in the course of the disease, a cervical collar may prevent this deformity (205). A cervical collar is recommended for patients with involvement of the odontoid process or subaxial subluxation whenever they are in an automobile or other mode of travel. If these patients need surgery for any reason intubation can be difficult because of the micrognathia, flexion deformity, and neck stiffness. Cervical fusion rarely is needed, and should be reserved for children with documented instability or progressive neurologic deterioration.

Intervertebral Disc Calcification

The first description of pediatric disc calcification appeared in 1924, and there are now more than 100 cases reported in the literature (209). It is slightly more common in boys than in girls (7:5 ratio), with an average age at presentation of 8 years (range, 8 days to 13 years). It occurs most often in the cervical spine, and is especially symptomatic when located there. The cause is unclear. Theories proposed are antecedent trauma (present in 30% of patients) and recent upper respiratory infections (present in 15% of patients, which may only reflect the normally high incidence of pediatric upper-respiratory infections). There is no evidence to suggest metabolic disorders.

The most common clinical presentation is neck pain, which occurs in about one-half of the children (209). The onset of symptoms is abrupt: between 12 and 48 h. Twenty-three percent of the children are febrile on presentation. Torticollis occurs in one-fourth of the children. Decreased cervical motion and spinal tenderness also can occur. Radicular signs and symptoms rarely may be seen, and they are never seen without local symptoms. Myelopathy is rare (3 of 127 cases).

Calcified deposits are seen delineating the nucleus pulposus. The number of calcified discs averages 1.7 per child (Fig. 21-26). No protrusions have been seen in the asymptomatic group; 38% of symptomatic children have detectable protrusions. Recent reports have also shown signal changes in the vertebrae on MRI (210).

FIGURE 21.26. A: A 7-year-old boy with symptomatic intervertebral disc calcification at the C6-C7 level, as seen on a lateral radiograph. **B:** He also showed asymptomatic involvement at the T3-T4, T4-T5, and T5-T6 levels, as seen on an anteroposterior radiograph.

Two-thirds of the children are free of symptoms within 3 weeks, and 95% are free of symptoms by 6 months. The radiographs show regression or disappearance of the calcific deposits in 90% of patients; about one-half of the radiographic improvement occurs within 6 months. Children who are asymptomatic may not show radiographic regression, even when followed for long periods. Children with multiple lesions show different rates of regression at the different disc levels. In some cases, persistent flattening of the vertebral bodies is noted into adulthood, and may result in early degenerative changes (211).

Because of this natural history, treatment is symptomatic unless there is spinal cord compression. Analgesics, sedation, and cervical traction can all be used, depending on the severity of symptoms. A short trial of a soft cervical collar also may be helpful. Contact sports probably should be avoided. Surgical intervention rarely is needed. Two cases have been reported in which anterior discectomy was performed (212,213).

Pyogenic Osteomyelitis and Discitis

Pyogenic osteomyelitis and discitis is a spectrum of disease defined as a symptomatic narrowing of the disc space, often associated with fever and infection-like symptoms and signs. It affects all pediatric age ranges, and is more common in boys than in girls. The cause is most likely infectious in nature; in about one-third of the children an organism can be isolated, usually *Staphylococcus aureus* (214,215).

The children present with pain, difficulty in walking and standing, fever, and malaise. This disorder usually involves the lumbar spine, with cervical involvement being rare. Early on, there is a loss of disc-space height; later, end-plate irregularities on both sides of the disc appear. Bone scans are very useful for identifying the presence of discitis and osteomyelitis in a child with systemic symptoms, when the anatomic location cannot be localized on clinical examination. The MRI findings are consistent with vertebral osteomyelitis (214,216). Other helpful diagnostic studies are determination of erythrocyte sedimentation rate and blood cultures. Disc and bone cultures are necessary only if the child does not respond to an initial course of rest and antibiotic treatment.

Many of these children improve spontaneously without treatment. The intervertebral disc space reconstitutes to varying degrees, but never to the normal height before illness. Sometimes spontaneous vertebral body fusion occurs. Initially nonsurgical treatment is given. This includes rest, immobilization, and intravenous antistaphylococcal antibiotics. Surgery is necessary only when there is no response to nonsurgical management; usually, biopsy and culture to isolate the infectious agent is all that is needed.

Tuberculosis

Mycobacterium tuberculosis infection in the cervical spine is rare compared with other levels of the spine. There will likely be an increase in North America as a result of the increasing number of immigrants from Third World countries, the rise of human immunodeficiency virus infection, and the emergence of drug-resistant strains. There have been two very thorough reviews of this subject (217,218). Four of 6 patients with upper cervical spine involvement, and 24 of 40 patients with lower cervical spine involvement, were children.

In cases of upper cervical spine involvement the children present with neck pain and stiffness; torticollis, headaches, and constitutional symptoms may also be present. Neurologic symptoms vary from none to severe quadriparesis. In cases of lower cervical spine involvement, the children present with the same symptoms, and also may have dysphagia, asphyxia, inspiratory stridor, and kyphosis. In children younger than 10 years of age, more diffuse and extensive involvement is seen, with large abscesses but with a decreased incidence of paraplegia and quadriplegia. The neurologic symptoms have a gradual onset over a period of 4 to 8 weeks. Sinus formation is not a prominent feature because of the thick cervical prevertebral fascia that contains the abscess. Cord compression occurs from the abscess and the kyphosis. Cultures and biopsies are not always positive. Because the infection is anterior, most cases will progress to spinal cord compression and paralysis if left untreated.

Increased width of the retropharyngeal soft tissue space is seen radiographically, as are osteolytic erosions. Instability at the C1-C2 level can be seen in some children; rarely is there a fixed C1-C2 rotatory subluxation. Kyphosis is present in one-fourth of patients with lower cervical spine involvement. Other useful imaging studies are chest radiography and renal studies.

Treatment involves antituberculous chemotherapy in all children. Surgery also is recommended for the cervical spine because it gives rapid resolution of the pain, upper respiratory obstruction, and spinal cord compression. This is in contrast to the thoracic and lumbar spine, in which chemotherapy alone is an established method of treating tuberculosis (219). Debridement is performed with or without grafting. For children younger than 2 years of age, grafting usually is not needed. For

children with upper cervical spine involvement, consideration should be given to anterior transoral drainage and fusion across the lateral facet joints. Most children need halo traction with reduction before drainage, if possible.

HEMATOLOGIC AND ONCOLOGIC CONDITIONS

The primary hematologic condition affecting the cervical spine is hemophilia (220). The involvement is usually asymptomatic, although mild neck discomfort may occur. Diminished lateral rotation can be noted on physical examination. Radiographic findings, which begin to occur in adolescence and early adulthood, consist of cystic changes in the vertebral bodies or end-plate irregularities. Rarely is C1-C2 instability present. These radiographic changes can occur in patients with all degrees of severity of hemophilia. The pathoanatomy of these changes in the cervical spine is not known.

Many of these degenerative changes occur earlier than in the normal population; the natural history of these premature changes in the hemophiliac population is not known. There are no treatment recommendations at present other than standard hemophiliac precautions.

Benign Tumors

The common benign tumors that involve the pediatric cervical spine (221,222) are eosinophilic granuloma, osteoid osteoma and osteoblastoma, osteochondroma, and aneurysmal bone cyst. All can be defined as neoplastic disorders without the propensity to metastasize. Although pathologically and physiologically benign, they can be clinically malignant if their surgical accessibility or risk of recurrence places the neural structures at high risk.

The majority of patients with benign cervical vertebral neoplasms are younger than 20 years of age and present with local neck pain (222). Radicular pain may occur in up to one-third of patients (223); gross motor or sensory deficits are much less common. Neoplasms can cause torticollis. Probably the most common neoplasm causing childhood torticollis is osteoid osteoma. In a recent series from the author's institution all four children with cervical osteoid osteomas presented with painful torticollis and decreased neck motion (224). The incidence in the literature of torticollis ranges from 10 to 100% in children with cervical osteoid osteomas (225,226 and 227). The pain of osteoid osteoma classically responds to aspirin or other nonsteroidal antiinflammatory medications.

With osteoid osteoma the typical radiographic feature is sclerosis (Fig. 21-27), although it is not always evident. Bone scans are very helpful to locate the lesion; CT is then used to further delineate the anatomy. The osteoid osteoma causes a sclerotic reaction in the surrounding bone, but usually does not invade the epidural space. It is usually located in the laminae, followed by the pedicle and the body. An osteoblastoma is usually a mixture of lytic and blastic elements (228). Bone scans are also positive, but usually are not needed to determine the presence or absence of disease because most tumors are seen on plain radiographs. CT is very helpful to further assess the anatomy, especially the presence or absence of epidural invasion, which is common in osteoblastoma. Typically, it is located in the posterior elements. Osteochondromas of the cervical spine (229,230) have the typical radiographic appearance seen in other parts of the body: expansile lesions with intact cortices and normal trabecular patterns, absence of calcification, and absence of soft tissue masses. Half of patients have multiple osteochondromatosis. The majority of those are in the laminae or spinous processes, and can be mistaken for osteoblastomas. Aneurysmal bone cysts are typically expansile lytic lesions with a thin rim of cortical bone and may involve contiguous vertebral elements (e.g., the posterior elements, pedicle, and body). CT is useful for determining the exact extent and the potential involvement and proximity of the vertebral artery and neural elements. Angiography may be needed. Aneurysmal bone cysts usually arise in the posterior elements (231). Eosinophilic granuloma usually exhibits vertebra plana radiographically (232). The CT or MRI is useful for determining the potential encroachment on the neural structures. Eosinophilic granuloma usually arises in the vertebral body, with varying degrees of involvement and collapse.

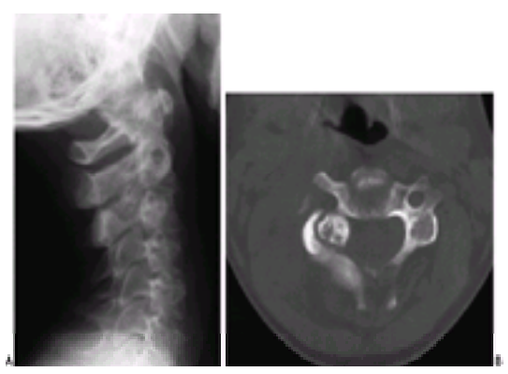

FIGURE 21.27. A 13-year-old boy had a 2-year history of neck pain that did not resolve with long-term chiropractic treatment. **A:** Plain radiographs show a sclerotic nidus with a surrounding lucency at the level of the C3 pedicle and the C2-3 foramen. **B:** Computed tomography scan confirms the typical appearance of an osteoid osteoma; note the proximity of the lesion to both the foramen and the nerve root as well as to the vertebral artery.

In the cervical spine the main concern is for vertebral artery and neural element involvement, which can lead to neurologic dysfunction. The intense inflammatory nature of osteoid osteoma or osteoblastoma, and its proximity to the neural elements, causes nerve root irritation. This irritation, pain, and muscle spasm may result in torticollis. Compressive myelopathy also can occur, especially in patients with epidural compression, such as that seen with aneurysmal bone cysts (231,233).

The treatment of eosinophilic granuloma in the cervical spine traditionally has been immobilization (e.g., collars, Minerva casts) and low-dose irradiation. Immobilization is continued until early healing has appeared radiographically. Low-dose irradiation should be reserved for lesions with neurologic deficits that are not surgically accessible. Multiple laminectomies should be avoided. Rarely has immobilization alone been used, and one of these children presented with total collapse of the vertebral body (232). Osteoid osteomas do not undergo malignant transformation. However, continued torticollis and pain may lead to fixed spinal deformities. For this reason, the author advocates surgical resection. Pain relief with complete resection is dramatic. Significant complaints of postoperative pain resembling the preoperative pain indicates either incomplete resection or recurrence. For osteoblastoma and aneurysmal bone cysts the primary treatment is surgical, and nonsurgical treatment is used only as adjunctive therapy. The surgical goal is complete primary excision; however, this is often impossible because of the particular anatomic location of the cysts. In these situations, adjunctive therapy is useful (e.g., radiotherapy for eosinophilic granuloma, or embolization for aneurysmal bone cysts if the nondominant vertebral artery is involved) (234).

Prophylactic fusion should be performed if the resection renders the spine unstable. The amount of resection necessary to render the spine unstable is not known in children; however, in adults, resection of more than 50% of one facet likely leads to segmental instability (235). Because the development of postlaminectomy cervical instability is even more likely in children than in adults, the author recommends an arthrodesis with any degree of facetectomy in children, and strong consideration should be given to an arthrodesis after any degree of laminectomy. Multiple laminectomies should be avoided, if at all possible; if necessary, fusion and stabilization also should be performed. Anterior fusion often is necessary because of insufficient posterior elements after surgical excision; supplemental halo cast or vest or Minerva cast immobilization usually is needed if fusion is required. The overall surgical management is individualized and multidisciplinary (e.g., orthopaedics, neurosurgery, radiotherapy, interventional radiology). Surgical complications include recurrence, pseudarthrosis of the fusion, neurologic deterioration, and vertebral artery injury (236).

Malignant Tumors

The majority of primary and metastatic malignant tumors involving the cervical spine occur in adults; rarely, the cervical spine in children can be involved by chordoma (237), leukemia, Ewing sarcoma (238), or metastatic neuroblastoma.

CHAPTER 22

THE UPPER LIMB

PETER M. WATERS

P. M. Waters: Orthopaedic Surgery Department, Harvard Medical School; Hand and Upper Extremity Surgery, Children's Hospital, Boston, Massachusetts 02115.

This chapter addresses the evaluation and treatment of the more common upper-limb and hand congenital differences, traumatic and posttraumatic conditions, neuropathic problems, and growth deformities. The sections of this chapter examine major diagnostic categories and anatomic regions. To avoid redundancy in the text as a whole, the reader will find more information regarding upper-extremity development (Chapter 2), fractures (Chapter 32), and limb deficiency (Chapter 30) in other chapters of this text.

Treatment of any upper limb or hand problem in a child needs to address the issues of function, growth, cosmetic deformity, and the emotional concerns of the child and family. All are important factors in determining a successful outcome. The means to improve function are to enhance the ability to place the hand in space; to improve deficiencies in grasp, release, or pinch function; and to improve skin mobility and sensibility (1). Treatment of physeal abnormalities improves growth-related loss of motion, function, pain, and musculoskeletal deformity. Extensive time and counseling are important to address the concerns of both the child and parents regarding the alteration in self-image that can occur with any hand deformity.

CONGENITAL DEFORMITIES

Pathogenesis

In utero, the arm bud appears 26 days after fertilization and 24 hours before the appearance of the leg bud. Growth is in a proximal-to-distal manner. Development is guided by the apical ectodermal ridge inducing the mesoderm to condense and differentiate (2). The upper limb anlage is initially continuous and extends to a hand paddle by day 31. The digital rays develop by day 36 with fissuring of the hand paddle, initially in the central rays, followed by the border digits. Mesenchymal differentiation also begins in a proximal-to-distal manner with chondrification, enchondral ossification, joint formation, and muscle and vascular development. Joint formation and digital separation require apoptosis, or programmed cell death. The entire process is complete by 8 weeks after fertilization (3). Other major organ system development is occurring simultaneously, which explains the associated cardiac, craniofacial, musculoskeletal, and renal anomalies that can occur with upper limb malformations.

Homeobox, or *HOX*, genes regulate the development of the limb (4). Their genetic expression controls the timing and extent of growth by regulating mesenchymal cells. At present, understanding of the genetic control of limb development, and therefore the occurrence of congenital differences, is expanding rapidly (5,6,7,8,9 and 10). For example, a mutation at the *HOXD13* site has been identified as a cause of polysyndactyly (11). Further understanding of the genetic control of limb development may revolutionize the treatment of congenital deficiencies.

Congenital differences occur in approximately 6 to 7% of live births, with 1% being multiple anomalies. Between 1 in 531 and 1 in 626 live births have been estimated to involve upper extremity anomalies (12,13). Only 1 to 2% of these congenital differences are the result of chromosomal abnormalities. At present, only a minor portion are known to be secondary to defined genetic causes. In the majority of cases, the cause of the congenital malformation is still unknown.

Classification

There is no perfect classification system for congenital differences of the hand and upper limb. The present accepted classification system for congenital differences was proposed by Swanson (14) and revised by the Congenital Anomalies Committee of the International Federation of Societies for Surgery of the Hand (15). This classification is based on embryologic failure, and defines deficiencies as terminal or intercalary, with a subclassification into longitudinal or transverse deficiencies. The subcategories are as follows: I, failure of formation of parts; II, failure of differentiation of parts; III, duplication; IV, overgrowth; V, undergrowth; VI, constriction band syndrome; and VII, generalized skeletal abnormalities.

This chapter focuses on the major anomalies in each classification group, but presents them by anatomic region. Care for the child with congenital differences involves more than surgical skill. From the moment of birth, these children may potentially be viewed by their parents, family, society, and, eventually, even themselves as impaired (16,17). It is critical that the treating surgeon help provide the emotional support and caring that allows the parents and child to appropriately grieve the loss of a normal hand (18). It is helpful to provide them with in-depth knowledge of the cause and treatment options (19). This process starts with the initial newborn visit, and continues throughout the growth and development of the child into an independent, self-reliant adult (20). Self-help groups, such as Superkids, are useful for many of these children and their families.

With a normal central nervous system, these children will not be impaired. They will merely develop their skills in a “different” way from their peers. They may need the help of skilled and caring parents, siblings, therapists, teachers, coaches, prosthetists, and surgeons to achieve their goals and dreams. Being part of helping

these children grow into unique and independent adults is exciting and rewarding for the surgeon.

ENTIRE LIMB INVOLVEMENT

Neuromuscular

Cerebral Palsy

Cerebral palsy is a nonprogressive disorder of the central nervous system. It occurs in 5 of 1,000 live births, and may be caused by perinatal anoxia, intraventricular hemorrhage, and congenital cerebral vascular accidents. It occurs most commonly in premature infants weighing less than 1,500 g (21,22). The resultant hemiplegia or quadriplegia can lead to significant upper extremity deformities and functional deficits. In hemiplegia, these individuals predominantly use the affected extremity as an assist for the unaffected extremity. In the quadriparetic, both upper limbs will have significant deformity and deficits. The quality of use of an affected extremity is dependent on many factors, including the presence of contractures, voluntary motor control, discriminatory sensibility, learning disabilities, and visual deficits (23,24,25,26 and 27). This section focuses on the deformities and deficits related to elbow flexion, forearm pronation, wrist palmar flexion and ulnar deviation, finger flexion, and thumb-in-palm deformity in these patients.

Upper-limb Contractures. Nearly three-fourths of patients with hemiplegia develop a forearm pronation contracture (28). The presence of a significant pronation contracture limits the ability to perform bimanual tasks (27,29). Individuals with greater than 60-degree contractures will either perform activities with one hand or use the dorsum of the affected hand or forearm to assist the unaffected hand. These individuals may benefit from surgical correction of their pronation deformity to improve the assistive function of that extremity. This often can be performed with simultaneous procedures to improve thumb-in-palm, wrist palmar flexion, or digital flexion deformities (30).

Elbow flexion contractures are often mild in patients with hemiplegia (28,31). Although nearly 50% of these patients will have a flexion contracture, the vast majority of these contractures are less than 30 degrees and do not limit function (32,33). There may be an associated radial head dislocation in a small number of patients, and this should be assessed radiographically before operative intervention (34). Patients with quadriparesis have greater degrees of elbow flexion contracture. However, these contractures rarely affect their ability to use their motorized wheelchairs, computers, or communication boards. In the care-dependent, nonfunctional quadriparetic, contractures may become severe enough to affect hygiene and care. If skin breakdown develops or is imminent, then surgery may be necessary.

Wrist and hand involvement is common in cerebral palsy. Limited motor function occurs with (i) poor release from wrist and finger flexor spasticity and weak digital extension; (ii) inadequate grasp from wrist palmar flexion spasticity and weak wrist extension; and (iii) minimal pinch from thumb-in-palm deformity. Discriminatory sensibility is deficient in more than 50% of these children. Poor voluntary control of the upper extremity limits functional placement of the hand in space (27,28). In addition, many of these children have visual and cognitive abnormalities that further impair hand function. At best, the majority of patients with spasticity have assistive hand function.

These children generally posture into elbow flexion, forearm pronation, wrist and palmar flexion, thumb-in-palm, and interphalangeal swan-neck deformities. These deformities may be a combination of spasticity and contractures. Pronation deformity and thumb-in-palm contracture seem to affect function the most (28). The combination of neurologic impairment and disuse affect growth in length and girth of the affected arm and hand (28).

Cerebral palsy upper extremity classification systems have been used to assess function (34,35) (Fig. 22-1). The House classification of function has nine levels, extending from 0 (does not use) to 8 (complete spontaneous use) (Table 22-1). In this useful scheme, there are four subgroups of patient function: no use (0), passive assist (1 to 3), active assist (4 to 6), and spontaneous use (7 and 8). Because spasticity changes with stress, growth, and central nervous system changes, it may be difficult on any one visit to accurately define a patient's level of function. This system is used with the input of the patient, family, and therapist to best define a patient's overall status. It is used to assess the outcome of treatments (30).

FIGURE 22-1. Data sheet for prospective analysis of hemiplegic function used at Children's Hospital, Boston.

Level	Designation	Activity Level
0	Does not use	Does not use
1	Poor passive assist	Uses as stabilizing weight only
2	Fair passive assist	Can hold extra object placed in hand
3	Good passive assist	Can hold extra object and stabilize it for use by other hand
4	Poor active assist	Can actively grasp object and hold it weakly
5	Fair active assist	Can actively grasp object and stabilize it well
6	Good active assist	Can actively grasp object and manipulate it against other hand
7	Spontaneous use, partial	Can perform bimanual activities easily and occasionally uses the hand spontaneously
8	Spontaneous use, complete	Uses hand completely independently without reference to the other hand

TABLE 22-1. HOUSE CLASSIFICATION OF UPPER EXTREMITY AND HAND FUNCTION FOR CEREBRAL PALSY PATIENTS

Treatment.

Nonoperative Care. In broad terms, the treatment options are to observe the patient's growth and development; use therapy, including splints; consider injections, such as phenol or Botox; and perform surgical reconstruction.

Physical therapy, starting in infancy, is the standard treatment for children with cerebral palsy. The rationale is that although the central nervous system deficit is static, the peripheral manifestations of spasticity and muscle imbalance are progressive with growth. By maintaining range of motion with passive therapy, it is hoped that contractures will not develop (28,36). However, no prospective information is available to validate this rationale. At present, formal therapy is used during the period of infancy. This is most intense in the first year of life, and progresses to a home program with less formal supervision. In many states, early intervention programs end at 3 years of age. Monitoring of function and range of motion is performed less regularly or through the school system, thereafter. During growth spurts that increase spasticity and lessen range of motion, or with specific activities that the patient finds difficult, brief periods of formal therapy are reinitiated (28).

Aside from passive range of motion and active-use programs, splints are often used. These may be daytime or nighttime splints. As Manske has observed, it is unclear whether they are cost-effective and alter long-term outcome (36). No objective study has been performed. However, most caretakers use splints in children

with developing contractures. Daytime splints are recommended only if they improve function in patients with dynamic contractures. The success of supplemental electrical stimulation is unclear at present.

Injection may provide useful information about the outcome of surgical procedures. At present, Botox is the most common form of neuromuscular injection (30,38), replacing xylocaine (39,40) and phenol (41,42). It is used at an initial dose of 1 to 2 U/kg of body weight, and should not exceed 6 U/kg per month. Injection into pronator, flexor carpi ulnaris, and thumb adductor are most often performed. Therapy should be performed aggressively to stretch agonistic musculotendinous units and strengthen antagonists. To date, Botox has been most effective for older patients with high levels of function and limiting spasticity. Its role in patients with contractures is limited and less effective, even though these patients may be the most involved. Its effectiveness in young children has not yet been studied critically. There are several ongoing prospective studies of Botox injections in the upper extremity and hand, so more definitive information should soon be available on the indications and effectiveness of its use in all age groups and at all levels of involvement. Complications involve antibody formation to the Botox.

Operative Care. The broad indications for surgery for patients with cerebral palsy include (i) contractures that cause hygiene and care problems not solved by therapy, splints, or casts; (ii) muscle imbalance or contractures that cause functional deficits that may be improved by tendon transfers, musculotendinous lengthening, and/or joint stabilization procedures; and (iii) cosmetic concerns (23,24,25,26 and 27,43). It may be difficult to identify the individual who will have improved function through surgical reconstruction. As Smith (22) so aptly pointed out, careful preoperative assessment is necessary to determine and select the appropriate patients and operations. Video recordings of activities of daily living and validated multiple-task assessment scales, such as the Jebsen scale, can be helpful in defining functional limitations. A recently completed, but not yet published, study by the author found video and House classifications reliable and useful for surgical planning.

Surgery has been shown to effectively improve the level of function in all forms of cerebral palsy (30). The best candidates are patients with hemiplegia and good voluntary control, sensibility, and motivation. The principle of surgery is to restore muscle imbalance by lengthening or releasing tight, spastic muscles, and augmenting weak, stretched muscles by tendon transfers and tenodesis procedures. Unstable joints need to be stabilized by soft tissue or arthrodesis procedures to maximize the outcome of tendon reconstruction. Multiple upper-extremity rebalancing procedures performed under one anesthesia seem to be best. This can also be performed in conjunction with simultaneous lower-extremity procedures if the patient and surgeons can tolerate it. It cannot be stressed enough to the patient and family that surgery will not achieve a normal hand. Even the best outcome will result in deficiencies of function, cosmesis, and sensibility. Patients, families, and surgeons need to be realistic about the expected results. However, in properly selected patients, surgery will clearly improve function and patient satisfaction (30). This is evident in individuals using the dorsum of the hand or forearm for bimanual tasks. However, it is imperative that both the family and the individual understand that surgery will never create a normal limb. The goal must be well defined and specific to the peripheral manifestation of an incurable, central disorder.

Mital (31) cited excellent results with surgical release of elbow flexion contractures in hemiplegic patients. He recommended release of the lacertus fibrosus, Z-lengthening of the biceps tendon, and musculotendinous lengthening of the brachialis fascia. In mild contractures, release of the lacertus fibrosus and musculotendinous lengthening of the brachialis alone may be sufficient.

More extensive elbow contractures are present in severe quadriparetics. The Z-lengthening of the biceps tendon and release of the brachialis fascia advocated by Mital (31) is not sufficient to obtain adequate release in these patients. In patients with greater than 90-degree contractures and skin breakdown, extensive release of the muscle origins from the medial and lateral epicondyles, biceps and brachialis tendons, and anterior elbow capsule is necessary to solve the hygiene and care-related problems that accompany these conditions.

Forearm hyperpronation significantly limits hand function (28) in patients with hemiplegia. Patients are forced to use the dorsum of the forearm for two-handed tasks. Wrist and finger flexion deformity is commonplace in patients with hemiplegia. The flexor carpi ulnaris (FCU) is usually the major deforming force at the wrist. Transfer of the FCU to the wrist extensors alleviates the deformity and improves the strength of the antagonist **[➥1.7]**. On occasion, the extensor carpi ulnaris (ECU) is the primary deforming force, as noted by more ulnar deviation than palmar flexion at the wrist. In these situations, the ECU is transferred to the extensor carpi radialis brevis (30). Simultaneous musculotendinous lengthenings of the finger flexors are necessary if the extrinsic finger flexors are tight in the neutral wrist position (26). Otherwise, the patient will develop a disabling clenched fist postoperatively. Z-lengthenings, superficialis to profundus flexor tendon transfers, and bony procedures are reserved for patients with severe contractures and limited function. In the unusual patient with passive digital extension, but no active digital extension, the FCU, ECU, or pronator teres (PT) can be transferred into the extensor digitorum communis. This will improve both wrist and digital extension.

Thumb-in-palm deformity will limit dynamic pinch and grasp function, and make hygiene difficult in severe contractures. Static contractures in the web space are corrected with web-space Z-plasties and adductor releases **[➥1.8]**. Hoffer et al. (32a) have shown by dynamic electromyography that release of the transverse adductor alone may lead to better pinch postoperatively in selected patients. At times, the static contractures include the flexor pollicis longus and brevis, and these need to be appropriately lengthened or released. Dynamic rebalancing is performed with tendon transfers to the weak abductors and extensors of the thumb. The donor muscles used are numerous and include the palmaris longus, flexor carpi radialis, and brachioradialis, among others. The recipient tendons include the extensor pollices brevis and longus and the abductor pollicis longus. Each patient must be individualized to correct his or her deformity and imbalance. Finally, the metacarpophalangeal (MCP) joint needs to be stable postoperatively. In most patients, this is achieved by muscle rebalancing. On occasion, a capsulodesis or arthrodesis procedure needs to be performed.

Finally, some patients with cerebral palsy have disabling swan-neck deformities of the interphalangeal joints. If the fingers extend at the proximal interphalangeal (PIP) joint beyond 40 degrees and lock, it can both limit grasp and cause pain. Multiple operations have been advised, including flexor digitorum superficialis tenodesis (26), intrinsic muscle slide (26), lateral band rerouting (44), spiral oblique ligament reconstruction, and resection of the motor branch of the ulnar nerve. The lateral band rerouting procedure provides both intrinsic and extrinsic rebalancing, and is effective in correcting the problem.

In summary, patients with cerebral palsy who have disabling dynamic spasticity and fixed contractures of the wrist and hand benefit from surgical reconstruction. Often, the more involved patients (House levels 0 to 2) respond best to musculotendinous lengthenings, tenodesis, and joint stabilization procedures. More functional patients (House levels 3 to 6) improve with dynamic tendon transfers and releases. Both groups of patients tolerate multiple simultaneous procedures (Fig. 22-2). However, surgery will not create a normal hand. The goals of surgery need to be realistic and obtainable. In properly selected patients, surgery will improve assistive function and cosmesis. For many of these children, especially adolescents, and their families the functional and cosmetic improvement is quite marked and satisfying.

FIGURE 22-2. Clinical photographs of hemiplegic tendon transfers for improving hand and upper limb function. **A:** Preoperative view of dynamic elbow flexion, forearm pronation, wrist flexion, and ulnar deviation with poor assist function. **B:** Postoperative active elbow extension with maintenance of active elbow flexion. **C:** Postoperative active wrist extension with the thumb out of the palm for active pinch. **D:** Postoperative active grasp function with the thumb abducted and extended actively. (Clinical case courtesy of Ann Van Heest, M.D.)

Complications. Recurrence of deformity, or failure to improve function, can occur. Proper preoperative selection to assess functional deficits and patient cooperativeness may lessen the risk of these problems postoperatively (23). Hematoma formation, wound breakdown, and infection can occur after extensive elbow releases (45). The institutionalized quadriparetic patient may be most at risk. If wound dehiscence occurs, and the joint is exposed, coverage with a rotation flap is the

treatment of choice.

Brachial Plexopathy

Brachial plexus birth palsy is rare, with an incidence between 0.1 and 0.4% of live births (46,47). Fortunately, many infants with minor birth palsies recover fully. These are the infants who initiate recovery of all muscle groups in the first 1 to 2 months of life. However, permanent impairment does occur. It is most likely in infants who do not initiate recovery before 6 months of life (48,49,50,51 and 52). Horner syndrome is also a major risk factor for a poor outcome (52). Most infants have involvement of the upper trunk (C5–C6; Erb palsy), although there can be additional involvement of C7. Less often, the entire plexus (C5 to T1) is affected. Rarely, the lower trunk (C7 to T1; Klumpke palsy) is most affected.

Perinatal risk factors include infants who are large for gestational age; prolonged labor; difficult delivery, including extraction techniques; and fetal distress. Shoulder dystocia is the mechanical factor that leads to an upper-trunk lesion in the difficult vertex delivery. Difficult arm extraction in a breech delivery can result in an avulsion injury (53). The degree of impairment is related to the level and magnitude of injury to the plexus. Neural injury is defined by the type (stretch, rupture, avulsion) and severity (Sunderland grades I to V). Prognosis by natural history has been best defined by the spontaneous rate of recovery of muscle strength in the first 3 to 6 months of infancy. Gilbert and Tassin (51) described the recovery of biceps function in infancy as a predictor of the outcome of spontaneous recovery. This finding was confirmed in a similar study by Waters (52). Their results showed that infants who did not recover biceps function by 3 months of life were not normal after 2 years of age. As a result of the failure of spontaneous recovery, Gilbert and colleagues recommend microsurgical reconstruction of the plexus in the first 3 to 6 months of life for infants who fail to recover biceps function (51,54,55). Michelow et al. (56) noted that return of biceps function alone had a 12% error rate in predicting outcome, as defined by long-term antigravity muscle strength. By using elbow flexion, elbow extension, wrist extension, finger extension, and thumb extension (the Toronto scale), their error rate for predicting poor outcome decreased to 5%. In this system each muscle group is scored as 0 (no motion), 1 (motion present but limited), or 2 (normal motion), for a maximum score of 12. A score of less than 3.5 predicted a poor long-term outcome without microsurgery. In all studies the presence of Horner syndrome, total plexus involvement, and failure of return of function by 3 to 6 months of life indicate a poor long-term outcome.

Clinical examination of an infant for motor-sensory function can be limited. It is important to distinguish true paralysis from the pseudoparalysis that comes with a neonatal clavicle fracture, humeral fracture, or septic shoulder. There can be clinical overlap because fractures also occur in infants with shoulder dystocia and infantile brachial plexopathy. Plain radiographs will identify the infant with clavicle and humeral fractures. In the neonate these fractures heal within 10 to 21 days. If limited motion persists after 1 month there will most likely be a concomitant brachial plexopathy. In the rare infant with a septic shoulder there will be evidence of systemic illness (altered vital signs, change in appetite, toxicity), marked irritability with glenohumeral range of motion, and abnormal white blood cell count. If there is doubt, ultrasonography will reveal the effusion, and arthrocentesis will be confirmatory.

The pupils should be assessed for Horner syndrome. Motor examination is limited to observation of spontaneous activity and stimulated movement by primitive reflexes in the infant. The Moro startle reflex and the asymmetric tonic neck reflex can elicit upper trunk movement in infants in the first 6 months of life. Classification of nerve injury in the ambulatory child has included physical examination assessment with the Mallet system. The modified Mallet system classifies upper trunk function by grading hand-to-mouth, hand-to-neck, and hand-on-spine activity, global abduction, global external rotation from 0 (no function) to 5 (normal function). Grades 2, 3, and 4 are illustrated (Fig. 22-3).

FIGURE 22-3. Mallet classification for brachial plexus birth palsy function about the shoulder. Grade 0 is no function; grade V is normal function; and grades II through IV are depicted for hand-to-mouth, hand-to-neck, external rotation, and hand-to-sacrum activity.

Radiography can demonstrate an associated fracture of the clavicle or proximal humerus. Radiographic assessment of the severity of brachial plexus injury has used myelography, combined computed tomography (CT) and myelography, and magnetic resonance imaging (MRI). Kawai et al. (57) compared the results of all three techniques with operative findings. Combined myelography and CT and MRI were more reliable than myelography alone. The presence of large diverticulae and meningoceles was indicative of root avulsion. Small diverticulae were diagnostic only 60% of the time. Electrodiagnostic studies, with electromyography and nerve conduction studies, are diagnostic of avulsion if there is no reinnervation after 3 months of age. However, the presence of reinnervation does not indicate the long-term quality of muscle recovery.

Pathoanatomy. Understanding the normal anatomy of the brachial plexus is critical to assessing and caring for an infant or child with brachial plexus palsy (Fig. 22-4). The brachial plexus supplies every muscle of the upper extremity except the trapezius. It is made up of spinal cord nerve root contributions from C5 to T1. Prefixed cords (22% of specimens) receive a contribution from C4. Postfixed cords are rare (1%) and receive a contribution from T2. The C5 and C6 roots join to form the upper trunk. The C7 root alone becomes the middle trunk. The C8 and T1 roots become the lower trunk. Each trunk has an anterior and a posterior division. The anterior divisions of the upper and middle trunks form the lateral cord. The posterior divisions of all three trunks form the posterior cord. The anterior division of the lower trunk continues as the medial cord. The terminal branches of the cords form the major nerves of the upper extremity. The posterior cord gives off the upper and lower subscapular and thoracodorsal nerves before bifurcating into the radial and axillary nerves. The medial cord branches are the medial pectoral, medial brachial cutaneous, and medial antebrachial cutaneous nerves, terminating in the medial contribution to the median nerve and the ulnar nerve. The lateral cord supplies the lateral pectoral nerve and the lateral branch of the median nerve, and terminates as the musculocutaneous nerve. With infantile brachial plexopathy, any of these nerves can be affected. However, the most severe injuries are avulsions of the nerve roots. The most common injuries are postganglionic ruptures of the upper trunk.

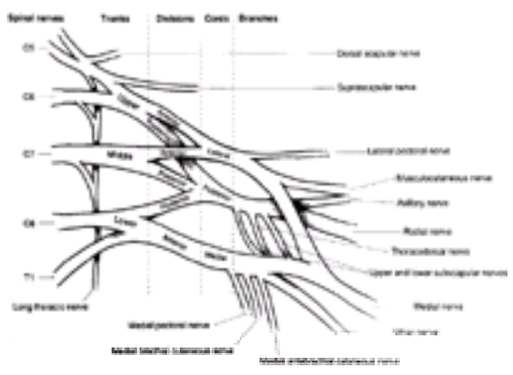

FIGURE 22-4. Anatomic representation of the brachial plexus.

Treatment

Nonsurgical. As mentioned above, all infants with brachial plexus birth palsies should be monitored for spontaneous recovery in the first 3 to 6 months of life. During this time it is important to maintain glenohumeral range of motion, especially passive external rotation. Many infants will initiate recovery in the first 6 to 8 weeks of life, and progress to a normal result. Those infants who do not initiate recovery until after 3 months of life may be microsurgical or reconstructive surgical candidates.

Microsurgery. The timing of microsurgical intervention is still debated. The range used clinically is from 1 month to after 6 months of life (47,51,52,53,54 and 55). The indications include absence of biceps recovery, Toronto score less than 3.5, and total plexopathy with Horner syndrome. At present, most centers throughout the world agree that an infant with a flail extremity and Horner syndrome should have microsurgical reconstruction between 1 and 3 months of life. A child with complete absence of upper-trunk function (shoulder abduction, elbow flexion) should have surgery between 3 and 6 months of life. Microsurgery involves resection of the neuroma and bypass nerve grafting or nerve transfer procedures. There is no role for neurolysis alone at any age, especially in the infant older than 6 months of age, based on the information published in peer-reviewed journals. The technique involves exploration of the brachial plexus and reconstruction of avulsion and nonconducting rupture injuries. If the proximal trunk or nerve roots are intact, sural nerve grafting across the neuroma is preferred. In the presence of an avulsion, intercostal and spinal accessory nerve transfers are performed. The results are not normal function, but they are improved over natural history alone (51,52). The controversy regarding the exact timing of intervention (i.e., no upper trunk function at 3 versus 6 months of age) may not be resolved without a prospective, randomized study.

Shoulder Surgery. Children with chronic upper trunk plexopathy may develop external rotation weakness and internal rotation contractures about the shoulder. This muscle imbalance will progressively alter the glenohumeral joint (49,50; Table 22-2). Function, especially with the arm in above-horizontal activities, will be impaired (48,50). These children clearly benefit from surgical intervention (50,56). In the rare situation of an infantile dislocation (58), open reduction and capsulorrhaphy are indicated. More commonly, these children have limited external rotation that affects function.

Type	CT/MRI Findings
I	Normal glenohumeral joint
II	Minimal glenoid hypoplasia (>5 degrees increased retroversion)
III	Posterior subluxation of the humeral head
IV	Development of a false glenoid
V	Posterior flattening of the humeral head
VI	Infantile dislocation
VII	Proximal humeral growth arrest

Findings are additive, with increasing severity from type I to type V.
(From ref. 50, with permission.)

TABLE 22-2. COMPUTED TOMOGRAPHY/MAGNETIC RESONANCE IMAGING (CT/MRI) CLASSIFICATION OF GLENOHUMERAL DEFORMITY IN CHRONIC BRACHIAL PLEXUS BIRTH PALSIES

In young children with nearly normal glenohumeral joints (normal or mild increase in glenoid retroversion; grades I and II) or slight posterior subluxation (mild; grade III), anterior musculotendinous lengthening of the pectoralis major and posterior latissimus dorsi and teres major transfer to the rotator cuff (59,60) will improve function (52). In addition, dynamic rebalancing of the muscle forces about the shoulder at a young age has the potential advantages of restoring more normal anatomy, preventing progressive glenohumeral joint deformity, and permitting glenohumeral joint remodeling. In the older child with more established and progressive deformity of the glenohumeral joint (more severe posterior glenoid flattening; advanced grade III), development of a false glenoid (grade IV) (Fig. 22-5), or humeral head dislocation and deformity (grade V), the joint deterioration is too advanced to tolerate a soft tissue procedure. However, humeral derotation osteotomy is indicated and will also improve function (52).

FIGURE 22-5. Magnetic resonance imaging scan of a type IV deformity with posterior humeral head subluxation and development of a false glenoid.

There are rare patients who need both osteotomy and tendon transfer. These patients have been in the middle range of deformity (grade III) and are relatively older (7 to 12 years). To date, it has been difficult to identify this small subset of patients preoperatively. Therefore, the transfer is performed initially, and only if the result is suboptimal more than 1 year later is the secondary-stage osteotomy performed. The role of glenoid osteotomy, its risks, and its benefits are still being defined for grade III and mild grade IV patients.

Elbow and Forearm Reconstruction. Elbow flexion and forearm supination deformities can occur with a permanent Klumpke (C8 to T1) or mixed brachial plexus lesion. Contractures, bony deformity, and joint instability are the result of muscle imbalance in a growing child. In the rare patient with residual C8 to T1 neuropathy with recovery of C5–C6 function, the elbow and forearm deformities are secondary to an intact biceps muscle in the presence of weak or absent triceps, pronator teres, and pronator quadratus muscles. Progressively, the biceps creates an elbow flexion and supination deformity from unopposed muscular activity. Soft tissue contractures develop, followed by rotation deformities of the radius and ulna (61). Radial head dislocation may occur (62). The wrist and hand often are in extreme dorsiflexion because of unopposed wrist dorsiflexors. In the position of forearm supination, gravity further exacerbates the dorsiflexion deformity. The patient is left without use of the hand, and performs bimanual activities using the volar and ulnar forearm as an assist. Often, shoulder abduction and internal rotation are required to improve assistive function. Those activities that require simultaneous elbow flexion and forearm pronation, such as dressing, eating, and writing (63), are significantly limited. In addition, the forearm and hand posture is a major cosmetic concern to both the patient and the family (64).

The biceps tendon can be treated by Z-lengthening and rerouting around the radius to convert it from a supinator to a pronator. This will improve elbow extension and forearm pronation. Surgically, the biceps tendon is identified as it inserts into the radial tuberosity. By dissecting lateral to the tendon, the brachial artery and median nerve are protected. A long Z-plasty of the tendon is performed from the musculotendinous junction to the insertion site. The distal attachment of the tendon is rerouted posteriorly around the radial neck, from medial to lateral. Care must be taken to stay adjacent to the radial neck to avoid injury or compression of the radial nerve. The distal tendon is reattached to its proximal counterpart in a lengthened position. This converts the biceps into a forearm pronator (63,64 and 65).

In the presence of a supination contracture, the rerouting procedure alone will fail because of recurrence of the deformity. Zancolli (63) suggested performing simultaneous interosseous membrane release. However, active pronation was maintained in only 50% of patients who underwent this procedure. Bony correction of the forearm deformity can be performed more predictably. Manske et al. (65) proposed staged procedures of tendon rerouting and forearm osteoclasis. Waters and Simmons (64) described simultaneous tendon rerouting and osteotomy, using intramedullary fixation to avoid multiple operations and loss of alignment. In both techniques, the forearm is positioned in approximately 20 to 30 degrees of pronation.

These patients clearly have significant improvement in their functional capabilities. Bimanual tasks, such as lifting, carrying, and transferring, are easier. The affected extremity becomes a better assistive extremity to the unaffected side. The wrist and hand now have greater assisted palmar flexion and resolution of their dorsiflexion deformity. In addition, the patients are usually pleased with their cosmetic results.

Arthrogryposis

Arthrogryposis multiplex congenita is a syndrome of unknown cause that presents at birth with joint contractures and muscle weakness. The incidence is approximately 1 per 3,000 live births (66). The clinical syndrome is variable and includes classic arthrogryposis (amyoplasia), distal arthrogryposis, and syndromic involvement (67). Intelligence is usually average or above average. Sensibility is normal. Upper-extremity involvement is frequent, with 72% of the 114 patients in the Gibson and Urs study affected (68). The wrist was most commonly involved, followed by the hand, elbow, and shoulder. In the classic presentation, the elbow is usually contracted in extension at birth. The shoulder is internally rotated with the forearm pronated. Often, there is wrist palmar flexion and ulnar deviation, and the fingers have flexion deformities (Fig. 22-6). The thumb is usually adducted and flexed in the palm (68,69,70 and 71). These children often have incomplete syndactylies of all web spaces. The first web space contracture is usually the most functionally significant. There usually is marked intrinsic muscle weakness. There may be camptodactyly or symphalangism of the PIP joints. All of this will limit hand function in these children.

FIGURE 22-6. A: Clinical photograph of an arthrogrypotic patient preoperatively, with elbow extension, forearm pronation, and wrist palmar flexion posturing and contractures. **B:** Intraoperative photograph of the outline of surgical incisions for tendon transfer of the latissimus dorsi to the biceps. **C:** Intraoperative photograph of the preparation of the latissimus dorsi transfer for active elbow flexion.

Involvement is generally bilateral. The absence of both passive and active elbow flexion is a significant functional liability in these children. The goal of orthopaedic management of the arthrogrypotic elbow is to improve self-feeding and independent hygiene skills by achieving both passive and active elbow flexion. The goal of treatment of the hand is to improve pinch, grasp, and release functions.

Treatment

Nonoperative Care. Initial care is with physical therapy to improve passive range of motion. Repetitive, gentle, passive manipulation of the involved joints may progressively lessen the contracture. This process is tedious and requires meticulous, gentle care by both the therapist and the family. Corrective splints and serial casts have been used with varying success. Caution is necessary because of the risk of fractures or dislocations that can occur as a complication of aggressive treatment of resistant contractures. At the elbow, the goal of therapy is to achieve at least 90 degrees of passive elbow flexion by 2 years of age. The majority of patients can achieve the desired passive elbow flexion through therapy (72). However, if this is not obtained, operative elbow release is recommended (72,73,74,75 and 76). When passive elbow flexion is obtained, therapy should then emphasize the use of adaptive trunk sway, head tilt, and table-assisted passive elbow flexion to improve feeding and hygiene tasks. Finally, if subsequent active elbow flexion does not develop, active elbow flexion tendon transfer should be considered at approximately 5 years of age (72). The majority of these children will have deficient biceps and brachialis musculature, and will fail to develop active elbow flexion.

Initial treatment of the wrist and hand should involve passive range of motion and nighttime splinting. The goal of therapy in the hand is to improve joint motion and digital strength. Fortunately, in many children their condition improves with growth and therapy during the first several years of life. If passive motion cannot be improved, surgical releases and tendon transfers may be necessary.

Operative Care

Posterior capsulotomy and triceps lengthening. As mentioned above, children who fail to achieve a functional arc of flexion at the elbow with manipulative therapy, splints, and casts, are candidates for operative elbow posterior capsulotomy and triceps lengthening. Surgery can be performed at 2 years of age. If delayed well beyond this age, progressive bony deformity can occur. The goal of operative intervention is to achieve at least 90 degrees of passive elbow flexion. Initially, the dominant extremity should have surgery. The presence of passive elbow flexion will improve independence in feeding, hygiene, play, and school activities (64,72).

Surgical exposure is by a standard posterior approach to the elbow. The triceps tendon is incised in an inverted V. The angle of the V needs to be acute enough to allow for appropriate triceps lengthening. The ulnar nerve is protected during the medial incision of the tendon. The distal flap of the triceps is elevated from the elbow capsule, but often the triceps and the capsule are confluent distally. The triceps lengthening alone usually does not improve passive elbow flexion. A transverse incision in the elbow capsule is then made. Full passive elbow flexion is gained. The triceps tendon is lengthened in a V–Y manner at 90 degrees of flexion.

Tendon transfers for elbow flexion. Arthrogrypotic children with passive elbow flexion of greater than 90 degrees and no active elbow flexion are candidates for tendon transfer. The transfers to be considered include (i) triceps (72,73); (ii) pectoralis major, using the sternocostal origin (74); (iii) pectoralis major, using the entire musculature on a neurovascular pedicle (74); (iv) latissimus dorsi (72,75); (v) lateral and proximal reinsertion of the flexor-pronator origin; (vi) sternocleidomastoid with a free tendon graft; and (vii) pectoralis minor with a free tendon graft. Each of these transfers has been described in limited series in the arthrogrypotic elbow. Until recently, no objective criteria had been proposed to compare the results of these various transfers (64,72). The muscle considered for transfer must be expendable and of sufficient strength to function actively against gravity after transfer. Each transfer has its inherent negative attributes: triceps transfer may weaken assistive ambulation in patients with lower extremity involvement, and may result in a flexion contracture; pectoralis major transfer may create asymmetric breast appearance in females; Steindler flexorplasty may worsen wrist and finger flexion contractures. Information gained to date indicates that the triceps transfer is most effective at improving strength, active range of motion, and function (64,72).

The triceps muscle is strong in most arthrogrypotic children. With transfer, it is usually successful in providing active elbow flexion in a functional arc. However, the triceps is important for crutch ambulation, rising from a sitting position, and wheelchair transfers in patients with lower-extremity involvement, and should be used cautiously for tendon transfer in these children. This operation involves the transfer of the antagonist to elbow flexion and leaves the patient without an active elbow extensor postoperatively. This can lead to progressive elbow flexion deformity with growth (72).

There are two options for transfer of the pectoralis major muscle for elbow flexion. The first choice is transfer of the sternocostal origin, as originally described by Clark (74a). This transfer can be problematic because the partial transfer may be too weak to provide antigravity strength for feeding and facial hygiene. In addition, the pectoralis major muscle crosses the shoulder and may lose strength trying to move both the shoulder and the elbow.

The second choice is transfer of the entire pectoralis major muscle on its neurovascular pedicles, as advocated by both Carroll and Doyle (74b). This operation has had favorable results in limited series of arthrogrypotic elbows. It involves transferring the insertion of the pectoralis major to the acromion. The origins of the clavicular and sternocostal heads, with attached anterior rectus abdominis fascia, are inserted distally into the proximal radius. The medial and lateral pectoral nerves and the lateral thoracic vessels are preserved. This transfer has the mechanical advantage of a linear contraction for elbow flexion and does not involve the loss of any strength in stabilizing or moving the shoulder. The proximal advancement of the insertion to the acromion or clavicle improves the lever arm and mechanical

advantage of the transfer. However, it may create an asymmetric appearance of the breasts in females, and this has been raised as an argument against transfer (64).

In patients with significant lower extremity involvement, with weak triceps or pectorals, or with failed pectoralis major or triceps transfers, a bipolar latissimus dorsi transfer, as described by Zancolli and Mitre (75), may be the optimal choice (Fig. 22-6). Preoperative assessment of the strength of the latissimus is important before transfer, but at times this is difficult to assess. An experienced pediatric physical therapist with extensive muscle evaluation experience may be helpful. Biopsy of the muscle has been tried, but is not predictive of outcome with transfer.

In summary, physical therapy should be initiated in infancy to obtain and maintain passive range of motion of the elbow. This will frequently result in passive elbow flexion of greater than 90 degrees. If by 24 months of age nearly full passive elbow flexion has not been achieved, elbow capsulotomy and triceps lengthening are recommended. After the age of 4 years, tendon transfer for elbow flexion in the dominant arm is recommended, with consideration given to intelligence, ipsilateral and contralateral upper-limb function, lower-extremity involvement, and available motors for transfer. All transfers have had success, but the triceps-to-biceps transfer gives the most predictably good results (64,72).

Wrist and hand reconstruction. The wrist palmar flexion contracture is addressed with FCU lengthening or transfer to the wrist extensors. Unfortunately, in many of these children the transfer is more of a tenodesis procedure than a dynamic transfer. In addition, there often is bony deformity, even in the very young. Smith (22) had recommended a proximal row carpectomy to correct the wrist flexion contracture. However, there frequently are carpal coalitions present that preclude that procedure. A dorsal, carpal, closing-wedge osteotomy can correct the deformity in the presence of a carpal coalition. This is an excellent procedure to correct the bone and wrist joint deformity that does not respond to therapy (71). Simultaneous FCU transfer can be performed to rebalance the wrist. An alternative to carpal osteotomy is radius and ulna dorsal osteotomies (67). However, these create an “S” deformity to the distal forearm, and physeal remodeling with growth tends to lead to recurrent wrist flexion deformity.

The thumb-in-palm contracture is addressed with a Z-plasty syndactyly release. Care must be taken not to overrelease the adductor. It may be providing the bulk of the pinch strength. Dynamic transfers for thumb abduction and extension are predominantly tenodesis procedures because of the limited strength of the donor muscles. Many of these children will have permanent limited motion and strength of their hands. Fortunately, their high level of intelligence allows them to be very adaptive in their functioning.

ELBOW AND FOREARM REGION

Congenital Dislocations

Congenital Radial Head Dislocations

Congenital dislocation of the radial head is a rare condition that may not be diagnosed until school age. It is usually an isolated condition, but it may be present in association with other congenital malformations and syndromes, including arthrogryposis and Cornelia de Lange, Larsen, and nail-patella syndromes (77,78,79 and 80). It may be associated with radioulnar synostosis (81,82) or other musculoskeletal anomalies, such as congenital hip dislocation, club feet, brachydactyly, clinodactyly, tibial fibular synostosis, congenital below-elbow amputation, and radial or ulnar club hand. Dislocations associated with Madelung deformity or familial osteochondromatosis (82) may be acquired, and will be considered elsewhere in this chapter.

Congenital radial head dislocation may be bilateral or unilateral (83). It is defined by the direction of subluxation or dislocation. The majority of congenital dislocations are posterior or posterolateral. It is important to distinguish the congenital dislocation from the posttraumatic dislocation. Because the condition frequently presents late, this distinction can be confusing (78,83). This is especially true for unilateral anterior dislocations in otherwise normal children (84,85 and 86). Radiographic criteria have been established to distinguish this lesion from a chronic, traumatic dislocation. These include a small, dome-shaped radial head; a hypoplastic capitellum; ulnar bowing with volar convexity in the anterior dislocation and dorsal convexity in the posterior dislocation; and a longitudinal axis of the radius that does not bisect the capitellum. The presence of these characteristics in the absence of any history of trauma to the affected elbow has been seen as evidence of a congenital radial head dislocation (64,78,87,88,89,90,91 and 92). In addition, bilateral involvement, the presence of other musculoskeletal or systemic malformations, and a positive family history all make a congenital cause more likely.

Clinical and Radiographic Features. These children often present after infancy. The most common reasons for presentation are (i) limited elbow extension; (ii) posterolateral elbow mass/prominence; and (iii) pain with activities, especially athletics (64,93). The elbow extension loss is frequently less than 30 degrees, and not of functional significance. This loss of motion is usually not noted early in life. The mass may be noted in infancy. Radiocapitellar incongruity can be a cause of pain and disability later in life (83,93). Unfortunately, many children present late with pain resulting from radiocapitellar articular changes. There is often chronic discomfort with school and sports activities. On occasion, these children may present with an acute loss of motion attributable to a loose osteochondral fragment. Some individuals remain asymptomatic, and the cosmesis of the deformity is their major concern.

On physical examination, the elbow may have cubitus valgus. A flexion contracture of up to 30 degrees often occurs with a posterior subluxation/dislocation. Hyperextension and/or loss of flexion may occur with an anterior dislocation. The radial head is palpable in its dislocated position. A congenital dislocation is not reducible by forceful manipulation, and should not be misinterpreted as a nursemaid's pulled elbow or a Monteggia lesion. There is usually limited forearm rotation, with supination being affected more than pronation. Clicking and crepitus may be present when there is intraarticular pathology (64).

Radiographs reveal the subluxation/dislocation (Fig. 22-7). The longitudinal axis of the radius does not bisect the capitellum, regardless of the angle of the radiograph. The radius and ulna are of different lengths. The ulna is bowed, with volar convexity in an anterior dislocation and dorsal convexity in the more common posterior dislocation. The capitellum is hypoplastic. The radial head will be dome-shaped, with a long, narrow radial neck.

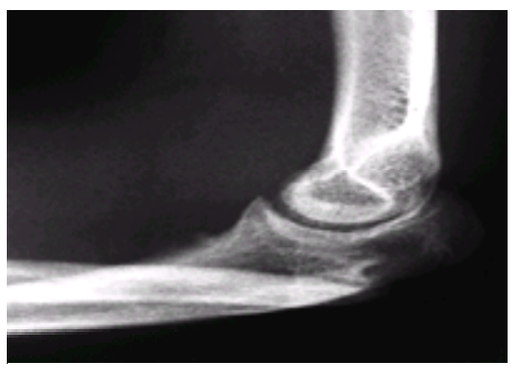

FIGURE 22-7. Lateral radiograph of congenital posterolateral dislocation of the radial head. There is evidence of tapering of the radial head and neck posteriorly, bowing of the ulna posteriorly, and a small dome-shaped radial head. These patients often have limited elbow extension, and develop intraarticular pain at the abnormal radiocapitellar articulation in adolescence.

Natural History. The presence of a congenital dislocated radial head is not an indication for operative intervention. Many patients with this disorder have no functional limitation and no pain. Their mild limitation of motion may not restrict them in any significant way. The degree of cubitus valgus is usually mild, and does not seem to put them at risk for ulnar neuropathy. Therefore, in the majority of cases a definitive diagnosis followed by observation is most appropriate. If the patient develops pain, functional or progressive limitation of motion, or restriction of elbow-related activities, then surgery needs to be considered (64).

Treatment

Operative Care. Ideally, the care of a congenital dislocated radial head would involve open reduction and restoration of normal anatomy. This has led many surgeons to consider open reduction of a congenital dislocation if the child presents in infancy (80,81,87,94). The logic is that if the radial head can be reduced early in infancy,

the deformity of the capitellum and the forearm may not occur or remodel with growth. This may prevent the long-term complications of pain, loss of motion, and osteochondral loose bodies. However, there have been only a small number of published cases of open reduction of congenital radial head dislocations (81,94,95). Techniques have included ulnar osteotomy and lengthening, radial shortening and osteotomy, annular ligamentous reconstruction, and the use of limb-lengthening devices to reduce the radial head (91,94,95 and 96). Sachar and Mih's report of open reduction via an anconeus approach and annular ligament reconstruction is the most promising series to date. They described seven cases of open reduction of a congenitally dislocated radial head with good success (94). Their operative findings included an abnormality of the annular ligament that was surgically correctable. The indications for this procedure, and the age limit, are still being defined in this relatively rare condition. It is reasonable to consider open reduction of the congenitally dislocated radial head in the infant younger than 1 to 2 years of age, provided that the family is well informed of the preliminary nature of the information regarding this procedure.

Most children with congenital radial head dislocation present later than infancy. Therefore, the most common procedures for this problem are excision of loose bodies and excision of the radial head. The indications for excision of a loose osteochondral fragment are the presence of pain, clicking or locking, and loss of motion. Usually, degenerative changes are too advanced for repair of the osteochondral fragment. There is some controversy regarding the indications and timing for excision of the radial head. In the skeletally immature patient the concern is the potential development of postoperative complications (see next section). These concerns have not been supported in the published literature on excision of the congenitally dislocated radial head. Most of these children do not present until adolescence with pain or progressive restriction of motion. In our series, the youngest patient with excision of a symptomatic congenital radial head without complication was 8 years of age (83). However, the presence of an asymptomatic dislocated radial head alone, without painful, progressive restricted range of motion, is not an indication for radial head excision. Indications for radial head excision must include progressive pain, progressive loss of motion, and progressive restriction of activities (64), regardless of age.

Complications. Throughout the twentieth century, standard textbooks and journal articles have condemned the concept of radial head excision in the skeletally immature individual. Postoperative complications of progressive cubitus valgus and potential associated ulnar neuropathy, proximal migration of the radius, with recurrent radiocapitellar impingement, radioulnar synostosis, and reformation of the radial head, have been cited (87,88,97,98 and 99). However, most of these problems occurred after radial head excisions to treat trauma. The admonishment to “never excise a radial head in a skeletally immature individual” still holds true in the posttraumatic situation. These complications are rare after excision for congenital radial head dislocations (83).

Reformation of the radial head is the most common problem with excision of a congenital dislocation (98,100,101). If it leads to recurrent radiocapitellar impingement, limitation of motion, and/or pain, then repeat radial head excision should be performed. Wrist pain does occur in the long term but seems to be mild and nonrestrictive (83). Fortunately, iatrogenic radial nerve injury is rare.

Congenital Humeroulnar Dislocations

Dislocation of the ulnotrochlear joint is exceedingly rare. Mead and Martin described a family with aplasia of the trochlea and humeroulnar dislocations (102). Ulnotrochlear dislocations have also been seen in hyperelasticity syndromes. These situations are rarer than the unusual posttraumatic persistent or recurrent dislocation.

A congenital dislocation will result in limited range of elbow motion that can affect function. The dislocation is usually palpable on examination. There may be axial malalignment, such as cubitus valgus. If severe, the valgus deformity can result in ulnar neuropathy. In recurrent dislocations secondary to hyperelasticity or associated with syndromes such as Rubinstein-Taybi syndrome (103), the elbow instability is palpable and even audible on examination. On occasion, with recurrent instability osteochondral injury can occur that will cause pain, clicking, or even locking on examination.

Elbow dislocation can also be seen with ulnar dysplasia and ulnar dimelia (104,105,106 and 107). The dysplastic ulnotrochlear joint in ulnar club hand can lead to elbow problems that limit motion and function. Ulnar dimelia, or mirror hand, is exceedingly rare. The forearm and elbow in this condition consist of two ulnae and no radius. This means that there are two olecranon processes articulating with the distal humerus. There are usually two poorly defined trochleae and no capitellum present. The olecranon processes may face one another. There is significant limitation of elbow and forearm rotation (64,108,109).

If the child presents before ossification of the secondary centers, it may be difficult to define the dislocation anatomically by plain radiography. MRI will be diagnostic, but will require sedation or general anesthesia in infancy. Ultrasonography may be diagnostic in skilled hands (64).

Natural History. Children with congenital dislocations will have limited elbow and forearm range of motion and strength that will affect function. They must compensate with shoulder, wrist, or trunk range of motion to perform recreational activities and activities of daily living. If unreduced, there is concern that chronic arthritic pain could develop. However, this is not well documented.

In children with recurrent instability, pain may develop secondary to osteochondral injury. This can lead to osteochondral loose bodies and arthrosis-like pain.

Treatment

Operative Care. The isolated, congenital elbow dislocation has been rarely treated with open reduction (64,103). These cases and operations are rare enough that generalized comment is difficult. The more abnormal the anatomy, the less likely that operative intervention will be successful.

In recurrent instability ligamentous reconstruction, transposition of the biceps tendon insertion to the coronoid process, and an anterior bone-block procedure have all been advocated (103,104). The choice or combination of procedures depends on the pathologic anatomy and the degree of instability.

It is the rare congenital elbow dislocation associated with ulnar dimelia and ulnar club hand that may warrant surgical reconstruction. Although ulnar dysplasia will be described in more detail in the wrist section of this chapter, it is worthwhile to discuss elbow reconstruction in this section. In type II ulnar club hand there is partial absence of the ulna distally (104,105 and 106). The proximal ulna articulates with the humerus but is usually unstable. With growth, the radius migrates proximally, leading to progressive loss of elbow flexion and extension. A supination deformity of the forearm may develop that limits forearm rotation (106). In these circumstances, creation of a single-bone forearm may improve cosmesis, stabilize the forearm, and improve elbow motion (104,108). As described by Bayne (104), with this procedure the ulnar anlage is completely excised and the adjacent ulnar artery and nerve are protected. Radial osteotomy is then performed proximally. The radius is placed distal to the ulna in an end-to-end manner. Intramedullary fixation is performed to connect the proximal ulna to the distal radius. If there is significant bowing of the radius distal to the osteotomy site, a second osteotomy is performed with passage of the intramedullary wire. If it is difficult to attain end-to-end fixation, then side-to-side fusion is acceptable. Resection of the dislocated proximal radius can be performed simultaneously or up to 6 months later. If there is any question of neurovascular compromise it is advisable to delay the proximal radius excision (104). At the time of proximal radius excision, the posterior interosseus radial nerve needs to be exposed and protected.

Wood recommends that reconstruction of the complex elbow deformity associated with ulnar dimelia should begin at the elbow with excision of the lateral olecranon process (108). Reconstruction of ligamentous structures may be necessary after excision to provide elbow stability. Excision of the lateral olecranon reportedly will provide improved passive elbow flexion and extension, but there may be continued limited active elbow flexion as a result of deficiencies in the biceps and brachialis musculature. Tendon transfers for active elbow flexion have reportedly had limited success (108). This condition (and reconstruction) is so rare that in-depth analysis of treatment options is not possible.

Congenital Synostoses

These entities are classified as failure of differentiation of parts with skeletal involvement. In this section, congenital radioulnar and elbow synostoses will be discussed.

Congenital Radioulnar Synostosis

Congenital synostosis of the proximal radius and ulna is a rare malformation of the upper limb. It is caused by a failure of the radius and ulna to separate, usually proximally.

During the embryonic period of fetal development, the humerus, radius, and ulna are conjoined. Longitudinal segmentation begins distally. For a time the proximal

ends are united and share a common perichondrium. Abnormal genetic or teratogenic factors can disrupt radioulnar joint development, leading to a bony synostosis. This represents a type I deformity. If rudimentary joint development occurs before developmental arrest, a rudimentary radial head will develop with a less severe degree of coalition. This is a type II deformity (110).

During this period of intrauterine development, the forearm is anatomically in a position of varying degrees of pronation (111). Failure of formation of the proximal radioulnar joint at this stage of differentiation will leave the forearm in its fetal position of pronation. With rare exceptions (112), the forearm is fixed in pronation with congenital radioulnar synostosis (111).

Congenital radioulnar synostosis is usually an isolated event. There is a three-to-two male predominance. Positive family histories have been reported (77,113,114). It is a bilateral occurrence 80% of the time (115). The condition is also seen in disorders such as acropolysyndactyly (Carpenter syndrome), acrocephalosyndactyly (Apert syndrome), arthrogryposis, acrofacial dysostoses of Najjar and mandibulofacial dystosis, and Klinefelter syndrome and its variants (116,117).

Although radioulnar synostosis is usually an isolated event, there may be associated anomalies of the musculoskeletal, cardiovascular, thoracic, gastrointestinal, renal, and central nervous systems. Cardiac anomalies include tetralogy of Fallot and ventricular septal defects. Thoracic anomalies include hypoplasia of the first and second ribs and the pectoral musculature. Renal anomalies involve anatomic malformations that can be screened by ultrasonography. In the central nervous system associated problems include microcephaly, hydrocephalus, encephalocele, mental retardation, delay in attaining developmental milestones, and hemiplegia. Musculoskeletal problems include clubfeet, dislocated hips, polydactyly, syndactyly, and Madelung deformity (64,81,115,118).

Clinical and Radiographic Features. These children present for evaluation when they have a functional deficit. Generally, the degree of fixed forearm pronation determines the disability and the age of presentation. The presence of bilateral synostosis in marked pronation significantly limits function, and leads to an earlier presentation. Most children will present for evaluation by school age. Radioulnar synostosis is often first noted by a teacher or daycare worker when comparing the affected child with peers performing the same tasks (64).

Functional complaints are variable and include (i) difficulty in holding or using small objects such as spoons or pencils; (ii) inability to dress owing to poor manipulation of belt buckles or buttons; (iii) backhanded positioning when holding objects such as bottles or toys; and (iv) difficulty competing in sports requiring upper-extremity dexterity. Feeding and accepting objects with an open palm are often difficult (64,115).

On physical examination, the elbow often has loss of its normal carrying angle and has a flexion deformity. The flexion contracture is usually minimal. Shortening of the forearm is more apparent in unilateral cases. Rotational hypermobility of the wrist compensates for the lack of forearm rotation (112,114). Despite this ligamentous laxity, patients do not appear to develop symptoms of carpal instability.

Almost all patients present in fixed pronation. In the series by Simmons et al. (115), approximately 40% of patients presented with pronation of less than 30 degrees, 20% had pronation fixed between 30 and 60 degrees, and 40% had more than 60 degrees of pronation. Pronation of greater than 60 degrees appears to be the most limiting.

Radiographs of patients with congenital radioulnar synostosis show anatomic variations from minor radial head deformities in patients with limited forearm rotation, to full synostosis and absence of the radial head in patients with no rotation (81) (Fig. 22-8). The more extensive synostoses are usually fixed in more pronation. Plain radiographic classifications have distinguished partial and complete synostoses. In the partial synostosis there is often a rudimentary radial head present, but it is posteriorly or posterolaterally subluxated. In the complete synostosis the radial head is absent, and the proximal radius and ulna are a single bony mass. There is always an increased anterior bow of the radius. On occasion, the synostosis can extend into the middiaphysis of the forearm.

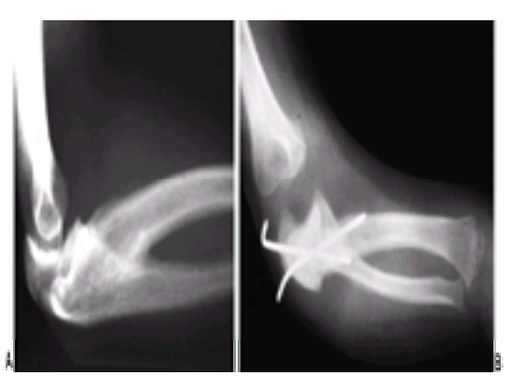

FIGURE 22-8. A: Preoperative radiograph of a congenital radioulnar synostosis. There is complete fusion of the proximal radius and ulna, and posterior dislocation of the radial head. The entire ulna is mildly hypoplastic. **B:** Postoperative radiograph of a derotation corrective osteotomy for this patient. A longitudinal wire is passed down the medullary canal of the ulna across the synostosis site. This Kirschner wire starts from the proximal ulnar apophysis. The osteotomy cut is performed through the synostosis. The transfixing wire is obliquely placed to secure the corrective derotation to a position of 0 to 20 degrees of pronation.

Occasionally, a patient will present with limited forearm rotation and normal radiographs. MRI of the proximal radius and ulna may reveal a cartilaginous synostosis that has yet to ossify or a fibrous tether that limits motion (64).

Natural History. In the absence of functional limitation, children with radioulnar synostosis should be observed. Those children with (i) synostosis in neutral-to-mild pronation (less than 60 degrees), (ii) significantly compensatory radiocarpal and intercarpal wrist rotation, and (iii) unilateral disease often compensate for lack of forearm rotation (64). These children present because they, their parents, and/or their teachers notice them performing home, school, or recreational tasks differently than their peers. However, when questioned extensively, they are without pain or functional disability (114). These children and their families are best served by counseling regarding the diagnosis and genetics of their problem, and reassurance that operative intervention would be unlikely to improve their condition.

Treatment.

Operative Care. The ideal treatment would be to restore normal forearm rotation. Many surgical attempts to do so have been tried. Reported procedures have included division of the bony bridge (111); resection of the synostotic proximal radius to save the bicipital tuberosity with (119,120 and 121) and without (122) muscle interposition; division of the interosseous membrane; and muscle, fat, fascia, or silastic interposition after synostosis excision (113,123). All had limited success at restoring motion. Artificial joint replacement, with a metallic swivel in the intramedullary canal of the radius between the supinator and pronator teres, also failed (121). Tagima et al. (123) reported improved forearm rotation with synostosis takedown, radial osteotomy, and interposition of either a silastic or a free fascial lateral arm flap. Intraoperatively, synostosis takedown procedures can dramatically improve motion, but there is a high incidence of loss of motion in the 6 to 12 months after surgery. At present, the functional gain does not seem to warrant this surgical intervention.

The alternative to synostosis excision is derotation osteotomy. The goal is to place the hyperpronated hand in a more functional position. The dominant extremity is given priority in bilateral cases. It is easiest to perform the osteotomy through the synostosis distal to the coronoid process. Before the procedure, an intramedullary ulnar Kirschner wire is placed to maintain control of the osteotomy. After completion of the osteotomy, the forearm can be rotated into the desired position of correction. Generally, patients undergoing derotation osteotomy have a fixed preoperative position of 60 to 100 degrees of pronation. The final corrected position is often 0 to 20 degrees of pronation (64). Ogino and Hikino advocated measuring the preoperative compensatory wrist supination to define the desired operative osteotomy correction (112). Once this position is achieved a second percutaneous Kirschner wire transfixes the osteotomy site obliquely, from the proximal ulna to the distal radius, across the derotated synostosis (Fig. 22-8). Because there is a high risk of compartment syndrome postoperatively (115,124), it is important to avoid internal fixation that would require a second operation for removal if neurovascular compromise occurs. Resection of bone at the synostosis site (112), or dorsal and volar fasciotomies through the operative incision, lessen the risk of compartment syndrome postoperatively (64) and should be performed routinely.

Patients undergoing derotation osteotomies have been noted to have significant improvement in function and cosmesis (115). Bimanual tasks are easier.

Single-handed tasks, such as holding a fork, no longer require backhanding in extreme hyperpronation. Activities of daily living, such as dressing and feeding, are performed more independently and with less adaptive shoulder and trunk motion.

Complications. The most significant complication is postoperative compartment syndrome. It has been reported in one-third of patients undergoing derotation osteotomy. This is attributable to changes in the vascularity and volume of the forearm compartments with derotation osteotomies in the range of 60 to 90 degrees (115). Compartment syndrome is more common in osteotomies with greater than 85 degrees of rotational correction. Prophylactic forearm fasciotomy, or resection of a segment of synostotic bone, reduces the incidence of this complication. If compartment syndrome is developing the compressive dressings should be removed promptly, and the limb should be placed horizontally at the level of the heart. Compartment pressure measurements are routinely performed in the presence of tense compartments in a child with the clinical appearance of compartment syndrome. In pediatric patients an increasing analgesia requirement and a high level of anxiety, are the most diagnostic clinical signs of compartment syndrome (125). Removal of the oblique transfixing Kirschner wire is performed if removal of dressings and proper elevation fail to improve the situation. Removal of the oblique Kirschner wire allows the forearm to rotate to its preoperative position, lessens the tension on the interosseous vessels, and reduces the volume of the forearm compartments. Finally, if these maneuvers do not resolve the problem, emergent skin and fascia decompression is mandatory (64,115).

With removal of the Kirschner wire in compartment syndrome there is a risk of loss of operative correction. The longitudinal ulnar Kirschner wire helps maintain control of the osteotomy site and allows for controlled, repeat derotation 5 to 10 days later. Although more rigid internal fixation may seem more desirable, it unnecessarily complicates the procedure, especially if compartment syndrome develops.

Elbow Synostosis

Elbow synostosis is very rare. It occurs in isolation or associated with syndromic conditions. Humeroradial is more common than ulnotrochlear synostosis (126,127 and 128). This is often in a position of elbow flexion from 60 to 90 degrees. Often, there is also limited or no forearm motion. On examination, there will be no elbow motion.

Elbow synostosis is often associated with other upper limb malformations, such as ulnar clubhand (127). It has been described in siblings with humeroradial synostosis, indicating a potential genetic inheritance pattern. It frequently occurs with phocomelia variants (126). The limitation of elbow motion limits function, particularly if the affected extremity is a dominant extremity. The placement of a functional hand in space is limited by the lack of flexion–extension at the elbow. Compensatory trunk, head, and shoulder motion is difficult to adapt. Associated hand anomalies can further limit function (64).

Treatment. Attempts at synostosis excision and restoration of elbow motion have had minimal success. Techniques have included excision with muscle, fat, silastic interposition, or distraction arthroplasties. Although intraoperatively the motion can be improved, recurrence of the synostosis usually develops postoperatively. The use of continuous passive motion devices, or distraction elbow hinge devices, has not improved results (64). If the ankylosis leads to dysfunctional positioning of the hand in space, such as in the presence of an ulnar clubhand, corrective osteotomy is indicated. Most often, this is a derotation osteotomy at the level of the synostosis (126). Correction of a marked flexion deformity acutely increases the risk of neurovascular compromise. There is no role for total elbow arthroplasty because of early mechanical failure (64).

Musculoskeletal

Osteochondromatosis

Deformity of the forearm is common in multiple hereditary osteochondromatosis, with between 30 and 60% of patients affected in various series (129,130 and 131). The most frequent problem seems to be distal ulnar osteochondroma, which selectively slows the growth of the ulna in the presence of continued radial growth. The resultant ulna shortening can lead to progressive bowing of the radius and/or possible radial head dislocation. At the wrist, there is increased radial angulation of the distal epiphysis, with ulnar deviation of the hand and ulnar translocation of the carpus (131,132,133 and 134). These deformities can lead to progressive loss of forearm rotation. If radial head dislocation occurs, loss of elbow motion and the development of pain can occur. This section focuses on the treatment of ulnar shortening, progressive radial bowing, and radial head subluxation. The principles outlined here for osteochondromatosis have also been used in congenital syndromes with forearm growth discrepancies, such as Conradi and Morquio syndromes (64).

Natural History. There are very limited natural history data on patients with deformity secondary to osteochondromatosis of the upper extremity. There is ample information on the indications for, and the results of, surgical excision of osteochondromas and forearm reconstruction for these patients with deformities (135,136 and 137). The Shriners group in St. Louis (138) attempted to obtain natural history data by surveying their patients by telephone. Their data suggest that adults with forearm, wrist, and hand deformities from osteochondromatosis do reasonably well with activities of daily living and occupational tasks. Unfortunately, their data were limited because they could not reach many of their patients, and no patients were examined.

Treatment Indications. The presence of an osteochondroma alone is not an indication for surgical excision. Excision of an osteochondroma will not predictably improve growth or prevent recurrence with growth. However, if the osteochondroma is a source of pain, limitation of motion, or neurovascular or muscular impingement, then excision is indicated. In addition, children with forearm osteochondromatosis may present with progressive deformity, loss of pronation and supination, and wrist or elbow pain related to joint subluxation. The limitations of forearm rotation may be caused by impingement of osteochondromas distally or proximally. When the loss of motion is secondary to impingement alone, rotation will improve with osteochondroma excision (131,132). In the presence of progressive forearm deformity, loss of rotation may also be related to bony malalignment, proximal radial head subluxation, or distal radioulnar joint dislocation. In these situations, rotation and radiocapitellar alignment can be improved by corrective radial osteotomy and ulnar lengthening (135). In the presence of radial head dislocation, reconstruction is very difficult. Attempts at reduction of the radial head by osteotomy or distraction lengthening techniques have had limited long-term success. Radial head excision has been advocated after skeletal maturity (136,137). The creation of a single-bone forearm may be the necessary salvage procedure (131,137,139,140).

Operative Management. Operative intervention is indicated in the presence of either progressive deformity that limits motion or radiocapitellar joint instability. The indications, specifically in terms of deformity, are ulnar-shortening greater than 1.5 cm, increasing distal radial articular angle greater than 30 degrees, ulnar carpal translocation greater than 60%, progressive radial bowing, and radial head subluxation (135). The key to radiocapitellar instability is to treat it before frank dislocation occurs. Once the radial head is dislocated obtaining and maintaining reduction is difficult.

The majority of patients with forearm deformities secondary to osteochondromatosis can be treated with a single-stage operative correction. The ulnar-shortening is addressed by simultaneous excision of the osteochondroma and Z-lengthening of the ulna. After the Z-osteotomy, distraction lengthening is carried out intraoperatively with an external fixator. When the desired lengthening is achieved, a plate is applied to maintain the length until bony healing is complete (64) (Fig. 22-9). This lengthening technique is, in essence, a rebalancing of the forearm skeleton. It realigns the proximal and distal radioulnar joints. In one series, lengthenings of 1 to 2.3 cm, leading to a neutral ulnar variance at the wrist, were obtained in a single stage (135). The majority of patients improved forearm rotation by an average of 40 degrees (64,135). Results indicate improved range of motion and function with minimal risk of complications.

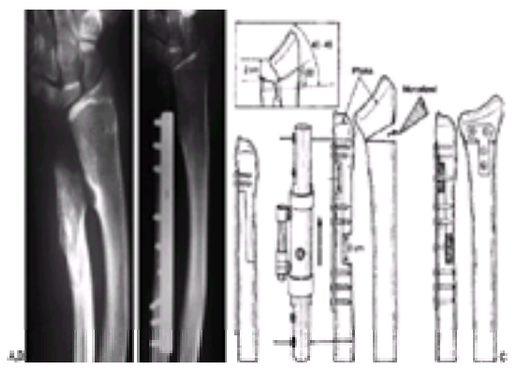

FIGURE 22-9. A: Preoperative radiograph of an osteochondromatosis patient with ulnar-shortening and mild radial deformity, with recent progressive loss of forearm

rotation. **B:** Postoperative radiograph of single-stage lengthening of the ulna. **C:** Illustration of the lengthening technique.

There are rare situations with osteochondromatosis in which correction cannot be obtained in a single procedure (96,141,142 and 143). The choice is to perform serial lengthenings or gradual distraction osteoclasis. Up to 13 cm of length has been obtained by distraction techniques (141,142). However, the rate of complications with distraction osteoclasis in the forearm has been cited as between 60 and 100%. Therefore, forearm lengthenings by distraction techniques should be performed cautiously by skilled surgeons. The options for distraction lengthening include unilateral external fixation frames (144,145 and 146), classic Ilizarov technique (145), or hybrid fixation using transverse Ilizarov wires at 90 degrees to half pins (143,147). Most surgeons performing distraction lengthening now use a hybrid technique to lessen the risk of neurovascular and muscle entrapment complications (141,142 and 143,147). The fixator is preassembled as part of preoperative planning, with a half ring proximally and a full ring distally. In those situations requiring angular correction, appropriate hinges need to be applied to obtain correction. Because each case is unique, the specifics of application are difficult to address in a review such as this. However, certain principles need to be adhered to. The pins need to be placed in the safe zone to lessen the risk of complications. Passive digital flexion and extension need to be full intraoperatively after pin placement to ensure postoperative maintenance of motion. The preferred site for corticotomy is the proximal ulna metaphysis to enhance regenerate bone (143). Lengthening begins 3 to 5 days after surgery and progresses at a rate of 1 mm per day, usually with an advance of 0.25 mm four times per day. Maintenance of passive and active range of motion of the shoulder, elbow, and digits is critical. Clearly, the loss of hand function is not worth the advantage of increased forearm length. Prevention and treatment of expected pin-track infection require meticulous pin care and liberal use of oral antibiotics. After the desired lengthening is achieved, the external fixator is left in place until there is sufficient regenerate bone to allow removal without the risk of fracture. In general, the fixator is left in place at least twice the time necessary to obtain lengthening (64).

In the presence of radial head dislocation, the distraction technique has been used in an attempt to reduce the radial head, before correction of the forearm deformity (96,143,147). A separate ring and olive wire are placed in the proximal radius. Progressive distal migration of the radial head has been used for radiocapitellar reduction. Once the radial head is reduced, the forearm correction is performed as described above. However, recurrent subluxation, joint stiffness, and pain have occurred after radial head reduction (64). The limited success of this procedure in this situation does not seem to warrant its use.

The creation of a radioulnar synostosis is indicated for either painful radial head dislocation or radius and ulna instability not salvageable by other means. In these circumstances, it can result in a stable, pain-free extremity (136). Radial head excision is performed to decompress the radiocapitellar joint and improve elbow range of motion. Correction of the deformities of the radius and ulna is performed at the same time as the radioulnar synostosis with internal fixation and bone grafting. Neutral rotation to 20 degrees of pronation is desired. Although this procedure is rarely indicated, these patients have excellent long-term results (136).

Pseudarthrosis

Congenital pseudarthrosis of the forearm is rare and clearly associated with neurofibromatosis. Wood (148) summarized the cases of forearm pseudarthrosis in the medical literature, and noted that 5% of patients with neurofibromatosis have pseudarthrosis of the upper or lower limb, whereas more than 50% of patients with congenital pseudarthrosis of the forearm have definitive neurofibromatosis, multiple café-au-lait spots, or a positive family history of neurofibromatosis. Congenital pseudarthrosis is most often seen in the tibia, but it has been described in all the long bones.

In a survey of the literature, Wood (148) found 46 cases of forearm pseudarthrosis. The ulna was involved in 20 cases (Fig. 22-10), the radius was involved in 15 cases, and both ulna and radius were involved in 11 cases. Twenty-three of these patients had either neurofibromatosis (18 patients) or a positive family history of neurofibromatosis (5 patients). Reports of this disorder range from a single case to up to six patients (149).

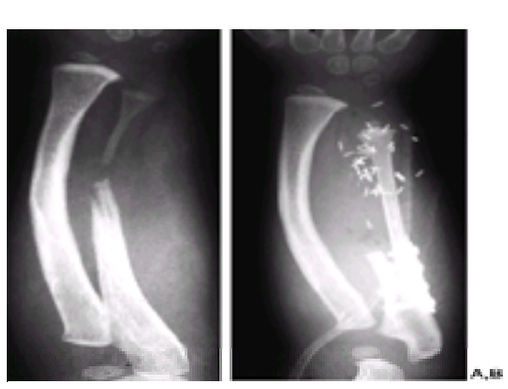

FIGURE 22-10. A: Preoperative radiograph of congenital pseudarthrosis of the ulna. Note the hypoplasia and tapering of the distal ulna. **B:** Postoperative radiograph of vascularized fibular transfer, with proximal epiphyseal and physeal transfer, to establish distal ulnar growth. If the patient is very young, the microvascular transfer must include revascularization of both the diaphysis and epiphysis of the fibula to obtain physeal growth. The most distal metallic clip indicates the top of the fibular epiphysis in the reconstructed distal radioulnar joint.

Similar to tibial pseudarthrosis, all reports describing treatment options for this problem outline the difficulty of obtaining union with conventional cast immobilization or corticocancellous autografting or allografting, with and without internal fixation techniques. The role of distraction lengthening techniques for congenital pseudarthrosis of the forearm is unclear. There are several reports of the use of vascularized fibular grafts (149,150) to heal the pseudarthrosis. These reports indicate a high rate of union with vascularized fibular transfer. This is the preferred treatment for this disorder at present. In the forearm the fibula is internally fixed to the proximal ulna. Distally, the fibula is secured to the soft tissues of the distal radioulnar joint and the triangular fibrocartilage complex (TFCC). The vascular anastomosis is end-to-side to the ulna artery. At the donor site of a skeletally immature patient, the distal fibula is fixed to the tibia to prevent valgus ankle instability after harvesting a vascularized fibular graft (148,151). The proximal fibular epiphysis can be transferred in the young patient to allow for growth. In this situation, the separate vascular supplies to the fibular diaphysis and epiphysis need to be preserved and maintained with the transfer. The soft tissue support of the lateral knee must be reconstructed.

Creation of a single-bone forearm has been performed successfully as a salvage procedure (149). In the presence of an associated radial head dislocation, this may be the only successful option (64).

WRIST REGION

Congenital

Radial Dysplasia

Radial dysplasia is classified as a longitudinal failure of formation. It occurs in between 1 in 30,000 and 1 in 100,000 live births (152,153). The underdevelopment, or aplasia, of the radius is universally associated with thumb hypoplasia, or absence, and hypoplasia or absence of the radial aspect of the carpus (154). The radial or preaxial deficiency has been classified by Bayne and Klug (152) into four types, ranging from a present but defective distal radial epiphysis (type I), to complete absence of the radius (type IV). The severity of the radial deficiency determines the extent of the associated deficiencies of the thumb, digits, ulna, and elbow (Fig. 22-11). Thus, the spectrum of anatomic deficiency can range from mild radial deviation of the wrist and minimal thumb hypoplasia, to complete absence of the thumb and radius; camptodactyly of the index, long, and ring fingers; foreshortening of the ulna; and a stiff elbow.

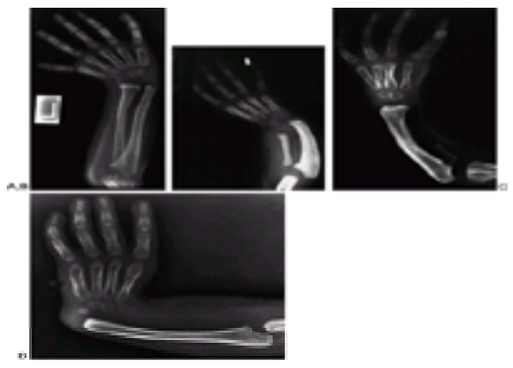

FIGURE 22-11. Classification of radial dysplasia types I through IV as represented by radiographs. **A:** In type I, the ulna variance is positive as a result of the foreshortened distal radius. **B:** In type II, both the proximal and distal radial physes have deficient growth, with more radial shortening and ulnar bowing. **C:** In type III, the radius is partially absent. **D:** In type IV, the radius is completely absent.

Pathogenesis. The pathogenesis of longitudinal deficiency of the radius is unknown. It has been postulated that injury to the apical ectodermal ridge during upper limb development is the cause (6,155). Factors such as intrauterine compression, an inflammatory process, vascular insult, maternal drug exposure (thalidomide, insulin), and irradiation have all been raised as possible etiologic causes (1). There is no known genetic cause except when radial deficiency is associated with other congenital abnormalities. The pattern of inheritance is autosomal dominant or autosomal recessive, depending on the syndrome. There are many associated congenital syndromes, including cardiac, craniofacial, hematopoietic, musculoskeletal, gastrointestinal, and renal organ syndromes. There are associated chromosomal abnormalities, including trisomy 13, 18, and 21. The occurrence is most often sporadic, and at present no definite cause is known.

Associated Anomalies. Although radial longitudinal deficiency can occur in isolation, it is commonly associated with other congenital malformations. Forty percent of patients with unilateral radial club hand, and 27% of patients with bilateral radial club hand, have associated malformations (156). It is imperative that these problems be assessed by clinical, radiographic, and laboratory evaluations as appropriate. These organ system malformations may present in a nonsyndromic pattern. Congenital cardiac, genitourinary, respiratory, skeletal, and neurologic problems occur in children with radial dysplasia. Similarly, many syndromes have been described in association with longitudinal deficiency of the radius. The most common are VACTERLS, Holt-Oram syndrome, Fanconi anemia, and thrombocytopenia with absent radius. VACTERLS includes the classic VATER of vertebral anomalies, anal atresia, tracheoesophageal fistula, and renal anomalies, as well as cardiac and lower-limb malformations, with a single umbilical artery (157,158 and 159). Holt-Oram syndrome is an autosomal dominant disease characterized by upper-limb malformations and major cardiac malformations (160). The gene for Holt-Oram syndrome has been identified. Fanconi anemia is also an autosomal dominant inheritance. In infancy, there are usually characteristic facial features (microphthalmos, strabismus, hearing deficits) (161). Pancytopenia often does not present until later in childhood. Fanconi anemia can now be identified by a mitomycin C test. Thrombocytopenia with absent radius is an autosomal recessive inheritance. The thrombocytopenia is present at birth. The platelet count usually improves with growth, and hand surgery should be delayed until it is safe (162,163).

Clinical Features. The clinical presentation of radial dysplasia depends on the severity of the malformation. Bayne et al. (164) have tried to clarify the spectrum of clinical deformity by classifying radial club hands from type I to type IV. Type IV deficiency is the most common. Type I deformity involves a defective distal radial physis. This leads to a minor foreshortening of the radius and a prominent distal ulna. Although there is mild radial deviation of the wrist throughout life, problems with radioulnar incongruity such as triangular fibrocartilage tears, ulnocarpal impaction syndrome, and distal radioulnar joint pain or loss of motion, usually do not occur. The major clinical issue is the associated thumb hypoplasia with opposition weakness. Type II deficiency involves limited proximal and distal radial physeal growth. As a consequence, the wrist is more radially deviated, and the ulna bows. The thumb hypoplasia is usually more significant, with more deficiency of the radial carpus. Type III deficiency is the absence of the distal two-thirds of the radius. The wrist is more severely deviated, and the hand has limited mechanical support. The ulna is thickened and bowed. The associated thumb and finger abnormalities of hypoplasia and camptodactyly are more common and severe. Type IV deficiency involves complete absence of the radius. The ulna bowing is marked. The thumb is usually absent. The index, long, and even ring fingers are often involved. The elbow may have limited range of motion. There is marked limitation of hand, wrist, and forearm function.

Pathoanatomy. Radial dysplasia involves skeletal malformations and soft tissue deficiencies on the preaxial or radial side of the hand, wrist, and forearm. The severity of the soft tissue loss parallels the skeletal deficiency. The preaxial muscles arise from the lateral epicondyle, and are normally innervated by the radial nerve. Thus, the radial wrist extensors and brachioradialis are absent or deficient. The pronator–flexor muscle mass is affected when its skeletal insertion sites are absent or hypoplastic. These structures can be only fibrous tissue (radial anlage) that maintains or worsens wrist and hand deformity with growth. Similarly, the neurovascular structures will be affected. The posterior interosseous and sensory branches of the radial nerve will be absent in a severe deformity. The radial artery is usually absent. The ulnar nerve and artery are usually present and unaffected. The blood supply to the hand comes through the ulnar artery, and possibly the interosseous vessels or a persistent median artery. The median nerve is usually present and serves as a neural supply to the hand with the ulnar nerve. However, the more severe the deformity of the hand and wrist, the more limited the neural and vascular supply will be to the hand.

Natural History. Generally, children with longitudinal deficiency of the radius have an unaffected central nervous system. As with any congenital upper limb malformation, children's creative minds allow them to perform all activities of life. However, they may need to use adaptive mechanisms. These generally include a spherical grip and lateral pinch to compensate for the absence of opposition (165). Fifty to 62% of patients with radial dysplasia have unilateral involvement. Even with severe unilateral radial dysplasia, these children will adapt their skills by increasing their use of the contralateral, normal hand and upper limb. Lamb (166) noted no functional impairment in patients with unilateral involvement. Individuals with bilateral involvement have more difficulty. Activities of daily living, such as hygiene, eating, and dressing, are affected. Adaptive techniques and alteration of clothes are often necessary. Despite these modifications, Bora and colleagues (167,168) noted that patients without surgical correction were more limited than surgically treated patients. Finally, the issue of the cosmetic and psychologic impact of radial dysplasia is difficult to quantify. The social setting is constantly changing, and peer perception plays a major role in an involved individual's self-perception. Parental and family perception and coping must have a profound effect on a developing child's self-image. There is limited objective psychologic information at present.

Treatment. Treatment should address the following problems with radial dysplasia: (i) unstable wrist with lack of support for the hand; (ii) digital weakness secondary to radially deviated wrist; (iii) intrinsic digital weakness and deformity; (iv) thumb hypoplasia or aplasia that results in lack of opposition; and (v) foreshortened ulna. All of these deformities affect function in the patient with radial dysplasia. In addition, there is a significant cosmetic difference in these children that can be improved by intervention.

Nonsurgical Intervention. The options for nonsurgical intervention in these children are corrective casting, bracing, and physical therapy. In infancy, the first goal is to achieve passive correction of the radial deviation deformity. In mild cases, this involves merely a home exercise program of wrist ulnar deviation, extension, and distraction stretching. In more severe cases, care involves corrective casting or splinting to gradually stretch the contracted soft tissues, then maintain the correction. The splints are used in conjunction with a passive range-of-motion program. If attempts to correct the static radial deviation contracture are not successful by 6 to 12 weeks of vigorous therapy and skilled bracing/casting, the use of distraction external fixation to obtain soft tissue and musculoskeletal alignment should be considered (169).

Once passive motion has been achieved, it is necessary to maintain the correction. Again, for mild cases, this can be done nonsurgically. A nighttime corrective splinting program during infancy and times of rapid growth is useful. This treatment is adequate for the majority of type I and type II malformations. In severe cases, the lack of a stable wrist out of the splint, impairs hand and limb function. These children are candidates for operative correction at 6 to 12 months of age.

Surgical Intervention. There are two indications for surgery: persistent wrist radial deviation contracture (Fig. 22-12) and functionally limiting thumb deficiency. The surgical options for the wrist contracture and lack of support for the hand have included bone graft procedures to the ulna, centralization, radialization, and wrist fusion (170). Surgical options for thumb aplasia are pollicization and microvascular toe-to-thumb transfer. Thumb hypoplasia can be surgically corrected with first web space deepening, MCP joint stabilization, and opponensplasty tendon transfer. Less clear indications exist for the surgical treatment of digital camptodactyly, ulnar foreshortening, and radial hypoplasia in type II deformities.

FIGURE 22-12. A patient with complete absence of the radius and thumb aplasia. Note the foreshortening of the forearm, 90-degree radial deviation at the wrist, and dimpling of the skin over the distal ulna, with the proximal and radially subluxated carpus and hand.

Potential contraindications for surgery include (i) lack of elbow flexion, such that the wrist deviation enables the patient to perform hand-to-mouth and hand-to-neck activities; (ii) severe index digital deformity and weakness that will result in failed pollicization; and (iii) severe medical problems that pose a risk to the patient's well-being.

The earliest forms of surgical correction for radial dysplasia involved improving the radial deviation deformity and lack of wrist support for the hand by grafting bone to the ulna. Albee (171), Starr (172), Entin (173), and Riordan (174) described the use of nonvascularized bone grafts from the proximal fibula to the ulna in Y-configuration to support the carpus and hand. These procedures resulted in significant short-term improvement. However, the transplant usually failed to grow, leading to recurrent deformity. Vascularized bone grafting has recently been advocated by Vilkki (175), in rare circumstances. Centralization of the carpus over the third metacarpal has been a standard treatment (166,167 and 168). Soft tissue release of the radial contracture, contouring of the ulna to match the carpus, and capsular reefing are performed. Stabilization is performed with pin fixation until healing. The problem with centralization is a high incidence of recurrence. Lamb (166) advocated modifying the technique by notching the carpus to inset the distal ulna. This lessened recurrence, but also decreased wrist motion and increased early ulnar physeal closure postoperatively. Function is clearly impaired when there is less than 30 degrees of wrist motion postoperatively. Buck-Gramcko (176) introduced radialization during the thalidomide crisis. The centralization procedure is modified by aligning the ulna with the second metacarpal. Tendon transfers from the radial aspect of the wrist (extensor carpi radialis, flexor carpi radialis, if present) to the dorsal, ulnar wrist are performed to rebalance the wrist and hand. The quality of the radial muscles clearly affects the success of the radialization procedure. With both centralization and radialization, correction is performed at the wrist. If there is a concomitant ulnar bow of greater than 30 degrees ulnar osteotomy should also be performed. This usually involves a multiple-level open osteotomy and intramedullary fixation. In those rare situations in which passive correction of the wrist is not possible by splinting, casting, or therapy, distraction and correction with an external fixator is performed. As described by Kessler (169), this can be performed in infancy (Fig. 22-13). Often, after 3 to 6 weeks of external fixation an open centralization or radialization procedure is performed. Wrist fusion is not performed in young patients. This leads to loss of wrist motion and potential loss of ulnar physeal growth. However, Catagni et al. (177) performed wrist fusion in conjunction with distraction lengthening in adolescent and young adult patients with recurrent deformity.

FIGURE 22-13. A: Clinical photograph of a patient undergoing progressive distraction lengthening to stretch the soft tissues, bring the hand out to length, and reduce the wrist over the ulna. This patient has a markedly foreshortened forearm. Preoperatively, there was volar, radial, and proximal subluxation of the carpus and hand that was not correctable with exercises and splinting. **B:** Radiograph of the same patient with the hand and wrist out to length and centralized. Note the severe proximal ulnar bowing that required osteotomy at the definitive open surgical procedure.

Generally, wrist reconstruction is performed before thumb reconstruction. Ideally, thumb reconstruction is performed before 18 months of life. This limits the learning process after central nervous system maturation regarding pinch. In the mild forms of radial dysplasia, the thumb hypoplasia causes functional problems involving decreased first web space, MCP joint instability, and weak thenar muscles. The first web space can be deepened with Z-plasties or rotation flaps (178,179). Release of adductor and first dorsal interosseous fascia is often necessary. The MCP joint can be stabilized with local fascia or use of extra flexor digitorum superficialis tendon length for ligament reconstruction. On occasion, MCP joint chondrodesis (fusion of the proximal phalanx epiphysis to the metacarpal head) or arthrodesis is appropriate. Opponensplasty is performed simultaneously with use of the abductor digiti quinti (180), ring-finger flexor digitorum superficialis (73), or accessory digital extensors. All have had reported success in providing opposition strength. Thumb aplasia is best addressed with pollicization (179,181). Toe-to-thumb microvascular transfers have been reported, but to date the results are less successful than those of index-finger pollicization. The quality of the index-finger donor determines the quality of the subsequent thumb. If there is significant camptodactyly the thumb will be stiff, weak, and poorly used in pinch activities. Compensation will occur by lateral pinch between adjacent digits. In a well-performed pollicization, the results are functionally and cosmetically pleasing to the patient, family, and surgeon.

Complications. Recurrent deformity and premature closure of the distal ulnar physis are the two major complications of wrist reconstruction. The occurrence of these problems depends on the procedure performed (centralization versus radialization) and the quality of the preoperative musculoskeletal and soft tissue anatomy. With radialization, the goal is to dynamically rebalance the wrist and maintain motion. If this fails to occur, radial deviation and flexion deformity will recur with growth. In addition, if there is limited elbow flexion, excessive flexion and radial deviation of the wrist will be used by the patient to compensate for the limited elbow flexion needed for activities of daily living, such as oral hygiene and feeding. This contributes to the recurrence rate.

Physeal arrest is more common with centralization procedures. The forearm is already foreshortened, but this is exacerbated by further loss of distal growth. Because 70 to 80% of forearm growth comes from the distal physis, postoperative growth arrest is a major cosmetic and functional problem.

Finally, in patients with radial dysplasia, pollicization procedures can have poorer results in terms of opposition strength and active range of motion (182). The opposition weakness may be improved by opponensplasty transfer (183,184), but there needs to be a strong donor for this to succeed. Otherwise, the patient will continue to compensate with lateral digital pinch on the ulnar side of the hand.

Ulnar Dysplasia/Ulnar Club Hand

Ulnar, or postaxial, longitudinal deficiency is less common than either radial or central longitudinal deficiency. It is classified as a failure of formation of parts. The incidence was found by Birch-Jensen to be 1 per 100,000 live births (153). Ogden et al. cited a male-to-female ratio of three to two, with only 25% of cases being bilateral (185).

Most cases are sporadic. There are reports of familial occurrence (186,187,188 and 189). It also occurs as a part of rare identified inheritable syndromes, such as ulnar mammary (Schnitzel) syndrome, Klippel-Feil syndrome (190,191), and other nongenetic syndromes such as Cornelia de Lange syndrome. It is associated with

musculoskeletal system malformations in up to 50% of cases. Contralateral upper-extremity deficiencies of phocomelia, transverse arrest, radial deficiency, and aphalangia occur commonly. Similarly, lower-extremity deficiencies, such as proximal focal femoral and fibular deficiencies, occur in almost one-half the cases. Unlike those with radial dysplasia, it is uncommon for patients with ulnar deficiency to have associated major organ system malformations. Ogino and Kato's experimental data may explain this finding (192). They produced major deficiencies in rat fetuses by injecting the mothers with the antimetabolite Myleran. The timing of injection during the gestational period determined the limb malformation produced. For example, ulnar deficiencies were produced by earlier injections than were radial deficiencies. Those fetuses that had ulnar deficiencies had more lethal cardiac malformations. This may explain why there are fewer major organ system malformations and a lower incidence of ulnar deficiency per live births.

Clinical Features. Bayne classified ulnar deficiency into four groups based on the musculoskeletal abnormalities of the elbow and forearm (193). Most clinicians use this system to define and establish treatment plans for these patients. Type I deficiency is hypoplasia of the ulna. Both distal and proximal physes of the ulna are present, but decreased in growth. There is minimal, nonprogressive bowing of the radius, and a variable presentation of hand malformations. Type II deficiency is the most common type and involves partial absence of the radius. There is a fibrous anlage extending from the distal ulna to the carpus. The hand is ulnarly deviated, with bowing of the radius, and these deformities may be progressive with growth. The elbow is stable if there is sufficient proximal ulna present. Again, digital malformations or absences are variable. Type III deficiency involves complete absence of the ulna. There is no ulnar anlage. The radius, wrist, and hand are usually straight. The elbow is unstable as a result of the lack of an olecranon. Hand malformations and absences are common. Type IV deficiency involves synostosis of the distal humerus to the proximal radius. There is an ulnar anlage present from the distal humerus to the carpus, with marked bowing of the radius and ulnar deviation of the hand. Hand anomalies are common also in type IV deformities (Fig. 22-14).

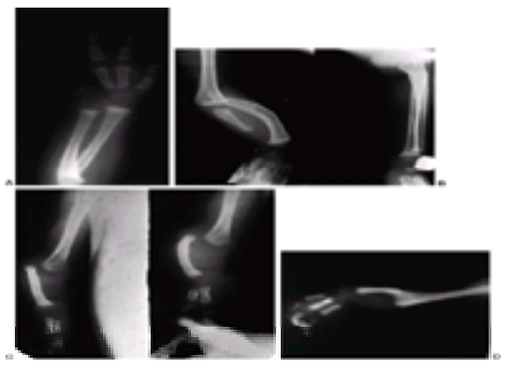

FIGURE 22-14. Classification of ulnar dysplasia types I through IV as represented by radiographs. **A:** Type I dysplasia represents deficiency of both the proximal and distal ulnar physes, with foreshortening of the ulna and mild bowing of the radius. **B:** Type II is the most common type and represents partial absence of the radius. **C:** Type III involves complete absence of the radius with an unstable elbow joint. **D:** Type IV includes complete absence of the radius and humeroulnar synostosis.

Cole and Manske (194) further classified ulnar deficiency by the presenting hand malformations. They divided the disorder into four types according to the deficiency of the first web space and thumb. Type A is a normal thumb and first web space. Type B involves a mild web contracture and thumb hypoplasia. Type C involves marked hypoplasia of the thumb with rotation of the thumb into the plane of motion of the other digits. Type D is absence of the thumb. In their series, 73% of the 55 patients had thumb deficiencies. This was similar to Broudy and Smith's findings of 16 hypoplastic thumbs and 5 absent thumbs in 26 patients with ulnar club hand (195).

In addition, in these patients the limb is foreshortened, and usually internally rotated. The glenoid may be dysplastic. The radial head is often dislocated, and range of motion of the elbow is limited in up to 40% of cases (196). These abnormalities make placement of the hand in space difficult. The hand malformations limit pinch, grasp, and release functions. Reconstructive surgery is indicated to improve hand and wrist orientation, thumb opposition, and digital motion and strength.

Treatment. There are few data regarding the natural history of untreated ulnar dysplasia. In 1927, Southwood stated, “From the functional viewpoint, therefore, the deformed limb is much more useful than its anatomical condition would lead one to expect” (197). This malformation is not associated with central nervous system deficiencies. As with all congenital malformations in people with normal brains, the patients will perform activities well, but differently. Treatment has to improve function and cosmesis to be warranted.

Nonsurgical treatment has predominantly involved therapy and corrective casting or splinting. In types I and III deficiencies, the mild ulnar deviation of the wrist and hand may be improved with serial casting, splinting, and passive exercises starting in infancy. In types II and IV deficiencies, the ulnar anlage may make nonsurgical correction of the severe ulnar deviation of the hand and wrist impossible.

There is considerable debate regarding the treatment of the severely ulnarly deviated hand that does not respond to casting/splinting. There is limited information to allow for critical evaluation of the options of (i) leaving the patient alone, (ii) performing excision of the ulnar anlage, or (iii) corrective radial osteotomy. Some of the confusion exists because not all of these deformities are progressive (198). As Flatt (1) makes clear, it is difficult to critically evaluate the literature because of limited objective measurements in previous studies. Finally, Flatt correctly points to the low incidence of this disorder as hampering objective assessment of the therapeutic options. As with many rare conditions, only multicenter, prospective studies can feasibly answer the questions.

The lack of this information allows for subjective interpretation of the treatment options, leading to reluctance to pursue aggressive surgical intervention. Within these limits, an attempt is made to outline treatment options and recommendations for wrist deformity, elbow instability, and digital and thumb deficiencies.

Resection of the ulnar anlage is indicated for progressive ulnar deviation of the wrist and hand of greater than 30 degrees. This can occur in types II and IV deficiencies (1,199). Through an ulna-based incision, the anlage is identified as it inserts into the carpus. The ulnar artery and nerve need to be protected. Resection should be performed until neutral positioning of the wrist can occur intraoperatively. If there is associated marked ulnar deviation of the radius, concomitant radial osteotomy can be performed. However, it is imperative to assess the location of the radial head and the status of forearm rotation before proceeding with anlage excision and consideration of radial osteotomy.

If there is a dislocated radial head and limited forearm rotation preoperatively in the type II deformity, anlage excision, resection of the radial head, and creation of a single-bone forearm should occur simultaneously. If there is acceptable forearm rotation preoperatively, it is best to correct only the wrist deformity and to monitor the status of the forearm and elbow with growth. Resection of the radial head for cosmetic reasons should be performed cautiously, because even the dislocated head may be providing some elbow stability in these patients.

Similarly, creation of a single-bone forearm may result in improved cosmesis, but the loss of forearm rotation may cause an unacceptable loss of function. In patients with type IV deficiency, there may be associated internal rotation posture to the arm that limits placement of the hand in space. If this is present, simultaneous external rotation osteotomy of the limb and ulnar anlage excision should be performed. This is clearly the case with patients with bilateral deformity who are unable to reach their mouths preoperatively.

Repair of digital and thumb deficiencies is indicated (Fig. 22-15). Syndactyly is common and should be corrected in infancy. Thumb hypoplasia or absence should also be repaired in infancy. Broudy and Smith (195) described a modified pollicization procedure for the malpositioned thumb in the plane of motion of the other fingers. Tendon transfers for intrinsic and extrinsic muscle deficiencies of the thumb and fingers are indicated if there are sufficient adequate donors available.

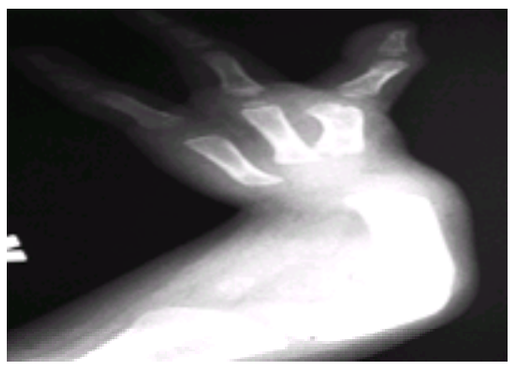

FIGURE 22-15. Radiograph of ulnar dysplasia with complete absence of the ulna, humeroradial synostosis, absence of the ulnar two rays, and thumb deformity.

Madelung Deformity

Madelung (200), in 1878, described a growth deformity of the distal radius. For reasons that are still unknown, the volar, ulnar aspect of the distal radial physis slows or stops growth prematurely. The continued normal growth of both the ulnar physis and the remaining dorsal, radial aspect of the radial physis results in ulnar overgrowth, carpal subluxation, and radial articular deformity (Fig. 22-16). Madelung deformity usually occurs in girls, and is most often bilateral (201). Its clinical appearance may not be present until the adolescent growth spurt, which is when most patients present. It is generally sporadic in presentation. It is also associated with Leri-Weill syndrome, a dyschondrosteosis form of mesomelic dwarfism that is inherited in an autosomal dominant manner (199,202). In addition, Madelung deformity has been associated with Hurler mucopolysaccharidosis, Turner syndrome, osteochondromatosis, achondroplasia, and Ollier disease (203). True Madelung deformity needs to be distinguished from a posttraumatic or postinfectious deformity.

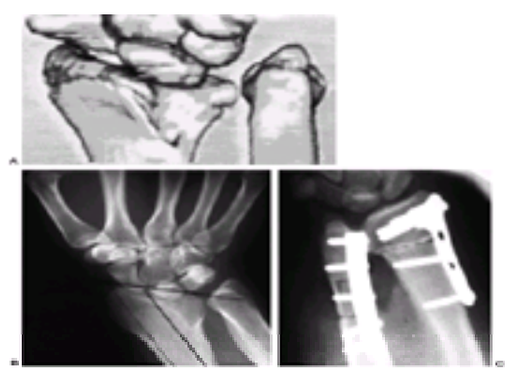

FIGURE 22-16. A: MRI scan of severe Madelung deformity. Note that the lunate fossa is markedly deficient and oriented ulnarly. **B:** Preoperative radiograph of a patient with Madelung deformity and debilitating ulnocarpal and radioulnar pain. There is nearly complete deficiency of the lunate fossa and subluxation of the carpus ulnarly, volarly, and proximally. The ulnar has a positive variance. **C:** Postoperative radiograph of a radiodorsal closing-wedge osteotomy of the radius and ulnar Z-shortening osteotomy in this patient. This procedure restored radial articular alignment, corrected the ulnocarpal impaction, and reduced the distal radioulnar joint.

Clinical and Radiographic Features. The clinical and radiographic picture is dependent on the age at presentation and the severity of the growth arrest. Generally, children do not appear until there is marked deformity, limitation of motion, and activity-related pain. Because the condition is usually bilateral, the subtle growth deformity that occurs before the adolescent growth spurt is often ignored. However, with early presentation there is a slight positive ulnar variance and loss of the volar, ulnar aspect of the radial lunate fossa (Fig. 22-16). The carpus subluxates volarly and into the gap between the radius and the ulna. These patients may have mild symptoms of ulnocarpal impaction with power grip activities, and distal radioulnar joint incongruity with forearm rotation. More often, individuals with Madelung deformity present late with marked deformity. There is an increased tilt of the radial articular surface from the dorsal radial corner of the styloid to the volar, ulnar aspect of the depleted lunate fossa. The ulnar variance is more positive, with carpal overlap and dorsal subluxation. The carpus migrates more proximal into the increasing diastasis between the radius and the ulna on anteroposterior radiographs. These patients have more pain and limitation of motion, especially forearm rotation and wrist extension.

Pathoanatomy. The skeletal features are well described. As mentioned previously, the arrest of the volar, radial aspect of the distal radial physis causes subsequent deformity of the radiocarpal, radioulnar, and ulnocarpal joints. Vickers and Nielsen (204), Linscheid (205), and Ezaki (201) have described abnormal tethering of soft tissues from the distal radius to the carpus and ulna. These have included aberrant ligaments (203,204) and pronator quadratus muscle insertions (205). It is unclear whether these structures are responsible for the growth deformity of the radius. Vickers and Nielsen's successful treatment of Madelung deformity by excision of the volar tethering soft tissues and prophylactic physiolysis of the volar radial physis indicates that there may be a causal relationship.

Treatment. The early descriptions of the treatment of Madelung deformity advocated treatment only for symptomatic patients at skeletal maturity (206). Originally, the mere presence of the deformity was not an indication for operative intervention in the asymptomatic patient, regardless of age. However, the growth discrepancy is easier to treat if it is dealt with early. Young patients become symptomatic and restricted with increasing growth deformity. Vickers and Nielsen advocated early intervention with physiolysis (204). The treatment principle is similar to that of Blount disease, with resection of the abnormal volar, ulnar physeal region of the radius and fat interposition. At the same time, any aberrant tethering anatomic structures are excised. Their case series indicates restoration of radial growth and prevention of progressive deformity. An alternative treatment for the patient presenting early is to perform ulnar and radial epiphysiodesis to prevent progressive deformity and symptoms. In the patient with bilateral disease, this treatment does not cause upper limb-length discrepancy.

The patient presenting late with marked deformity and symptoms is more problematic. The radial deformity can be addressed by either dorsal, radial closing-wedge osteotomy or volar opening-wedge radial osteotomy and bone grafting. The ulnar overgrowth is treated with an ulnar-shortening procedure (Fig. 22-17). Alternative methods of ulnar-shortening include resection of the distal ulna and a Sauve-Kapandji procedure. However, there may already be significant deterioration of the articular cartilage, wrist ligaments, or triangular fibrocartilage that results in continued pain and limitation of motion postoperatively.

FIGURE 22-17. A: Cleft hand with absent middle ray. **B:** Incomplete syndactyly of the first web space in the same patient. Closure of the cleft must include deepening of the first web space to maintain maximum hand function.

HAND REGION

Congenital

Cleft Hand and Symbrachydactyly

Central defects of the hand have been described in the past as typical or atypical. Since 1992, the International Federation of Societies of Surgery of the Hand has classified typical cleft hands as cleft hands and atypical cleft hands as part of symbrachydactyly. Cleft hands represent a partial or complete longitudinal deficiency in the central portion of the hand. The elbow, forearm, and wrist are usually normal. There are often ulnar and radial-sided syndactylies and digital hypoplasia. Cleft hands often occur in conjunction with cleft feet. In that situation, there is an autosomal dominant inheritance pattern. However, the penetrance is variable, with nearly one-third of the known carriers of the gene having no malformations (207,208). In addition, the phenotypic expression in affected individuals is variable. Cleft hands are also associated with other syndromes and malformations, such as cleft lip/palate (ectrodactyly, ectodermal dysplasia, cleft syndrome), other craniofacial syndromes, Cornelia de Lange syndrome, congenital heart disease, ocular malformations, and imperforate anus (208,209). The incidence is estimated at between 1 per 90,000 and 1 per 100,000 live births (153,210,211). Various classification schemes have been used. Most are based on the deficiencies centrally (212,213). Manske and Halikis proposed a classification system of cleft hands based on the thumb and first web space (214). This scheme aids the surgeon in surgical reconstruction decisions and thus may be the most useful classification.

Symbrachydactyly is defined by unilateral central digital deficiencies and simple syndactylies. It is a sporadic event without genetic inheritance. There are no associated anomalies. The feet are normal. It is a unilateral process, often with multiple absent digital rays. There are often finger nubbins present, which is a situation not seen with cleft hands. Symbrachydactyly is a transverse deficiency that may or may not be a separate entity from transverse absence of digits (208). These entities are distinct from the amputations associated with constriction band syndrome. Symbrachydactyly should be viewed as a clinical entity distinct from cleft hand, with a very different treatment plan.

Treatment.

Cleft Hands. As Flatt (1) poignantly stated, “The cleft hand is a functional triumph and a social disaster.” The wide central cleft allows for outstanding grasp, release, and pinch functions. Sensibility is normal. The cleft hand, therefore, functions usually without limits.

Treatment of the cleft hand centers on closure of the cleft. However, surgical closure of the cleft must be accompanied by appropriate treatment of the first web space and thumb to avoid limiting the patient. The skin flaps designed for cleft closure, however, must take into account the status of the first web space (Fig. 22-17). If the first web space is normal or mildly narrowed (Manske types I and IIA), simple cleft closure, such as with a Barsky flap (215), can be performed. If necessary, a simultaneous but separate Z-plasty widening of the first web space can be performed (Manske types IIA and IIB). If the first web space has a marked syndactyly (Manske type III), the flap designs use the redundant skin of the cleft closure to create a first web space. The adduction contracture of the thumb is released, and the index ray is transposed ulnarly at the same time. The Snow-Littler, Miura, and Ueba flaps (216,217,218 and 219) all involve transposition of the cleft skin to the first web space, with simultaneous transposition of the index ray ulnarly. If there is a transverse bone across the cleft, this needs to be removed to prevent progressive deformity. Often there is a conjoined flexor and extensor across the base of the cleft which needs to be released. Sometimes carpal closing-wedge osteotomy is necessary to close the cleft. In addition, the stability of the index- and ring-finger MCP joints needs to be maintained or restored. Associated fourth web space syndactylies are separated with Z-plasties and skin grafts. There may be associated camptodactyly or clinodactyly of the adjacent digits requiring corrective splinting or surgery.

Symbrachydactyly. The treatment of symbrachydactyly in the United States is probably the most individualized of that of any of the congenital malformations. The range of options include (i) leaving the child alone; (ii) nonvascularized transfers to the soft tissue nubbins of the phalanges (219,220); (iii) microvascular toe transfer(s) (221,222,223,224 and 225); (iv) web space deepening; (v) digital distraction lengthening or bone grafting (226); and (vi) prosthetic use. In addition, families and patients are very interested in the possibilities of transplantation and laboratory cellular growth of digits. There is no correct answer at present. The choice is greatly influenced by the family's desires and the surgeon's experience and biases. There are few peer-reviewed published studies regarding functional and cosmetic outcomes to more objectively guide the decision. However, there are clear principles to help guide all parties to the best choice for them.

The primary goal is to improve pinch. In the presence of a normal thumb and web space, all of the choices listed above will work. In this situation, treatment options focus on the quality of the other digital rays. If the soft tissue pockets of the digits are adequate, nonvascularized transfer of the proximal phalanx of the toes is a very good choice. Although it will not provide normal digital length, it will provide stability for lateral pinch. This must be performed before 18 months of age and include the periosteum and collateral ligaments (219,227). The proximal phalanx is harvested through an extensor tendon–splitting dorsal approach. The proximal phalanx is harvested extraperiosteally, while protecting the neighboring tendons and neurovascular structures. At the metatarsophalangeal joint, the collateral ligaments, dorsal capsule, and volar plate are detached proximally from the metatarsal, while leaving intact their distal attachments to the phalanx. At the PIP joint, those soft tissues are left attached to the middle phalanx. With transfer to the hand, the proximal soft tissues of the toe phalanx are sutured to the corresponding soft tissues of the recipient site. The best results for phalangeal survival and growth are realized when this procedure is performed before 1 year of age. The quality of the soft tissue pocket clearly affects the outcome. Multiple phalangeal transfers can be performed simultaneously. In the presence of a normal thumb and first web, digital lengthening can be performed. In addition, digital lengthening has been performed successfully after nonvascularized toe phalangeal transfer (226). Finally, prosthetic use has been tried. The major problems with prostheses are that children function as well or better without them because the prostheses are insensate. In the adolescent and adult a cosmetic prosthesis may be used for social reasons (228). It should be noted that the finest cosmetic prostheses are very expensive.

If there is a deficient first web space, deepening of the web with release of the adduction contracture is appropriate. At times, this may require resection or transfer of the index metacarpal (Fig. 22-17) to achieve a useful web for pinch and grasp functions. If there is absence of the thumb digital transposition or microvascular transfer is indicated.

Microvascular toe transfer should be performed only with a child older than 2 years of age; a well-informed family; the presence of proximal nerves, vessels, tendons, and muscles to create a viable and functional transfer; the presence of carpal or metacarpal support for the transfer; and an experienced surgical team (208). Unfortunately, even though this procedure is being performed more commonly, objective data regarding functional, cosmetic, and psychologic outcomes are still minimal in children.

Constriction Band Syndrome

Constriction band syndrome, amnionic band syndrome, or amnion disruption sequence is the result of disruption of the inner placental wall, the amnion. This early amnionic rupture often results in oligohydramnios and amnionic bands. The fibrous bands from the amnionic wall wrap around the digits, causing constricting digital bands, amputations, and syndactylies (229,230 and 231). This syndrome is a mechanical deformation rather than a malformation, as originally proposed by Streeter (232).

There is no inheritance pattern. This syndrome occurs in 1 of 15,000 live births (233). It is associated with other musculoskeletal deformations in 50% of cases, the most common being clubfeet. There may be devastating cleft lip and facial deformations as a result of deforming amnionic bands. There are no associated major organ system malformations.

In the hand, the ring finger is most frequently affected. This may be because in a clenched fist, the ring finger is the longest. The band may merely cause an indentation. However, if it is circumferential, the constriction ring may lead to distal edema or cyanosis (Fig. 22-18). Intrauterine amputations are the result of vascular insufficiency caused by the tourniquet-like bands. At times, this can be noted at birth with a necrotic or severely compromised phalanx distal to a constricting band. Syndactyly occurs when the bands attach adjacent digits (Fig. 22-19). There often are skin clefts proximal to the syndactyly, indicating the embryonic formation of a web space before the amnionic rupture and subsequent deformation. The extremity proximal to the band is normal. The development of the underlying tendons, nerves, vessels, and muscles is also normal.

FIGURE 22-18. An amnionic band causing digital ischemia in a neonate in the newborn nursery. Although rare, this condition requires immediate removal of the band to prevent further soft tissue digital loss.

FIGURE 22-19. Bilateral amnionic band syndrome with deep constriction rings on the left hand and partial acrosyndactyly and amputations on the right hand.

Clinical Treatment. Impending tissue necrosis is an indication for emergent removal of the band to relieve vascular compromise. This is a rare situation, usually seen only in the neonatal period. Removal of neonatal constricting bands that are causing vascular compromise generally can be performed outside the operating room. The band will literally unravel or debride like an eschar. Improved venous drainage is almost immediate.

Multiple minor band indentations without vascular compromise or functional or cosmetic problems do not require treatment. Constricting rings that cause distal deformity are treated with excision of the constriction ring and staged Z-plasty reconstruction **[➥1.3]**. Complete excision of the ring is necessary to recontour the digit or limb. The depth of excision can extend to the periosteum. Such digits usually have chronic impaired venous outflow with marked distal swelling. In these situations, it is imperative to preserve distal venous drainage and the deep neurovascular structures. Careful dissection of the veins, arteries, and nerves is performed on both sides of the deep constricting band. These structures are then delicately freed from the band to preserve their longitudinal integrity. It is recommended that complete circumferential excision not be performed in one procedure. Rather, excision up to 270 degrees at one time may be safest for preservation of vascular inflow and outflow. Z-plasties are performed after ring excision to prevent recurrence.

Syndactyly release with Z-plasties and skin grafts follows the basic principles outlined in the section on syndactyly. The unique features with amnionic band syndrome are acrosyndactyly secondary to constricting bands and the presence of epithelialized incomplete web space proximal to the syndactyly.

In the rare situation of constricting bands causing progressive deformity in digits of unequal length, early digital separation is necessary. More often, the acrosyndactyly separation can be performed after 6 months of life. There is usually limited skin for coverage, and creative flap design is needed to cover all the web spaces. Abundant skin graft is necessary. Distal release of complex syndactylies may require excision of osseous or cartilaginous synostoses. The embryologic remnant of the web is usually too distal and small to serve as an acceptable web reconstruction. Excision of that epithelial tract is usually performed. If that primitive web is used, it often needs to be deepened secondarily.

The most severe cases involve absence or deficiency of the thumb. The reconstruction can include metacarpal or phalangeal transposition from the index finger (234,235), nonvascularized toe phalangeal transfer, or vascularized toe transfer. It is imperative to reconstruct the thumb for pinch and proper grasp and release functions in these patients.

Because the underlying tissues are normal, as is the central nervous system, these patients have outstanding hand function after reconstruction. There are clear cosmetic differences, but minimal functional differences between them and their peers.

Syndactyly

Syndactyly is one of the most common congenital differences. It occurs because of a failure of separation of the digital rays *in utero*. Normal differentiation of digits occurs during the fifth to eighth weeks of gestation. Failure of normal programmed cell death results in *syn* (together) *dactylos* (digits). The incidence is between 1 per 2,000 and 1 per 2,500 live births (1). It can occur in isolation or as part of a syndromic condition. It is often an inheritable condition, whether in isolation or as part of a syndrome. It is bilateral and symmetric in up to 50% of patients. It is more common in boys than in girls.

Syndactyly is classified by the extent of, and the tissues involved in, the webbing. Digital separation *in utero* starts distally and proceeds proximally. Normally, the third web space is the most distal web, followed by the second, fourth, and first web spaces. The normal commissure of the web extends over 30 to 35% of the length of the proximal phalanx (236). The bones, joints, tendons, and neurovascular structures separate before the skin. If separation fails to occur or ends prematurely syndactyly results. If it extends over the entire length of the phalanges then it is complete. Complete syndactyly is when the web is more distal than normal (Fig. 22-20); complex syndactyly is when there is osseous connection between the digits; and simple syndactyly is when the digits are joined by skin only (236). Acrosyndactyly involves webbing of the tips of all the digits. Syndactyly secondary to amnionic band syndrome is not a malformation, but an *in utero* disruption, and will be considered separately. Syndactyly can also be a part of other major developmental problems in the hand that affect hand function, such as brachydactyly, camptodactyly, clinodactyly, symphalangism, and polydactyly. These are the most complicated syndactylies in terms of surgical decisions and care.

FIGURE 22-20. A: and **B:** A 1-year-old child with complete simple third web space syndactyly. In this patient, the distal eponychial folds and nail plates are already

separate. The underlying joints, tendons, nerves, and blood vessels should be separate and normal.

Clinical and Radiographic Features. Syndactyly most often affects the third web space of the hand. It is sequentially less common in the fourth, second, and, finally, first web space (1). It may be associated with syndactyly of the toes. In isolated syndactyly, often one of the parents will have an incomplete syndactyly of the fingers and/or toes. As mentioned above, there are many chromosomal, craniofacial syndromic, and generalized syndromic conditions associated with syndactyly. These all need to be evaluated before treatment of the syndactyly. The most important aspect of the hand evaluation for syndactyly is determination of the quality of the affected digits. In simple syndactyly, these digits are usually normal except for their skin union. In more complex situations, the digits may have malalignment, limited motion, and limited strength after surgical separation. Plain radiographs will reveal osseous union and marked joint and bony malalignment. However, in infancy, the areas of chondral abnormalities in the joints, physes, and between digits exhibiting syndactyly will not be visible on plain radiographs. MRI and arteriography are used only in very complex situations to define digital anatomy preoperatively.

Treatment. Patients with incomplete syndactyly may choose not to undergo surgical separation. If the syndactyly does not extend beyond the PIP joint this will not limit function. However, it may affect wedding ring wear in the third web space, and for this reason, some patients request separation.

Most parents and children with complete syndactyly desire separation of the digits for functional and cosmetic reasons. There are rare situations in which a family declines surgery for complete syndactyly. Because of the discrepancy in the lengths of the adjacent digits, this usually results in some degree of bony malalignment and joint contracture. This is most marked in the border digit syndactylies (first and fourth web spaces), and least marked in the third web space. Leaving the digits joined also precludes independent function of the affected digits. There are also syndromic and chromosomal situations in which the overall health or mental capacity of the patient does not warrant the risks of surgical separation. Finally, there are situations of complex syndactyly in which the affected digits are too hypoplastic, malaligned, or stiff to warrant separation. Otherwise, the standard treatment is surgical separation of the affected digits **[➥1.4]**.

Unfortunately, separation is not as simple as parents wish, i.e., the simple division of the conjoined skin. The uncovered soft tissues result in linear scars with long-term joint contractures, digital malalignment, and loss of motion and function (198,238). Standard treatment now consists of (i) local rotation flap coverage for the commissure; (ii) zig-zag incisions, avoiding the interdigital creases to prevent scar contractures; and (iii) full-thickness skin grafts to cover all areas of the digits not covered by local flaps (Fig. 22-21). In addition, special attention is given to the eponychial reconstruction with either local flaps or composite grafting (239).

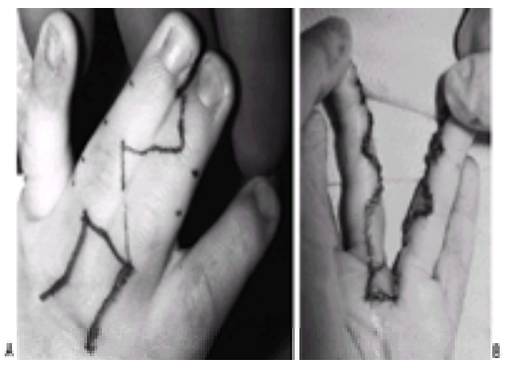

FIGURE 22-21. A: Intraoperative photograph of a 1-year-old child with complete syndactyly treated with dorsal rotation flap coverage and Z-plasties, as outlined. Note the skin marks on the lateral borders of the ring and long fingers to outline the apex and base of each Z-plasty. This allows for precision placement of corresponding volar and dorsal Z-plasties. **B:** Intraoperative photograph after dorsal-to-volar rotation flap coverage for web space, Z-plasties, and full-thickness skin grafting.

Surgery is generally performed in infancy, when anesthesia and surgical handling of the tissues are safe. There is some controversy regarding the best age for surgery (1,240), but in most institutions it is performed at around 12 months of age (241). After 6 months of age, the anesthesia risk is equivalent throughout childhood. With magnification, surgery can be performed safely and skillfully during infancy. The only controversy concerns surgical healing and scarring. Neonatal releases result in more scarring. There is some evidence that surgical release performed at around 18 months of age may result in less scarring and recurrent web contractures than release during infancy (242). However, this is a very difficult developmental age for elective surgical intervention.

Complete separation of the digits in the neonatal period has had a higher rate of complications. Border digits of unequal length need to be separated earlier to lessen angular and rotatory deformity in the longer digit (Fig. 22-22).

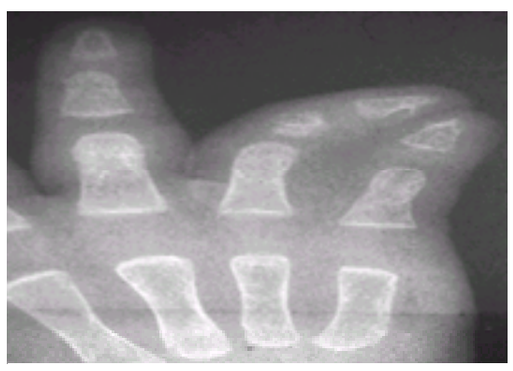

FIGURE 22-22. Radiograph of complex syndactyly of the fourth web space with progressive deformity of the ring finger. This should be released early in infancy to prevent progressive deformity. The abnormal middle phalanx of the ring finger may still require corrective osteotomy.

In incomplete syndactyly that is proximal to the PIP joint, surgery usually involves the use of local flaps such as double-opposing Z-plasties and “stickman” flaps. Separation may not be to normal depth, but patients often prefer avoiding skin grafting. If the incomplete syndactyly extends to the middle phalangeal region, full-thickness skin grafting is necessary.

In simple, complete syndactyly, surgery involves the use of a dorsal rotation flap into the web, Z-plasty flaps the length of the digits, and full-thickness skin grafts to cover the defects. The fascial connections between the digits extending from Grayson's and Cleland's ligaments need to be separated. Any synostosis or synchondrosis union of the distal phalanges needs to be divided. Conjoined nails are divided, and the exposed eponychial and paronychial regions are reconstructed with local flaps or composite grafts. If the common digital nerve extends beyond the desired web deepening, epineural separation is performed proximally. If the common digital artery bifurcates distally, ligation of one of the proper digital arteries may be necessary to attain the desired separation. This is one of the major reasons why surgery is not performed on both sides of a single digit in multiple syndactylies.

Complex syndactylies are more likely to have abnormal underlying joints, bones, neurovascular structures, muscles, or tendons. The separation of skin follows the same principles as in complete syndactyly. With significant digital malalignment, skin incisions may need to be modified to maximize coverage. After separation of the skin, all abnormal connections of fascia, tendons, bones, joints, nerves, and arteries need to be addressed individually. Phalangeal deformity may require osteotomy. Joint instability may require ligamentous reconstruction. Joint stiffness, camptodactyly, or symphalangism may need to be dealt with subsequently. Neural, vascular, and nail problems are managed in a manner similar to that described for complete syndactyly. Tendon reconstruction is performed primarily if possible. Brachydactyly

is usually addressed subsequently, if at all.

Acrosyndactyly separation begins early in life, especially if it is bilateral. Adjacent webs are not separated simultaneously. Generally, the first and third webs are separated together, as are the second and fourth webs. Abundant full-thickness skin graft is usually required. Sufficient time between procedures (3 to 6 months) lessens worries about flap necrosis and scar contracture. In syndromic conditions, such as Apert syndrome, the acrosyndactyly is more complex and the end result is never normal.

Complications. Fortunately, the most worrisome complication, an avascular digit, is almost never encountered and should be avoidable. Adhering to the axiom of never operating on both sides of a digit during the same procedure prevents this devastating complication. Careful dissection of the digital vessels in complex situations lessens the risk of avascularity at the initial or subsequent operations. Preoperative vascular studies in complicated situations prepare the surgeon, and allow the surgeon to avoid intraoperative surprises and dangers. Flap necrosis and scar contracture are more common. The flaps should be secured without tension, and their vascularity should be checked with deflation of the tourniquet at the completion of the procedure. If in doubt, lessen the tension and use skin graft. Skin graft failure is usually caused by inadequate immobilization and excessive shear forces applied to the grafts. Secure immobilization with the compressive dressing, long-arm cast, and sling and swathe bandages, is necessary to protect the grafts. Infection is rare but will result in marked scar contractures that require reoperation. Nail deformity and poor eponychial coverage are common when there is an initial conjoined nail. The use of composite grafts seems to lessen the incidence of these complications. Web space creep is common with growth, but often does not require reoperation unless digital contractures develop. Use of local rotation flaps and skin grafts will resolve this problem. Finally, angular deformity may require osteotomy or joint reconstruction.

Polydactyly

Polydactyly is a common congenital malformation. It can occur on the radial (preaxial), central, or ulnar (postaxial) portion of the hand. Preaxial or thumb polydactyly usually occurs in isolation and will be addressed in the thumb section of this chapter. Central polydactyly is very rare, is usually associated with syndactyly, and the underlying digits are rarely normal. It can be inherited in an autosomal dominant manner. It affects girls more than boys, and it is often bilateral. Postaxial or small-finger polydactyly has a variable racial incidence, with the occurrence in blacks estimated to be as high as 1 per 300 live births, and that in whites estimated to be 1 per 3,000 live births (243,244 and 245). It is often bilateral. Polydactyly has been classified by Stelling (246) and Turek (247) into three types. Type I involves soft tissue alone and is very common in the black population. Type II involves phalangeal duplication articulating with a single or bifid metacarpal head. Type III involves a complete ulnar ray duplication, including the metacarpal. There is also a universal classification of polydactyly proposed by Buck-Gramcko and Behrens (248) that denotes the digit involved by roman numeral (I to V), the extent of bifurcation by abbreviation (DIST [distal], DIP [distal interphalangeal], MId [middle], PIP [proximal interphalangeal], PROX [proximal], MCp [metacarpophalangeal], MET [metacarpal], CMc [carpometacarpal], C [carpal], and IC [intercarpal]), and RUD [rudimentary polydactyly]). The major issue for the surgeon is not the classification of the polydactyly, but whether excision alone, or reconstruction, is warranted. Only postaxial soft tissue polydactyly (type I, or rudimentary) can be treated by excision alone. All other forms require reconstruction. Central polydactyly is usually an isolated malformation. Postaxial polydactyly in blacks is almost always an isolated malformation. Postaxial polydactyly in whites without a positive family history may be associated with chromosomal abnormalities, other syndromes, or other malformations.

Treatment. Soft tissue polydactyly on the ulnar side can be treated with excision during the newborn period (Fig. 22-23). Unfortunately, too often this has been performed with a suture ligature in inexperienced hands. The result is a persistent nubbin caused by incomplete excision of the base of the digit. If a suture ligature is used, it needs to cause necrosis of the entire digit. Otherwise, it may be best to perform an elliptical excision under local anesthesia. Care is taken to ligate the digital vessels with this excision. Other than failure to completely excise the digit, complications are rare, and the hand is normal afterward. The parents should be aware of the future genetic implications for them and their children.

FIGURE 22-23. A: Complete postaxial polydactyly with phalangeal duplication with a conjoined metacarpal. **B:** Radiograph of the same patient. Reconstruction will consist of excision of the duplicate phalanges, contouring of the bifid metacarpal head, and transfer of the metacarpophalangeal joint ulnar collateral ligament and the hypothenar musculature to the reconstructed fifth digit. **C:** Simple polydactyly with only soft tissue attachment. This can be excised in the newborn nursery under local anesthesia. Be careful of suture ligature because the entire stalk needs to be excised to avoid leaving a residual nubbin.

More complex postaxial polydactylies require excision and reconstruction in the operating room (Fig. 22-23). Besides excising the redundant parts, transfer of the hypothenar muscles (abductor digiti quinti, flexor digiti quinti) from the sixth to the fifth digit is necessary. In type II polydactyly, the MCP joint collateral ligaments are also transferred to the reconstructed fifth digit. If the metacarpal head is enlarged or bifid, intraarticular osteotomy is appropriate. With this procedure, the origins of the collateral ligament and the metacarpal physis need to be preserved. In type III polydactyly, the entire ray is resected, and the basilar joint is stabilized. The outcome in both type II and type III malformations is usually cosmetically and functionally normal.

Treatment of central synpolydactyly is much more complex (249,250). The major decision is whether independently functioning digits are feasible. The choices are to leave the digits conjoined to attempt reconstruction to a five-digit hand, or to perform ray resections of part or all of the synpolydactyly. Often the involved digits have bone and joint malalignment, hypoplasia, and poor motor, nerve, and vascular supplies. The reconstructed digit is usually smaller, stiffer, weaker, and malaligned. The family needs to be well aware of this from birth, so that their expectations are realistic as far as surgical reconstruction and digital function are concerned. Treatment decisions in this condition are often personal, based on the family's desires and the surgeon's biases.

Camptodactyly

Camptodactyly translates from Greek to mean “bent finger.” It involves a flexion deformity of the PIP joint, most commonly in the small finger. It may present in infancy or in adolescence. It may involve a single digit or multiple digits (Fig. 22-24).

FIGURE 22-24. An adolescent patient with marked camptodactyly of the small, ring, and long fingers. There are proximal interphalangeal joint flexion contractures in

each digit, and the patient is actively hyperextending the metacarpophalangeal joints to compensate for those contractures.

Camptodactyly may be associated with multiple systemic malformations. Its incidence is unknown but has been cited at less than 1% of the general population (251,252). Most cases appear in infancy, and there is equal gender distribution (253). Less commonly, it may first appear in adolescence, usually in girls (254). Some cases are familial with an autosomal dominant inheritance with variable penetrance patterns. Most cases are isolated, without a positive family history. Up to two-thirds of the patients have bilateral small-finger involvement.

There is debate about the cause. In simple terms, there is an anatomic imbalance between the flexor and extensor mechanisms (253). This may be secondary to an abnormal insertion of the lumbricals, flexor digitorum superficialis, or retinacular ligaments (255,256,257,258,259 and 260). The volar skin is usually tight. With growth, these anatomic abnormalities cause PIP joint contracture and phalangeal bony abnormalities. The distal proximal phalanx becomes narrowed volarly and flattened dorsally, with loss of the normal contour of the head. The articular surface can become incongruous, with notching of the base of the middle phalanx (261). Initially, the patient can compensate for the PIP joint flexion contracture by MCP and distal interphalangeal joint hyperextension (Fig. 22-25). This keeps the digital pulp of the affected fingers in line with the other digital rays. Thus, the mild contracture in the older child may not need treatment. However, as the contracture progresses beyond 30 degrees and toward 90 degrees, it becomes more difficult for the patient to compensate. Camptodactyly is usually progressive with growth.

FIGURE 22-25. Radiograph of a thumb with type IIIB hypoplasia without a carpometacarpal joint and proximal thumb metacarpal. This is usually treated with pollicization. Less often, treatment is by reconstruction, potentially including a microvascular toe metatarsophalangeal transfer to form a thumb carpometacarpal joint. Note the radial dysplasia in this patient.

Treatment. Treatment should attempt to restore normal flexor–extensor balance. The options for treatment are splinting and surgical reconstruction. Most authors recommend an initial treatment program of progressive extension stretching and splinting with dynamic or progressive static splints. Parents are instructed to perform frequent home exercises for their infants; affected adolescents are similarly instructed to perform a home program for themselves. The goal is to achieve full passive extension. It is hoped that active extension will follow. Many authors (254,262,263 and 264) report success with a splinting program in a majority of cases. The best results are in the mild cases in young patients. The patients are followed until the end of growth to treat recurrence.

There is significant debate regarding the indications for surgery. McFarlane and colleagues strongly recommend surgical intervention to reconstruct the aberrant insertion of the lumbrical (259,260). However, the published surgical results are disappointing in terms of outcome (259,260,263,265). Surgery is reserved for severe contractures not amenable to splinting treatment. Specifically, surgery has its best results in patients in whom the finger is flexed into the palm and obstructs use of the hand. The principle of surgical intervention is to correct the abnormal anatomy. This involves release of the aberrant lumbrical (251,259,260) or flexor digitorum superficialis (256), and insertion in conjunction with volar Z-plasties and PIP joint release (265). Local flaps or full-thickness skin grafts are often necessary for volar skin coverage. Tendon transfer to the extensor mechanism is performed when there is full passive extension of the PIP joint, but no active extension (266). The results of soft tissue reconstruction often merely change the arc of motion rather than normalize it. Preoperatively, patients have significant flexion contracture. Postoperatively, they generally have difficulty achieving full active and passive flexion.

There frequently are bony changes present at the PIP joint that preclude restoration of normal motion or alignment. In the presence of marked radiographic evidence of bone and joint changes, Oldfield (267) and Flatt (1) have stated that corrective extension osteotomy may be most effective at improving alignment and function. This salvage operation has limited published data to objectively evaluate its results (251).

In summary, with treatment of camptodactyly it is unusual to achieve a perfectly aligned and mobile digit. The parents and patients should be aware of this from the outset of care. In addition, deformity can recur with growth and persistent muscle imbalance.

Clinodactyly

Clinodactyly is abnormal angulation (greater than 10 degrees) of the digit in the radioulnar plane. It is usually caused by a misshapen middle phalanx. The middle phalanx is trapezoidal, with less height on the radial side. This results in deviation at the distal interphalangeal joint. Clinodactyly is most often seen in the small finger and is usually bilateral. This form of clinodactyly has an autosomal dominant inheritance (268,269,270 and 271). Clinodactyly is also frequently associated with syndromes (Holt-Oram, Turner, Silver, and Cornelia de Lange syndromes) and chromosomal abnormalities (trisomy 18 and 21), and should alert the primary neonatal examiner to look for associated malformations or problems. For example, clinodactyly of the thumb is seen in Rubinstein-Taybi syndrome (272,273) and diastrophic dwarfism (274,275). In addition, it is common with other congenital differences of the hand. Finally, mild clinodactyly is commonplace in otherwise normal people. In these situations the major issue is cosmesis. Function is affected only when the deformity is severe enough to impinge on the adjacent digit with flexion.

Treatment. Treatment is based on the degree of deformity. Most cases are mild and nonprogressive and, therefore, do not warrant surgical intervention. Progressive, severe clinodactyly may interfere with flexion and grip. In these rare situations the progressive deformity is secondary to altered physeal growth. The middle phalangeal physis may be a bracket delta phalanx. Treatment options are bracket resection and surgical realignment. Physeal bar resection and fat graft interposition have been reported by Vickers (276,277) to restore longitudinal growth and provide correction. Surgical realignment can be in the form of opening-wedge, closing-wedge, and reverse-wedge osteotomies. Osteotomy should be delayed until there is sufficient ossification of the middle phalanx to allow for precise cuts. Generally, this is around school age. The complications of osteotomy are persistent deformity and loss of interphalangeal motion. Loss of motion in a patient whose indication for surgery was cosmetic is unacceptable to most patients, their families, and surgeons.

HAND: THUMB

Congenital differences of the thumb occur in all categories of congenital hand anomalies described by the American Society and the International Federation of Societies for Surgery of the Hand. Failure of formation occurs with aplasia of the thumb, and this is often associated with other radial-sided longitudinal deficiencies. Failure of separation occurs with thumb–index syndactylies, which are common with other syndactyly syndromes. Duplication is seen with thumb polydactyly. Undergrowth, with thumb hypoplasia, and overgrowth, with macrodactyly and triphalangeal thumbs, occur. Finally, thumb abnormalities with constriction band syndrome and generalized musculoskeletal disorders are common. The list is exhaustive, and this section will cover the more common congenital thumb malformations.

Trigger Thumbs/Digits

Trigger thumb represents an abnormality of the flexor pollicis longus and its tendon sheath at the A1 pulley. There is a palpable mass (Notta nodule), representing the flexor pollicis longus constriction at the A1 pulley. In the past, trigger thumbs were defined as congenital. However, this condition is acquired in the first 2 years of life, as indicated by prospective screening of neonates who failed to yield any trigger thumbs (278,279). The cause appears to be a size mismatch between the flexor

pollicis longus and the A1 pulley that leads to progressive constriction. Unlike adult trigger digits, there does not appear to be an inflammatory component (280); 30% of the cases are bilateral. Isolated trigger thumbs have no associated syndromes. However, trigger digits are seen with neurologic syndromes (trisomy 18) and mucopolysaccharidoses (281). There is no familial inheritance pattern. Trigger thumb patients present at ages ranging from infancy to school age. Often, the diagnosis is missed until local trauma brings attention to the thumb. In the emergency setting the flexed interphalangeal joint can be mistaken for an interphalangeal joint dislocation. Radiographs are misleading because of limited phalangeal ossification. A palpable nodule at the A1 pulley is diagnostic. If the trigger is long-standing, compensatory hyperextension of the MCP joint develops to effectively bring the thumb out of the palm. In addition, there may develop mild radial deviation of the interphalangeal joint secondary to eccentric flexor pull.

Treatment

In infants younger than 9 months of age, Dinham and Meggit (282) found that 30% of trigger thumbs may resolve spontaneously. In infants older than 1 year of age, less than 10% of trigger thumbs resolved spontaneously. Ger et al. (283) found lack of resolution with observation for 3 years in their patients. There is limited evidence that splinting will be of benefit (284), and often it is not well tolerated. Surgical release of the constricting A1 pulley and flexor tendon sheath is the treatment of choice **[➥1.5]**. This is indicated in infants without spontaneous resolution by 1 year of age, and in any toddler or older child presenting with a locked trigger thumb. Incision is made transversely in the digital crease to lessen scarring. Care must be taken to avoid iatrogenic injury to the superficial digital neurovascular bundles. The oblique pulley needs to be preserved to prevent flexor tendon bowstringing. Recurrence is extraordinarily rare, if at all.

Trigger digits are more often multiple, and can be associated with central nervous system disorders and syndromes (trisomy 18, mucopolysaccharidoses). The pathology appears to predominate at the decussation of the flexor tendons under the A2 pulley, and not at the A1 pulley alone. The triggering appears to occur as the flexor digitorum profundus passes through the chiasm of the flexor digitorum superficialis. Surgical recurrence is high in pediatric trigger digits. This may be because A1 pulley release alone is not sufficient to solve the problem. Further opening of the chiasm or resection of a slip of the flexor digitorum superficialis is often necessary to prevent recurrence (281).

Hypoplasia/Aplasia of the Thumb

Children with thumb hypoplasia or aplasia will have deficient prehension and grasp. Thumb hypoplasia or aplasia can occur in isolation, or be associated with other radial-sided deficiency syndromes (Holt-Oram and Fanconi syndromes). It is seen universally with radial dysplasia. It is common with other congenital malformations (181,285), including those of the cardiac, craniofacial, musculoskeletal, renal, gastrointestinal, and hematopoietic systems. It may involve hypoplasia of the metacarpals (Cornelia de Lange syndrome, diastrophic dwarfism) or phalanges (Rubinstein-Taybi and Apert syndromes). Neonatal examination of a child with thumb deficiency should prompt a thorough multiple-system examination for other malformations.

In general terms, thumb hypoplasia includes a contracted first web space, unstable MCP joint, thenar weakness, and interphalangeal joint stiffness or instability. Buck-Gramcko (286) and Manske et al. (287) have modified the Blauth (288) classification for thumb hypoplasia. This classification system is useful for treatment considerations. There are five types of thumb hypoplasia in the Buck-Gramcko modification of the Blauth classification (Table 22-3). A type I thumb is essentially a normal thumb, except for diminished size. A type II thumb is even smaller and narrower, with a contracted first web space and thenar atrophy. Type III thumbs have marked atrophy or absence of both the intrinsic and extrinsic musculature. The thumb is globally unstable and underdeveloped. Manske et al. (287) further subdivided type III thumbs into A and B categories. Type IIIA thumbs have a stable carpometacarpal (CMC) joint, whereas type IIIB thumbs have absence of the proximal metacarpal and trapezium. Type IIIB thumbs have no basilar joint stability (Fig. 22-24). Type IV thumbs are the classic *pouce flottant* or “floating thumbs.” A type V thumb demonstrates complete aplasia of the thumb.

Type	Findings
I	Smaller thumb with hypoplasia of abductor pollicus brevis and opponens pollicus
II	Narrow first web space, laxity of the ulnar collateral ligament of the metacarpophalangeal joint, thenar muscle hypoplasia
III	Global thenar weakness and metacarpophalangeal joint collateral ligament instability, partial aplasia of the first metacarpal, extrinsic weakness
IIIA	As above, with present proximal metacarpal and carpometacarpal joint
IIIB	Absent proximal metacarpal, with deficient carpometacarpal joint
IV	Pouce flottant (floating thumb); no bony support
V	Thumb aplasia

Findings are additive with increasing severity.
(Adapted from refs. 286–288, with permission.)

TABLE 22-3. MODIFIED BLAUTH CLASSIFICATION OF CONGENITAL THUMB HYPOPLASIA

The pathoanatomy is dependent on the severity of the thumb hypoplasia. Universally, the thumb ray bones are smaller and narrower. The interphalangeal joint is usually underdeveloped and stiff. The first web space is contracted in all except the rare type I thumb. The MCP joint usually has ulnar collateral ligament insufficiency, but may be globally unstable. The thenar intrinsics are deficient, and may be completely absent in the more severe forms of hypoplasia. The thumb extrinsic musculature is progressively deficient in the classification scheme. The major anatomic determining factor for reconstruction is the status of the CMC joint. Type IIIB and type IV thumbs have no basilar joints. Plain radiographs are helpful in distinguishing the skeletal development, including the carpus and distal radius.

Treatment

The choice in the treatment of children with thumb hypoplasia is surgery or not. If left alone, these children will adapt. They will use lateral pinch between the long and index fingers. However, the deficiencies in pinch, grasp, and fine motor activities will be significant. Surgical reconstruction can improve function and cosmesis, and should be advised.

Reconstruction of the hypoplastic thumb, therefore, includes first web space deepening; opponensplasty, with either the abductor digiti quinti or the ring-finger flexor digitorum superficialis tendon; and MCP joint stabilization, with either ligamentous reconstruction or arthrodesis. Blauth types I to IIIA should be reconstructed according to these principles (Fig. 22-26). The choice of first web space deepening procedure includes two-part and four-part Z-plasties or the use of dorsal rotation flaps from the index finger, thumb, or hand. The degree of contracture determines the amount of skin necessary to provide a normal depth and breadth to the web for pinch and grasp activities. The abductor digiti quinti transfer for opposition can be used in the infant with a relatively stable MCP joint. Care must be taken to protect the proximal neurovascular pedicle to the abductor muscle, with dissection near the pisiform (184). In older children or patients with marked instability of the MCP joint, the ring-finger flexor digitorum superficialis is used for opposition. The additional tendon length can be used for ligamentous reconstruction. Besides the flexor digitorum superficialis tendon, local fascia from the adductor can be mobilized for ligamentous augmentation at the MCP joint. If soft tissue procedures fail, or the instability at the MCP joint is too severe, fusion can be performed. The physis of the proximal phalanx needs to be preserved to maximize growth of the thumb ray. Chondrodesis of the metacarpal head to the epiphysis of the proximal phalanx is desired.

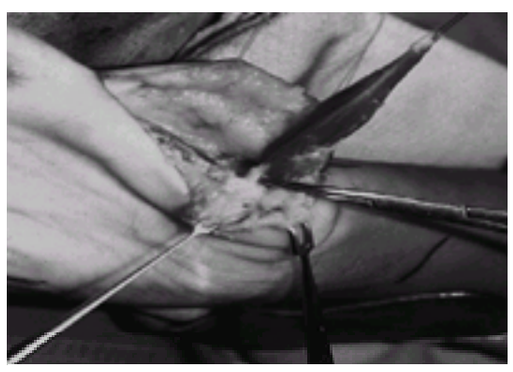

FIGURE 22-26. Intraoperative photograph of a Huber opponensplasty with abductor digiti quinti transfer to the abductor pollicis brevis. The snap identifies the proximal neurovascular pedicle to the muscle that needs to be preserved for successful dynamic transfer.

Thumb hypoplasia with the absence of a basal joint (type IIIB), *pouce flottant* (type IV), or aplasia of the thumb (type V) are candidates for pollicization of the index finger. The major area of controversy is still the type IIIB thumb. In the absence of a CMC joint, the results of reconstruction have been disappointing (289). It is a difficult decision for the parents to accept pollicization in these children because of the appearance of the thumb. However, reconstruction without a CMC joint leads to continued lateral pinch of the index and long fingers, rather than use of the reconstructed thumb. CMC joint reconstruction, with microvascular transfer of a toe metatarsophalangeal joint, rarely has been performed in children with type IIIB thumbs (289). This is an alternative to pollicization in these children. Surgery is performed later and is quite extensive. Pollicization involves the conversion of the triphalangeal index finger, without a basilar joint and a narrow web space, to a biphalangeal thumb with a CMC joint and a deep first web space. The removal of the index metacarpal and the use of the index metacarpal epiphysis as the trapezium enable the surgeon to properly position and cover the thumb. The technique described by Buck-Gramcko is used most commonly (178,179) (Fig. 22-27). In congenital absence of the thumb, this is better than microvascular toe transfer. Thumb reconstruction or pollicization is generally performed between 6 and 18 months of age. The quality of the pollicized digit is dependent on the quality of the original index finger, in terms of tendon function and joint motion. Patients with thumb aplasia and radial dysplasia generally do poorer, because the involved index finger has deficient musculature and camptodactyly. Manske and McCarroll performed secondary opposition transfers in children with poor pollicization (183). The best results are seen in children with aplasia alone, and normal index fingers (Fig. 22-28).

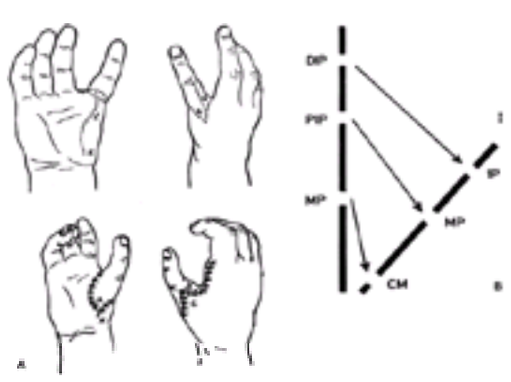

FIGURE 22-27. Illustrations of the pollicization procedure as popularized by Buck-Gramcko. **A:** The skin incisions are outlined that provide first web space flap coverage as the pollex is positioned for opposition. **B:** The triphalangeal index finger is converted to a biphalangeal thumb. The index metacarpal is excised, except for the distal epiphysis. The changes in joints from the index finger to the thumb, and the tendon transfers to provide opposition and pinch function, are as follows: extensor indicis proprius ® extensor pollicis longus; extensor digitorum II ® abductor pollicis longus; interosseus palmaris I ® adductor pollicis; interosseus dorsalis I ® abductor pollicis brevis. *DIP,* distal interphalangeal; *PIP,* proximal interphalangeal; *MP,* metacarpophalangeal; *IP,* interphalangeal; *CM,* carpometacarpal; *I* and *II,* number of finger.

FIGURE 22-28. A: A 1-year-old child with thumb aplasia. The surgical incisions for index pollicization are outlined. These flaps provide for deep first web space. **B:** Postoperative long-term follow-up photograph after pollicization. Aesthetically, it is important to set the first web space at the proper depth.

Thumb Duplication

Preaxial Polydactyly

Thumb duplication may be a misnomer because it implies that there are two normal thumbs, whereas in fact, both thumbs are hypoplastic. In isolation, thumb duplication is usually a sporadic occurrence. It may be associated with genetic syndromes, such as acrocephalopolysyndactyly (Nocack and Carpenter types) and Holt-Oram or Robinow syndromes. If associated with a triphalangeal thumb, it can be autosomal dominant. Preaxial polydactyly is a rare occurrence, with an incidence estimated at 0.08 per 100,000 live births. There are many different classification systems, including the universal (291), Marks and Bayne (292), and Wassel (293) systems. Classification by the Wassel system is dependent on the number of bifid or duplicated phalanges or metacarpals, starting distally and progressing proximally (Fig. 22-29). A bifid distal phalanx is Wassel type I. A duplicated distal phalanx is type II (Fig. 22-30), which constitutes approximately 20% of all thumb duplications. A duplicated distal phalanx with a bifid proximal phalanx is type III. A thumb with duplicated proximal and distal phalanges is type IV, which is the most common type (approximately 40%) (Fig. 22-31). Duplicated proximal and distal phalanges with a bifid metacarpal is type V. Duplication of all phalanges and metacarpals is type VI. Any duplication with a triphalangeal thumb is type VII, which accounts for approximately 20% of thumb duplications.

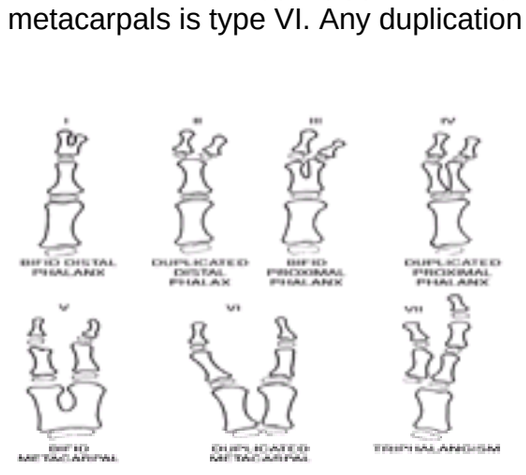

FIGURE 22-29. Wassel classification of thumb duplications. Type IV is the most common, with an incidence of 40%. Types II and VII have an incidence of approximately 20% each.

FIGURE 22-30. A 1-year-old patient with Wassel type II thumb duplication. These distal phalanges and nail plates are nearly equivalent. Unfortunately, the Bilhaut-Cloquet recombination procedure has not been rewarding in this circumstance. Surgery should consist of reconstruction of the best thumb.

FIGURE 22-31. A: An adolescent with the more common Wassel type IV thumb duplication. **B:** Results at the conclusion of the surgical reconstruction. Surgery included excision of the radial proximal and distal duplicated digits, transfer of the thenars and metacarpophalangeal joint radial collateral ligament to the reconstructed thumb, and contouring of the skin by excision of redundancy and Z-plasties.

The pathoanatomy is dependent on the type of polydactyly. The nails, bones, joints, ligaments, muscles, tendons, nerves, and blood vessels are split among the two digits. In addition, there can be hypoplasia or aplasia of any of the normal anatomic elements of a thumb. Plain radiographs will generally provide definitive information regarding skeletal pathoanatomy. Careful surgical exploration will define the soft tissue anatomy.

Treatment. Surgical reconstruction is the treatment of choice to improve function and cosmesis. Unlike postaxial polydactyly, ablation in the nursery is not recommended, even for the simplest preaxial polydactyly. Too often, the thenar musculature and collateral ligaments insert on the radius-based digit and can be lost with simple excision (294,295 and 296).

Treatment involves excision of the more hypoplastic thumb and reconstruction of the more developed thumb **[➥1.6]**. Generally, the radius-based digit is excised. The soft tissue elements usually bifurcate at the level of the skeletal split. Transfers of the shared or aberrant tendons, nerves, and ligaments to the reconstructed thumb are necessary to maximize outcome.

The extensor pollicis longus tendon is usually bifid. The flexor pollicis longus usually inserts on the ulnar thumb, although it can be bifid or insert on the radial thumb. The thenar musculature and the radial collateral ligament to the MCP joint usually insert radially, especially in the common type IV polydactyly (Fig. 22-31). They need to be transposed. The radial digital nerve may be present only in the radial thumb, and should be transposed to the radial aspect of the reconstructed thumb. The bifid proximal phalanx or metacarpal needs to be excised in type II or IV, respectively. Primary phalangeal or metacarpal osteotomy is indicated with axial malalignment. The more developed thumb often has a larger nail and distal phalanx. However, some Wassel type II malformations have almost equally sized distal phalanges and nails (Fig. 22-30). Surgical recombination of the distal phalanx and nail beds (Bilhaut-Cloquet procedure) in types I and II malformations has been disappointing because of poor nails, loss of joint motion, and physeal closure. It still appears best to accept the more hypoplastic distal phalanx than to consider recombination of the nail and phalanx. Adduction contracture of the first web space should be treated with Z-plasty to deepen the web space. The need for additional surgery with growth may be as high as 40%.

Angular deformity of the proximal and distal phalanges into a zig-zag posture is the most common problem (297,298,299 and 300). Reconstruction with osteotomy, tendon transfers, ligament reconstruction, or arthrodesis may be necessary to improve both function and cosmesis.

Triphalangeal Thumbs

Triphalangeal thumbs are usually inherited in an autosomal dominant manner. This is true whether they are associated with thumb polydactyly (301) or seen in isolation. The extra phalanx is the middle phalanx. It may be wedge-shaped or rectangular. The thumb may be in a position of opposition, or in the plane of motion of the other fingers. The latter situation may indicate an index finger duplication with an absent thumb. This concept is supported not only by the clinical and radiographic appearance of the most radial digit, but also by the dermatoglyphics (302). The triphalangeal thumbs studied contained the radial loops normally seen in the index finger and not in the thumb.

Triphalangeal thumbs can be associated with musculoskeletal malformations, such as cleft feet and preaxial polydactyly (303); congenital heart disease, including Holt-Oram syndrome (160); hematopoietic abnormalities, such as Fanconi and Blackfan-Diamond syndromes (304,305); and imperforate anus (306).

Classification and pathoanatomy are dependent on the type of triphalangism. Type I involves a delta middle phalanx with radial deviation deformity (Fig. 22-32). Type II involves a normal middle phalanx, but an opposable thumb. Type III is an index-finger duplication with all digits in the same plane. In types I and II triphalangism, the first web space is normal. In the five-fingered hand (type III), there is a contracted first web space that limits prehension. Similarly, usually the thenar musculature is normal in type I and type II triphalangeal thumbs, whereas it is absent in type III triphalangism. In addition, the triphalangeal thumb may be hypoplastic and have associated extrinsic musculature weakness.

FIGURE 22-32. A: Triphalangeal thumb with a delta phalanx and a marked radial deviation deformity. **B:** Postoperative photograph after excision of the delta phalanx

and rotation flap reconstruction of the soft tissues.

Treatment

Rarely, patients with triphalangeal thumbs prefer not to undergo surgical reconstruction. Patients with significant cosmetic differences and limitation of pinch prefer reconstruction for both functional and cosmetic reasons. A malaligned and elongated triphalangeal thumb in the same plane as the other digits is cosmetically different and functionally limited for prehension activities.

Depending on the type of triphalangeal thumb, surgery may involve web space deepening, excision of the extra phalanx (307), opposition transfer (308), or a modified pollicization procedure (308,309 and 310). The delta phalanx is usually excised to correct the length and angular deformity of the type I triphalangeal thumb (Fig. 22-32). If this procedure is performed in infancy, usually a stable interphalangeal joint can be reconstructed. In older children, or in children with abnormal phalanges and interphalangeal joints, a combination of shortening osteotomy and arthrodesis is preferred. In these situations, physeal growth of a biphalangeal digit should be preserved. In the five-fingered hand a modified pollicization procedure is necessary to provide a deep first web space and an opposable thumb.

TRAUMATIC INJURIES

Fractures to the pediatric hand are commonplace, accounting for approximately one-fourth of all childhood fractures (311). The two peak ages for these fractures are adolescence (from sport-related activities) and infancy (from crush injuries). The majority of fractures are nondisplaced, nonphyseal injuries. Physeal injuries, however, can account for up to 40% of finger fractures (312,313), with a Salter-Harris II fracture of the small finger proximal phalanx being the most common. The majority of pediatric hand fractures do well regardless of treatment (314). Malunion and growth disturbance are rare (312,315). However, there is a subset of pediatric hand injuries that will do poorly if not recognized and treated appropriately. The purpose of this section is to review those fractures that are problematic.

Overview

The bones of the digits have only one secondary center of ossification. These appear between birth and 3 to 4 years of age. The epiphyses of the phalanges are proximal. The epiphyses of the metacarpals are distal, except for the thumb, in which the physis is proximal. Distally in the thumb, there can be a second epiphysis or pseudoepiphysis. Ossification of the phalangeal condyles is progressive with growth, but in preschool children the condyles may be predominantly cartilaginous. Radiographic evaluation of injuries in young children may be difficult because of the chondral nature of the epiphysis and the intraarticular portions of the condyles. It is important to obtain true anteroposterior and lateral radiographs of the injured digits. Digital MRI can be performed in the diagnostically confusing situation. Operative exploration may also be appropriate in problematic situations.

To protect the anatomic healing of a traumatized digit in a young child, maximal protection is necessary. It is often necessary to protect the preschool-age child with a long-arm mitten cast. The older child often needs a short-arm mitten cast. Single-finger splinting is difficult to maintain, even in an adolescent. If the fracture is painful, or requires immobilization to maintain reduction, casting of the entire hand is appropriate. Fortunately, the majority of pediatric fractures are nondisplaced and stable (316). The outcome will be successful regardless of immobilization technique. In these situations, the patients are changed to simple buddy taping as soon as it is comfortable. However, it is imperative not to mistake a problematic injury for a simple one and treat it with benign neglect. Such a mistake will lead to long-term loss of alignment, motion, and function that may not be salvageable by secondary surgical reconstruction.

Distal Phalanx Injuries

Nail Plate Injuries, Physeal Fractures, Mallet Fingers, and Tip Amputations

The vast majority of injuries to the distal phalangeal region are secondary to crush injury. These injuries are most common in the toddler and preschool-age groups. The mechanism of injury is usually a digit caught in a door. Adults, often parents, are frequently involved in the accident, which makes the situation emotionally charged. The injuries can include partial or complete amputation, nail-bed laceration, and distal phalangeal fracture. All of these sites of trauma need to be addressed in the care of the child. In addition, time and energy need to be spent in helping the family cope with the emotional trauma.

Tip Amputations. A distal phalangeal crush injury in a toddler usually includes a partial amputation with a nail-bed laceration and a distal phalangeal tuft fracture (Fig. 22-33). The fractures are generally minor avulsions that heal without problems. The partial amputation often extends dorsally through the nail bed, leaving some volar pulp intact. The volar soft tissue attachments maintain the vascularity to the distal tip. Meticulous repair under conscious sedation and/or local anesthesia usually leads to normal long-term outcome. The technique involves initial repair of the eponychial folds to properly align and stabilize the digit. It is imperative to then meticulously repair the nail-bed laceration with fine, absorbable suture (i.e., 6-0 chromic suture) and loupe magnification, to prevent long-term nail deformity. The dorsal roof of the eponychium is preserved by placement of a spacer for several days after repair. Even when there is nearly complete amputation, with apparently nonviable distal tissue, soft tissue repair almost always leads to survival of the tip. Uncomplicated repair of the partial amputation and nail-bed laceration will generally heal without permanent change of the nail or phalanx. However, neglected nail-bed injuries have a high rate of permanent deformity (310,317).

FIGURE 22-33. Typical distal phalangeal crush injury with nail and pulp laceration. Repair requires nail plate removal, absorbable suture repair of the lacerated nail bed, and anatomic closure of the eponychial skin.

Care of the complete amputation at the level of the nail, or distally, is more controversial. First, this is a much more difficult situation emotionally for the child and family. The injury often occurs while the child is under adult supervision. There usually is significant stress and guilt associated with the amputation. The parents universally want the tissue replaced. However, this injury is beyond the trifurcation of the digital arteries near the level of the distal interphalangeal joint, so the tissue is not replantable. The debate concerns whether to suture the amputated part back on without vascular anastomoses (a composite graft), or to allow healing by secondary intention (318). Replacement of the amputated soft tissue initially makes the family feel better, but usually is not necessary. The amount of soft tissue amputated is small. The physis is proximal and not affected. Subsequent growth will be normal. The overall digital length, therefore, will be nearly normal. The cosmetics of composite grafting and healing by secondary intention are generally equal in the long term. Long-term sensibility and function seem to be equivalent. In addition, in the short term replacement of the amputated part may be more stressful for the family and child, with multiple dressing changes, superficial necrosis of the distal tip, and slow healing. Therefore, if the soft tissue loss is minor, reassurance to the family of the long-term result and treatment with serial dressing changes are best. This is true as well for the situation in which a minimal portion of exposed bone is debrided. However, if the piece includes the eponychium or the entire sterile and germinal matrix of the nail, composite grafting of the amputated part is preferred. There is a chance that this will heal and preclude secondary reconstructive surgery.

Physeal Fractures and Nail-bed Entrapment. Some children will present with distal laceration and flexion, or mallet, posture to the distal phalanx. Radiographs will

reveal a displaced physeal fracture with widening dorsally. Too often, these children will be diagnosed with mallet finger and treated with splinting. This is not an extensor tendon disruption. The extensor mechanism is intact because the terminal tendon inserts into the more proximal epiphysis. The deformity is caused by entrapment of the proximal nail bed (germinal matrix) in the physeal fracture site (319). If not recognized early, the open injury can become secondarily infected. The clinical appearance of the finger and the radiographic physeal changes may be interpreted as distal phalangeal osteomyelitis. However, antibiotic treatment alone or surgical debridement of the distal phalanx is not the proper treatment for this late-presenting fracture. Surgical repair of the nail bed is necessary to prevent long-term nail and distal phalanx growth problems. Under local, regional, or general anesthesia, the nail plate should be removed. By flexing the distal phalanx, the entrapped nail bed can be gently extracted. The germinal matrix needs to be meticulously repaired to avoid long-term nail-plate problems. At times this requires more proximal exposure by raising an eponychial flap. After repair of the nail bed the nail plate can be replaced to preserve the dorsal roof of the eponychium, and to provide an internal splint for the fracture and repair (319,320). Placement of a cautery hole in the nail plate will lessen the risk of subsequent hematoma and paronychial infection.

Mallet Fingers. True mallet fingers are rare in the preadolescent child. In this age group, physeal fracture is more common. In the adolescent, mallet injuries with disruption of the extensor mechanism are more common and adult-like. As long as there is no entrapment of the germinal matrix, as noted above, these injuries can be treated with immobilization. Rarely, the entire epiphysis can be displaced with the extensor mechanism (321,322). If recognized early, this injury should be treated with open reduction of the dislocated epiphysis. The rare, chronic mallet finger in the young child has been treated successfully with tenodermodesis (323).

Phalanx Fractures

Phalangeal Neck Fractures

Phalangeal neck fractures are problematic. They are usually caused by crush injury. As the child attempts to extract the affected digit, the condyles become entrapped and a fracture occurs in the subcondylar region (316,324,325). The condylar fragment displaces into extension and often malrotates. The fragment is tethered by the collateral ligaments as it rotates dorsally up to 90 degrees. The condylar fragment is small, and has a precarious blood supply through the collateral ligaments. The subcondylar fossa is obliterated, blocking interphalangeal flexion (Fig. 22-34). If not properly recognized and treated, complications of malunion, loss of motion, and avascular necrosis can occur. Too often, the severity of the fracture is underappreciated in the urgent care setting. The patient presents late, with inappropriate immobilization and a significantly healed fracture. In addition, the fracture is unstable and often will displace after closed reduction (326). The treatment of choice is closed reduction and percutaneous pinning. In a young child, this can be accomplished with a single oblique pin. In an older child, crossed pins prevent malrotation. Placement of the pins in the distal fragment requires careful localization of the fragment and avoidance of the extensor mechanism. If open reduction is necessary, the collateral ligaments should not be dissected from the distal fragment. Careful dissection lessens the risk of avascular necrosis.

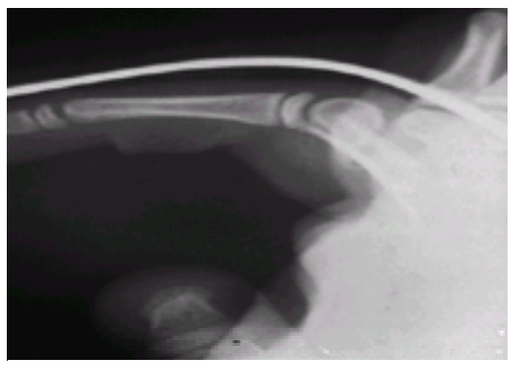

FIGURE 22-34. Phalangeal neck displaced fracture with loss of the subchondral fossa. This leads to loss of digital flexion. This fracture requires prompt attention, anatomic reduction, and pin stabilization.

Open reduction, when there is marked callus, may cause avascular necrosis. The fracture is generally too healed for successful closed reduction and percutaneous pinning. If there is still lucency along the fracture line, percutaneous osteoclasis can be performed (327). A pin is placed dorsally in the fracture site under fluoroscopic control, and used to reduce the fracture. The subcondylar fossa can be reconstituted, and the fracture can be pinned percutaneously.

If the fracture is completely healed upon referral, late subchondral fossa reconstruction can be performed if there is a bony block to flexion (325). An average of 90 degrees of PIP joint flexion has been obtained with subchondral fossa reconstruction (325). Remodeling of the fracture is rare because of the significant distance from the physis, but it has been described in a case report of a middle phalanx phalangeal neck fracture (328).

Intercondylar Fractures

Intercondylar fractures in young children are often small osteochondral fractures. These carry a high risk of nonunion, malunion, and avascular necrosis (310,329). This is particularly true in the middle phalanx if the injury is a crush injury that alters the local blood supply. The fracture is intraarticular, generally displaced, and requires anatomic reduction for a successful outcome. Most often, the fracture needs to be treated aggressively with open reduction. The collateral ligament attachments to the fragment are preserved to lessen the risk of avascular necrosis. On occasion, bone grafting is necessary to maintain articular congruity and prevent collapse. Even with well-performed open reduction, complications of this fracture can occur in the young patient (329). Avascular necrosis usually resolves by revascularization, but often not before collapse. Articular malunion can occur (Fig. 22-35). Loss of motion may not limit function.

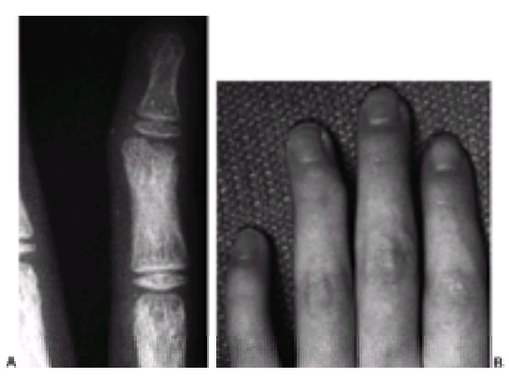

FIGURE 22-35. A: Radiograph of a displaced intercondylar fracture with articular malunion. **B:** Clinical photograph of a similar patient. This injury requires acute anatomic reduction and pin stabilization to prevent long-term loss of motion, malalignment, and potential pain and arthritis.

In the adolescent, treatment of intercondylar fractures is similar to that in adults. Anatomic reduction and pin fixation are necessary to restore the joint surface, and to prevent loss of reduction that can occur with this unstable fracture. Generally, the procedure can be performed closed, using distraction and a percutaneous towel clip to obtain reduction (330). Open reduction can be performed with a volar, midaxial, or dorsal approach. This is appropriate for fractures that cannot be reduced closed, or for comminuted fractures. Restoration of an anatomic joint will lessen the risk of loss of motion, malalignment, or long-term arthritis (Fig. 22-35).

Diaphysis-level phalangeal fractures are rare in the young child, and more common in the teenager. The major issue with these fractures is malrotation (312) (Fig. 22-36). Frequently, children will not actively move the finger in the acute setting to allow for accurate assessment of digital alignment. However, close inspection of the nail plates will reveal the digital malalignment. In addition, the examiner can test digital alignment by tenodesis of the wrist. With passive wrist extension, the

fingers flex and point toward the volar scaphoid tubercle. Digital alignment is generally symmetric. Children will tolerate this test, even when they are in too much pain or are too frightened to actively move their digits. Tenodesis assessment needs to be performed on all phalangeal and metacarpal fractures, regardless of radiographic appearance. If closed treatment is chosen never immobilize a solitary finger, but secure it to the adjacent digits to prevent subsequent loss of reduction and malrotation.

FIGURE 22-36. A: Displaced proximal phalanx fracture with malrotation. **B:** Tenodesis testing revealing malrotation. By passively extending and flexing the wrist, the digits will passively flex and extend, respectively. Malalignment is evident.

If the fracture is malrotated and unstable, reduction with pin or screw stabilization is necessary (331,332). Although malrotation is uncommon, it is a major problem if missed until after healing. The malrotated digit impairs the function of the adjacent digits because the digits will overlap in flexion. Then, malrotation can be corrected only with osteotomy.

Physeal Fractures

Physeal fractures constitute 30 to 70% of pediatric finger fractures (311,312 and 313,315). A Salter-Harris II fracture of the small finger is the most common of these fractures. Closed reduction of the abducted fracture is performed in MCP flexion to lessen the restraint of the more distal web space. The surgeon's thumb or a cylindrical object such as a pencil can be used. Postreduction stability is maintained by taping the digit loosely to the adjacent digit and applying a short-arm mitten cast. Less common type III physeal fractures require open reduction if there is greater than 2 mm of diastasis or articular step-off.

Metacarpal Fractures

Distal metacarpal metaphyseal (boxer) fractures are common in adolescence. The mechanism is a closed fist injury, most often to the small finger metacarpal. These fractures are usually juxtaphyseal and malaligned, with apex dorsal angulation. In the acute setting, closed reduction and cast immobilization with three-point fixation for 3 weeks is preferred for displaced fractures. This includes volar-to-dorsal pressure on the metacarpal head and dorsal-to-volar pressure on the more proximal shaft. Often, these patients will not seek medical attention until there is significant healing. Fortunately, the fracture is adjacent to the distal metacarpal physis, and the flexion malunion can remodel if there is sufficient growth remaining. This fact has led some clinicians to approach these fractures with neglect to allow for remodeling. Indeed, depending on the age of the patient, remodeling of the flexion deformity can occur. However, malrotation will not remodel. In addition, if remodeling is slow or fails to occur, the prominence of the metacarpal head in the palm can be limiting.

The rare unstable, or multiple, metacarpal fracture(s) should be treated with closed reduction and percutaneous pinning. Two smooth pins are placed under fluoroscopic control, from ulnar to radial, distal to the fracture site(s), from the fifth to the fourth or third metacarpal, as necessary. Late open reduction of the juxtaphyseal fracture carries the risk of physeal injury and should be avoided. Diaphyseal fractures of the fifth metacarpal have a higher risk of malunion that will not remodel. Closed reduction and percutaneous pinning to the adjacent metacarpals is the treatment of choice. Corrective osteotomy may be necessary in the severe, malunited diaphyseal fracture that fails to remodel the flexion deformity with growth.

The major issue with other diaphyseal metacarpal fractures, especially if there are multiple metacarpal fractures, is malrotation. Active digital motion or passive tenodesis of the wrist will reveal malrotation. Anatomic reduction and pin, screw, or plate fixation will correct the malrotation.

Thumb Fractures

The unique features of fractures of the thumb are seen in Salter-Harris III fractures of the proximal phalanx, and at the base of metacarpal fractures. The type III physeal fracture of the thumb proximal phalanx is the skeletally immature equivalent of an adult ulnar collateral ligament disruption (333) (Fig. 22-37). These fractures require open reduction and internal fixation to restore joint stability and anatomic alignment of the joint and physis. During surgical exposure, remember that the ligament is intact so that, after adductor takedown, the MCP joint is exposed through the fracture site, rather than through inadvertent incision of the ligament. The long-term results of anatomic open reduction are excellent. Metaphyseal fractures at the base of the thumb metacarpal often displace. Immobilization and observation, even with displaced fractures, are appropriate as long as there are at least 2 years of growth remaining, because the malunited dorsoradial prominence will remodel during the ensuing 6 to 12 months (317) (Fig. 22-38). Most parents would prefer to wait for remodeling rather than have operative reduction and pinning. The presence of a Bennett fracture with articular malalignment requires anatomic alignment of the intraarticular component and pin fixation of the thumb metacarpal to the adjacent second metacarpal and carpus.

FIGURE 22-37. A: Salter-Harris III displaced proximal phalanx fracture of the thumb. This fracture requires open reduction and internal fixation to restore articular congruity and ligamentous stability. **B:** Postoperative radiograph of a similar patient with pins in place.

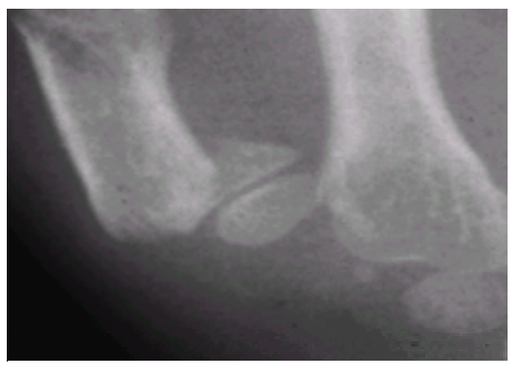

FIGURE 22-38. Displaced base in a metacarpal thumb fracture. Because this fracture is juxtaphyseal, adjacent to the carpometacarpal joint with universal motion, its remodeling potential is almost unlimited if the patient is younger than 10 years of age. Treatment choices are closed reduction and pinning, or cast immobilization and biologic remodeling for the ensuing 6 to 12 months of growth. This patient was treated in a cast.

Wrist Injuries

Scaphoid Fractures

Scaphoid fractures occur from a fall on an outstretched wrist. The pain is often mild, rather than the severe pain a child or parent expects from an acute fracture. This leads some patients and families to ignore the acute injury and not present until late. When the child presents acutely, there will be tenderness to palpation over the anatomic snuff-box (the region dorsoradially at the wrist between the extensor pollicis longus and the extensor pollicis brevis tendons), the volar scaphoid tubercle, and with axial compression of the thumb carpometacarpal joint. Radiographs may reveal the fracture. The best view is an anteroposterior view in 30 degrees of ulnar deviation (scaphoid view). If the radiographs are diagnostic for the fracture, long-arm immobilization in a thumb spica cast is best. If the radiographs are negative, but the child is tender, as noted above, protected immobilization for 2 weeks is advised. Repeat clinical and radiographic examination should be performed out of cast 2 weeks later if tenderness persists. If there is still doubt about the diagnosis, MRI or CT is advised. The CT scan shows the bony alignment better, but the MRI scan gives added information about the vascularity to the proximal pole, and better outlines the cartilage surfaces in a young child. CT scans are used for the acute fracture in the adolescent. MRI scans are used for the acute injury in the child younger than 10 years of age.

Previously, it was written that most scaphoid fractures in the skeletally immature patient were distal pole or avulsion fractures (329). Distal pole fractures heal readily with cast immobilization without risk of nonunion or avascular necrosis. However, scaphoid wrist fractures are becoming more common in the adolescent age group. These fractures can displace and carry the same risks of nonunion and avascular necrosis in the child as they do in the adult. Similarly, nonunions are becoming more commonplace (334,335). Treatment of an established nonunion in a child should be with open reduction, bone grafting, and, potentially, internal fixation. Internal fixation screws have been used in children with both acute displaced wrist fractures and established nonunions (328,334,335) (Fig. 22-39). The issue of whether a bipartite scaphoid, even if bilateral, is congenital or posttraumatic, remains unresolved. However, if symptomatic, it should be treated in the same way as a traumatic nonunion. The success of open reduction, bone grafting, and internal fixation for a scaphoid nonunion is high in children (334,335).

FIGURE 22-39. A: Scaphoid nonunion in an adolescent. **B:** Postoperative iliac crest bone grafting and internal fixation for a similar scaphoid fracture nonunion.

Wrist Pain, Triangular Fibrocartilage Complex Tears, and Ligamentous Injuries

Atraumatic Ligamentous Instability. Most adolescents with chronic wrist pain have overuse injuries. These patients often have generalized ligamentous laxity or a hyperelasticity syndrome. The wrist pain is similar to the patellofemoral knee pain and multidirectional shoulder instability pain seen in this age group. Overuse, growth, and resultant muscle weakness all contribute to joint instability. On physical examination, there is often systemic evidence of generalized laxity (elbow cubitus valgus, pes planus, knee hyperextension, passive hyperextension of the index finger parallel to the dorsal forearm, and thumb abduction to the volar forearm). At the wrist, there will be increased midcarpal translation to volar and dorsal applied stress. This passive midcarpal instability will be equivalent on both the affected and the unaffected wrist. However, the affected side often will have painful clicking. Plain radiographs may reveal a volar tilt to the lunate on the lateral view. MRI scans and arthrograms appear normal. These children respond to alteration of activities and strengthening, as in other growth-related overuse injuries in the teenager. It is the author's experience that resistive strengthening with therapeutic putty is best.

Traumatic Scapholunate Ligamentous Injuries. Posttraumatic injuries to the scapholunate ligament rarely occur in children. Most descriptions of these injuries have been case reports (336). However, it is the author's experience that these traumatic ligamentous injuries are occurring more frequently with today's higher level of athletic competition in this age group. On physical examination, the tenderness is usually more focal than in atraumatic ligamentous laxity wrist pain. Asymmetric clicking with applied ligamentous stress testing is common. Static injuries are more common in adults, and will show an increased scapholunate distance and a flexed scaphoid on plain radiographs. Most scapholunate injuries in children are dynamic injuries, with normal plain radiographs. In addition, the scapholunate distance in children has been difficult to interpret because of eccentric ossification and the chondral nature of the carpus in the young. A recent study of pediatric wrist radiographs developed an age standard for scapholunate distances in both sexes (337). This will help in the evaluation of pediatric carpal injuries. MRI scans may reveal the ligamentous injury. Arthroscopic examination of the wrist is diagnostic and often therapeutic. Many of these injuries are partial tears of the ligament, with an associated chondral lesion of the radius. This leads to mechanical impingement that often responds favorably to arthroscopic debridement. It is rare that there will be a complete ligamentous disruption in this age group. However, symptomatic complete scapholunate disruptions need to be treated with ligamentous reconstruction.

Triangular Fibrocartilage Complex Tears (TFCC)

Posttraumatic chronic wrist pain that does not respond to prolonged rest and therapy needs to be evaluated for intraarticular pathology. Similar to scaphoid fractures and intercarpal ligamentous injuries, the epidemiology of TFCC tears may be changing to include the adolescent. Physical examination for TFCC tears includes ulnocarpal compressive testing, lunate-triquetral stress testing, and distal radioulnar joint stress testing. Painful clicking with these maneuvers, especially if asymmetric, may be indicative of a tear. However, many children with nondissociative laxity have similar findings on physical examination. Plain radiographs are normal. The MRI may be diagnostic, but there has been a high incidence of false-negative readings for adolescent TFCC tears. In skilled hands arthroscopy is definitive for diagnosis, and often treatment (Fig. 22-40).

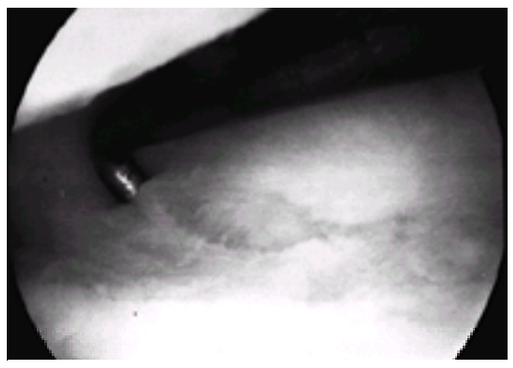

FIGURE 22-40. Arthroscopic photograph of a triangular fibrocartilage complex (*TFCC*) peripheral tear. The tear is along the peripheral edge of the TFCC, where the blood supply enters and aids in healing. Repair is by arthroscopic suture techniques in this situation.

TFCC tears occur in the skeletally immature. Most tears are associated with ulnar styloid fracture nonunion, radial growth, ulnar overgrowth, and/or ulnocarpal impaction syndrome. Isolated tears also occur. In adolescents and children, these tears are usually peripheral tears that respond well to surgical repair (338). Isolated tears can be repaired arthroscopically. Tears associated with radial and ulnar bony deformities are repaired at the time of corrective osteotomy (Fig. 22-41). Treatment should also include appropriate excision of the ulnar styloid nonunion, shortening of the impacting ulna, osteotomy of the deformed radius, and stabilization of the distal radioulnar joint, if necessary (338).

FIGURE 22-41. A: Radiograph of ulnocarpal impaction associated with radial growth arrest, ulnar overgrowth, and a triangular fibrocartilage complex (TFCC) tear. **B:** Repair of the TFCC, ulnar-shortening, and radial osteotomy with bone grafting were performed.

Dislocations

Most hyperextension injuries to the finger interphalangeal joints in children result in a tear of the volar plate. There may be associated minimal Salter-Harris III physeal avulsions of the adjacent phalanx (Fig. 22-42). These injuries are stable. Treatment should be brief immobilization for comfort, followed by buddy taping until the patient is asymptomatic. Prolonged treatment with splints can lead to PIP joint stiffness. True interphalangeal dislocations occur less often. The dislocation is usually dorsal, and occurs more commonly at the PIP joint than at the distal interphalangeal joint. Closed reduction with distraction and dorsal-to-volar manipulation are generally successful.

FIGURE 22-42. A: Volar plate injury with nondisplaced minor volar and dorsal avulsion injuries. This injury needs minimal immobilization and prompt initiation of range-of-motion exercises to minimize the risk of permanent flexion contracture. **B:** This injury has a more significant fracture fragment and joint subluxation. This requires anatomic reduction of the proximal interphalangeal joint and an extension block splint to allow for motion within the range of joint stability.

Rarely, a displaced epiphysis, flexor tendon, or interposed volar plate can block reduction, and will require open reduction. MCP joint dislocation of the thumb or index finger can be simple or complex (326). Simple dislocations are reducible in the emergency setting. Complex dislocations are irreducible, and have an interposed volar plate blocking closed reduction. Plain radiographic evidence of widening and lateralization of the joint, as well as bayonet apposition of the proximal phalanx and metacarpal, indicate an irreducible situation.

Open reduction of a complex dislocation can be performed by a volar (339,340) or a dorsal (341,342) approach. In the volar approach, the radial neurovascular bundle is tented just beneath the skin by the metacarpal head. It is imperative to be cautious with the skin incision to prevent iatrogenic laceration. By either approach, the volar plate needs to be incised to allow reduction of the joint and anatomic realignment of the flexor tendons, sesamoids, and collateral ligaments. Postoperative treatment is by early protected motion with buddy taping and extension block splinting. Chronic instability is rare, but limited MCP motion is not. The digital neurapraxia secondary to the dislocation will resolve in this age group.

Tendon Lacerations

The classification system, in terms of zones of injury for flexor tendon lacerations, is the same for the child as it is for the adult. The diagnosis of flexor tendon injury, operative care, and postoperative rehabilitation may be more difficult in the child. This is especially true in the toddler and preschool-age child, in whom patient cooperation is limited. Often, the presenting digital cascade, and digital excursion with wrist tenodesis, serve as the basis for the diagnosis of flexor tendon laceration (Fig. 22-43). If in doubt, explore the wound under anesthesia. Repair of the tendon lacerations in zones I and II requires meticulous technique with fine sutures. Repair can be performed electively in the first 1 to 2 weeks with equivalent results. However, if there is any concern regarding the vascular status of the digit, repair should be emergent, with exploration of the digital neurovascular bundles. In the infant, the core suture may be as fine as 6-0 and the epitenon suture may be 8-0. Postoperative immobilization in a cast for 4 weeks is effective protection. Subsequent rehabilitation is necessary to regain maximal passive and active motion.

FIGURE 22-43. Photograph of an altered digital flexion cascade with passive wrist extension tenodesis. This is diagnostic of a flexor tendon laceration in the long finger.

There have been no differences in total active motion (TAM) between early mobilization protocols and cast immobilization for 4 weeks in children younger than 15 years (343). The results of isolated profundus tendon lacerations in zone I averaged 90 to 94% of normal TAM. Isolated profundus lacerations in zone I averaged 71 to 78% TAM. Combined superficialis and profundus lacerations in zone II averaged 72% TAM. However, if cast immobilization continued beyond 4 weeks there was a significant decrease in TAM to 40% by 6 weeks. There was no difference in the results by age groups from birth to 15 years.

Associated nerve or palmar plate injuries diminished the results slightly. Postoperative tendon rupture is rare. Two-stage reconstruction of unrecognized zone II lacerations in children younger than 6 years has had poorer results than in adults, with a higher rate of complications and a mean TAM of approximately 60% of normal. Results were better with supervised rehabilitation (344).

The principles of the treatment of extensor tendon lacerations in the adult apply to the child as well. Direct repair in the emergency room under sedation, or in the operating room under general anesthesia, is preferred. Cast immobilization, in a protected position of wrist dorsiflexion and digital extension, is continued for 4 weeks after repair. Results are excellent with primary repair. Associated fractures, dislocations, and flexor tendon injuries lessen the results.

Amputations

Distal fingertip complete or partial amputations are very common in children, and have been discussed in detail in the section of this chapter on distal phalangeal injuries. Treatment of more proximal, complete digital amputations with replantation in children as young as 1 year of age is now standard. In children, the indications for replantation are more liberal than in adults, and include multiple-digit, thumb, midpalm, hand, and distal forearm amputations as well as single-digit amputations in zones I and II. Crush amputations from doors, heavy objects, or bicycle chains have a peak incidence at 5 years, whereas sharp amputations occur more commonly in adolescence. Digital survival rates from replantation range from 69 to 89% in pediatric series. More favorable digital survival was seen with sharp amputations, body weight greater than 11 kg, more than one vein repaired, bone shortening, interosseous wire fixation, and vein grafting of arteries and veins. Vessel size generally exceeds 0.8 mm in digital replants in children, and is not a technical problem for the skilled microvascular surgeon. Index- and long-finger replants have done better than small finger replants in children. A survival rate of 95% was seen in children if prompt reperfusion occurred after arterial repair with at least one successful venous anastomosis, compared with 0% survival if one or both of these factors were absent (345) (Fig. 22-44). Neural recovery rates far exceed those cited in adults, with return of two-point discrimination less than 5 mm often present (346). Tenolysis may rarely be necessary after tendon repair. Two-stage flexor tendon reconstruction in children has a higher rate of complications than in adults. Growth arrest or deformity is more common if there is a crush component to the amputation. These digits rarely are normal after replanting, and the results in children are better than in adults, in terms of sensibility and recovery of range of motion. Microvascular toe-to-thumb transfer is a very successful alternative to pollicization in the case of a failed replant in a young child (347) (Fig. 22-45).

FIGURE 22-44. Postoperative digital replantation in a child at the middle phalangeal level of the index finger. The lacerations and tendon injuries in the adjacent digits were repaired simultaneously. Single-digit replantation procedures are indicated in children.

FIGURE 22-45. A: Traumatic amputation of the thumb in a 2-year-old child. **B:** Postoperative photograph of the same patient after microvascular toe-to-thumb transfer for thumb reconstruction.

CHAPTER 23

DEVELOPMENTAL HIP DYSPLASIA AND DISLOCATION

STUART L. WEINSTEIN

S L. Weinstein: Department of Orthopaedic Surgery. University of Iowa Hospital, Iowa City, Iowa 52245.

GROWTH DISTURBANCE OF THE PROXIMAL FEMUR

In the pediatric orthopaedic literature, the long-standing terminology of “congenital dysplasia or dislocation of the hip” (CDH) has been progressively replaced by the use of “developmental dysplasia or dislocation of the hip” (DDH). The former term is attributed to Hippocrates. The term “congenital” implies that a condition existed at birth. The American Academy of Orthopaedic Surgeons (1), the Pediatric Orthopaedic Society of North America, and the American Academy of Pediatrics have endorsed the name change of this entity from CDH to DDH, because the latter is more representative of the wide range of abnormalities seen in this condition (2).

The term “developmental” is more encompassing and is taken in the literal sense of organ growth and differentiation, which includes the embryonic, fetal, and infantile periods. This terminology includes all cases that are clearly congenital and those that are developmental, and it incorporates subluxation, dislocation, and dysplasia of the hip. Because this change in terminology has not yet been incorporated into the *International Classification of Disease*s, the term “CDH,” which has existed in the literature for years, will continue to be used in many publications.

One of the most confusing areas in DDH is the terminology used to discuss the condition. What different investigators mean by “instability,” “dysplasia,” “subluxation,” and “dislocation” varies considerably. In this chapter, the term “DDH” denotes developmental dysplasia of the hip and encompasses all the variations of the condition described. Within this spectrum are two entities: subluxation and dislocation. For the newborn, the term “dysplasia” refers to any hip with a positive Ortolani sign, which is a hip that may be provoked to subluxation (i.e., partial contact between the femoral head and acetabulum), provoked to dislocation (i.e., no contact between the femoral head and the acetabulum), or reduced from either of these positions. The distinction between these two entities is often difficult, especially given the subtleties of arthrographic and ultrasonographic classifications. Because further subclassification in the newborn has no influence on treatment, the author prefers to use the term “dysplasia” to encompass these entities and other variations. The term “developmental dislocation” refers here only to complete irreducible dislocations.

NORMAL GROWTH AND DEVELOPMENT OF THE HIP JOINT

For normal hip joint growth and development to occur, there must be a genetically determined balance of growth of the acetabular and triradiate cartilages and a well-located and centered femoral head. Embryologically, the components of the hip joint, the acetabulum, and the femoral head develop from the same primitive mesenchymal cells (3,4,5 and 6) (Fig. 23-1). A cleft develops in the precartilaginous cells at about the seventh week of gestation. This cleft defines the acetabulum and the femoral head. By the eleventh week of intrauterine life, the hip joint is fully formed (5,6 and 7). Theoretically, the eleventh week is the earliest time at which a dislocation could develop, although this rarely happens (7). Acetabular development continues throughout intrauterine life, particularly by means of growth and development of the labrum (3,6). In the normal hip at birth, the femoral head is deeply seated in the acetabulum and held within the confines of the acetabulum by the surface tension of the synovial fluid. It is extremely difficult to dislocate a normal infant's hip, even after incising the hip joint capsule (8,9). The retaining force is similar to that of a suction cup. Hips in newborns with DDH are not merely normal hips with capsular laxity; they are pathologic entities.

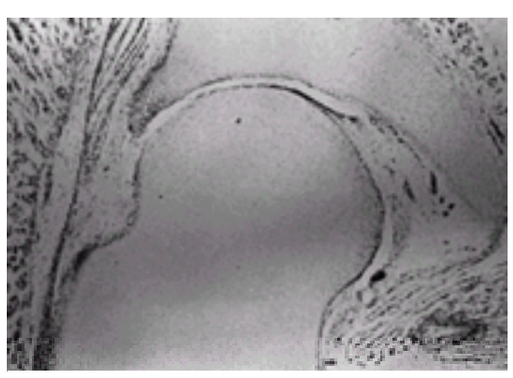

FIGURE 23-1. Embryonic hip. The components of the hip joint, the acetabulum, and the femoral head develop from the same primitive mesenchymal cells. A cleft develops in the precartilaginous cells at about the seventh week of gestation, defining the acetabulum and the femoral head.

After birth, continued growth of the proximal femur and the acetabular cartilage complex is extremely important to the continuing development of the hip joint (3,7,10,11). The growth of these two members of the hip joint is interdependent.

Acetabular Growth and Development

The acetabular cartilage complex (Fig. 23-2) is a three-dimensional structure, triradiate medially and cup-shaped laterally. The acetabular cartilage complex is interposed between the ilium above, the ischium below, and the pubis anteriorly. Acetabular cartilage forms the outer two-thirds of the acetabular cavity, and the nonarticular medial wall of the acetabulum is formed by a portion of the ilium above, the ischium below, and portions of the triradiate cartilage.

FIGURE 23-2. Normal acetabular cartilage complex of a 1-day-old infant. The ilium, ischium, and pubis have been removed with a curet. The lateral view shows the cup-shaped acetabulum. (From ref. 11, with permission.)

Thick cartilage, from which a secondary ossification center, the os acetabulum, develops in early adolescence, separates the acetabular cavity from the pubic bone (11). The fibrocartilaginous labrum is at the margin of the acetabular cartilage, and the joint capsule inserts just above its rim (12) (Fig. 23-3).

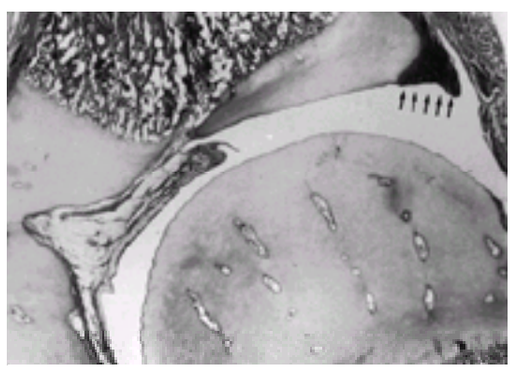

FIGURE 23-3. Coronal section through the center of the acetabulum in a full-term infant. Note the fibrocartilaginous edge of the acetabulum, the labrum (*arrows*), at the peripheral edge of the acetabular cartilage. The hip capsule inserts just above the labrum.

The triradiate cartilage is a triphalanged structure. One phalange is oriented horizontally between the ilium and the ischium. One phalange is oriented vertically and interposed between the pubis and the ischium. The third phalange is located anteriorly and slanted superiorly between the ilium and the pubis (Fig. 23-4).

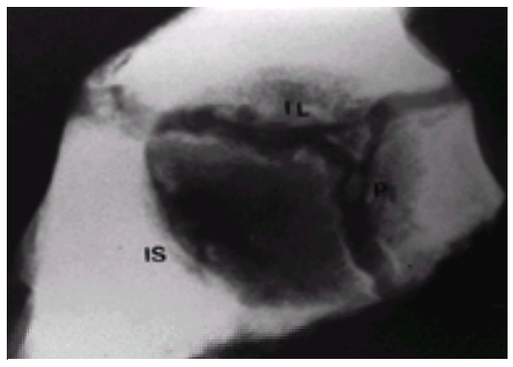

FIGURE 23-4. Lateral roentgenogram of the acetabulum of a 9-year-old girl. Two centers of ossification are seen within the cartilage adjoining the pubis (*P*) and appear to be developing within the vertical phalange of the triradiate cartilage. The positions of the ischium (*IS*) and the ilium (*IL*) are indicated. (From ref. 11, with permission.)

The triradiate cartilage is the common physis of these three pelvic bones. The entire acetabular cartilage complex is composed of very cellular hyaline cartilage (Fig. 23-3). The lateral portion of the acetabular cartilage is homologous with other epiphyseal cartilages of the skeleton (13). This is important in understanding normal growth and development and the shape of the acetabulum in skeletal dysplasias and injury. The labrum, or fibrocartilaginous edge of the acetabulum, is at the margin of the acetabular cartilage. The hip joint capsule inserts just above the labrum. The capsule insertion is continuous with the labrum below and the periosteum of the pelvic bones above.

Articular cartilage covers the acetabular cartilage on the side that articulates with the femoral head. On the opposite side is a growth plate, with its degenerating cells facing toward the pelvic bone it opposes. New bone formation occurs in the metaphysis adjacent to the degenerating cartilage cells. Growth of the acetabular cartilage occurs by means of interstitial growth within the cartilage and appositional growth under the perichondrium. This fact is most important when considering various innominate bone osteotomies, because surgical injury to this important area may jeopardize further acetabular growth.

Each phalange of the triradiate cartilage is composed of very cellular hyaline cartilage. This cartilage contains many canals. Each side of each limb of the triradiate cartilage has a growth plate. Interstitial growth within the triradiate cartilage causes the hip joint to expand its diameter during growth.

Growth of the Proximal Femur

In the infant the entire proximal end of the femur, including the greater trochanter, the intertrochanteric zone, and the proximal femur, is composed of cartilage. Between the fourth and seventh months of life, the proximal femoral ossification center appears. This bony centrum continues to enlarge, although with a slowly decreasing rate, along with its cartilaginous anlage until adult life, when only a thin layer of articular cartilage remains over it. The proximal femur and the trochanter enlarge by appositional cartilage cell proliferation (14).

The three main growth areas in the proximal femur are the physeal plate, the growth plate of the greater trochanter, and the femoral neck isthmus (14) (Fig. 23-5). A balance among the growth rates of these centers accounts for the normal configuration of the proximal femur, the relation between the proximal femur and the greater trochanter, and the overall femoral neck width. The growth of the proximal femur is affected by muscle pull, the forces transmitted across the hip joint by weightbearing, normal joint nutrition, circulation, and muscle tone (15,16 and 17). Any alterations in these factors may cause profound changes in development of the proximal femur (18).

FIGURE 23-5. The infant proximal femur has three physeal plates: the growth plate of the greater trochanter, the growth plate of the proximal femoral physeal plate, and the growth plate of the femoral neck isthmus connecting the other two plates.

During infancy, a small cartilaginous isthmus connects the trochanteric and femoral growth plates along the lateral border of the femoral neck and is a reflection of their previous common origin. This growth cartilage contributes to the lateral width of the femoral neck and remains active until maturity.

It is the normal growth of these three physes that determines adult femoral neck configuration. Disturbances in growth in any of these three growth plates by whatever mechanism alter the shape of the proximal femur. Hyperemia secondary to surgery or inflammatory conditions may stimulate growth in any or all of these growth plates (14).

The proximal femoral physeal plate contributes approximately 30% of the growth of the overall length of the femur. Any disruption to the blood supply or damage to the proximal physeal plate results in a varus deformity caused by the continued growth of the trochanter and the growth plate along the femoral neck (14,19). Partial physeal arrest patterns may be caused by damage to portions of the proximal femoral physeal plate. The relation between the growth of the trochanter and the physis of the proximal femur should remain constant; it is measured by the articular trochanteric distance, which is the distance between the tip of the greater trochanter and the superior articular surface of the femoral head. The greater trochanter usually is classified as a traction epiphysis, depending on normal abductor pull for growth stimulation. The trochanter, like the proximal femur, grows by appositional growth.

Determinants of Acetabulum Shape and Depth

Experimental studies and clinical findings in humans with unreduced dislocations suggest that the main stimulus for the concave shape of the acetabulum is the presence of a spherical femoral head (10,13,20,21 and 22). Harrison determined that the acetabulum failed to develop in area and depth after femoral head excision in rats (13). He also demonstrated atrophy and degeneration of the acetabular cartilage, although the growth plates of the triradiate cartilage remained histologically normal, as did the length of the innominate bones. These experimental findings are characteristic of humans who have had untreated hip dislocations (Fig. 23-6).

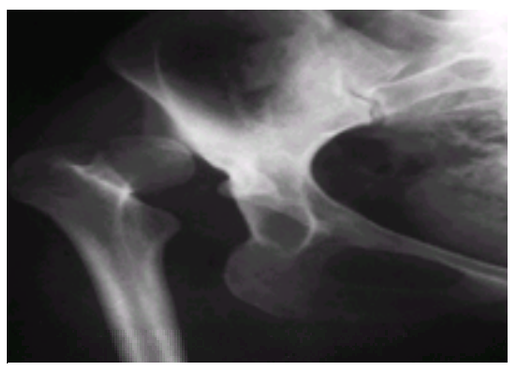

FIGURE 23-6. Untreated dislocation of the hip. Note the lack of the concave shape and the shallowness of the acetabulum.

For the normal depth of the acetabulum to increase during development several factors must act in concert. There must be a reduced spherical femoral head. There also must be normal interstitial and appositional growth within the acetabular cartilage, and periosteal new bone formation must occur in the adjacent pelvic bones (10,11). The depth of the acetabulum is further enhanced at puberty by the development of three secondary centers of ossification (Fig. 23-7). These three secondary centers of ossification are homologous with other epiphyses in the skeleton (11,13). The os acetabulum develops in the thick cartilage that separates the acetabular cavity from the pubis bone. The os acetabulum is the epiphysis of the pubis and forms the anterior wall of the acetabulum. The epiphysis of the ilium, the acetabular epiphysis, forms a major portion of the superior edge of the acetabulum. A third small epiphysis also forms in the ischial region (11,13,23).

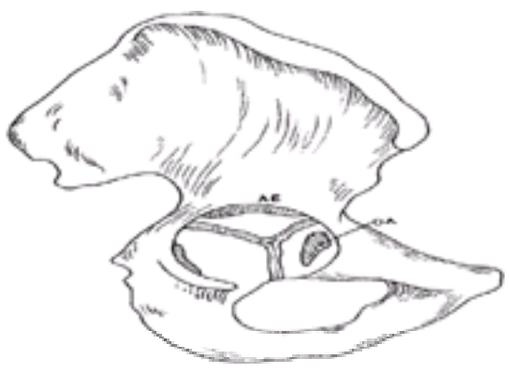

FIGURE 23-7. Diagram of the right innominate bone of an adolescent. The os acetabulum (*OA*) is shown within the acetabular cartilage adjoining the pubic bone. The acetabular epiphysis (*AE*) is within the acetabular cartilage adjoining the iliac bone, and another small epiphysis is within the acetabular cartilage adjoining the ischium (**left**). (Adapted from ref. 11, with permission.)

Normal acetabular growth and development occur through balanced growth of the proximal femur, the acetabular and triradiate cartilages, and the adjacent bones. This balance, which is probably genetically determined, may be at fault in DDH. There is ample evidence to suggest that an adverse intrauterine environment also plays an important role in the pathogenesis of hip dysplasia (11,24,25,26,27 and 28).

PATHOANATOMY

Dislocations in Newborns

In the newborn with DDH, the tight fit between the femoral head and the acetabulum is lost. The femoral head can be made to glide in and out of the acetabulum, with a palpable sensation known clinically as the “Ortolani sign” (11,16,29,30). DDH in the newborn refers to a spectrum of anatomic abnormalities, from mild dysplastic

changes to the severe pathoanatomic changes that are found in the rare idiopathic teratologic dislocation, and more commonly in teratologic dislocations associated with conditions such as myelomeningocele and arthrogryposis.

The most common pathologic change in the newborn with DDH is a hypertrophied ridge of acetabular cartilage in the superior, posterior, and inferior aspects of the acetabulum. This ridge was referred to by Ortolani as the “neolimbus” (16,30). The neolimbus is composed of hypertrophied acetabular cartilage (9,29) (Fig. 23-8). There often is a trough or groove in the acetabular cartilage caused by secondary pressure of the femoral head or neck. It is over this ridge of acetabular cartilage that the femoral head glides in and out of the acetabulum, with the palpable sensation referred to as the Ortolani sign (9,16,30).

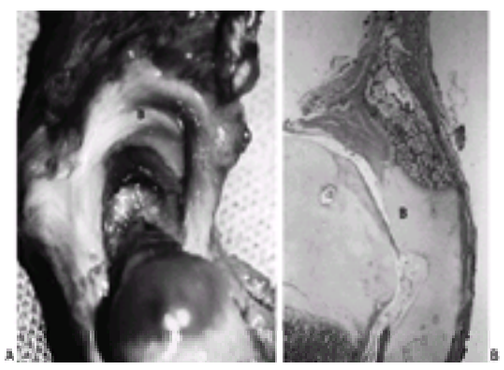

FIGURE 23-8. A: Right acetabular cavity and femoral head of a newborn baby with bilateral congenital hip dysplasia. There is an acetabular bulge (*B*) or neolimbus along the upper acetabular cartilage, and the acetabular cavity is small. **B:** Frontal section of the same hip. The femoral head is very large in relation to the acetabular cavity. Note how the labrum is everted and adheres to the joint capsule above. The neolimbus (*B*) is composed of hypertrophied acetabular cartilage. (From ref. 29, with permission.)

In the typical newborn with DDH, there is empirical evidence that the pathologic changes are reversible, because there is a 95% success rate of treatment using simple devices such as the Pavlik harness and the von Rosen splint (31). These changes are typical of 98% of DDH cases that occur at or around birth. However, about 2% of newborns have teratologic (antenatal) dislocations not associated with a syndrome or neuromuscular condition (23,26). In these rare cases, the pathologic and clinical findings are similar to those seen in late-diagnosed DDH, which is described below.

Acetabular Development in Developmental Hip Dysplasia

Acetabular development in treated DDH cases may be different from that described for the normal hip. This is particularly true for the late-diagnosed case. The primary stimulus for normal growth and development comes from the femoral head within the acetabulum (10,21,22). When there is a delay in diagnosis and treatment, some aspects of normal growth and development are lost. The femoral head must be reduced as soon as possible, and the reduction must be maintained to provide the stimulus for acetabular development. If concentric reduction is maintained, the acetabulum has the potential for recovery and resumption of normal growth and development for many years (32,33 and 34).

The age at which a dysplastic hip can still return to “normal” after reduction remains controversial (32,34,35,36,37,38,39,40,41 and 42). The resumption and adequacy of acetabular development is a multifactorial problem that depends on the age at which the reduction is obtained and on whether the growth potential of the acetabular cartilage and the proximal femur is normal. The capacity of the acetabular cartilage to resume normal growth depends on its intrinsic growth potential, whether it has been damaged by the subluxated or dislocated femoral head, and whether it has been damaged by various attempts at reduction. In the treated DDH patient, especially in late-diagnosed cases, accessory centers of ossification contribute to acetabular development (Fig. 23-9). Accessory centers of ossification in the acetabulum are seen in only 2 to 3% of normal hips, and they rarely appear before 11 years of age. However, among patients treated for DDH, the centers may be present in as many as 60% of hips, usually appearing from 6 months to 10 years after reduction (32,34,35,43) (Fig. 23-9). In treated DDH cases, these accessory centers of ossification should be sought on every sequential radiograph to determine if acetabular development is progressing. This is an important factor to consider when deciding if surgical intervention is necessary to correct residual acetabular dysplasia. Although the presence of these centers indicates continued growth in the acetabular cartilage, they may be indicative of injury to the cartilage in this area.

FIGURE 23-9. A: An 18-month-old girl with bilateral high dislocations. Note the poorly developed acetabula with well-developed secondary acetabula. **B:** At 33 months of age, the irregular ossification centers in the left and right hip have coalesced, with a slight improvement in the acetabular index. **C:** When the girl is 7 years of age, an anteroposterior (AP) view shows the appearance of the accessory centers of ossification in the periphery of the acetabulum. **D:** The accessory centers of ossification are somewhat better appreciated in the abduction view at 7 years of age. **E:** An AP view at 8 years of age shows the coalescence of the accessory centers of ossification, increasing the depth of the acetabulum. Note the excellent *sourcii* formation. **F:** The accessory centers of ossification are well demonstrated in an abduction view at 8 years of age.

PATHOGENESIS, EPIDEMIOLOGY, AND DIAGNOSIS

Causes of Developmental Dysplasia of the Hip

Many factors contribute to DDH. Genetic and ethnic factors play a key role, with the incidence of DDH as high as 25 to 50 cases per 1,000 live births among Lapps and Native Americans and a very low rate among the southern Chinese population and persons of African descent (27,44,45,46,47,48,49,50,51,52,53,54,55,56,57 and 58).

A positive family history for DDH may be found in 12 to 33% of affected patients (28,44,58). One study reported a tenfold increase among the parents of index patients and a sevenfold increase among siblings compared with the general population (44). There is some suggestion that femoral neck or acetabular anteversion may be an etiologic factor (27,29,35,60,61 and 62).

The genetic effects on the hip joint in patients with DDH are revealed in primary acetabular dysplasia, various degrees of joint laxity, or a combination of both. Intrauterine mechanical factors, such as breech position or oligo- hydramnios, and neuromuscular mechanisms, such as myelomeningocele, can profoundly influence genetically determined intrauterine growth (5,6,63,64). The first-born child is more likely to be affected than subsequent children. Any of the factors contributing to an “adverse” intrauterine environment may influence the development of the hip joint, and postnatal influences may also contribute to the development of DDH

(5,28,65,66 and 67).

Risk Factors and Incidence

White infants have an increased incidence of DDH among first-born children (8,24,25,68,69,70 and 71). The unstretched abdominal muscles and the primigravida uterus may subject the fetus to prolonged periods of abnormal positioning, forcing the fetus against the mother's spine. This restraint limits fetal mobility, especially hip abduction. The high rate of association of DDH with other intrauterine molding abnormalities, such as torticollis and metatarsus adductus, lends some support to the theory that the "crowding phenomenon" plays a role in the pathogenesis (8,71,72 and 73). Oligohydramnios, which is associated with limited fetal mobility, is associated with DDH (8,71). The left hip is the most commonly affected hip; in the most common fetal position, this is the hip that is usually forced into adduction against the mother's sacrum (8,46,71).

DDH is more common among female patients (80% of cases) and children born breech. In the general population, breech presentations occur in about 2 to 4% of vaginal deliveries; for children with DDH, the reported incidence is higher, with Carter and Wilkinson (24,25) reporting 17% and Salter reporting 23% (80). Twice as many girls as boys are born breech (74). Fifty-nine percent of breech presentations are first-born children (24,25,74). Ramsey and MacEwen demonstrated that 1 of 15 girls born breech has evidence of hip instability. In animal studies, the prolonged maintenance of an abnormal position, such as the breech position, is associated with the production of DDH (21,22).

The postnatal extrauterine environment may significantly influence the development of DDH. In societies that use swaddling (i.e., hips forced into adduction and extension) in the postnatal period, the incidence of DDH is high, possibly as a result of the forceful positioning of the legs in extension and adduction in the face of normal newborn hip flexion and hamstring contractures (28,46,56,62,67,75,76,77 and 78).

The influence of hip capsular laxity on the development of DDH has been addressed by many investigators. Newborns with DDH may have capsular laxity. Hip capsular laxity has been implicated in the pathogenesis of DDH, because the diagnostic test for DDH, the Ortolani sign, depends on the head gliding in and out of the dysplastic acetabulum over a ridge of abnormal acetabular cartilage. Proponents argue that because reversible dysplasia can be produced in animals by producing ligamentous laxity the acetabular dysplasia seen in DDH is a secondary phenomenon (21,22,28,29,79,80). LeDamany demonstrated that the acetabulum is shallowest at birth (61). Râlis and McKibbin confirmed LeDamany's anatomic work in a small number of patients (79). They too demonstrated that the acetabulum was shallowest at birth and that this, combined with the normal joint laxity of the infant, makes the time around delivery a high-risk period for dislocation (79,81). These anatomic experiments were repeated by Skirving and Scadden in African neonates (27). In the African neonate, the acetabulum was deeper more frequently and in a narrower range, possibly explaining why DDH is almost nonexistent among persons of African descent. This finding also provided indirect evidence of acetabular dysplasia as a primary cause of DDH.

Laxity of the hip joint capsule is often seen in newborn infants and has been documented by ultrasonography (82). The laxity may allow some instability without a positive Ortolani sign. In postmortem examination of seven stillborn infants, the hips demonstrated instability with a negative Ortolani sign; arthrograms demonstrated slight pooling of the contrast media medially. On gross examination the hip capsules were stretched, and the femoral heads could be pulled slightly away from the acetabula. However, the hips were anatomically and histologically normal, unlike the postmortem findings reported for all infants with positive Ortolani signs (9,11,30,54,59,83). In addition to the normal physiologic capsular laxity expected in the newborn, DDH is not a feature of conditions characterized by hyperlaxity, such as Down, Ehlers-Danlos, and Marfan syndromes (30).

Combining the epidemiologic and etiologic factors, a high-risk group of patients can be identified. This group includes any patient who has more than one of the factors listed in Table 23-1. For an infant manifesting any combination of these factors, the physician should be alert to the possibility of DDH.

Breech position
Female gender
Positive family history or ethnic background (e.g., Native American, Laplander)
Lower limb deformity
Torticollis
Metatarsus adductus
Oligohydramnios
Significant persistent hip asymmetry (e.g., abducted hip on one side, adducted hip on the other side)
Other significant musculoskeletal abnormalities

TABLE 23-1. HIGH-RISK FACTORS FOR DEVELOPMENTAL DYSPLASIA OR DISLOCATION OF THE HIP

The incidence of DDH is influenced by geographic and ethnic factors and by the diagnostic criteria used by the examining physician. Another important factor is the diagnostic acumen of the examiner. The age of the patient at the time of diagnosis must be taken into account, because the physical findings and manifestations of the condition change with increasing delay in diagnosis (8,9,11,28,30,54,59,71,82,83,84,85,86 and 87).

Most DDH cases are detectable at birth (88,89). Despite newborn screening programs, some cases are not detected, and there is some evidence to suggest that a few cases may arise after birth (28,85,90,91,92,93,94,95,96,97,98 and 99). Moreover, the problem of whether acetabular dysplasia is primary or secondary to an unrecognized dislocation or subluxation that has reduced spontaneously remains unanswered. The results of newborn clinical screening programs estimate that 1 of every 100 newborns examined has evidence of some hip instability (i.e., positive Ortolani or Barlow sign), although the true incidence of dislocation is reported to be between 1 and 1.5 cases per 1,000 live births (9,41,84,92,93,94,95,100,101,102,103 and 104).

Diagnosis

The clinical diagnostic test for DDH was originally described by LeDamany in 1912 (61). LeDamany referred to the palpable sensation of the hip gliding in and out of the acetabulum as the *signe de ressaut*. In 1936, Ortolani, an Italian pediatrician, described the pathogenesis of this diagnostic sign (30,83). Ortolani called the palpable sensation the *segno dello scotto*. Fellander and colleagues likened this diagnostic sign to the femoral head gliding in and out of the acetabulum over a ridge and referred to this palpable sensation as the "ridge phenomenon" (105). This ridge was named the *neolimbus* by Ortolani. This ridge, over which the femoral head glides in and out of the acetabulum, is composed of hypertrophied acetabular cartilage (9,29,30,83) (Fig. 23-8).

Unfortunately, inadequate translation of LeDamany's and Ortolani's works into English resulted in the use of the term "click" to describe this diagnostic sign. High-pitched soft tissue clicks are often elicited in the hip examination of newborns. These clicks are usually transmitted from the trochanteric region or the knee and have no diagnostic significance (105). This poor understanding of the pathoanatomy of the primary diagnostic sign of DDH in the newborn has no doubt led to overdiagnosis and overtreatment of infants (102,106,107 and 108).

Another diagnostic test, the Barlow maneuver, is often referred to as the "click of exit." The Barlow maneuver is a provocative maneuver in which the hip is flexed and adducted and the femoral head is palpated to exit the acetabulum partially or completely over a ridge of the acetabulum (84). Many physicians refer to the Ortolani sign as the "click of entry," which is caused when the hip is abducted, the trochanter is elevated, and the femoral head glides back into the acetabulum. Some physicians make treatment decisions on the basis of whether they feel that the hip is Ortolani- positive versus Barlow-positive, feeling that the Barlow-positive hip is more stable. Because Ortolani and LeDamany described the palpable sensation as the femoral head exits or enters the acetabulum, the author prefers to use the Ortolani sign to refer to the palpable sensation of subluxating or dislocating the hip and to reducing a subluxated or dislocated hip. The author also makes no treatment distinction between the Ortolani sign and the Barlow sign.

Complete irreducible dislocations are extremely rare in newborns and are usually associated with other generalized conditions, such as arthrogryposis, myelodysplasia, and other syndromes. These perinatal teratologic dislocations are at the extreme end of the DDH pathologic spectrum and account for only 2% of

cases in newborn examination series (9,46,47,109,110). They are usually manifested by the secondary adaptive changes more characteristic of the late-diagnosed case.

Although the clinical examination remains the gold standard (111), ultrasonography has gained popularity worldwide as a screening tool. Its cost effectiveness has yet to be documented for wholesale screening of DDH (see imaging section on page 916).

Late Diagnosis

If the diagnosis of DDH is not made early, preferably in the newborn nursery, secondary adaptive changes develop (45). The most reliable physical finding in late-diagnosed DDH is limitation of abduction (Fig. 23-10). Limited abduction is a clinical manifestation of the various degrees of adductor longus shortening associated with hip subluxation or dislocation (47). Other manifestations of late-diagnosed DDH may include apparent femoral shortening, also called the Galeazzi sign (Fig. 23-11); asymmetry of the gluteal (112), thigh, or labial folds (113); and limb-length inequality (Fig. 23-12). In patients with bilateral dislocations, clinical findings include a waddling gait and hyperlordosis of the lumbar spine (Fig. 23-13).

FIGURE 23-10. A 15-month-old child with left hip dislocation. Note the limited abduction of the hip.

FIGURE 23-11. A 15-month-old girl with developmental dislocation of the left hip. Note the apparent femoral shortening.

FIGURE 23-12. A 1-year-old white girl with developmental dislocation of the left hip was referred for toe walking. Note the apparent limb-length inequality and the asymmetry of the thigh and labial folds.

FIGURE 23-13. A 2-year, 5-month-old white girl with bilateral hip dislocations. **A:** Note the waddling gait and hyperlordosis. **B:** Radiograph shows high bilateral dislocations and poorly developed acetabula with well-developed secondary acetabula where the femoral heads articulate with the ilia.

If DDH goes undetected, normal hip joint growth and development are impaired. With increasing age at detection and reduction, particularly for children older than 6 months of age the obstacles (intraarticular and extraarticular) to concentric reduction become increasingly difficult to overcome by simple treatment methods, such as use of the Pavlik harness, and closed or open reduction usually must be performed under general anesthesia. Restoration of normal acetabulum development is less likely as age at detection increases (23,29,41,104,114,115).

In the late-diagnosed case, the extraarticular obstacles to reduction include the contracted adductor longus and the iliopsoas. These muscles are shortened because of the hip being in the subluxated or dislocated position, allowing secondary muscle-shortening.

The intraarticular obstacles to reduction in late-diagnosed DDH include the ligamentum teres, the transverse acetabular ligament, the constricted anteromedial joint capsule, and, rarely, an inverted and hypertrophied labrum (29,116). In the late-diagnosed case, the most significant intraarticular obstacle to reduction is some

degree of anteromedial hip capsular constriction (29,117,118,119,120 and 121). The ligamentum teres may be thickened, and it may become the primary obstacle to reduction in some cases. In children of walking or crawling age, the ligamentum teres may be significantly elongated and enlarged. Its sheer bulk precludes concentric reduction without excision of the ligament. The transverse acetabular ligamentum may hypertrophy secondary to the constant pull of the ligamentum teres on its attachment at the base of the acetabulum (29,121). This effect decreases the diameter of the acetabulum.

A rare finding in other than teratologic dislocations is a true inverted labrum or limbus (i.e., hypertrophied labrum) (118) (Fig. 23-14). The acetabular labrum may be iatrogenically inverted and may be an obstacle to reduction in patients previously treated with unsuccessful closed reductions. Arthrograms are often misinterpreted as showing an inverted labrum (122); the shadow thought to be the inverted labrum or limbus is instead the neolimbus described by Ortolani (9,29,41,123) (Fig. 23-15). This neolimbus is epiphyseal cartilage and is almost never an obstacle to reduction. It must not be removed, because removal impairs acetabular development (9,124).

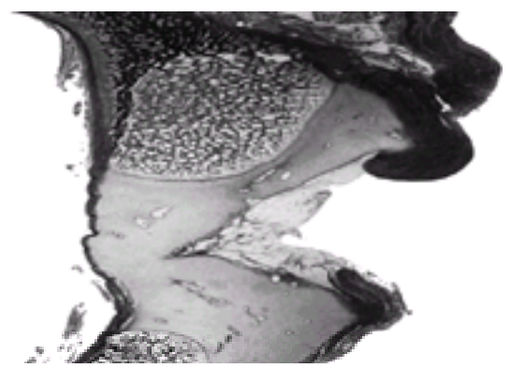

FIGURE 23-14. A coronal section of the acetabulum demonstrates the hypertrophic labrum (limbus) extending over the margin of a slightly thickened acetabular cartilage. The thick capsule extends upward above the inverted labrum, from which it is separated by a shallow groove. In this section through the ilium the growth plate is slanted upward laterally, but endochondral ossification is normal. At the margin of the roof periosteal bone growth is retarded. (From ref. 9, with permission.)

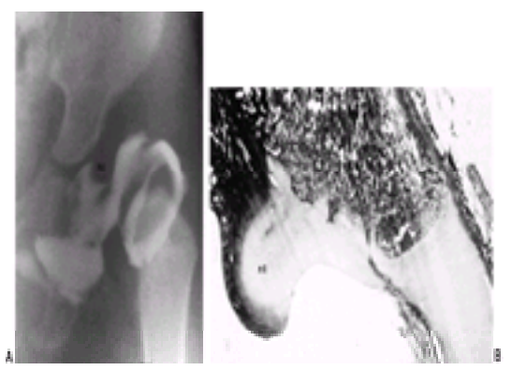

FIGURE 23-15. A: Arthrogram of the left hip in a 15-month-old child with complete dislocation. Note the shadow of the neolimbus (*nl*). **B:** A histologic specimen demonstrates hypertrophied acetabular cartilage of the neolimbus (*nl*), consistent with the arthrographic appearance in **A**.

The cartilage of the neolimbus may be primarily abnormal or may be damaged by a traumatic open or closed reduction. A response to this damage may be responsible for the appearance of the previously discussed accessory centers of ossification seen in treated cases of DDH (9) (Fig. 23-9).

Diagnostic Imaging and Radiography

The use of ultrasonography in the diagnosis and management of children with DDH remains controversial (125,126,127,128,129,130,131,132,133,134,135,136,137,138,139,140,141,142,143,144,145,146, 147,148,149,150,151,152,153,154,155 and 156). Many proponents strongly recommend that ultrasonography be used as a routine screening tool in the newborn nursery and that it be used extensively in the management of all DDH problems (157,158 and 159). The use of ultrasonography in orthopaedic practice was pioneered by Graf in Austria in the 1970s (139,140). Harcke and colleagues in the United States (141,142,143,160), Terjesen and colleagues in Norway (149,150,151 and 152), and Clarke in Great Britain (131,132 and 133) have been the prime motivators in evaluating this tool for the diagnosis of DDH and other hip disorders.

Ultrasonography can be used in two basic ways to evaluate the child with DDH: morphologic assessment and dynamic assessment. The morphologic assessment, as pioneered by Graf, focuses primarily on critical evaluation of the anatomic characteristics of the hip joint (Fig. 23-16). This is accomplished by measuring two angles on the ultrasound image: the a angle, which is a measurement of the slope of the superior aspect of the bony acetabulum, and the b angle, which evaluates the cartilaginous component of the acetabulum. The hip is classified into four types and several subtypes according to various factors (139,140) (Fig. 23-17). In the evaluation of Terjesen and colleagues, the percentage of acetabular coverage of the femoral head (i.e., percent coverage) is a key measurement (149,152,161).

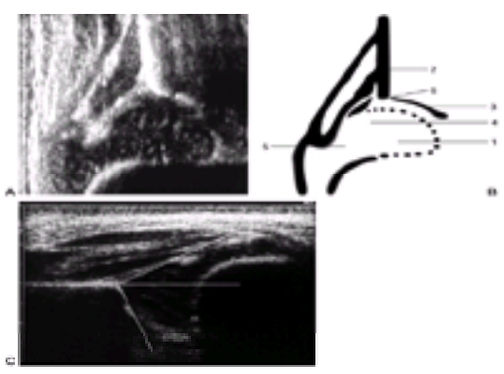

FIGURE 23-16. A: Ultrasonography of a normal newborn. **B:** Anatomic drawing of hip landmarks (after Graf): *1*, femoral head; *2*, iliac limb; *3*, bony acetabular roof; *4*, acetabular labrum; *5*, joint capsule; *6*, osseous rim. **C:** Ultrasonograph of a newborn. Note the a angle and the b angles.

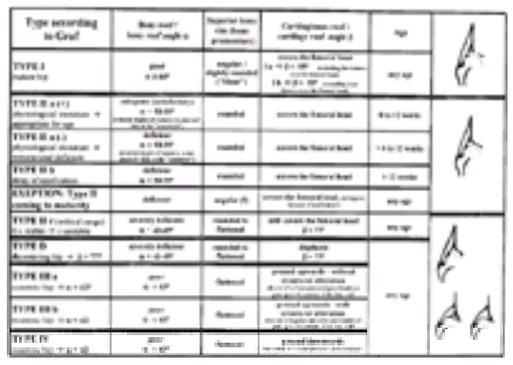

FIGURE 23-17. Sonographic hip types. (Courtesy of Prof. R. Graf, Stolzalpe, Austria.)

The morphologic approach to ultrasonography is widely practiced in Europe. This approach has been criticized because of substantial interobserver and intraobserver variations in the measurement of various angles, particularly the b angle (142).

The availability of equipment with which motion can be observed in real time in multiple planes provides a means of seeing what occurs during the Ortolani or Barlow maneuver. The use of dynamic ultrasonography, as popularized by Harcke and colleagues, has been criticized for being excessively operator-dependent and requiring a subjective assessment of the findings (141,142 and 143).

The indications for ultrasonography in the diagnosis and treatment of DDH are not universally established. Because there are many controversies yet to be resolved, ultrasonography cannot be advocated as a routine screening tool (142). Although it is used as such in Europe, prospective longitudinal studies documenting the outcomes of minor anatomic abnormalities found in ultrasonographic examinations need to be completed (162,163). Its routine use in newborn nurseries has resulted in overdiagnosis above the expected incidence of DDH and cannot be considered cost-effective (144,164,165 and 166). Its use for only high-risk infants (Table 23-1) may eventually prove cost-effective (166). However, Clarke and colleagues showed that screening all high-risk infants and all infants who had any abnormality on physical examination did not reduce the prevalence of late-diagnosed cases (128,132,133).

Some centers advocate the use of ultrasonography for all Ortolani-positive infants to assess stability at the completion of treatment (142). An ideal indication for ultrasonography is for guided reduction of a dislocated hip in an infant (167). Ultrasonography can be used to check the reduction of the hip and its stability during Pavlik harness treatment at 7- to 10-day intervals. This may temporarily obviate the need for radiographic evaluation. Other uses for ultrasonography in the treatment of DDH include monitoring of the hip position while the patient is in traction, before attempts at reduction and evaluating closed reductions in the operating room. The distinct advantage of ultrasonography is that it provides some anatomic evaluation of the hip joint without exposing the infant to radiation.

Debate continues regarding the appropriate planes for evaluation and whether an orthopaedic surgeon, the treating physician, or a radiologist with expertise in ultrasonography should perform the evaluation. In the newborn DDH is not a radiographic diagnosis; the diagnosis should be made by clinical evaluation, which may be enhanced by ultrasonography if the examination results are questionable. Some groups have used vibration arthrometry (168,169 and 170).

After the newborn period the diagnosis of DDH should be confirmed by radiography. Many radiographic measurements can be made, but there are wide interobserver and intraobserver variations in these measurements (171,172). Because it is difficult to standardize the radiographic positioning of infants, many centers use positioning frames (173).

When monitoring the treatment of children with DDH, it is essential to notice changes in the radiographic measurements over time and not to make significant decisions based on a single radiograph. The classic radiographic features of late-diagnosed DDH include an increased acetabular index (26,174,175,176,177,178 and 179), disruption of the Shenton line, a widened pelvic floor (180), an absent teardrop figure (181,182,183,184,185,186 and 187), delayed appearance of the femoral ossific nucleus on the involved side or dissimilar sizes of the ossific nuclei, abnormality in Smith centering ratios (21,22,34), decreased femoral head coverage, and failure of the medial metaphyseal beak of the proximal femur, and, subsequently, the secondary ossification center to be located in the lower inner quadrant, as defined by the Hilgenreiner and Perkins lines (86,188,189) (Fig. 23-18). When the triradiate cartilage is closed, the acetabular angle of Sharp (i.e., from the inferior edge of the teardrop figure to the edge of the acetabulum) is a useful measurement of acetabular dysplasia (190).

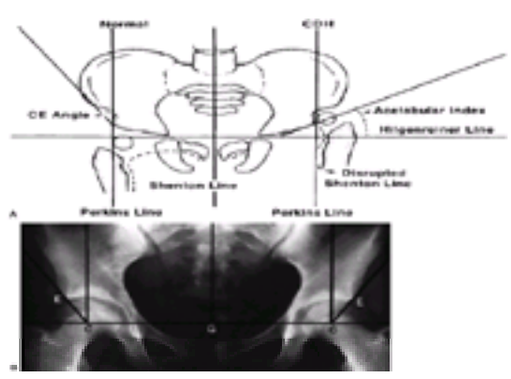

FIGURE 23-18. A: Radiographic parameters. *CDH*, congenital dysplasia of the hip; *CE Angle*, center-edge angle. **B:** Center-edge angle of Wiberg. *C*, Center of the femoral head; *E*, bony edge of the acetabulum; *G*, gravity line.

In children younger than 8 years of age, the acetabular index is a reasonable measure of acetabular development (171). The center-edge (CE) angle becomes useful only after 5 years of age and is most useful in the adult patient (43) (Fig. 23-18B). Radiographs show only the ossified portion of the pelvic bones and the proximal femur. Excellent acetabular coverage of the femoral head may be found, albeit by unossified cartilage (Fig. 23-19). If this cartilage does not ossify, the residual dysplasia may eventually lead to subluxation and degenerative joint disease.

FIGURE 23-19. Arthrogram of a 5-year-old white girl 3 years after open reduction. Note the excellent coverage of the femoral head by unossified acetabular cartilage.

The Shenton line provides only a qualitative estimate of dysplasia during the first few years of life. After 3 or 4 years of age, the Shenton line should be intact on all views of the hip; thereafter, any disruption of the Shenton line indicates an abnormality in the relation between the proximal femur and the acetabulum. This relation must be restored to prevent degenerative joint disease in later life (23,43,56,62,115).

Magnetic resonance imaging has been used for DDH diagnosis and evaluation, as well as for documentation of femoral head acetabular relationships after closed or open reduction (191,192). With advances in software, this modality will no doubt provide useful information in the future. The need for anesthesia for pediatric patients limits the utility of this modality (193,194,195 and 196).

NATURAL HISTORY

Course in Newborns

The natural history of untreated DDH in the newborn is quite variable. Yamamuro and Doi followed 52 hips with positive Ortolani signs for a 2-year period without treatment for the first 5 months. Of the 12 they called “dislocated” hips, 3 (25%) were radiographically normal at 5 months of age. Of the 42 they called “subluxable” hips, 24 (57%) were normal at 5 months (78).

Barlow reported that 1 of every 60 infants born has instability (i.e., positive Barlow sign) of one or both hips (84). More than 60% of these stabilize during the first week of life, and 88% stabilize during the first 2 months, without treatment. The remaining 12% become true congenital dislocations and persist without treatment. Pratt and colleagues followed 18 “dysplastic” hips in patients younger than 3 months of age who were diagnosed based on clinical and radiographic parameters for an average of 11.2 years and found that 15 were roentgenographically normal (77).

Coleman followed 23 untreated DDH patients younger than 3 months of age who were diagnosed based on clinical and radiographic criteria. He found that 26% of the femoral heads became completely dislocated, 13% had partial contact of the femoral head with the acetabulum, 39% remained located but retained dysplastic features, and 22% were normal (46).

Most unstable hips in newborns stabilize soon after birth, some may go on to subluxation or dislocation, and some may remain located but retain anatomic dysplastic features. Because it is not possible to predict the outcome of unstable hips in newborns, all newborns with clinical hip instability, as manifested by a positive Ortolani or Barlow sign, should be treated.

Course in Adults

In adults, the natural history of untreated complete dislocation varies, and is affected by societal considerations (56,66,197,198,199 and 200). Despite complete dislocation there may be little or no functional disability.

The natural history of complete dislocation depends on two factors: the presence or absence of a well-developed false acetabulum, and bilaterality (23,56,66,114,201,202). Wedge and Wasylenko demonstrated only a 24% chance of a good clinical result with a well-developed false acetabulum, but with a moderately developed or absent false acetabulum, the patients had a 52% chance of a good clinical result (56,66). Of 42 patients with complete dislocations, 13 had roentgenographically confirmed degenerative joint disease, such as loss of joint space, cyst formation, sclerosis, osteophyte formation, and flattening of the femoral head. Of these 13 patients, 10 (76%) had poor clinical results.

Milgram reported the gross and histologic features of a case of bilateral DDH discovered at postmortem examination (203). This 74-year-old man had no hip or thigh pain and only mild backache for 5 years before his death. His femoral head had no articulation with any portion of the ilium. The femoral head was covered with a thickened, markedly elongated hip joint capsule. The only degenerative changes occurred where the lesser trochanter abutted the overhanging superior acetabular rim. In the absence of a false acetabulum, most patients with complete dislocations do well, maintaining good range of motion with little functional disability (Fig. 23-20). Completely dislocated hips with well-developed false acetabula are more likely to develop roentgenographic degenerative joint disease changes and have poor clinical results (Fig. 23-21). Factors that lead to the formation or lack of formation of a false acetabulum remain unknown (23).

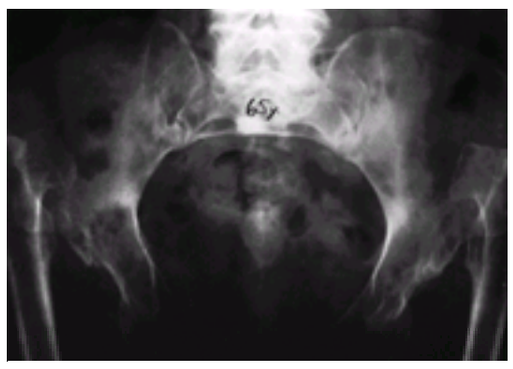

FIGURE 23-20. A 65-year-old white woman with bilateral, untreated developmental dislocations of the hips complained of some low back pain, but had no hip pain. She had a waddling gait and hyperlordosis.

FIGURE 23-21. Roentgenogram of a 43-year-old woman with complete dislocation of both hips. She is asymptomatic on the right, but has disabling symptoms from the left hip. She has no false acetabulum on the right, but has a well-developed false acetabulum on the left with secondary degenerative changes. (From ref. 23, with permission.)

Back pain may occur in patients with bilateral dislocations. It is thought that this pain is secondary to the hyperlordosis of the lumbar spine that is associated with bilateral dislocations (23,56,66,197,198,203,204) (Fig. 23-22).

FIGURE 23-22. A 45-year-old white woman with bilateral complete dislocations, hip flexion deformity, and marked hyperlordosis. The patient's only complaints were referable to her back.

In unilateral complete dislocations, secondary problems of limb-length inequality, ipsilateral knee deformity and pain, scoliosis, and gait disturbance are common. Limb-length inequalities of as much as 10 cm have been reported in patients with unilateral dislocations. These patients develop flexion adduction deformities of the hip, which may lead to valgus deformities of the knee. The valgus knee deformity is often associated with attenuation of the medial collateral ligament and lateral compartment degenerative joint disease, although some medial compartment disease has been described (23,56,66,115,198,202). The same factors involved in the development of secondary degenerative disease in the false acetabulum and in the associated clinical disability in bilateral cases affect unilateral dislocations.

Course of Dysplasia and Subluxation

The natural history of dysplasia and subluxation in untreated patients is important because of the likelihood that these findings can be extrapolated to residual dysplasia and subluxation after treatment (115,127,205,206 and 207).

After the neonatal period, the term “dysplasia” has an anatomic and an radiographic definition. Anatomic dysplasia refers to inadequate development of the acetabulum, the femoral head, or both (47). All subluxated hips (i.e., those in which there is some contact between the femoral head and the acetabulum) are by definition anatomically dysplastic. Radiographically, the major difference between dysplasia and subluxation is determined by the integrity of the Shenton line. In hip subluxation, the Shenton line is disrupted and the femoral head is superiorly, laterally, or superolaterally displaced from the medial wall of the acetabulum. In radiographic dysplasia, the normal Shenton line relation is intact (56,66,208,209) (Fig. 23-23). In the literature describing the natural history of DDH, these two roentgenographic and clinical entities often are not separated. Moreover, secondary degenerative changes may convert a radiographically dysplastic hip to a subluxated hip (206,209,210 and 211) (Fig. 23-24 and Fig. 23-25).

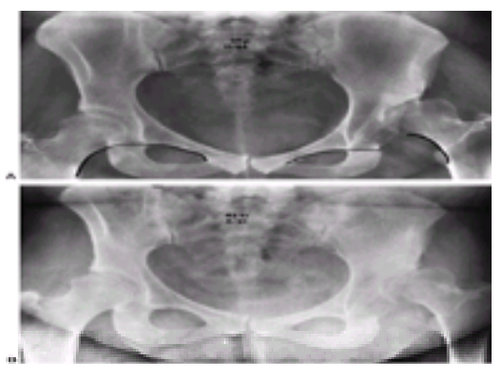

FIGURE 23-23. Radiographic subluxation and dysplasia. **A:** A 36-year-old woman with bilateral anatomically abnormal (dysplastic) hips. The left hip is radiographically subluxated, with the Shenton line disrupted, and the right hip is radiographically dysplastic, with the Shenton line intact. **B:** Seven years later, note the marked loss of joint space in the secondary acetabulum of the left hip and very early disruption of the Shenton line on the right. The right hip is asymptomatic, and the left hip is about to undergo total hip arthroplasty.

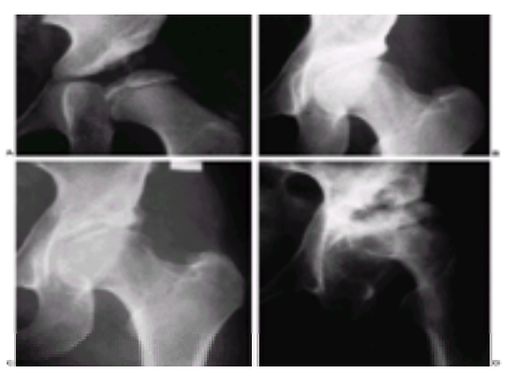

FIGURE 23-24. Anteroposterior radiographs made after closed reduction of developmental dislocation of the hip that had been performed when the patient was 2 years, 4 months of age. **A:** Thirty-nine months after reduction, when the patient was 5 years, 7 months of age, the accessory centers of ossification are visible in the acetabular cartilage. **B:** Fifteen years after reduction, when the patient was 17 years of age, the Shenton line is intact and there is mild, acetabular dysplasia. **C:** Forty-two years after reduction, when the patient was 44 years of age, degenerative changes are present. **D:** Fifty-one years after reduction, when the patient was 53 years of age, the hip is subluxed and has severe degenerative changes (Iowa Hip Rating, 48 of 100 points). The patient subsequently underwent total hip replacement. (From ref. 206, with permission.)

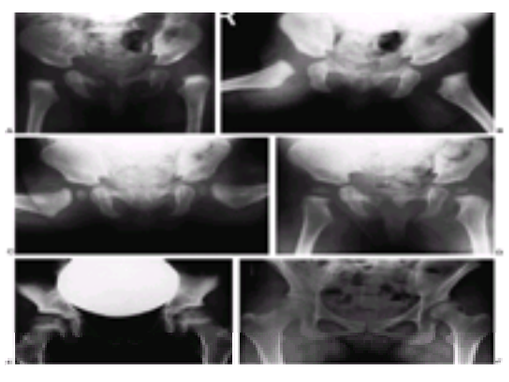

FIGURE 23-25. A 4-month-old white girl with left hip dislocation and right hip subluxation. **A:** Anteroposterior (AP) view. **B:** Abduction view. **C:** Abduction view at 7 months of age, 3 months after closed treatment. **D:** AP view at 7 months of age, 3 months after closed treatment. **E:** AP view at 7 years of age. Note the mild anatomic dysplasia of both hips. **F:** AP view at 15 years of age. Note the bilateral anatomic dysplasia. The right hip is radiographically dysplastic, and the left hip is

radiographically subluxated.

Anatomic abnormalities are seen roentgenographically in subluxation and dysplasia, but the natural histories of these two radiographic entities are different. Residual radiographic subluxation after treatment for DDH invariably leads to degenerative joint disease and clinical disability (23,56,65,115,206,209). The rate of deterioration is directly related to the severity of the subluxation and the age of the patient (206,209).

There is considerable evidence that residual radiographic acetabular dysplasia leads to secondary degenerative joint disease, especially in female patients, although there are no predictive radiographic parameters (206,209,211,212). The reasons for degenerative changes in radiographically dysplastic hips are probably mechanical in nature and related to increased contact stress with time. A certain “overpressure” (213,214) may correlate with long-term outcome. Aspherical femoral heads (e.g., secondary to aseptic necrosis) tend to experience even more severe degrees of overpressure. It appears that radiographic degenerative joint disease correlates with the magnitude of the overpressure and the time of exposure (213).

Because the physical signs of radiographic hip dysplasia are usually lacking, cases are often diagnosed only incidentally on the basis of roentgenograms taken for other reasons or after the patient develops symptoms (24,25,43,74,211). Stulberg and Harris found that 50% of their patients with radiographic dysplasia and degenerative joint disease had radiographic evidence of dysplasia in the opposite hip (211). Melvin and associates, in their unpublished 30- to 50-year follow-up of DDH, demonstrated that 40% of the patients with DDH had roentgenographic evidence of dysplasia in the opposite hip (198). It has been estimated that 20 to 50% of degenerative joint disease of the hip is secondary to subluxation or residual radiographic acetabular dysplasia (43,56,209,211,212,215,216 and 217). Wiberg suggested that there was a direct correlation between the onset of roentgenographic degenerative joint disease and the amount of dysplasia as measured by the decrease in the CE angle (43) (Fig. 23-16).

Cooperman and colleagues, in a roentgenographic study of degenerative joint disease and its relation to the severity of radiographic acetabular dysplasia, reviewed the 17 cases on which Wiberg based his conclusions (209). They concluded that 7 of 17 hips were actually subluxated. These subluxated hips were the most anatomically dysplastic; their CE angles averaged 2 degrees, and all 7 had roentgenographic degenerative changes by 42 years of age. The other 10 hips in Wiberg's series were radiographically dysplastic. They had intact Shenton lines and an average CE angle of 10 degrees. None of these patients developed radiographic degenerative joint disease before 39 years of age; however, degenerative changes became apparent roentgenographically by 57 years of age. In this review of Wiberg's series, the decrease in CE angle was associated with an increase in anatomic acetabular dysplasia and an increased likelihood that the hip was subluxated. Subluxation was the primary factor in the development of degenerative joint disease in this group. Subluxation predictably leads to degenerative joint disease and clinical disability over time.

Cooperman and associates described 32 hips (28 patients) with radiographic evidence of acetabular dysplasia (i.e., CE angle less than 20 degrees, but without subluxation, and the Shenton line intact), at an average follow-up of 22 years (209). All patients eventually developed radiographic evidence of degenerative joint disease. However, there was no linear correlation between the CE angle and the rate of development of degenerative joint disease, as had been suggested previously by Wiberg. A decreased CE angle was associated solely with increasing radiographic evidence of acetabular dysplasia and not with subluxation, because patients with subluxation had been excluded in this series. Cooperman and colleagues demonstrated that radiographic evidence of acetabular dysplasia leads to radiographically detectable degenerative joint disease, but the process may take decades. This study also demonstrated that the conventional radiographic parameters used to describe dysplasia (e.g., CE angle, acetabular index of Sharp, percent coverage, depth, inclination) could not predict the rate at which a radiographically confirmed dysplastic hip joint would develop roentgenographic evidence of degenerative joint disease.

Stulberg and Harris demonstrated that there is no roentgenographic picture of degenerative joint disease uniquely associated with preexisting acetabular dysplasia (211). In 80% of patients with dysplasia, the CE angle is usually less than 20 degrees, but acetabular shallowness, as measured by acetabular depth, affects all of these patients. The investigators also demonstrated that the CE angle, the criterion most commonly used to quantitate dysplasia, could be affected by many parameters, including roentgenographic positioning and the changes accompanying the normal development of degenerative joint disease. The secondary degenerative changes in a dysplastic acetabulum may give the hip a normal-appearing CE angle. In their series of 130 patients with primary or idiopathic degenerative joint disease, Stulberg and Harris were able to demonstrate that 48% had evidence of primary acetabular dysplasia, and that acetabular dysplasia frequently occurred in females with degenerative joint disease.

Additional evidence for the association between radiographic evidence of acetabular dysplasia and degenerative joint disease comes from the southern Chinese population. In an epidemiologic study from Hong Kong, where the incidence of childhood hip disease is low, the incidence of adult osteoarthritis (nontraumatic) is also low (52,53).

Wedge and Wasylenko reported three peak periods of pain in subluxation, depending on the severity of the subluxation (56,66). Patients with the most severe subluxation usually had the onset of symptoms during the second decade of life. Those with moderate subluxation presented during their third and fourth decades, and those with minimal subluxation usually experienced the onset of symptoms around menopause.

Patients who present soon after symptom onset rarely have the classic signs of degenerative joint disease, such as decreased joint space, cyst formation, double acetabular floor, and inferomedial femoral head osteophytes. The only radiographic feature present at symptom onset may be increased sclerosis in the weightbearing area. This increased sclerosis is secondary to increasing osteoblastic stimulation in response to the decreased width of the weightbearing surface; the increase of the normal per unit load strains the bone. The mechanism of pain in these instances is purely speculative (Fig. 23-22).

In cases of subluxation, the mean age at symptom onset is 36.6 years for women and 54 years for men. Severe degenerative roentgenographic changes become evident approximately 10 years later, by 46.4 years of age for women and 69.6 years of age for men.

Patients with subluxated hips usually have symptom onset at a younger age than patients with complete dislocations. After pain and radiographically evident degenerative disease starts, the disease progresses rapidly. Harris reported that symptoms of degenerative joint disease associated with radiographic evidence of acetabular dysplasia occurred early in life and that almost 50% of the patients in his series with acetabular dysplasia had their first reconstructive procedure before 60 years of age, with fewer than 5% having their first reconstruction after 60 years of age (212).

TREATMENT OF HIP DISLOCATION

Newborns and Infants Younger Than 6 Months of Age

Based on the understanding of normal growth and development of the hip, the fundamental treatment goals in DDH are the same, regardless of age. The first goal is to obtain reduction and maintain that reduction to provide an optimal environment for femoral head and acetabular development (114). As has been demonstrated by many follow-up studies of treated DDH, the acetabulum has the potential for development for many years after reduction as long as the reduction is maintained (32,34,35). The femoral head and femoral anteversion can remodel if the reduction is maintained (206,218). Further intervention is necessary only to alter an otherwise adverse natural history, as in the treatment of residual dysplasia and the prevention or treatment of subluxation. The later the diagnosis of DDH is made the more difficult it is to achieve these goals, the less potential there is for acetabular and proximal femoral remodeling, and the more complex are the required treatments. With increasing age and complexity of treatment the risk of complications is greater, and the patient is more likely to develop degenerative joint disease.

The diagnosis of DDH ideally should be made in the newborn nursery (219). If the diagnosis is made in the nursery, treatment should be initiated immediately (220). Triple diapers or abduction diapers have no place in the treatment of DDH in the newborn. They give the family a false sense of security and are generally ineffective. Any success with the use of triple diapers or abduction diapers could be attributed to the natural resolution of the disorder.

The most commonly used device for the treatment of DDH in the newborn is the Pavlik harness (Fig. 23-26). Although other devices are available (e.g., von Rosen splint, Frejka pillow), the Pavlik harness remains the most commonly used device worldwide (33,81,221,222,223,224,225,226,227,228,229,230 and 231). When appropriately applied, the Pavlik harness prevents hip extension and adduction, which can lead to redislocation, but it allows further flexion and abduction, which lead to reduction and stabilization. By maintaining the Ortolani-positive hip in a Pavlik harness on a full-time basis for 6 weeks, hip instability resolves in 95% of cases.

FIGURE 23-26. Newborn with bilateral hip dislocations in a Pavlik harness. Appropriately applied, the harness prevents hip extension and adduction which can lead to redislocation, but allows further flexion and abduction, which lead to reduction and stabilization.

The Pavlik harness may be used effectively until 6 months of age for any child with residual dysplasia, subluxation, or complete dislocation. After 6 months of age the failure rate for the Pavlik harness is greater than 50% because it is difficult to maintain the increasingly active and crawling child in the harness. It may also be used to achieve reduction of a dislocated hip in a child in this age group. Ideally, the harness should be applied as soon after birth as the diagnosis is made.

Mubarak and colleagues and others described the disadvantages associated with the use of the Pavlik harness for the treatment of DDH (31,232). They pointed out that failures of treatment most often result from problems related to the physician, the device, or the patient.

Physician-related errors fall into two categories: inappropriate indications and persistence of inadequate treatment. The Pavlik harness is contraindicated in patients with significant muscle imbalance, such as those with myelodysplasia or cerebral palsy. It is also contraindicated for patients who have significant joint stiffness, such as children with arthrogryposis. The harness will fail if it is applied in a child with excessive ligamentous laxity, as seen in Ehlers-Danlos syndrome (31).

The persistence of inadequate treatment is a multifactorial problem. Physicians using the harness must be well versed in its appropriate application and the adjustments that are necessary throughout the course of treatment if treatment is to be successful. It is important that the physician treating the patient understand when a treatment failure has occurred, so as not to prolong treatment with the harness and cause secondary pathologic changes, called 'Pavlik harness disease" (233). Persistence of treatment may damage the femoral head, injure the acetabular cartilage, and impair future bone growth. An inappropriately applied harness is a physician failure, not an orthotic failure (232,234).

Another major Pavlik harness problem is related to the specific orthotic device. Not all Pavlik harnesses are the same; the strap attachment sites vary. However, since the article by Mubarak and colleagues, most harnesses on the market meet the requisite standards they outlined (31,232).

Some problems are patient related. Certain family, social, and educational situations make compliance impossible. In these situations, the Pavlik harness would be inappropriate, and closed reduction and casting may be the more judicious approach. The family must be educated about the importance of the harness, its care and maintenance, how the child should be bathed while wearing the harness, and the consequences of failure to achieve success. Family noncompliance can lead to failure, and the use of a visiting nurse may be helpful in these situations.

Application of the harness (Fig. 23-26) should be demonstrated for the family members. The chest halter strap should be positioned at the nipple line, and the shoulder straps are set to hold the cross strap at this level. The leg and foot stirrups must have their anterior and posterior straps oriented anteriorly and posteriorly to the child's knees. Hip flexion should be set at 100 to 110 degrees. These straps should be in the anterior axillary line. The posterior abduction strap should be at the level of the child's scapula and adjusted to allow comfortable abduction within the *safe zone* (235), which is defined as the arc of abduction and adduction that is between redislocation and comfortable, unforced abduction. The posterior strap acts as a checkrein to prevent the hip from adducting to the point of redislocation. Ultrasonography is a useful means of documenting relocation of the Ortolani-positive hip.

There is great variability in treatment regimens with the Pavlik harness. If the Pavlik harness is used to stabilize an unstable hip (i.e., an Ortolani- or Barlow-positive hip), the harness is used full time for 6 to 12 weeks after clinical stability is achieved. Most hips stabilize in days to weeks. The harness is checked at 7- to 10-day intervals to assess hip stability and to adjust the flexion and abduction straps to allow for growth of the infant. Clinical examination is usually sufficient to check the progress at each visit; ultrasonography may be used, but radiographs are unnecessary.

In a child younger than 6 months of age with a complete dislocation, the Pavlik harness may be used in a trial of guided reduction. In this case, the harness must be applied with enough hyperflexion and abduction to point the femoral head toward the triradiate cartilage. This situation is the ideal indication for the use of ultrasonography to follow the reduction. When the harness is used for guided reduction, the infant should be checked at 7 to 10 days to determine whether the reduction is being accomplished. Clinical examination alone may be adequate, but initial radiographs should be obtained to document adequate flexion and redirection of the femoral neck toward the triradiate cartilage in the harness. After clinical stability is achieved, radiography is not indicated until about 3 months of age to assess acetabular development (Fig. 23-27). Ultrasonography is an excellent means of documenting progress toward and completion of successful reduction (236).

FIGURE 23-27. A 5-month-old child with left developmental dislocation of the hip. **A:** Anteroposterior (AP) view of the pelvis at diagnosis. The acetabular index is increased, the medial floor of the acetabulum is widened, and the acetabular teardrop figure is absent. There is a well-developed secondary acetabulum, the Shenton line is disrupted, and the femoral ossific nucleus is decreased in size. The femoral head is located in the upper outer quadrant, as defined by Hilgenreiner and Perkins lines. **B:** AP view of the pelvis with a hip Pavlik harness in place to demonstrate an excellent reduction. Note the hyperflexed position. **C:** AP view of the pelvis at 9 months of age shows reduction, early appearance of the teardrop figure, and improvement in the acetabular index. **D:** AP view of the pelvis at 31 months of age. There is marked improvement in the acetabular teardrop figure and acetabular development. **E:** AP view of the pelvis at 5 years of age. There has been continued improvement in acetabular and femoral head development.

Although the Pavlik harness has provided a 95% overall success rate for the treatment of the Ortolani-positive hip, the success rate for using the harness to guide the reduction of a subluxated or dislocated hip in a child younger than 6 months of age is 85% (31,224,237).

The use of the Pavlik harness can be associated with complications; most of these complications are iatrogenic and can be avoided. Inferior dislocations may occur with prolonged excessive hip flexion (238,239). Hyperflexion may also induce femoral nerve compression neuropathy; this condition generally resolves after the harness is removed. It is important during each examination to make certain that the patient has active quadriceps function. Brachial plexus palsy may occur from

compression by the shoulder straps, and knee subluxations may occur from improperly positioned straps.

Skin breakdown may occur in the groin creases and in the popliteal fossa if great care is not taken in keeping these areas clean and dry. Instruction with regard to bathing and skin care is essential.

The most disastrous consequence of Pavlik harness treatment is damage to the cartilaginous femoral head and the proximal femoral physeal plate (240,241). This is usually secondary to forced abduction in the harness or persistent use of the harness, despite the failure of guided reduction in a complete dislocation.

Children 6 Months to 2 Years of Age

It is difficult to maintain a child older than 6 months of age in a Pavlik harness because of the child's activity levels. In this age group subluxated or dislocated hips should be treated by closed or open means as necessary, because success rates using the Pavlik harness are less than 50%.

In the late-diagnosed patient or the patient who fails treatment with the Pavlik harness, the obstacles to reduction are different, treatment has greater risks, and the results are far less predictable. The principal goals in the treatment of the late-diagnosed patient are similar to those for the newborn. The goal is to obtain reduction, to maintain that reduction to provide an adequate environment for femoral head and acetabular development, and to avoid proximal femoral growth disturbance (Fig. 23-28).

FIGURE 23-28. A 6-month-old girl with apparent left hip subluxation and acetabular dysplasia secondary to excessive anteversion. **A:** Diagnostic anteroposterior (AP) view of the pelvis. Note the increased acetabular index, the poorly developed teardrop figure, and the small ossific nucleus. **B:** AP view of the pelvis in the fixed abduction brace. Excellent reduction of the hip has been achieved. **C:** AP view of the pelvis at 5 years of age. The left hip appears normal.

For patients older than 6 months of age at diagnosis and those who have failed a trial of Pavlik harness reduction, closed reduction is indicated. In most centers, closed reduction and spica cast immobilization usually are preceded by a period of skin or skeletal traction (242,243,244,245,246,247,248,249,250,251 and 252) (Fig. 23-29). The theoretical purpose of the traction is to facilitate reduction by allowing gradual stretching of the soft tissue structures impeding reduction and stretching of the neurovascular bundle to avoid inciting aseptic necrosis of the proximal femur by sudden reduction. Generally, 1 to 2 weeks of skin or skeletal traction are sufficient. Skin traction is the most commonly used method, although some physicians recommend skeletal traction (242). Skin tapes should be applied above the knee to distribute the traction over a large area (Fig. 23-29). The author prefers to wrap Elastoplast tape loosely over tincture of benzoin from the ankle to the upper thigh. It is important not to stretch the Elastoplast tape at all; it should merely lie on the skin in a circumferential manner, with each edge directly opposing the preceding edge. Buck traction tapes are then applied from above the ankle to the thigh and to the foot plate; weights may be added to both legs, so that the buttocks “lightly” touch the bed. The author has used this method for a number of years without adverse consequences. The direction of application of the traction forces (e.g., overhead, longitudinal, divarication) and the duration of traction (days to months) vary worldwide.

FIGURE 23-29. A 1-year-old child with bilateral hip dislocations in traction. Closed reduction and spica cast immobilization usually are preceded by a period of skin or skeletal traction.

Prereduction traction, although still used by most treating physicians, is a somewhat controversial topic (253). Traction theoretically stretches contracted muscles, allows reduction without excessive force, and decreases the need for open reduction. These ideas are lacking the support of scientifically valid studies. The assessment of the adequacy of closed reduction and the need for open reduction varies and is subjective. Fish and colleagues surveyed the members of the Pediatric Orthopaedic Society of North America on this topic (254). Most pediatric orthopaedic surgeons thought that traction did reduce the incidence of necrosis in the treatment of DDH. Only 5% of responders did not use traction in their practice. The purpose of traction is to allow gradual relaxation of secondarily contracted muscles, such as the iliopsoas and adductor longus; theoretically, this allows reduction without creating excessive joint forces. However, the relevant reports on this subject are subjective. Several articles on open and closed reduction without the use of preliminary traction report incidences of proximal femoral damage comparable to those found in series in which prereduction traction was used (41,255,256 and 257). These researchers think that the main obstacles to reduction are intraarticular and therefore would not be affected by the use of traction. Controversy also exists about the amount of weight applied, the direction of the force application, and the duration of applied traction. There are no clinical or experimental studies of the direct effects of traction, and there are no well-controlled studies that analyze the effect of traction as a single variable.

The complications of traction include skin loss and ischemia to the lower extremities attributable to inappropriate application. Neurocirculatory checks must be performed frequently, and traction must be applied in a carefully supervised manner. In appropriate circumstances traction may be used at home (258,259 and 260). This markedly decreases the costs associated with hospitalization. Patients usually are hospitalized for 24 h to allow their parents to become familiar with the traction apparatus, to learn how to monitor neurocirculatory status, and to become totally familiar with the potential risks and danger signs. The patient and family must be cooperative; a visiting nurse is often helpful in instituting this program.

Closed reductions are performed in the operating room. Gentle reduction must be done under general anesthesia. The hip is gently manipulated into the acetabulum by flexion, traction, and abduction. An open or percutaneous adductor tenotomy usually is necessary in these cases because of secondary adduction contracture, and to increase the safe zone, which lessens the incidence of proximal femoral growth disturbance. The reduction must be documented (29,261,262,263,264 and 265) (Fig. 23-30). Because large portions of the femoral head and acetabulum are cartilaginous, arthrography is a useful tool in assessing the obstacles to and the adequacy of reduction (266,267 and 268). Dynamic arthrography using fluoroscopy helps to achieve both of these goals. Intraoperative ultrasonography may also be used.

The reduction is maintained in a well-molded plaster cast. The plaster must be well molded dorsal to the greater trochanters to prevent redislocation (Fig. 23-31). The “human position” of hyperflexion and limited abduction is the preferred position (269,270) (Fig. 23-32). The amount of apparent hip flexion during cast application is often greater than the flexion seen on radiographs. Wide, forced abduction or forced abduction with internal rotation should be avoided because these approaches are associated with an increased incidence of proximal femoral growth disturbance (Fig. 23-33).

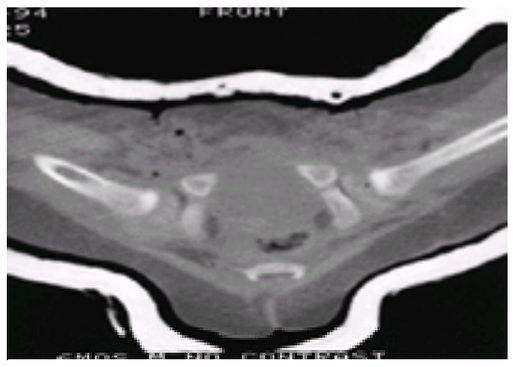

FIGURE 23-31. This computed tomography scan documents a successful closed reduction of a right hip dislocation. The plaster cast is molded dorsal to the greater trochanters to help prevent redislocation.

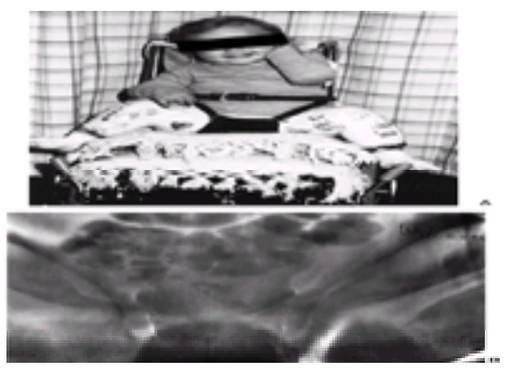

FIGURE 23-32. A: The “human position” of hyperflexion and limited abduction is the preferred position after closed reduction. The patient shown had bilateral reductions. **B:** Single-cut tomogram documents the hyperflexed, minimal abduction position.

FIGURE 23-33. Wide abduction should be condemned. This position is associated with a high incidence of damage to the proximal femoral epiphysis and the physeal plate.

The author prefers to use plaster of Paris because of its plasticity, but some surgeons prefer to use synthetic materials. The time of maintenance of reduction in the plaster cast varies considerably. The author prefers to maintain the plaster below the knee on the involved side and above the knee on the uninvolved side for approximately 6 weeks, regardless of the patient's age. At that time, the plaster on the involved side (or sides) is cut to above the knee to allow some hip rotation and knee range of motion for an additional 6 weeks.

Twelve weeks after closed reduction, the plaster cast is removed and replaced by an abduction orthotic device to be used on a full-time basis for 2 months, except during bathing, and then at nap time and at night until acetabular development is normal. The use of abduction orthotic devices after reduction of DDH varies widely. The greatest rate of improvement in acetabular development occurs during the first 18 months after reduction. Reduction after casting should be documented by radiography, single-cut tomography, computed tomography, magnetic resonance imaging, or ultrasonography (144,264,265,271) (Fig. 23-31). The adequacy of closed reduction is somewhat subjective. In the author's opinion anatomic reduction is the only acceptable reduction (Fig. 23-30C). The use of the femoral head as a “dilating sound” to overcome the intraarticular obstacles to reduction may cause damage to the femoral head and make open reduction more difficult (233,272,273).

FIGURE 23-30. Arthrograms demonstrate closed reduction of developmental dysplasia of the left hip in an 8-month-old infant. **A:** Untreated. **B:** Reduced. There is no pooling of dye medially. The acetabular cartilage completely covers the femoral head. **C:** Reduction in a plaster cast. Note the arthrographic shadow of the transverse acetabular ligament (*arrow*). **D:** Nine years after reduction. Note the symmetric acetabular and proximal femoral development.

In patients 6 months to 2 years of age, open reduction is indicated if there is failure of closed treatment, persistent subluxation, soft tissue interposition, and reducible but unstable reductions other than in extreme positions of abduction. There has been some controversy in recent years regarding whether the incidence of damage to

the proximal femur is decreased if open reduction is delayed until the femoral ossific nucleus is present. This notion was recently dispelled (274).

The goals of open treatment are to obtain reduction, maintain the reduction, avoid damage to the femoral head, and provide an optimal environment for acetabular and proximal femoral development. Open reduction of a DDH may be accomplished with a variety of surgical approaches (38,41,117,119,120,121,179,235,275,276,277,278,279,280 and 281).

The most commonly used surgical approach to open reduction is the anterolateral Smith-Petersen approach **[➥3.2]** with a modified “bikini” incision, as described by Salter and Dubos (280). This is a standard approach to the hip joint and is familiar to most surgeons. In the late-diagnosed DDH patient, any associated capsular laxity can be plicated through this approach. If the surgeon thinks that a secondary procedure, such as pelvic osteotomy, is necessary, it also can be accomplished through the same surgical approach (38,279,280 and 281).

One of the advantages of the anterior Smith-Petersen approach is that the hip is immobilized in a functional position, with minimal hip flexion and some degree of abduction. If this approach is used in conjunction with a capsular plication, the postoperative immobilization period is usually 6 to 8 weeks.

The disadvantages may include greater blood loss than with the various medial and anteromedial approaches, possible damage to the iliac crest apophysis and the hip abductors, and postoperative stiffness. If this approach is used in bilateral cases the procedures usually are staged at 2- to 6-week intervals.

The various medial approaches have the advantage of approaching the hip joint directly over the site of the obstacles to reduction (41,117,119,120,121,277,282,283,284,285 and 286). The medial approach described by Ferguson **[➥3.4]** is in the plane between the adductor brevis and the adductor magnus (117,287). Advocates of this approach think that its advantages include minimal soft tissue dissection, direct access to the medial joint capsule and the iliopsoas tendon, avoidance of damage to the iliac apophysis and abductor muscles, minimal blood loss, and excellent cosmesis. However, it is a less familiar approach to most surgeons, and visualization is somewhat impaired. Capsular repair cannot be accomplished through this approach. The stability of the reduction is maintained only by the postoperative cast. This approach is somewhat difficult to use in older patients, and no concomitant surgical procedures can be performed through the same incision. Questions have been raised about a higher incidence of proximal femoral growth disturbance after use of this approach.

A third approach to open reduction in this age group is the anteromedial approach originally described by Ludloff and modified by Weinstein and Ponseti (41,104,114,119,288,289,290,291 and 292). The approach is made in the interval between the femoral neurovascular bundle and the pectineus muscle **[➥3.3]**. The advocates of this approach cite minimal blood loss (i.e., transfusion is never necessary) and the fact that it is the most direct approach to the obstacles to reduction. There is minimal muscle dissection in this approach; only the iliopsoas and the adductor longus are sectioned. Both hips can be reduced during the same operative procedure, the scar is extremely cosmetic, and there is no damage to the hip abductor muscles or the iliac apophysis. Postoperative stiffness is not a problem.

There are several disadvantages to the anteromedial approach. It is not a familiar approach to most surgeons. Only open reduction can be accomplished; no secondary procedures can be performed through this incision. It is difficult to use in older patients because of the depth of the hip joint and the difficulty with visualization. If the surgeon thinks that capsular plication should be performed it cannot be done through this approach. The medial femoral circumflex vessels (i.e., the primary blood supply to the proximal femur) are in the operative field. Moreover, visualization is claimed by some to be poor, and the approach is associated with a higher incidence of aseptic necrosis (293,294). In the author's experience of more than 200 cases, visualization is excellent (Fig. 23-34) and the incidence of aseptic necrosis with a minimum 4-year follow-up is approximately 14%, which is well in line with the results of other series of open reductions (121,295). Capsular plication appears to be unnecessary in this age group because in a successful closed reduction the capsule tightens and the scar induced by the surgical procedure helps to provide capsular stability. This approach, however, depends on the placement of a well-molded cast. The approach to casting after reduction is the same as that described above for closed reduction. A certain degree of capsular stability is gained through the prolonged postoperative immobilization that is necessary. No residual stiffness has been experienced.

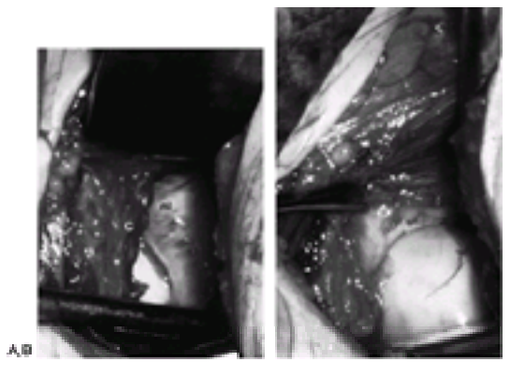

FIGURE 23-34. A: Open reduction through an anteromedial approach in a 14-month-old child. Note the anterior joint capsular edge (*c*) and the neolimbus (*nl*). **B:** The hip is reduced under direct view. The femoral head is well seated in the acetabulum, and the anterior edge of the hip capsule is everted by a hemostat.

Most physicians use abduction orthotic devices for some period after cast removal. Some use them on a full-time basis for several months, then part-time, usually during the night and napping hours, until acetabular development has caught up to the opposite, normal side. It is important in assessing acetabular development after open or closed reduction to look for accessory ossification centers. These give the treating physician an idea of whether the cartilage in the region of the neolimbus in the periphery of the acetabulum has the potential for ossification.

In patients younger than 2 years of age, a secondary acetabular or femoral procedure is rarely required. The potential for acetabular development after closed or open reduction is excellent and continues for 4 to 8 years after the procedure (34,35,41,296,297 and 298). The most rapid improvement in acetabular development—as measured by parameters such as the acetabular index, development of the teardrop figure, and thinning of the medial floor—occurs in the first 18 months after surgery (32,34,35,41,296,299,300). Femoral anteversion and any coxa valga associated with the untreated condition have an excellent chance to resolve during this time. However, some surgeons think that every child older than 18 months of age should undergo hip osteotomy accompanying open reduction because of the poor acetabular development potential (38,279,280,301,302).

Children Older Than 2 Years of Age

In a child older than 2 years of age at the time of diagnosis of DDH, open reduction is usually necessary. In this age group the treating surgeon must also consider whether to perform concomitant femoral shortening in conjunction with the open reduction. In children older than 3 years of age, femoral shortening to avoid excessive pressure on the proximal femur gives far lower rates of proximal femoral growth disturbance than does preliminary traction followed by open reduction (303,304,305,306 and 307) (Fig. 23-35). Schoenecker and Strecker reported a 54% incidence of aseptic necrosis with a 32% incidence of redislocation, with the use of skeletal traction in patients older than 3 years of age (304).

FIGURE 23-35. A: Preoperative anteroposterior roentgenogram of a 4-year-old girl with developmental dislocation of the left hip. **B:** Eighteen months after reduction and femoral shortening accessory centers of ossification are appearing in the lateral portion of the acetabular cartilage.

The age range of 2 to 3 years is considered a “gray zone,” with some surgeons advocating preliminary traction before open reduction and others performing concomitant femoral shortening (308,309 and 310). In this age range because the potential for acetabular development is markedly diminished, many surgeons recommend a concomitant acetabular procedure in conjunction with the open reduction or 6 to 8 weeks after the open reduction. The decision about whether to perform a secondary acetabular procedure is subjective. The author prefers to judge stability at the time of open reduction. If good stability is evident, the author prefers to observe acetabular development for the next few years, and if acetabular development is not improving by radiographic criteria (e.g., decreasing acetabular index, improvement in teardrop appearance and shape) (186), the author considers secondary acetabular procedures.

The most common accompanying procedure performed in this age group in conjunction with open reduction is innominate osteotomy as described by Salter (38,311) **[➥3.5]** or by Pemberton (37,312,313,314,315 and 316) **[➥3.7]**. Anatomic deficiency of the acetabulum in this age group usually is anterior, and the Salter innominate osteotomy gives anterior coverage, although at the expense of posterior coverage. The Pemberton osteotomy provides coverage anteriorly, and various degrees of lateral coverage, depending on the direction of the osteotomy cuts.

In this age group the standard anterolateral approach described by Smith-Petersen with the Salter modification is the ideal approach, because it enables capsular plication, immobilization of the hip joint in a more functional position, and innominate osteotomy at the same time through the same incision.

A theoretical advantage of open reduction accompanied by femoral shortening is that it can be used to correct any anatomic abnormality, such as excessive femoral anteversion. The disadvantages of femoral shortening include the need for a second incision and internal fixation for the osteotomy, requiring another operation for hardware removal.

After 3 years of age, open reduction of the hip should be accompanied by femoral shortening, and probably by a concomitant acetabular procedure, depending on hip stability at the time of surgery (307,310,317,318). The acetabular procedure may be performed at the time of open reduction, 6 weeks later, or at a later date, depending on acetabular development.

Treatment of Acetabular Dysplasia in Children 6 Months to 2 Years of Age. In children between 6 months and 2 years of age, acetabular dysplasia diagnosed incidentally or as a residual result after Pavlik harnessing, open reduction, or closed reduction is often treated with a fixed abduction orthotic device. The theory behind use of the fixed abduction brace is that dysplasia is associated with mild hip instability and that the device can correct that instability. These devices can be used only if the hip is well reduced, as verified on a radiograph taken with the patient wearing the brace (Fig. 23-28). The abduction device usually is worn full time for several months, then is worn at night and during nap time until acetabular development is normal, as measured by the acetabular index.

The complications of a fixed abduction device include skin breakdown and proximal femoral growth disturbance. It is important in positioning the device that the hip not be placed in extreme positions of abduction to avoid interruption of the vascular supply to the proximal femur.

SEQUELAE AND COMPLICATIONS

Residual Femoral and Acetabular Dysplasia

Based on natural history studies, it is the goal of treatment to have a radiographically normal hip at maturity to prevent degenerative joint disease in the future. Hip subluxations must be corrected. The evidence demonstrates that residual acetabular dysplasia, even in the absence of subluxation, eventually leads to degenerative joint disease, so this also should be corrected. The goal of treatment of DDH is to have a hip as anatomically normal as possible by the end of skeletal growth.

When evaluating the patient with persistent dysplasia, the relation between the acetabulum and the femur must be assessed. Anatomic dysplasia can involve the acetabulum, the proximal femur, or both. In DDH cases, the deficiency is most commonly on the acetabular side or the dysplasia is significantly greater on the acetabular side. If there has been a disturbance of proximal femoral growth secondary to previous treatment the femoral side may be more dysplastic.

Dysplasias of the hip joint can be evaluated with plain radiographs taken in the standing position, when possible, and with standard evaluations of acetabular development, as determined by the acetabular index, the acetabular angle of Sharp, and the CE angle. In young children with DDH most cases of acetabular deficiency are anterior, and in adolescents and adults with DDH, the acetabular deficiencies can be anterior, posterior, or global (38,80,279,319,320,321 and 322). Excessive femoral anteversion can be ascertained clinically, but is most accurately measured by computed tomography (323). There has been an increased interest in evaluating dysplasia by means of three-dimensional computed tomography (207,324,325). However, computed tomography cannot show the cartilaginous component of the proximal femur or the acetabulum; therefore, it is most useful for the patient at or close to maturity.

Deformities of the femoral neck assume significance only if they lead to subluxation of the joint: lateral subluxation with extreme coxa valga or anterior subluxation with excessive anteversion (179). In general, patients with DDH usually have normal neck–shaft angles. They may have persistent anteversion that gives the radiologic appearance of subluxation.

If acetabular dysplasia persists for 2 to 3 years after closed or open reduction and the patient has residual anteversion, proximal femoral rotational osteotomy should be considered **[➥4.1–4.3]**. Excessive anteversion or valgus of the proximal femur may contribute to hip joint instability and failure of normalization of acetabular growth. Varus derotation osteotomies are indicated in children with hip dysplasia, because it is assumed that the femoral head directed toward the center of the acetabulum stimulates normal acetabular development (178,204,326,327). This approach may also be indicated to correct residual deformity from a partial physeal arrest as a result of aseptic necrosis. Intertrochanteric osteotomies can provide adequate medialization of the femoral shaft and prevent further varus deformity of the proximal femur (328,329).

Before performing varus derotation osteotomy, the surgeon must be certain that the femoral head can be concentrically reduced; if not, this procedure must be accompanied by open reduction. An anteroposterior pelvic film of the hip with apparent coxa valga and anteversion shows lateralization and subluxation of the femoral head (Fig. 23-36). Before surgery, the surgeon must document that the femoral head is concentrically reduced on an anteroposterior pelvic radiograph with the patient's legs abducted 30 degrees and maximally internally rotated (Fig. 23-36). This position allows visualization of the actual femoral neck angle.

FIGURE 23-36. A 3-year-old white girl 2 years after closed reduction. **A:** Anteroposterior (AP) view of the pelvis. Note the persistent acetabular dysplasia and apparent coxa valga. **B:** The radiograph shows the leg abducted approximately 30 degrees and maximally internally rotated. The femoral head is seated well within the acetabulum, and the Shenton line is restored. **C:** AP view of the left hip 6 weeks after varus derotation osteotomy. **D:** AP view of the left hip 18 months after varus derotation osteotomy, with hardware removal. The Shenton line has been restored, there is improved teardrop figure development, and accessory centers of

ossification appear in the periphery of the acetabular cartilage.

When the Shenton line is disrupted, the proper relation of the proximal femur usually can be restored by derotation osteotomy, with or without various degrees of varus. After reduction is obtained in most cases of DDH the femoral neck anteversion, which exists in most patients, corrects spontaneously (330). The varus derotation osteotomy is used alone in such cases by surgeons who think that redirection of the femoral head toward the center of the acetabulum stimulates normal acetabular development (132,326,331,332,333,334,335 and 336). The proximal femoral varus derotation osteotomy, if used to “stimulate” more normal acetabular development, must be performed in children younger than 4 years of age (326). After 8 years of age, no improvement in acetabular dysplasia can result from this procedure. These osteotomies must be done in the intertrochanteric region to provide adequate medialization of the femoral shaft. Performing the osteotomy in the intertrochanteric area avoids posterior displacement of the lesser trochanter and prevents excessive varus deformity of the femur, which can lead to mechanical abnormalities at the knee (337).

In small children, any leg-length discrepancy resulting from varus osteotomy should resolve by growth stimulation and restoration of the normal neck–shaft angle (338). In teenagers, however, more than a 15-degree correction of varus deformity may result in limb shortening. The varus osteotomy, if excessive, can cause lateralization of the shaft, shifting the mechanical axis medial to the knee joint. This is an undesirable effect; varus osteotomy should be accompanied by shaft medialization. If the osteotomy is transfixed with smooth wires they can be removed after 6 to 8 weeks. Internal fixation devices are usually removed 12 to 18 months postoperatively; if they are not removed in young children, they become encased within the proximal femur, which could pose problems if future operations become necessary.

In the adolescent or adult patient with residual dysplasia in whom there is no potential for acetabular growth and remodeling, changing the orientation of the proximal femur does not increase the weightbearing area but does shift the weightbearing area to another portion of the femoral head (339,340 and 341). Proximal femoral osteotomies in the adolescent or adult group are indicated only as adjuncts to pelvic operations and in extreme cases of coxa valga and subluxation (179,340) (Fig. 23-37).

FIGURE 23-37. A 10-year-old girl with the diagnosis of developmental dysplasia of the hip made at 5 years of age. She had previously undergone open reduction, but had residual proximal femoral and acetabular deformities. **A:** Preoperative anteroposterior radiograph of the pelvis. **B:** Three years after varus derotation osteotomy and Staheli slotted acetabular augmentation.

Indications for the treatment of residual radiographic acetabular dysplasia depend on the age of the child and whether or not the patient has symptoms (342). The goal of treatment is to restore the anatomy to as near normal as possible by skeletal maturity. After concentric reduction is obtained and maintained, the potential for acetabular development continues for many years (32,34,35,41,206). However, after 4 years of age, this potential for restoration of normal anatomy decreases. For minimal residual dysplasias in children younger than 4 years of age observation can be continued, but for significant dysplasia surgical intervention should be entertained.

The treatment options for acetabular dysplasia traditionally are divided into four groups. The first group consists of osteotomies of the pelvis that redirect the entire acetabulum. This redirection of the entire acetabulum provides coverage of the femoral head by acetabular articular cartilage. These osteotomies include the Salter innominate osteotomy (38,80,279,280,281,343,344,345) (Fig. 23-38) **[➥3.5]**, the Sutherland double-innominate osteotomy (346), the triple-innominate osteotomies of Tonnis (179,347,348,349,350,351 and 352), Steel (353,354,355,356,357 and 358), and Ganz (359,360), the spherical osteotomies of Wagner (361,362 and 363) **[➥3.10]** and Eppright (364), and others (365,366,367 and 368). These procedures involve complete cuts through various pelvic bones and rotation of the acetabulum.

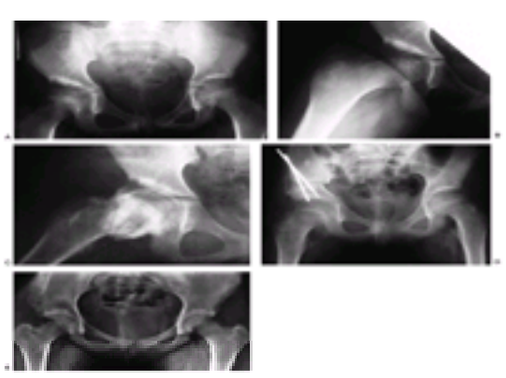

FIGURE 23-38. An 8-year-old white girl with residual right acetabular dysplasia. **A:** Anteroposterior (AP) radiograph of the pelvis. **B:** AP view of the pelvis with abduction, flexion, and slight internal rotation; the femoral head appears slightly uncovered. **C:** Similar view with the addition of an arthrographic dye. Note the excellent coverage of the proximal femur by unossified acetabular cartilage. **D:** Immediately after the innominate osteotomy. **E:** Four years after the innominate osteotomy.

Other acetabuloplasties that involve incomplete cuts and hinge on different aspects of the triradiate cartilage include the acetabular procedures described by Pemberton (37,312,314,315,316,369) and Dega (370,371,372 and 373) **[➥3.7–3.9]**. These procedures can theoretically decrease the volume of the acetabulum because they depend on the triradiate cartilage as the fulcrum.

A third group of acetabular reconstructive procedures involves placing bone over the hip joint capsule on the uncovered portion of the femoral head. These procedures provide coverage of the femoral head by capsular fibrous metaplasia (374,375). They include the various shelf procedures (376,377,378,379,380,381 and 382) **[➥3.12]** and the medial displacement osteotomy described by Chiari (383,384,385,386,387 and 388) **[➥3.11]**.

Correction of residual dysplasia theoretically provides for a better weightbearing surface for the femoral head, restores the normal biomechanics of the hip, and may increase the longevity of the hip by preventing degenerative joint disease. Unfortunately, only prospective, long-term follow-up studies of these procedures can provide unambiguous answers.

Shelf procedures were described before 1900 and were used widely until the mid-1950s, when Chiari described his medial displacement osteotomy (384). Later, Salter, Pemberton, and others described various pelvic osteotomies used to redirect the acetabulum and cover the femoral head with articular cartilage. In 1981,

Staheli and Chew introduced a modification of a previously described shelf arthroplasty, which gained widespread popularity when used alone for significant anatomic dysplasia and in conjunction with various rotational procedures as an augmentation to provide increased femoral head coverage (382) (Fig. 23-37).

Although intuitively it seems better to cover the femoral head with articular cartilage than to rely on fibrous metaplasia, it is impossible to be certain about the long-term results of shelf arthroplasty, because no such results exist.

In the young child, acetabular deficiencies generally are assessed by arthrography and by inspection at the time of open reduction. For reduced hips with residual dysplasia, the author has found that the problem is not one of deficiency of the acetabulum, but a failure of the peripheral acetabular cartilage to ossify (Fig. 23-38). In most cases, an arthrogram at the time of surgery shows excellent coverage of the femoral head by the unossified acetabular cartilage. This cartilage fails to undergo normal development because it is intrinsically abnormal or because it was damaged by the femoral head in the unreduced position, causing pressure necrosis. Given enough time, some of this acetabular cartilage may resume normal ossification and correct a large amount of the dysplasia. However, in the author's experience of a large number of patients treated with open and closed reduction, this does not happen in many cases, and intervention should be undertaken after the acetabulum has had a reasonable chance to develop on its own (121,206,389). The osteotomy of the iliac bone and the neovascularity stimulated in healing may increase the ossification of the otherwise unossified acetabular cartilage. In any case, the redirection of the acetabulum restores more normal bony anatomy and normal biomechanics that also may be a factor in stimulating ossification (234).

The best means of evaluating acetabular dysplasia in the mature patient includes three-dimensional computed tomography (123,390,391,392,393,394 and 395), the false profile view, and plain radiography (396) (Fig. 23-39). For young, immature patients, computed tomography does not provide adequate assessment of the deficiencies because it does not show the acetabular cartilage.

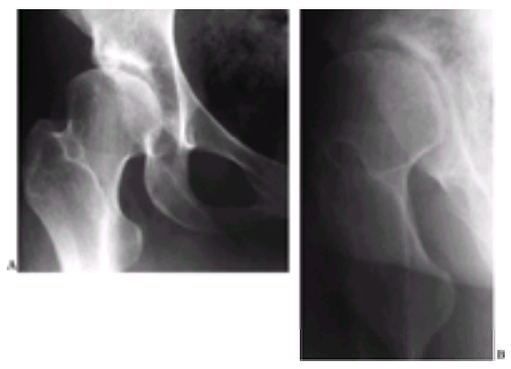

FIGURE 23-39. A 34-year-old woman with residual dysplasia after closed reduction of right developmental dysplasia of the hip at age 16 months. She now has mild pain. **A:** Anteroposterior view of the hip. **B:** False profile lateral view demonstrating anterior deficiency of the acetabulum.

Concentric reduction is an absolute requirement for all osteotomies other than the shelf or Chiari procedures. Osteotomies that depend on the triradiate cartilage as the fulcrum must be done in patients with open triradiate cartilage. The Salter innominate osteotomy, which hinges on the symphysis pubica, is better performed in the infant, child, and adolescent because of the flexibility of the symphysis pubica. However, this osteotomy can be performed in adults. The procedure is more likely to succeed when the CE angle is greater than 10 degrees.

An important factor to be considered when planning correction of acetabular dysplasia is the amount of dysplasia that needs to be corrected. The amount of coverage obtained by osteotomies such as the Salter procedure is limited, but osteotomies that cut all three pelvic bones provide the ability to obtain greater coverage (397,398). The closer the cuts are placed to the acetabulum the greater the femoral head coverage. The triple-innominate osteotomies described by Tonnis and Ganz provide greater rotational possibilities than that described by Steel. The osteotomies that are closest to the acetabulum (e.g., Eppright, Wagner) provide the greatest potential for redirection, but these require significant technical expertise and have higher rates of complications.

The shelf arthroplasty and the Chiari osteotomy may be performed for well-reduced hips, but they usually are reserved for hips that lack significant femoral head coverage which could not be obtained by means of one of the other procedures that provides coverage with articular cartilage mentioned above (399,400). Many of these procedures can be performed in patients with early degenerative changes in the hope of delaying the onset of arthroplasty or fusion. Further discussion of these issues is beyond the scope of this chapter.

The procedures that involve hinging on the triradiate cartilage, such as the Pemberton osteotomy, have the potential to injure the triradiate cartilage and cause premature closure, but these complications are not common (401). Procedures that must cross the triradiate cartilage, such as the Ganz osteotomy, and induce closure cannot be done in patients with open triradiate cartilage. In shelf arthroplasties performed in immature patients it is important to avoid cutting the ilium in the region of the groove of Ranvier because this may severely impair acetabular development. Acetabular rotational procedures that depend on hinging on the cartilage of the symphysis pubica or various portions of the triradiate cartilage are better performed in younger patients. Rotational pelvic osteotomies in the face of subluxation may lead to severe damage to the femoral head.

The general prerequisites for rotational osteotomies include complete concentric reduction and release of muscle contractures, including the iliopsoas and hip adductors, a congruous joint, and good range of motion. These procedures are best performed before 6 years of age, but the age limits vary considerably, depending on the surgeon.

The double-innominate osteotomy of Sutherland and Moore aims to allow greater rotation of the pelvic fragment by cutting through the pubis, instead of hinging only on the symphysis pubica (346). Complications of this procedure can involve injury to the spermatic cords, bladder, and urethra. The triple-innominate osteotomy allows even greater coverage by means of cuts of all three hip bones.

The Chiari medial displacement osteotomy hinges on the symphysis pubica, with the distal fragment displacing medially and upward (Fig. 23-40 and Fig. 23-41). This medialization results in reduction of the lever arm to reduce joint loading. Abductor muscle function is theoretically improved. Patients may limp for as long as 1 year. There is some concern that bilateral Chiari osteotomies may interfere with a woman's ability to deliver children. This is one of the few procedures for which long-term results exist, and these show that, in the absence of subluxation and degenerative joint disease, good long-term results may persist for many years (112,386,402,403,404,405,406,407,408,409,410,411 and 412).

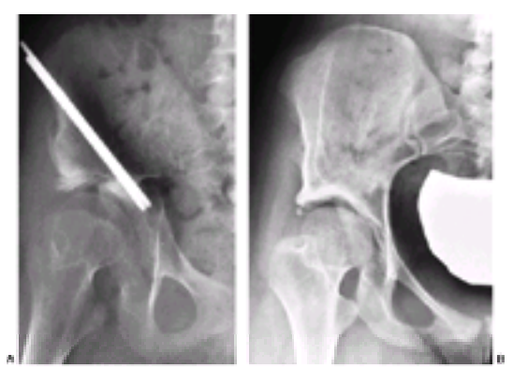

FIGURE 23-40. An 11-year-old white girl with pain and residual right hip subluxation with severe acetabular dysplasia. **A:** Immediately after the right Chiari osteotomy. Note the additional graft placed anteriorly. **B:** Eight years postoperatively there is excellent remodeling of the acetabulum with *sourcil* development.

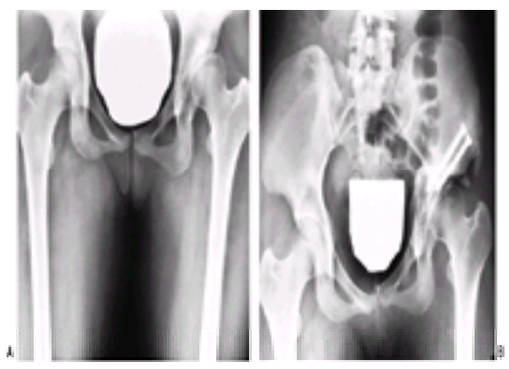

FIGURE 23-41. A white girl underwent open reduction of the left dysplastic hip at 18 months of age. She presented at 17 years of age with subluxation, as seen on the radiograph. **A:** Preoperative anteroposterior view of the pelvis. **B:** Eight weeks after Chiari osteotomy. Note the additional graft placed anteriorly.

Decision-making is somewhat difficult for the asymptomatic mature patient. For the asymptomatic adolescent with minimal radiographic dysplasia (because degenerative arthritis is a probability but not a certainty) the author prefers to inform the family about the potential for an adverse natural history and recommend surgery only at the onset of symptoms. There usually is a long interval between symptom onset and radiographic degenerative joint disease (66). The patient can be reassured that if symptoms develop surgical treatment can help to avoid long-term degenerative joint disease. However, faced with an adolescent with radiographic evidence of subluxation, regardless of the symptoms, the author recommends surgical correction, because an adverse natural history is certain without treatment.

Disturbance of Growth of the Proximal Femur

The most disastrous complication associated with the treatment of DDH involves various degrees of growth disturbance of the proximal femur, including the epiphysis and the physeal plate. This is commonly referred to by the term “aseptic necrosis.” Because there has never been a study of a pathologic specimen from a patient with what is called aseptic necrosis, the author prefers to use the term “proximal femoral growth disturbance” (206). These growth disturbances can be precipitated by experimental vascular injuries in animals and resemble the growth disturbances seen in humans with treated DDH. The disturbance may be caused by vascular insults to the epiphysis or the physeal plate or by pressure injury to the epiphyseal cartilage or the physeal plate (272,273,413,414,415,416,417,418,419,420,421,422,423,424,425,426,427 and 428). The blood supply to the proximal femur is described in Chapter 24.

Growth disturbance of the proximal femur in DDH occurs only in patients who have been treated. This may also occur in the opposite normal hip in a patient who has been treated (429,430). The reported incidence of proximal femoral growth disturbance varies from 0 to 73% (206,208,431,432). Different opinions exist about the reasons for this variation (433,434,435 and 436). The use of prereduction traction (206,208,242,245,419,431,437), adductor tenotomy (270,421,438), open or closed reduction (41,117,122,294,419,439,440 and 441), the force of reduction (431,438,442,443), the position of postoperative immobilization (242,245,270,272,422,424,425,427,444), and the age at reduction (242,245,250,422) have been implicated as etiologic factors. Others think that the incidence may be much less variable than the means by which it is assessed (206,434).

In an extensive study of the development of ischemic necrosis published by the German Society for Orthopaedic and Traumatology (3,316) conservatively treated hips and 730 operatively treated hips were evaluated to determine the factors associated with the development of ischemic necrosis (179). The factors associated with necrosis included high dislocations and dislocations with inversion of the labrum, narrowing of the introitus between the superior labrum and the transverse ligament in the position of reduction, inadequate depth of reduction of the femoral head (greater than 3 mm from the acetabular floor), older patients (older than 12 months), immobilization in 60 or more degrees of abduction for joint instability, and adductor tenotomy.

Westin and colleagues thought that the marked variation of the reported incidence indicated a lack of definition of terms (437). Thomas and associates concluded that there was some association between the reported incidence in a given series and the rigor with which the diagnosis had been sought (434). Buchanan et al. thought that if signs of growth disturbance were not present within 12 months of reduction they were highly unlikely to appear (242).

Bucholz and Ogden (414) and Kalamchi and MacEwen (419) identified a lateral physeal arrest pattern that may not be evident until a patient is older than 12.5 years of age (mean, 9 years) (Fig. 23-42). This is the most common pattern of growth disturbance reported. Kalamchi and MacEwen stressed that it may be difficult to identify this group early, and studies reporting growth disturbances with follow-up periods of less than 12 years must be regarded as preliminary and may not reflect the actual incidence of proximal growth disturbance (419).

FIGURE 23-42. A 5-year-old girl who underwent varus derotation osteotomy, an innominate osteotomy for residual dysplasia, 3 years after open reduction. **A:** Anteroposterior (AP) view 3 months postoperatively. **B:** AP view at 9 years of age. Note the valgus tilt to the proximal femur. **C:** AP view at 11 years of age. Note the lateral tether, a typical type II physeal plate tether, and how the tether produces hip subluxation. A physeal growth arrest pattern may not be evident until a patient is 9 years of age or older.

The incidence of proximal femoral growth disturbance increases with delay in reduction (245,250). Younger patients have a lower rate of growth disturbance. Kalamchi and MacEwen, however, documented an increase in the incidence of the severe form (type IV) in younger patients (419). Salter and colleagues (270) and Ogden (424,425) proposed that the femoral head in DDH is most vulnerable to ischemic changes during the first 12 to 18 months of life, when it is composed mostly of cartilage. According to some orthopaedic specialists the risk of total head involvement becomes somewhat less after the appearance of the femoral ossific nucleus, although, as mentioned above, this concept was recently challenged (250,274).

Prereduction traction to bring the proximal femur epiphysis to the level of the triradiate cartilage is considered essential by many surgeons to decrease the incidence of proximal femoral growth disturbance. Gage and Winter thought that there was a direct correlation between inadequate traction and the incidence of growth disturbance. They studied a group of patients to quantify prereduction hip positions (245). Weiner et al. found that in patients younger than 1 year of age traction for longer than 21 days substantially reduced the rate of growth disturbance (250). Buchanan and colleagues recommended a minimum of 2 weeks of traction until achievement of a 2+ traction station using the Gage and Winter scale (238). Skeletal traction gradually increased over several weeks, and an average of 39% of body weight usually was required to achieve this position. In contrast, Cooperman et al. studied 30 DDH hips with aseptic necrosis and 30 hips without necrosis and found, at an average 39-year follow-up, that the degree of initial displacement that had to be overcome to obtain reduction was comparable in both groups and that it was not a factor in the development of proximal femoral growth disturbance (416). Some of the worst results were seen in patients with minimal superior dislocation. Schoenecker and Strecker demonstrated that the results of traction were not as good as the results of femoral shortening in older patients with DDH (304). Gibson

and Benson thought that although preliminary traction protects against growth disturbance, there was no relation between the original degree of displacement of the proximal femur and the final result (304).

Several factors associated with an increased incidence of proximal femoral growth disturbance have been documented in the clinical setting and in experimental studies. These include extremes in positioning of the proximal femur in abduction and abduction with extreme medial rotation. Extremes in position can cause compression of the medial femoral circumflex vessel as it passes the iliopsoas tendon and compression of the terminal branch between the lateral femoral neck and the acetabular margin (270,424,425). Anatomic and experimental investigations have persistently shown that strong medial rotation with concomitant abduction and extreme abduction alone (i.e., the Lorenz position) can compromise the blood flow to the capital femoral epiphysis. If the hip is maximally abducted against firm resistance, the blood flow can be completely or almost completely arrested. The same is true in forced medial rotation. The blood vessels and blood supply to the proximal femur can be occluded outside the femoral head by compression or as the vessels cross through the epiphyseal cartilage (270,273,428). Schoenecker and colleagues showed a diminution of epiphyseal profusion by increased pressure, which was relieved after the external fixation device was removed (272,427).

The extreme positions of abduction, frequently called the “frog-leg position” (Fig. 23-33) and used in cases of unrelieved adduction contracture, as seen in dislocations, uniformly result in severe growth disturbances of the epiphysis (269,270,427).

Extreme positions can also cause pressure necrosis of the vulnerable epiphyseal cartilage and the physeal plate. This has been experimentally shown by Law and colleagues (421) and by Schoenecker and associates (427). These studies and others demonstrated the severe effects of cartilage necrosis (179,270,273). These effects can also be precipitated by circumscribed pressure, such as the use of the vulnerable femoral head as a dilating sound to overcome the intraarticular obstacles to reduction.

Severin advocated the use of the femoral head placed in close apposition to the acetabulum to induce regression of the obstacles to reduction (122). The idea is that sustained pressure from the femoral head causes the labrum to adapt itself to the spherical contour of the head. This maneuver can be used to obtain reduction, but the price may be an increased incidence of necrosis (179,438). Although the use of prereduction traction has been implicated as a factor in reducing the incidence of necrosis, the German Orthopaedic Study Group did not find this to be the case (179).

The continued use of closed techniques in an attempt to have the femoral head overcome the intraarticular obstacles to reduction can lead to severe necrosis (179). If closed reduction is attempted, in the author's opinion the only acceptable reduction is an anatomically perfect reduction; otherwise, the hip must be reduced openly to prevent damage to the vulnerable femoral head (179,351,445).

The most widely used classification of proximal femoral growth disturbance is that of Salter and colleagues (270) (Table 23-2). The author disagrees with the inclusion of coxa magna, because coxa magna is often seen after open reduction as a result of the stimulation of blood flow to the proximal femur (446,447 and 448). It is also often difficult to ascertain if some of the residual deformities seen after treatment of DDH are alterations in the proximal femur secondary to disturbances that occurred before the reduction or are the result of complications associated with the reduction. One of the most common deformities seen is flattening of the medial aspect of the proximal femur, which occurs because of pressure of the femoral head lying against the ilium before reduction.

Salter Class	Features
1	Failure of the appearance of the ossific nucleus of the femoral head within 1 year after reduction
2	Failure of growth of an existing ossific nucleus within 1 year after reduction
3	Broadening of the femoral neck within 1 year after reduction
4	Increased radiographic bone density, followed by fragmentation of the femoral head
5	Residual deformity of the femoral head and neck when reossification is complete; these deformities include coxa magna, coxa plana, coxa vara, and a short, broad femoral neck

(From ref. 270, with permission.)

TABLE 23-2. CLASSIFICATION OF THE FEMORAL HEAD

Another area of uncertainty is the issue of temporary irregular ossification of the femoral epiphysis and whether this represents damage to the epiphyseal cartilage or merely multiple ossification centers that eventually coalesce. These areas may be analogous to the accessory centers of ossification seen in the periphery of the acetabulum. This pattern usually does not result in growth disturbance of the proximal femur. Only long-term follow-up studies of this entity can resolve this issue.

Kalamchi and MacEwen developed a classification of necrosis that emphasized the growth disturbances associated with various degrees of physeal arrest (419). This classification (Fig. 23-43) puts all the growth disturbances seen in the ossific nucleus into one category if they are not associated with physeal involvement. Bucholz and Ogden provided an additional classification based on patterns of vascular supply resulting in partial or total ischemia (414). There are few studies documenting the interobserver or intraobserver reliability of these classifications of growth disturbance. As many as 25% of hips may not fit into a particular classification.

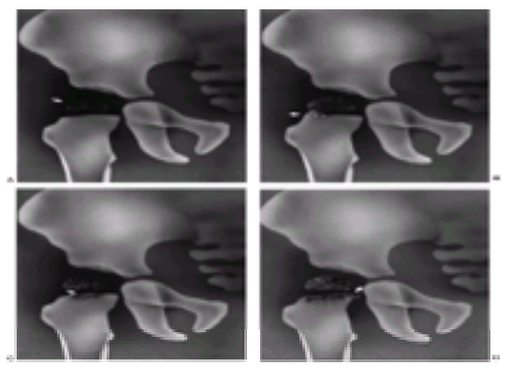

FIGURE 23-43. Classification of proximal femoral growth disturbances. **A:** Group I. **B:** Group II. **C:** Group III. **D:** Group IV. (Adapted from ref. 419, with permission.)

O'Brien and associates discussed the importance of identification of growth disturbance lines to predict future deformity of the proximal femur (449,450) (Fig. 23-44). These growth arrest lines may provide the physician with early evidence of a future problem. However, the utility of this approach must await long-term follow-up studies.

FIGURE 23-44. A 3-year-old girl with right developmental dysplasia of the hip. **A:** Preoperative radiograph. **B:** Ten months after operative open reduction, femoral shortening, and Pemberton osteotomy. Note the presence of growth arrest line at the proximal femur (O'Brien lines; *arrows*); also note similar lines on the opposite normal hip.

Long-term follow-up studies exist of patients suffering from proximal femoral growth disturbance (179,416). The results indicate that any alteration of proximal femoral growth disturbance decreases the longevity of the hip.

In the treatment of the residual effects of necrosis, reduction must be maintained by corrective femoral and/or acetabular procedures (451,452). With arrest of the proximal femoral physeal plate, trochanteric overgrowth ensues producing an abductor lurch (Fig. 23-45). If identified, greater trochanteric physeal plate arrest may maintain articular trochanteric distance if performed in children younger than 8 years of age (19,453,454); otherwise, distal transfer of the greater trochanter may be necessary (371,455,456 and 457) **[➥4.9]**.

FIGURE 23-45. A 14-year-old girl with residual dysplasia, type III growth arrest, and trochanteric overgrowth. The patient had bilateral open reductions at 14 months of age. She suffered a type III growth arrest of the proximal femur with resultant disturbance of growth of the proximal femur and corresponding acetabular deformity and trochanteric overgrowth. Her Trendelenburg test was negative. Some patients with this deformity have an abductor lurch, necessitating distal transfer of the greater trochanter.

The painful hip in the teenager with residual proximal femoral growth disturbance and dysplasia may be caused by a torn labrum (458,459). The diagnosis can be made using contrast-enhanced computed tomography or magnetic resonance imaging, and treatment may require open repair or excision. Another cause of pain includes early degenerative joint disease, which should be treated by the previously described methods to correct residual subluxation and dysplasia. In extreme cases, hip fusion or early total joint arthroplasty may be the only alternatives available. These circumstances are rare among patients younger than 30 years of age.

The key to the diagnosis and management of DDH is early detection. This results in a 95% success rate of treatment with a low risk of complications. It is the initial treating physician who has the greatest chance of successfully achieving a normal hip. Orthopaedic surgeons must educate primary care colleagues in making the diagnosis early and initiating prompt referral.
