CHAPTER 24

LEGG-CALVÉ-PERTHES SYNDROME

STUART L. WEINSTEIN

S. L. Weinstein: Department of Orthopaedic Surgery, University of Iowa Hospital, Iowa City, Iowa 52245.

EARLY HISTORY

Legg-Calvé-Perthes syndrome is a disorder of the hip in young children. The condition was described independently in 1910 by Legg (1), Calvé (2), Perthes (3), and Waldenstrom (4,5). In the late 19th century, however, Hugh Owen Thomas (6), Baker (7), and Wright (8) described patients with supposed hip joint infections that resolved without surgery, whose histories were consistent with Legg-Calvé-Perthes syndrome. Maydl (9), in 1897, reported this condition and thought it was a related condition of congenitally dislocated hip (10).

In 1909, Arthur Legg presented a paper on five children with a limp after injury. This paper was published in 1910. He called this condition an “obscure affectation of the hip,” and postulated that pressure secondary to injury caused flattening of the femoral head (1). In that same year, Calvé reported 10 cases of a noninflammatory self-limiting condition that healed with flattening of the weight-bearing surface. He postulated that the cause of this condition was an abnormal or delayed osteogenesis. He reported coxa vara and increased femoral head size in these patients, and on physical examination, all of the patients had decreased abduction (2). Perthes simultaneously reported six cases of what he termed “arthritis deformans juveniles.” He postulated that this was an inflammatory condition (3). In his description of the condition, Waldenstrom postulated that the disease was a form of tuberculosis (4,5).

Perthes was the first investigator to describe the pathologic and histologic features of the disorder (11). He reported on a 9-year-old boy with symptoms for 2 years. Examination of the portion of the excised head revealed numerous cartilage islands throughout and “strings” connecting the joint cartilage and the physeal plate. Perthes noted the marrow spaces to be widened, with fatty infiltration; he saw no evidence of inflammation. He believed that the cartilage islands were new, and that this was an osteochondritis, not a tubercular, process (11). Schwartz (12), an associate of Perthes, described the pathologic changes in a 7-year-old boy with a 2-year history of symptoms and reported similar findings. Waldenstrom (13) suggested the use of the term *coxa plana* to make the description of the disease consistent with that of other hip deformities, such as coxa vara and coxa valga. Sundt (14,15) published the first monograph on Legg-Calvé-Perthes syndrome, reporting on 66 cases and the pathology of the condition. The essential feature in all of his cases was the cartilaginous islands in the epiphysis. Sundt attributed the disease to an “osteodystrophy due to dysendocrinia of a hereditary disposition.” He believed that people so predisposed would get Legg-Perthes disease after they sustained an injury to the hip (i.e., infection or trauma). Sundt was the first person to introduce the modern concept of the “susceptible child.”

Phemister (16), reporting on the curettage findings of a 10-year-old child with an 8-month history of symptoms, described areas of bone necrosis, granulation tissue, old bone with new bone formation, and osteoclasts. He interpreted these findings as an inflammatory and infectious process. In 1922, Riedel (17) reported on two cases and presented the histology. He described the thickening of the articular cartilage and noted that the junction between the bone and the articular cartilage was filled with blood. He also noted that the physeal plate was destroyed and that there were many cartilage rests. Dead bone was surrounded by a rich granulation tissue, and many giant cells were present. He also noted that farther away from the main disease process, the marrow was fibrotic with inflammatory infiltrates. Riedel was the first investigator to notice that there were blastic and clastic changes at the same time working on the same bone trabeculae. In his second specimen he found regeneration of the cartilage in the subchondral area, cell atrophy, and some inflammatory cells. That same year, Waldenstrom (18) proposed the first radiographic classification of the disease process, based on 22 patients followed until the completion of growth. Since then, most of the orthopaedic literature has centered on the etiologic, epidemiologic, and prognostic factors in Legg-Calvé-Perthes syndrome and follow-up of various treatment modalities (19).

EPIDEMIOLOGY AND ETIOLOGY

Legg-Calvé-Perthes syndrome occurs most commonly in the age range of 4 to 8 years (20), but cases have been reported in children from 2 years of age to the late teenage years. It is more common in boys than in girls by a ratio of 4 or 5 to 1 (21). The incidence of bilaterality has been reported as 10 to 12% (20,22). Although the incidence of a positive family history in patients with Legg-Calvé-Perthes syndrome ranges from 1.6 to 20% (10,20,23,24,25,26,27,28 and 29), there is no evidence that Legg-Calvé-Perthes syndrome is an inherited condition (30).

Wynne-Davies and Gormley (20) reported on a series of 310 index patients with Legg-Calvé-Perthes syndrome. They noted that of the children of affected index patients, only 2% had Legg-Calvé-Perthes syndrome. In this series, all twins were discordant, including one monozygotic pair. Eleven percent had abnormal birth presentations, including breech and transverse, compared with the 2 to 4% incidence that would be expected in the general population. There is an increased incidence of Legg-Calvé-Perthes syndrome in later-born children, particularly the third to the sixth child, and a higher percentage in lower socioeconomic groups (31,32). Parental age of affected patients is higher than in the general population (20,29,33).

Legg-Calvé-Perthes syndrome is more common in certain geographic areas, particularly in urban rather than rural communities, giving rise to the suspicion of a nutritional cause, possibly a trace element deficiency (31,32,33,34,35,36,37 and 38). There is also a recently reported strong association (33% of affected patients) of Legg-Calvé-Perthes disease with the psychological profile associated with attention deficit hyperactivity disorder (39). Malloy and colleagues (40,41) noted that birth weight was lower in affected children. Harrison and colleagues (42) reported that children with Legg-Calvé-Perthes syndrome lagged behind their chronologic age, and 89% of the involved individuals had delayed bone age. Ralston demonstrated that this delay in skeletal maturation averaged 21 months, but that during the healing stages of the disease there would be recovery of height and weight through increased growth velocity (43,44 and 45). There may be certain racial factors in that there is an increased frequency of Legg-Calvé-Perthes syndrome in Japanese people, other Asians, Eskimos, and central Europeans, and a decreased frequency in native Australians, Americans Indians, Polynesians, and blacks (10,36,46,47).

There is considerable evidence of anthropometric abnormalities in children with Legg-Calvé-Perthes syndrome. Cameron and Izatt (48) reported that affected boys were 1 inch shorter and affected girls were 3 inches shorter compared with normal nonaffected children. Burwell and colleagues (49,50 and 51) and others (31,52,53) demonstrated that affected children are smaller in all dimensions, except for head circumference, and shorter in the distal portions of the extremities as opposed to the proximal portions. Loder et al. (54), in a more recent study, demonstrated that pelvis bone age in boys was less delayed than hand and wrist bone age. The short stature of the patient affected with the disorder at a young age tends to correct during adolescence, whereas patients affected at an older age tend to be small throughout life (29). Eckerwall et al. (55) followed 110 affected children longitudinally and showed that these children were shorter at birth and remained short during the entire growth period, and that growth velocity never changed. Burwell and colleagues (51) demonstrated an abnormality of growth hormone–dependent

somatomedin in boys with Legg-Calvé-Perthes syndrome, whereas Tanaka and colleagues (56), Fisher and associates (23), and Kitsugi and colleagues (57) reported contrary results.

Growth hormone regulates postnatal skeletal development. The effects of growth hormone on postnatal skeletal development are mediated, in part, by the somatomedins (insulin-like growth factors) (58). Somatomedin C (IGF1) is the principal somatomedin responsible for postnatal skeletal bone maturation (58). Plasma IGF1 levels have been reported to be significantly reduced in affected children during the first 2 years after the diagnosis of Perthes disease. These alterations were accompanied by a tendency toward growth arrest and impaired weight gain. This is accompanied by an acceleration in growth and weight gain during the healing stages of the disease.

In plasma nearly all IGF1 is bound to specific binding proteins. However, the major binding protein (IGFBP3) levels are normal during the first 2 years after the diagnosis of Perthes disease (59,60). Low levels of circulating IGF1 and failure of IGF1 to increase normally during the prepubertal years in patients with Perthes disease, in conjunction with reportedly normal growth hormone levels, raise the possibility of decreased responsiveness of growth plate chondrocytes and hepatocytes (58). The combination of moderately reduced IGF1 levels with normal IGFBP3 has been reported in normal-variant short stature children. The skeletal maturation delay and retarded bone age reported in patients with Perthes disease, in conjunction with the findings described above, could be considered a retention of the infantile hormone pattern (60).

Malnutrition is one factor that leads to low IGF levels, and this could be related to the reportedly increased incidence of Perthes disease in low-income families. The disproportionate skeletal development affecting the distal portions of the body reflects a tendency toward infantile body proportions. This correlates with the reduced IGF1 levels in the face of normal binding proteins (61). Controversy still exists in that a recent study by another group of investigators reported results opposite to those reported by Neidel et al. (60), with serum levels of IGF1 being normal, and those of IGFBP3 being lower in children with Perthes disease compared with controls (62). Another recent study, while confirming the skeletal maturation delay in children with Perthes disease, demonstrated no difference in IGF1 measured with IGF2-blocked binding sites and IGFBP3 serum concentrations with respect to bone age (63). This group disputed the claims of disturbance of the hypothalamic-pituitary-somatomedin axis in patients with Perthes disease. The reported differences in the various studies, in some cases, may be attributable in part to the methods used to measure IGF1. There is an increased incidence of hernia in patients with Legg-Calvé-Perthes syndrome and their first-degree relatives. There is also an increased incidence of minor congenital abnormalities in affected patients (24,64,65 and 66).

The cause of Legg-Calvé-Perthes syndrome remains unknown. Many etiologic theories have been proposed. In the early part of the 20th century most investigators thought that it was a disease of an inflammatory or infectious nature (3,4 and 5,67,68 and 69). Phemister (16,70) believed that the disease was an infectious process, although cultures were negative. Axhausen (67) believed that it was caused by bacillary embolism in which the infection either was not manifested, or was too weak and healed quickly. As late as 1975, Matsoukas (71) demonstrated an association between Legg-Calvé-Perthes syndrome and prenatal rubella.

Until the 1950s, trauma was considered by many investigators to be the cause, or a significant contributing factor, of Perthes disease (1,72,73,74,75,76,77 and 78). As with most childhood orthopaedic conditions, a significant number of patients may relate an episode of trauma to the onset of symptoms.

Many authors, particularly eastern European investigators, thought that Legg-Calvé-Perthes syndrome was of congenital origin, and that there was a relationship between this disease and congenitally dislocated hips (79,80,81,82,83,84 and 85). Glimcher (86) proposed that cytotoxic agents of external or endogenous origin may be responsible for bone cell death. At one time, Perthes disease was believed to be related to hypothyroidism (87,88 and 89); this has since been disproved (90,91). Recent reports demonstrate moderately increased plasma concentrations of free thyroxin and free triiodothyronine in Perthes disease patients compared with controls (61). The causative effects on Perthes disease of the aforementioned findings, and the reduced levels of IGF1 reported in the early disease stages, have yet to be determined. These findings do, however, provide additional evidence that growth-related systemic abnormalities exist in patients with Legg-Calvé-Perthes syndrome (61).

Transient synovitis has been thought by many investigators to be a precursor to the condition. Gershuni (92) reported that 25% of children with benign transient synovitis developed Legg-Calvé-Perthes disease, whereas Jacobs (92a) reported three cases of Legg-Calvé-Perthes disease among 25 patients with acute transient synovitis. Although all hips with Perthes disease have synovitis, especially early in the course of the disease, and many have persistent synovitis for years (93,94,95,96 and 97), a review of the literature reveals that an average of 1 to 3% of patients with a history of transient synovitis later develop Legg-Calvé-Perthes syndrome (98,99,100,101,102 and 103). Chuinard (104) and Craig and colleagues (74,75) have proposed that excessive femoral neck anteversion is a causative factor in the development of Legg-Calvé-Perthes syndrome.

Most current etiologic theories involve vascular embarrassment. The blood supply to the proximal femur has been elucidated by many authors. The terminology used in the literature varies. However, there are three main sources of blood to the proximal femur: an extracapsular arterial ring, the ascending cervical (retinacular branches) vessels, and the artery of the ligamentum teres (105) (Fig. 24-1). The extracapsular ring is formed mostly by the medial and lateral femoral circumflex vessels. This ring gives rise to the ascending cervical branches, which are extracapsular, and these in turn give rise to the metaphyseal and epiphyseal branches. The anterior portion of the extracapsular ring is formed primarily by the lateral femoral circumflex artery. The posterior, lateral, and medial aspects of the ring are formed by the medial femoral circumflex artery. Chung (105) found that the greatest volume of blood flow to the femoral head comes through the lateral ascending cervical vessel (the termination of the medial femoral circumflex artery), which crosses the capsule in the posterior trochanteric fossa. Both Trueta and Pinto de Lima (106,107) and Chung (105) demonstrated that the anterior vascular anastomotic network (Fig. 24-1) is much less extensive than the posterior anastomotic network, particularly in specimens from patients aged 3 to 10 years, which correlates with the age range of Legg-Calvé-Perthes syndrome. Chung also demonstrated that the anterior anastomotic network was incomplete more often in boys, which correlates with male gender predominance in Legg-Calvé-Perthes syndrome. Ogden (108) found vessels crossing the physeal plate in some of his specimens, but Chung disagreed, believing that the vessels did not actually cross the plate, but passed through the peripheral perichondral fibrocartilaginous complex.

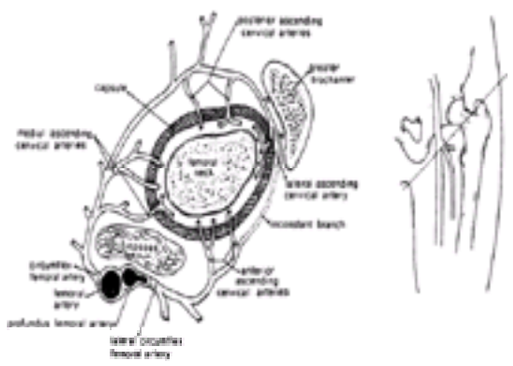

FIGURE 24-1. The blood supply to the normal proximal femur in a child. (Adapted from ref. 105, with permission.)

Interruption of the blood supply to the femoral head in Perthes disease was first demonstrated in 1926, when Konjetzny (69) showed obliterative vascular thickening in a pathologic specimen. Theron (109) used selective angiograms to demonstrate obstruction of the superior retinacular artery in patients with Legg-Calvé-Perthes syndrome. In 1973, Sanchis and colleagues (110) proposed the second infarction theory. They experimentally infarcted the femoral head of animals labeled with tetracycline. They were unable to produce a typical histologic picture of Legg-Calvé-Perthes syndrome with only a single infarction. With a second infarction, however, they were able to show a more characteristic histologic picture of Legg-Calvé-Perthes syndrome. Inoue and colleagues (111) later correlated this double-infarction theory with human histologic material. Clinical correlation for this theory is provided by reports of recurrent Perthes disease (112,113) (Fig. 24-2). Salter and Thompson (114,115) proposed that Legg-Calvé-Perthes syndrome is a complication of aseptic necrosis, and that a fracture manifested radiographically by a subchondral radiolucent zone initiates the resorptive phase. Kleinman and Bleck (116) demonstrated increased blood viscosity in a group of patients with Legg-Calvé-Perthes syndrome, possibly leading to decreased blood flow to the femoral epiphysis. Vascular embarrassment, caused by intraosseous venous hypertension and venous obstruction, has been demonstrated by several authors (30,117,118).

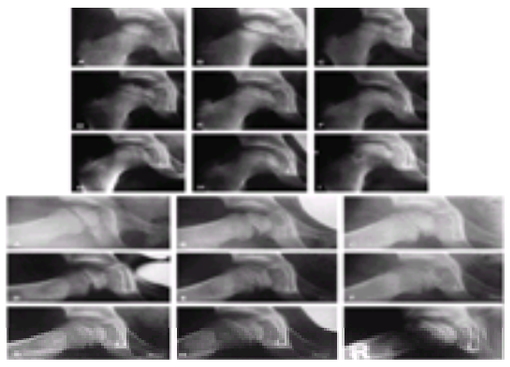

FIGURE 24-2. A 4-year, 8-month-old girl was treated for left hip Perthes disease (late fragmentation phase) beginning in January 1983. Anteroposterior (**top**) and Lauenstein (**bottom**) views of the right hip at different stages, January 1983 to December 1987. **A:** View of the right hip at the time of initial presentation, with no signs of involvement (January 1983). **B:** Early involvement, patient still asymptomatic (September 1983). **C** to **F:** Progressive healing of the right femoral epiphysis in May 1984 (**C**), August 1984 (**D**), May 1985 (**E**), and November 1985 (**F**). **G:** The femoral head was completely healed by December 1986. **H:** Recurrent changes in the density of the femoral head and a subchondral fracture that involves less than 50% of the head (Catterall group 2) were seen in June 1987. **I:** Complete involvement of the ossific nucleus (Catterall group 4) with diffuse metaphyseal reaction and cysts was seen in December 1987. (From ref. 113, with permission.)

Recent attention has been centered on reports of protein C and S deficiencies in patients with Perthes syndrome (119,120,121 and 122). Thrombophilia induced by low levels of protein C or S, or by resistance to activated protein C, has been associated with the development of osteonecrosis and with arterial thrombosis (120,121,122 and 123). These investigators have suggested routine screening of the levels of protein C, protein S, and lipoprotein(s); plasminogen activator-inhibitor activity; and stimulated tissue-plasminogen activator activity in patients with Perthes syndrome (120). They believe that another value of routine coagulation screening for children who have Legg-Perthes disease lies in the familial nature of the autosomal dominant coagulopathies. These disorders are associated with thrombotic events in 60% of adult family members. The authors believe that the diagnosis of a coagulation disorder in a child who has Legg-Perthes disease can and should lead to studies in first-degree relatives, with the goal of preventing thrombotic events in families. More recent literature has refuted the role of thrombophilia in the cause of Perthes disease (124,125).

PATHOGENESIS

Histologically, the changes seen in Legg-Calvé-Perthes syndrome must be put in perspective. Few human specimens have been studied, and each specimen studied represents only one stage in the disease process. Most specimens are from curettage or core biopsies, which show only one portion of the involved head at a time.

In the developing normal human femoral head, the secondary center of ossification is covered by cartilage that is composed of three zones (Fig. 24-3). The superficial zone has the morphologic properties of adult articular cartilage. Beneath this zone is the zone of epiphyseal cartilage, which is histochemically different. The zone becomes thinner as the skeleton matures and the epiphyseal bone enlarges in size. Underneath the epiphyseal cartilage is a thin zone formed by small clusters of cartilage cells that hypertrophy and degenerate. Capillaries penetrate this zone from below, and bone forms at a much slower rate than in the metaphysis (126).

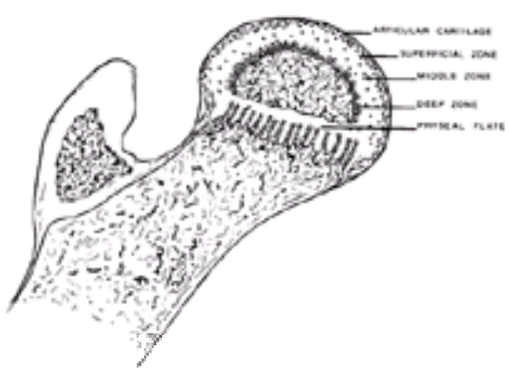

FIGURE 24-3. Proximal femur in a child.

Histologic changes of the epiphyseal and physeal cartilage of patients with Legg-Calvé-Perthes syndrome (Fig. 24-4 and Fig. 24-5) were described as early as 1913. These and current studies demonstrate that the superficial zone of the epiphyseal cartilage covering the affected femoral head is normal but thickened. In the middle layer of the epiphyseal cartilage, however, two types of abnormalities are seen: areas of extreme hypercellularity, with the cells varying in size and shape and often arranged in clusters, and areas containing a loose fibrocartilage-like matrix. These abnormal areas in the epiphyseal cartilage have histochemical and ultrastructural properties different from normal cartilage and fibrocartilage. Areas of small secondary ossification centers are evident, with bony trabeculae of uneven thickness forming directly on the abnormal cartilage matrix (126,127,128,129,130 and 131). The superficial and middle layers of epiphyseal cartilage are nourished by synovial fluid and continue to proliferate, whereas only the deepest layer of the epiphyseal cartilage is dependent on the epiphyseal blood supply, and is affected by the ischemic process (126,129,132,133,134,135,136,137 and 138).

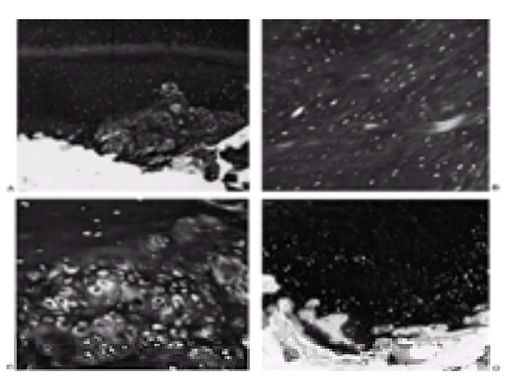

FIGURE 24-4. A: Superficial zone cartilage and epiphyseal cartilage of the femoral head. The superficial zone cartilage is normal and is Alcian blue positive. The epiphyseal cartilage stains with periodic acid–Schiff, but only the perilacunar rims stain with Alcian blue. In the epiphyseal cartilage there is an area of disorganized abnormal Alcian blue–positive cartilage. (Alcian blue with 0.6 mol/L magnesium chloride; original magnification, ×25.) **B:** Abnormal area of epiphyseal cartilage. The matrix has a fibrillated appearance and is strongly Alcian blue positive. (Alcian blue with 0.6 mol/L magnesium chloride; original magnification, ×100.) **C:** Junction between the normal and abnormal epiphyseal cartilage. Normal cartilage is periodic acid–Schiff positive, whereas the abnormal cartilage is very cellular, and retains Alcian blue positivity at high concentrations of magnesium chloride. (Alcian blue with 0.7 mol/L magnesium chloride; original magnification, ×165.) **D:** Extensive area of abnormal epiphyseal cartilage in the femoral head. Bone seems to form directly on the abnormal cartilage. Abnormal cartilage retains intense Alcian blue positivity at a high concentration of magnesium chloride, but loses that positivity and becomes strongly positive to periodic acid–Schiff at the bone-cartilage junction. (Alcian blue with 0.7 mol/L magnesium chloride, periodic acid–Schiff, and Weigert hematoxylin stains; original magnification, ×40.) (From ref. 126, with permission.)

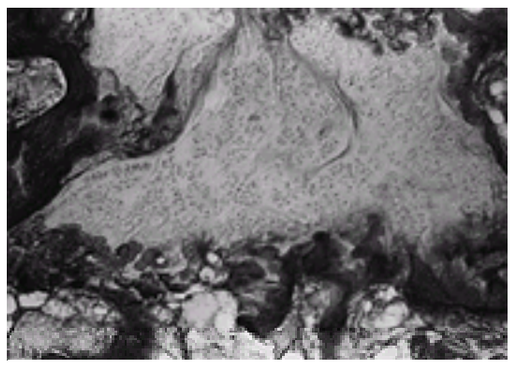

FIGURE 24-5. Photomicrograph showing a large area of cartilage between the bone trabeculae of the femoral neck. (Original magnification, ×80.) (From ref. 127, with permission.)

The physeal plate in Legg-Calvé-Perthes syndrome shows evidence of cleft formation with amorphous debris and extravasation of blood. In the metaphyseal region, endochondral ossification is normal in some areas, but in others the proliferating cells are separated by a fibrillated cartilaginous matrix that does not calcify (Fig. 24-5). The cells in these areas do not degenerate but continue to proliferate without endochondral ossification, leading to tongues of cartilage extending into the metaphysis as bone growth proceeds in adjoining areas (126,127,131,139,140 and 141).

Catterall and colleagues (139) have demonstrated thickening, abnormal staining, sporadic calcification, and diminished evidence of ossification in the deep zone of the articular cartilage of the unaffected hip. They also demonstrated the physeal plate in these unaffected hips to be thinner than normal, with irregular cell columns and cartilage masses remaining unossified in the primary spongiosa.

Some of these cartilage changes have been seen in other epiphyseal plates, such as the greater trochanter and the acetabulum (142). In the human specimens described by Ponseti (127), the physeal plate lesions were long-standing in view of the fact that there was only necrotic bone in the femoral head and no evidence of repair. Catterall and colleagues reported similar cartilaginous lesions in a patient with Catterall group 1 disease, in which there is no sequestrum formation (129,131) (Fig. 24-6). The various reported physeal plate and epiphyseal plate lesions resemble the lesions produced by Ponseti and Shepard in rats by the administration of aminonitrils (143). These epiphyseal and physeal plate changes, in conjunction with the unusual and precarious blood supply of the proximal femur, make the femoral head vulnerable to the effects of physeal plate disruption.

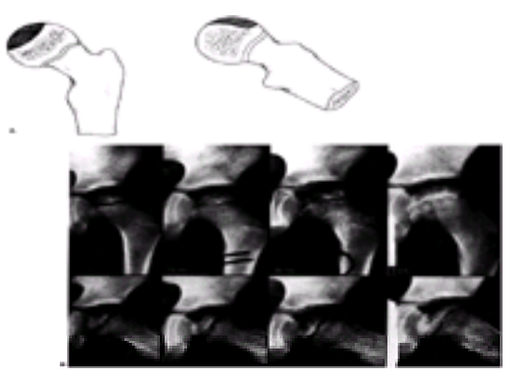

FIGURE 24-6. A: Catterall group 1 disease shows anterior head involvement with no evidence of sequestrum, a subchondral fracture line, or metaphyseal abnormalities. **B:** Catterall group 1 disease 1 week to 5 years after symptom onset.

Skeletal surveys of patients with Legg-Calvé-Perthes syndrome confirm the histologic abnormalities by demonstrating irregularities of ossification in other epiphyses, especially Kohler disease of the navicular (67,127,144). Harrison and Blakemore (145), studying 153 consecutive patients with unilateral Legg-Calvé-Perthes disease, found that 48% had contour irregularities in the contralateral normal capital epiphysis compared with 10% of matched controls. Aire and colleagues (146) demonstrated that the unaffected hip showed anterior and lateral flattening at the time of diagnosis of the affected hip. These data suggest that Legg-Calvé-Perthes disease is a generalized process affecting other epiphyses, and therefore should not be referred to as a disease, but should be called Legg-Calvé-Perthes syndrome.

Disorganization of the physeal plate, together with minimal trauma, may interrupt the continuity of retinacular vessels, causing necrosis (126,127). This finding, in conjunction with the aforementioned epidemiologic, histologic, and radiologic data, supports the belief that Legg-Calvé-Perthes syndrome may be a localized manifestation of a generalized disorder of epiphyseal cartilage in the susceptible child (10,30,43,52,65,126,147,148).

Radiographic Stages

Radiographically, Legg-Calvé-Perthes syndrome can be classified into four stages: initial, fragmentation, reossification, and healed. In the initial stage (18,149), one of the first signs of this condition is failure of the femoral ossific nucleus to increase in size because of a lack of blood supply (Fig. 24-7). The affected femoral head appears smaller than the opposite, unaffected ossific nucleus. Widening of the medial joint space, as initially described by Waldenstrom (18,151) (Fig. 24-7), is another early radiographic finding. Widening has been theorized by some researchers to be caused by synovitis. Others have proposed that this finding is secondary to decreased head volume caused by necrosis and collapse and a secondary increase in blood flow to the soft tissue parts, such as the ligamentum teres and pulvinar, causing the head to displace laterally (149,152). Synovitis is present in patients with Perthes disease to varying degrees (93,94,96,97,153,154), but the medial joint space widening is probably most often an apparent radiographic phenomenon secondary to epiphyseal cartilage hypertrophy (Fig. 24-8).

FIGURE 24-7. Anteroposterior roentgenogram of a hip in a patient who developed Legg-Calvé-Perthes disease. On the initial film, taken 6 months after symptom onset, the right ossific nucleus is smaller than the left, and the medial joint space is widened. Note also the retained density of the ossific nucleus compared with the normal hip and the relative osteopenia of the viable bone of the proximal femur and pelvis. Ten months after symptom onset, the evolution of the radiographic changes are seen. (From ref. 150, with permission.)

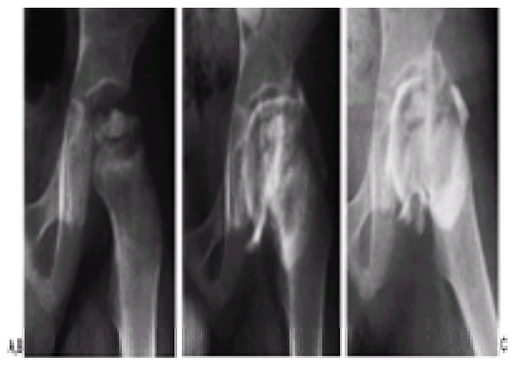

FIGURE 24-8. A 4-year, 9-month-old boy with Catterall group 4 disease and at-risk status. **A:** Plain radiograph. **B:** Arthrogram in neutral abduction, adduction, and rotation. There is enlargement and flattening of the cartilaginous femoral head, and the lateral margin of the acetabulum is deformed by the femoral head. **C:** Arthrogram in abduction and slight external rotation. The femoral head hinges on the lateral edge of the acetabulum, further deforming the lateral acetabulum. Slight pooling of dye is seen medially.

In the initial stage, the physeal plate is irregular and the metaphysis is blurry and radiolucent (82) Fig. 24-9B). The femoral ossific nucleus appears radiodense (155). This relative increased radiodensity may be caused by osteopenia of the surrounding bone (156,157), or an increase in the mass of bone in the area.

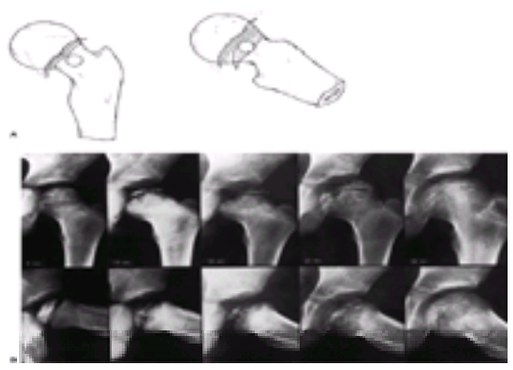

FIGURE 24-9. A: Catterall group 4 disease shows whole head movement, with either diffuse or central metaphyseal lesions and posterior remodeling of the epiphysis. **B:** Catterall group 4 disease 2 months to 52 months after onset of symptoms. Note the stages: 14 months, fragmentation; 18 months, early reossification; 25 months, late reossification; 52 months, healed. Note also the growth-arrest line and evidence of reactivation of the growth plate along the femoral neck.

The second radiographic stage is called the “fragmentation phase” (18,149). Radiographically, the repair aspects of the disease become more prominent (Fig. 24-9B). The bony epiphysis begins to fragment, and there are areas of increased radiolucency and increased radiodensity. Increased radiodensity at this stage may be caused by new bone forming on old bone (158,159,160,161 and 162) and thickening of existing trabeculae (160). The subchondral radiolucent zone (i.e., crescent sign) first described by Waldenstrom (151,163), and later popularized by Caffey (164), is one of the very early signs of Legg-Calvé-Perthes syndrome in the fragmentation stage (Fig. 24-2; Fig. 24-10). According to Salter and associates (115,165), this radiographic finding results from a subchondral stress fracture, and the extent of this zone determines the extent of the necrotic fragment.

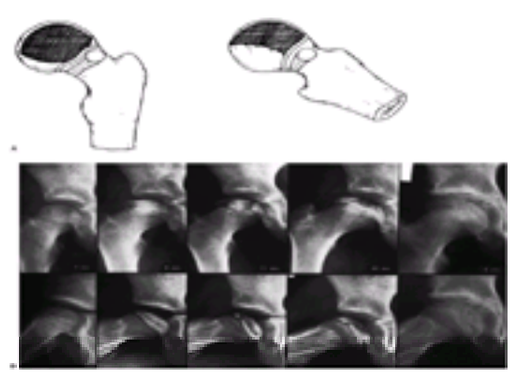

FIGURE 24-10. A: Catterall group 3 disease shows large sequestrum involving three-fourths of the head. The junction between the involved and the uninvolved portions is sclerotic. Metaphyseal lesions are diffuse, particularly anterolaterally, and the subchondral fracture line extends to the posterior half of the epiphysis. The lateral column is involved. **B:** Catterall group 3 disease 4 months to 6 years after symptom onset. Note the involvement of the lateral pillar, as well as the subchondral radiolucent zone on the radiograph taken 8 months after onset of symptoms.

The third radiographic stage is the reparative or reossification phase (18,149). Radiographically normal bone density returns, with radiodensities appearing in areas that were formerly radiolucent. Alterations in the shape of the femoral head and neck become apparent (Fig. 24-9B).

The final stage is the healed phase. In this stage, the proximal femur is left with any residual deformity from the disease and the repair process (Fig. 24-9B). Legg-Calvé-Perthes syndrome cannot be compared with aseptic necrosis after fracture of the neck of the femur or traumatic dislocations of the hip in the young child. In these situations, the vascular insult to the femoral head usually heals rapidly without going through the prolonged stages of fragmentation and repair that are seen in children with Legg-Calvé-Perthes syndrome (126,166,167).

Pathogenesis of Deformity

The head deformities that occur in Legg-Calvé-Perthes syndrome come about in many ways. First, there is growth disturbance in the epiphyseal and physeal plates. In the physeal plate, this may result in premature closure with resultant deformity, such as central physeal arrest, causing a shortened neck and trochanteric overgrowth (168,169) (Fig. 24-11). The repair process itself may cause physical compaction resulting from structural failure and displacement of tissue elements (86). During the healing process, the femoral head will deform according to the asymmetric repair process and the applied stresses. The molding action of the acetabulum during new bone formation also may be a factor (170,171). With deformity of the femoral head, the acetabulum, particularly its lateral aspect, is deformed secondarily.

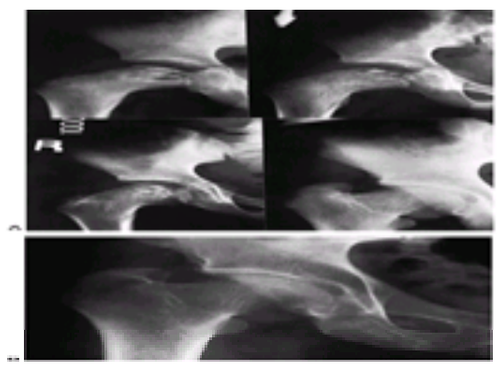

FIGURE 24-11. A: A 6-year-old boy with Catterall group 4 disease. Age 6 years, 2 months, fragmentation stage (**upper left**). Age 6 years, 9 months, early reossification stage (**upper right**). Age 8 years, 9 months, healed (**lower left**). Age 16 years, 2 months, skeletally mature (**lower right**). Patient healed with a central physeal arrest pattern. **B:** A 51-year-old patient at 45-year follow-up. He was asymptomatic and had a full range of motion (Iowa Hip Rating, 95 of 100 points). At maximal fragmentation the hip is classified as showing Catterall group 4, Salter-Thompson type B, and lateral pillar type C disease.

The articular cartilage of the femoral head shows changes in shape secondary to the disease process itself. The deepest layer of the articular cartilage is nourished by the subchondral blood supply. This layer is often devitalized in Legg-Calvé-Perthes syndrome (129,132,133,134 and 135,137). The superficial layers that are nourished by synovial fluid continue to proliferate, causing an increase in the thickness of the articular cartilage. With trabecular collapse and fracture and articular cartilage overgrowth, significant head deformities develop that are manifested clinically by loss of abduction and rotation (Fig. 24-8).

The source of vessel ingrowth is under debate. Many investigators (132,133,172) have demonstrated that the new blood vessels arise from the metaphysis and the metaphyseal periosteum, and penetrate between the epiphysis and the joint cartilage into the epiphysis. Other investigators have shown metaphyseal vessels penetrating the physeal plate into the epiphysis (108,173). When the blood supply of the subchondral area is restored, it generally comes from the periphery and moves to the center, restoring endochondral ossification at the periphery first and causing asymmetric growth (93,137) (Fig. 24-12). In addition, there is abnormal ossification of the disorganized matrix of the epiphyseal cartilage. Finally, there is periosteal bone growth and reactivation of the physeal plate along the femoral neck, with abnormally long cartilage columns leading to coxa magna and a widened femoral neck (126,127).

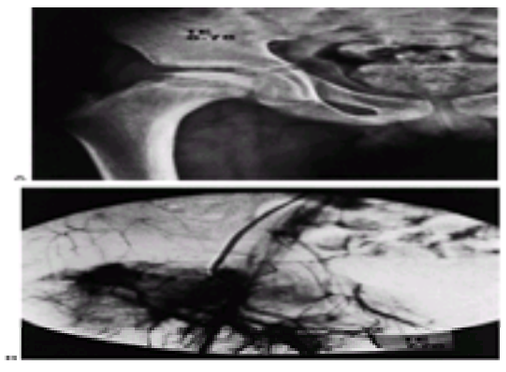

FIGURE 24-12. A: A 12-year-old boy with total head involvement in the early fragmentation stage of the disease. **B:** Subtraction arteriogram demonstrating the avascularity of the central portion of the head, with increased vascularity at the periphery. (Courtesy of J. G. Pous, M.D., Montpellier, France.)

The actual deformity that develops is profoundly influenced by the duration of the disease. This, in turn, is proportional to the extent of the epiphyseal involvement, the age of the patient at disease onset, the remodeling potential of the patient, and the stage of disease when treatment is initiated. An additional factor is the type of treatment (174,175,176 and 177).

Patterns of Deformity

Four patterns of residual deformity result from Legg-Calvé-Perthes syndrome: coxa magna, premature physeal arrest patterns, irregular head formation, and osteochondritis dissecans (169,178). Coxa magna (Fig. 24-9B) develops with ossification of the hypertrophied articular cartilage, and also from reactivation of the physeal plate along the femoral neck. This also occurs in conjunction with periosteal new bone formation along the femoral neck.

Premature physeal plate closure generally leads to one of two patterns of arrest: central or lateral. In the central arrest pattern, the femoral neck is short and the epiphysis is relatively round (Fig. 24-11). There is trochanteric overgrowth and mild acetabular deformity. In the lateral arrest pattern, the femoral head is tilted externally (Fig. 24-13). There is also trochanteric overgrowth. The epiphysis is oval, with a corresponding acetabular deformity (169,178).

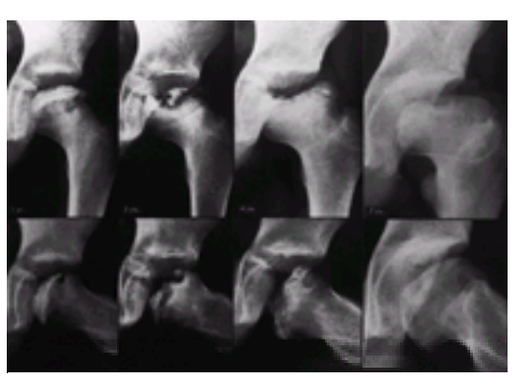

FIGURE 24-13. A 7-year follow-up from presentation in a patient with Catterall group 4 disease, who had a lateral growth-arrest pattern. At maximal fragmentation, the radiographic classification would be Salter-Thompson type B and lateral pillar type C disease. (From ref. 179, with permission.)

The irregular head may occur secondary to certain patterns of physeal arrest, but it also may be an iatrogenic deformity from attempts at “containment” of a noncontainable head (Fig. 24-14). After the femoral head becomes deformed and is no longer containable within the acetabulum, the only motion that is allowed is in the flexion and extension plane, with abduction leading to hinging on the lateral edge of the acetabulum. This hinge abduction causes acetabular and secondary head deformity (180,181 and 182) (Fig. 24-8).

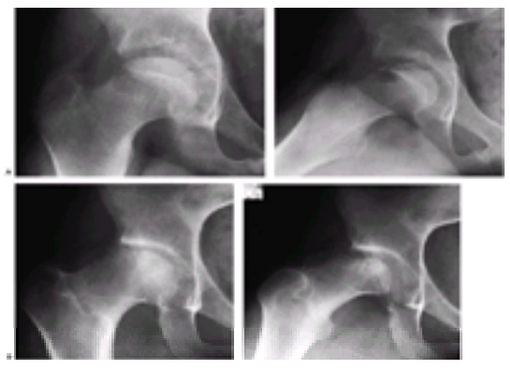

FIGURE 24-14. An 11-year, 3-month-old girl with Catterall group 3 disease had a noncontainable head, yet was treated for a long time in an abduction brace. **A:** Anteroposterior radiograph in the early fragmentation stage (**left**) and Lauenstein radiograph in the early fragmentation stage (**right**). **B:** At age 14 years, the patient was skeletally mature, and had an irregular femoral head. Anteroposterior radiograph (**left**) and Lauenstein radiograph (**right**). (From ref. 179, with permission.)

The fourth and least common (3% incidence) residual deformity that occurs in Legg-Calvé-Perthes syndrome is osteochondritis dissecans (Fig. 24-15). This usually occurs with the late onset of disease, and with prolonged, ineffectual repair (169,178,183,184 and 185).

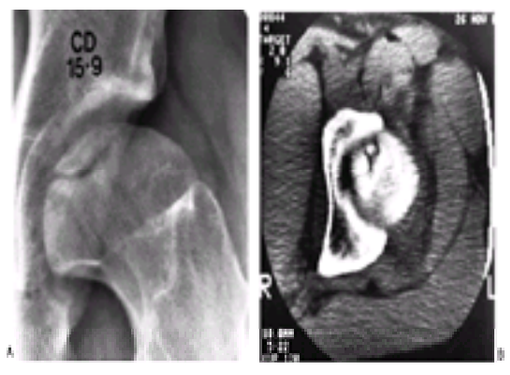

FIGURE 24-15. A: A 15-year-old boy, with onset of disease at 8.5 years of age, returned to the physician with pain and synovitis. Anteroposterior radiograph demonstrates osteochondritis of the femoral head. **B:** Computed tomographic scan shows multiple fragments that appear as one on the radiograph.

NATURAL HISTORY

The formulation of disease treatment requires that the treating physician knows what happens to the patient without treatment (natural history), and what prognostic factors lead to an adverse outcome. The treating physician must determine which of these adverse prognostic factors can be affected by treatment. A treatment plan is then initiated, and long-term follow-up determines whether treatment favorably alters the natural history of the disease over the long term. The fundamental problem in developing treatment plans for patients with Legg-Calvé-Perthes syndrome is the paucity of natural history data (65,186,187,188 and 189).

Catterall (186) compared 46 untreated hips of Murley and Lloyd-Roberts with a matched control group of 51 hips treated with a weight-relieving caliper. The average age at diagnosis was 4 years, 6 months, and the average follow-up was 10 years, 5 months, with a range of 4 to 18 years. The patients were evaluated according to the grading system of Sundt, which requires some subjective assessments (190). The 10-year average follow-up in this series is too short to determine the outcomes of patients and thus the natural history of the disease, because most patients with childhood hip disease do well, regardless of the radiographic appearance in their early years (191,192,193 and 194). In addition, no data are presented on the interrater or intrarater reliability of the outcome criteria.

Catterall also reported on 97 untreated patients gathered from around the British Isles. The average follow-up in this series was only 6 years, and the results were graded according to the system of Sundt (190). The outcomes of this group of patients (Table 24-1) are widely quoted in the literature as a comparison for outcomes of various treatment modalities. Unfortunately, very few articles in the literature use the same grading system for outcomes, and the follow-up of this group is too short to be defined as natural history.

	Good	Fair	Poor
Group 1	27 —92%	1	0
Group 2	25	6	2
Group 3	4	7	11 —91%
Group 4	0	4	10
Total	56 (57%)	18 (19%)	23 (24%)

(From ref. 65, with permission.)

TABLE 24-1. RESULTS OF 97 UNTREATED HIP

The only other article labeled “natural history” in the literature (189) is not a natural history study, but a study of patients treated by different methods, from three centers. This study attempted to establish a relation between residual deformity and degenerative joint disease, and to identify clinical and radiographic factors in the active phase of disease that would be predictive of hip deformity and degenerative joint disease. Thus, decision-making with reference to treatment is difficult because of the lack of true long-term natural history data.

Long-term Follow-up Results

Although there is little information available on natural history, there are many long-term follow-up studies of patients with Legg-Calvé-Perthes syndrome. The long-term studies that are available suffer from the faults of retrospective long-term reviews, in that most series contain only small numbers of patients, with many of the original patients not traced; original radiographs often are not available. Many of the longer series contain patients diagnosed in the years 1910 to 1940, when little was known about the disease, prognostic factors, and radiographic classifications. In most series, patients are combined, regardless of the extent of epiphyseal involvement, age at disease onset, age at the beginning of treatment, and stage of the disease at treatment initiation. Various treatment modalities are combined in many series, and control groups generally are absent. Because of these inherent problems, different grading systems used to judge clinical and radiographic end results, and lack of interrater and intrarater reliability data, it is difficult to compare and contrast the various reported series. Despite these shortcomings, a great deal has been learned about the prognosis in Legg-Calvé-Perthes syndrome.

In reviewing long-term follow-up studies, it is apparent that results can improve with time, because remodeling potential continues until the end of growth (65,195)

(Fig. 24-9 and Fig. 24-10). Mose wrote that, “for a precise prognosis, conclusions from any measurements ought not be made before the patient reaches the age of 16, when growth stops,” (194). Reviews of the outcomes of treatment modalities before skeletal maturity must be viewed as preliminary reports.

Twenty to 40 years after the onset of symptoms, the majority (70 to 90%) of patients with Legg-Calvé-Perthes syndrome are active and free of pain. Most patients maintain a good range of motion, despite the fact that few patients have normal-appearing radiographs. Clinical deterioration and symptoms of increasing pain, decreasing range of motion, and loss of function are observed only in patients with flattened irregular heads at the time of primary healing, and in patients with premature physeal closure, as indicated by neck shortening, head deformity, and trochanteric overgrowth (175) (Fig. 24-13).

Danielsson and Hernborg (196) reported a 33-year follow-up of 35 patients. Twenty-eight of the 35 patients were free of pain, with 34 of 35 functioning without restrictions. In a 34-year follow-up, Hall (197) reported 71% satisfactory results in 209 cases. Perpich and colleagues (198) reported a 30-year follow-up of 37 patients. The average Iowa Hip Rating was 93 of a possible 100 points. Eighty-five percent of the patients had good clinical results, despite the fact that only 33% had spherical femoral heads, as rated by the Mose Sphericity Scale (194) (Fig. 24-16). Forty-three percent of the patients had poor Mose ratings; however, of these patients, 76% had good clinical results.

FIGURE 24-16. Mose Sphericity Scale.

Ratliff (199) followed 34 patients for an average of 30 years, and noted that 80% were fully active and free of pain, whereas only 40% were roentgenographically normal. He followed 16 of these patients for an additional 11 years (200), and noted that, despite the fact that only one-third of them had good anatomic results, “deterioration rarely occurred and many patients had no pain and normal activity.”

Yrjonen (191) followed 96 patients (106 hips), all of whom had noncontainment treatment, for an average of 35 years. At maturity, 61% had poor results by the Mose criteria. In a final follow-up, 48% had evidence of degenerative joint disease. However, at an average 35-year follow-up, only 4% had undergone total hip arthroplasty, with an additional 13% having clinical symptoms significant enough to warrant arthroplasty. Ippolito and colleagues (192) reported on 61 patients with an average follow-up of 25 years. Only 19% of their patients had poor results, as measured by the Iowa Hip Rating, at final follow-up. W.J. Cumming (personal communication, 1993) reported on 82 patients with 95 involved hips treated by prolonged frame recumbency, with an average follow-up of 38 years. Only 10% of the patients had required arthroplasty at follow-up, with an additional 10% having symptoms significant enough to warrant arthroplasty.

Gower and Johnston (201) reported on 30 nonoperated hips with an average 36-year follow-up. This series is representative of the 20- to 40-year long-term series reported in the literature. The average Iowa Hip Rating for these 30 patients was 91 points. The typical patient had minimal shortening, absent or mild hip pain, and minimal or no functional impairment, with respect to job and activities of daily living. Ninety-two percent of the patients had Iowa Hip Ratings greater than 80 points, and only 8% of the patients had undergone arthroplasty.

In follow-up studies beyond 40 years, hip function begins to deteriorate. In another study of the Iowa group of patients at 48-year follow-up, McAndrew and Weinstein (193) reported that only 40% of patients maintained an Iowa Hip Rating of greater than 80 points. Forty percent of the patients had undergone arthroplasty, and an additional 10% were suffering from disabling osteoarthritis symptoms, but had not yet undergone arthroplasty (Fig. 24-17). Thus, at 48-year follow-up, 50% of the patients had disabling osteoarthritis and pain, and an additional 10% had Iowa Hip Ratings of less than 80 points. The prevalence of osteoarthritis in this group of patients was ten times that found in the general population in the age range of the studied patients (175). Mose followed a group of patients into the seventh decade of life. All of the patients with irregular femoral heads had degenerative arthritis. Of those patients with femoral heads that Mose classified as “normal, ball shaped,” no patient had degenerative joint disease by the middle of the fourth decade, but 67% had severe degenerative arthritis by the middle of the seventh decade (194). Therefore, the follow-up studies beyond 40 years demonstrate marked reduction of function, with the overwhelming majority of patients developing degenerative joint disease by the sixth and seventh decades (175,189,192,193 and 194).

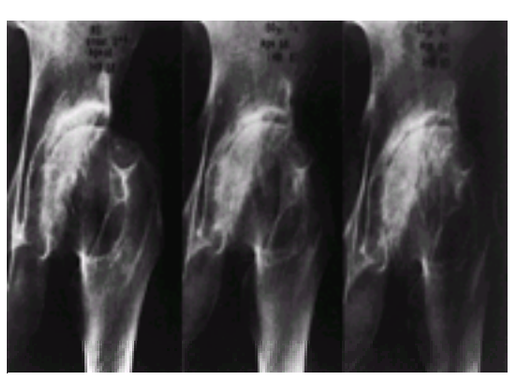

FIGURE 24-17. This patient had disease onset at 8.3 years of age. At 46 years of age (38-year follow-up), the Iowa Hip Rating was 88 points (**left**). At 58 years of age (50-year follow-up), there was a loss of 21 points on the Iowa Hip Rating, to 67 (**center**). At 60 years of age, just before arthroplasty, the Iowa Hip Rating was 60 points (**right**). (From ref. 175, with permission.)

Prognostic Factors

In reviews of long-term series of patients with Legg-Calvé-Perthes syndrome, certain clinical and roentgenographic features have been identified that have prognostic value (175,179,180,191,202,203,204 and 205) (Table 24-2). The most important prognostic factor in outcome is the residual deformity of the femoral head, coupled with hip joint incongruity (206,207 and 208). Femoral head deformity and joint incongruity are multifactorial problems. They are interrelated with all of the other prognostic factors. It must be kept in mind that Legg-Calvé-Perthes syndrome represents a growth disturbance of the proximal femur; the epiphyseal and physeal cartilage is abnormal. Other key factors involved in the development of deformity include the extent of epiphyseal involvement and the varying degrees and patterns of premature physeal closure associated with this condition (209).

Deformity of the femoral head
Hip joint incongruity
Age at disease onset
Extent of epiphyseal involvement
Growth disturbance secondary to premature physeal closure
Protracted disease course
Remodeling potential
Type of treatment (?)
Stage at treatment initiation

TABLE 24-2. PROGNOSTIC FACTORS

Stulberg and colleagues (189) established a relation between residual deformity and degenerative joint disease. This was accomplished by retrospectively examining the long-term outcomes of patients from three different centers treated by various methods (e.g., bed rest, spica cast, ischial weight bearing, brace, crutches, cork shoe lift on the normal side, combination of methods). They attempted to identify clinical and radiographic factors in the active phase of the disease that were predictive of the development of hip deformity. They proposed a radiographic classification of deformity related to long-term outcome (Table 24-3). The more deformity at maturity (i.e., the higher the Stulberg classification), the worse the long-term outcome. However, as noted from long-term follow-up studies, it is the class 5 hips that deteriorate the earliest; they usually have significant symptoms by the end of the fourth decade (191,192,193 and 194). Patients with aspherical congruency (Stulberg class 3 and 4 disease) may have satisfactory outcomes for many years, with most patients undergoing significant functional deterioration in the fifth and sixth decades of life (191,192,193 and 194). This classification scheme, which attempts to classify a three-dimensional deformity using two-dimensional parameters, has recently been shown to have poor interrater and intrarater reliability (210). The general principles expressed by Stulberg and colleagues (189), however, have been shown to have validity with reference to long-term outcome studies. That is, the more out of round the femoral head is, and the greater the discrepancy between the shape of the femoral head and the shape of the acetabulum, the greater the chance of development of early degenerative joint disease.

Class	Radiographic Features	Congruency
1	Normal hip	Spherical
2 (Fig. 24-9 and 24-10)	Spherical femoral head; same concentric circle on anteroposterior and frog-leg lateral views, but with one or more of the following: coxa magna, shorter-than-normal neck, abnormally steep acetabulum	Spherical
3 (Fig. 24-11 and 24-12)	Ovoid, mushroom-shaped (but not flat) head; coxa magna, shorter-than-normal neck, abnormally steep acetabulum	Aspherical
4 (Fig. 24-13)	Flat femoral head and abnormal line of the head, neck, and acetabulum	Aspherical
5 (Fig. 24-14)	Flat head, normal neck and acetabulum	Aspherical incongruency

TABLE 24-3. STULBERG CLASSIFICATION

O'Garra (211), Salter and Thompson (114,115), and others (65,91,127,180,186,212) have confirmed Waldenstrom's original finding that partial or anterior head involvement leads to a more favorable prognosis than whole-head involvement. Catterall (65,128,186) demonstrated the importance of the extent of epiphyseal involvement with regard to prognosis, and proposed four groups, based on the presence or absence of seven radiographic signs in 97 untreated hips (Fig. 24-6, Fig. 24-9, Fig. 24-10 and Fig. 24-18). He compared the final radiograph with the initial radiograph, using the clinical grading of Sundt (190); 90% of the good results in untreated patients were in groups 1 and 2, whereas 90% of the poor results were in groups 3 and 4. This commonly used classification has been criticized as being difficult to use, in that there may be a great deal of interobserver error (202,213). It also has been criticized as being insufficiently prospective, because it may take up to 8 months for the hip to be far enough into the fragmentation phase to determine the extent of epiphyseal involvement (214,215). Furthermore, it also has been noted that the classification may change when radiographs taken during the initial phase are compared with those taken at maximal fragmentation (215,216).

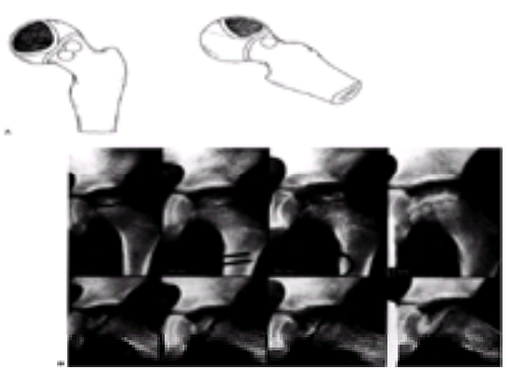

FIGURE 24-18. A: Catterall group 2 disease showing anterolateral involvement, sequestrum formation, and a clear junction between the involved and uninvolved areas. There are anterolateral metaphyseal lesions, and the subchondral fracture line is in the anterior half of the head. The lateral column is intact. **B:** Catterall group 2 disease. Three to 40 months after symptom onset, the lateral pillar is still intact.

Salter and Thompson (115) described a simplified two-group classification based on prognosis and determined by the extent of the subchondral fracture line, which appears early in the course of the disease: in group A, less than half of the head is involved (Catterall groups 1 and 2), and in group B, more than half of the head is involved (Catterall groups 3 and 4). The major determining factor between groups A and B is the presence or absence of a viable lateral column of the epiphysis. This intact lateral column (i.e., Catterall group 2, Salter-Thompson type A) may shield the epiphysis from collapse and subsequent deformity (Fig. 24-18).

The importance of the maintenance of the integrity of the lateral column and the height of the femoral head has been described by several authors (65,197,202,217,218). Hall (197) reported on the long-term follow-up (34 years) of 209 hips. He considered loss of femoral head height, as seen on the initial radiograph, an important prognostic sign. All of his patients in whom there had been a loss of 2 mm or more of height of the femoral head, compared with the unaffected hip, had unsatisfactory results in adult life. When the height of the head was within 2 mm of that of the unaffected hip on the initial radiograph, all but six hips had done well.

Herring and colleagues (202) proposed a radiographic classification based on the radiolucency of the lateral pillar of the femoral head on anteroposterior films during the fragmentation phase of the disease (Table 24-4) (Fig. 24-11, Fig. 24-13 and Fig. 24-19). The lateral pillar occupies the lateral 15 to 30% of the femoral head width on an anteroposterior radiograph. The central pillar occupies approximately 50% of the head width, and the medial pillar occupies 20 to 35% of the medial aspect of the head width on an anteroposterior radiograph.

Type A	No involvement of the lateral pillar; lateral pillar is radiographically normal; possible lucency and collapse in the central and medial pillars, but full height of the lateral pillar is maintained
Type B	Greater than 50% of the lateral pillar height is maintained; lateral pillar has some radiolucency, with maintenance of bone density at a height between 50 and 100% of the original height of the lateral head
Type C	Less than 50% of lateral pillar height is maintained; lateral pillar becomes more radiolucent than in type B, and any preserved bone is at a height of <50% of the original height of the lateral pillar

(From ref. 202, with permission.)

TABLE 24-4. LATERAL PILLAR CLASSIFICATION

FIGURE 24-19. Lateral pillar classification (See Table 24-4 for a description of **A, B,** and **C**).

Herring and colleagues reported on the outcomes of 93 hips in 86 patients with radiographic follow-up to maturity (202). Intraobserver reliability was reported to be 0.78, with a good correlation of outcome, as measured by the classification of Stulberg and colleagues (189). The importance of the integrity of the lateral column is seen in other classifications, with patients in Salter-Thompson type A and Catterall groups 1 and 2 having intact lateral columns. The results of treatment in long-term outcome studies show this to be an important prognostic factor (192,202,216,219,220) (Fig. 24-20).

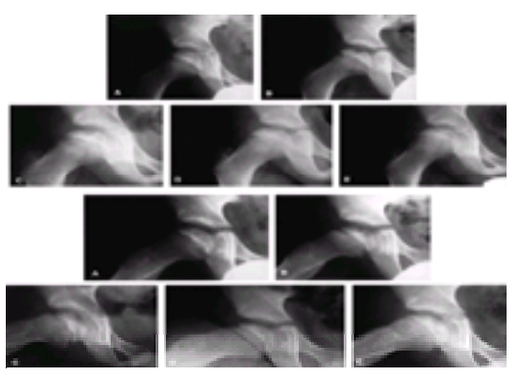

FIGURE 24-20. Anteroposterior (**top**) and lateral (**bottom**) views of a 7-year-old boy who presented with hip pain and a limp. **A:** At presentation, the patient was in the initial radiographic stage of the disease; his prognosis was indeterminate. **B:** Six months after presentation, he had minimal loss of height of the lateral pillar and some radiolucency in that region, as well as significant bone resorption centrally. Note how the lateral pillar maintains its height throughout the course of the disease. **C** to **E:** One year (**C**), 18 months (**D**), and 3 years (**E**) after onset of disease. The patient had only mild symptoms on occasion, and maintained good range of motion throughout the disease course. Only symptomatic treatment was provided.

In analyzing the unexpectedly poor results in each category, Catterall (65,180,186,221,222) identified certain radiographic signs, known as “at-risk signs,” that were associated with poor results (Fig. 24-21). Results in untreated patients show that there were no poor results in patients who did not have two or more of the radiographic at-risk signs during the active stage of the disease. Radiographic at-risk signs include the Gage sign, which is a radiolucency in the lateral epiphysis and metaphysis, and calcification lateral to the epiphysis. These two signs are indicative of early ossification in the enlarged epiphysis. They are present only when the head is deformed. These signs are present when the changes are reversible with treatment (65,223). A third at-risk sign is metaphyseal lesions. These metaphyseal radiolucencies may herald the potential for a growth disturbance of the physeal plate (141,224,225). The final two at-risk signs are lateral subluxation and the horizontal growth plate (226). Lateral subluxation is indicative of a widened head. The horizontal growth plate (adducted hip) is indicative of a developing femoral head deformity that, if left untreated, will lead to fixed deformity, hinge abduction, and subsequent further deformity. These radiographic at-risk signs are manifested clinically by loss of motion and adduction contracture. Catterall reported no poor results in patients not manifesting at-risk signs. The validity of the Catterall classification and the at-risk signs has been confirmed by several series (215,227,228,229,230,231,232,233 and 234), but questioned by others (192,202,216,235).

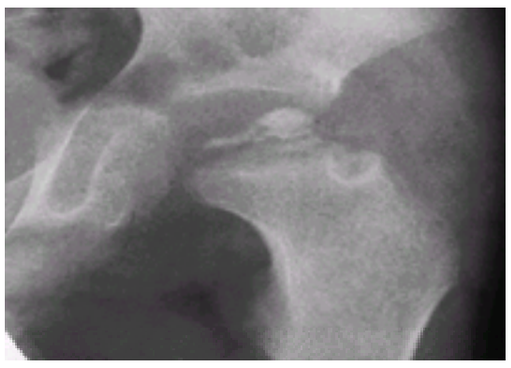

FIGURE 24-21. A 6-year, 5-month-old boy with Catterall group 4 disease demonstrates all of the at-risk signs.

Stulberg and colleagues (189) identified lateral and superior subluxation, which are indicative of significant growth disturbance and flattening of the femoral head, as the key factors associated with the development of class 3 and 4 hips and poor long-term outcome (i.e., after 40 years). Disease onset after age 9 years and partial head involvement, particularly anterosuperior quadrant involvement, were associated with the development of a class 5 hip and the early onset of degenerative joint disease (i.e., third to fifth decade of life).

The duration of the disease is related to the extent of epiphyseal involvement. In general, the greater the extent of epiphyseal involvement, the longer the duration and course of the disease. End results are worse with prolonged disease duration (195,202,236,237). The sex of the patient also relates to the extent of epiphyseal involvement, in that girls affected by Legg-Calvé-Perthes syndrome have a poorer prognosis than boys (238,239). This may be explained by the fact that there are more girls (who tend to be more skeletally mature than comparably aged boys, and hence have less remodeling potential) with Catterall groups 3 and 4 disease, which have a less favorable prognosis (147).

Age of disease onset is the second most significant factor related to outcome; only deformity is more significant. Eight years seems to be the watershed age in most long-term series (175,193,240,241); however, some authors believe that the prognosis is markedly worse for long-term outcome in patients older than 6 years of age at disease onset (192). W.J. Cumming (personal communication, 1993) estimated that 45% of patients with onset of Perthes disease after the age of 6 years have undergone arthroplasty by age 60 years. Patients older than 11 or 12 years, even with Catterall group 2 or Salter-Thompson type A disease, may have poor anatomic and clinical results, even with treatment (242). Age at healing, however, is probably a more important factor (Fig. 24-11). The overall skeletal maturation delay (45) in patients with Legg-Calvé-Perthes syndrome, and the usual compensation for this delay during the pubertal growth spurt (43), contribute to the favorable prognosis in the young patient. The more immature the patient at the time of entering the reossification stage, the greater the potential for remodeling. At-risk signs are also less likely to occur in younger patients, particularly those younger than 5 years of age.

The key relationship for outcomes (prognosis) is femoral head shape and its relationships to acetabular shape (congruency) and joint motion. The shape of the acetabulum is dependent on the geometric pattern within it during growth (170,243,244). In addition, the acetabulum continues to have significant potential for development until age 8 or 9 years (78,80,245). If a young patient develops a deformity, the immature acetabulum conforms to the altered femoral head shape. This may lead to the development of an aspherical congruency (Stulberg classes 3 and 4) that may be compatible with normal function for many years. In older patients (whether “older” means older than 6 years or older than 8 years is subject to debate), the acetabulum cannot conform to the shape of a deformed femoral head; hence, there is a greater chance of the development of an incongruous relationship, leading to early degenerative joint disease (189,191,192,193 and 194,244,246).

The importance of premature physeal arrest secondary to the disease process cannot be overemphasized. Keret and colleagues (171), in a study of 80 patients with Legg-Calvé-Perthes syndrome, showed that 90% of them had interference with physeal growth, with 25% having premature physeal closure. They demonstrated a direct correlation between the severity of physeal involvement and deformity of the head. Clarke and Harrison (247) reported that 47% of 31 patients who presented with painful hips after Legg-Calvé-Perthes syndrome, at an average age of 27 years, had evidence of premature physeal closure.

Various methods have been used to measure the sphericity of the femoral head and congruency at healing. Goff (10,46,248) used a transparent protractor with concentric circles drawn at 2 mm of radial difference to evaluate femoral head shape. Mose further developed Goff's method and applied it clinically. This is the most commonly used method of measuring sphericity (99,249,250 and 251) (Fig. 24-16). It is not clear from the criteria of Mose whether the measurement under consideration is the difference between the outline of the femoral head on the anteroposterior and lateral radiographs or the deviation from a given circle, measured in millimeters, on either the anteroposterior or the lateral radiograph, or a combination of these two parameters. This variability in the application of the method of Mose and colleagues is evident in the literature on Legg-Calvé-Perthes syndrome (90,229,230,252,253,254 and 255).

In general, the template with concentric circles is superimposed on the anteroposterior and lateral roentgenograms. In the author's practice, if the outline of the femoral head is a perfect circle in both projections, it is rated good; less than 2 mm of deviation is rated fair; and more than 2 mm of deviation from a circle, in the anteroposterior or lateral projection, is rated poor. Regardless of measurements used, it is important to realize that, with growth and remodeling of the femoral head and acetabulum, the various parameters used to measure head deformity and congruency may change.

The shape of the head and its congruency, as measured at skeletal maturity, are probably the most reliable indicators of prognosis and the development of degenerative joint disease. Catterall (65) showed, in a follow-up of untreated patients, that 33% of the patients improved in anatomic grade. Twenty percent of these patients improved two anatomic grades; all of these patients were younger than 5 years of age at disease onset. However, it also must be remembered that the various deformities of the femoral head and acetabulum congruency are three-dimensional parameters that cannot be measured adequately by two-dimensional radiographs. Thus far, the only existing radiographic parameter that correlates with good clinical outcome is a perfectly spherical head. Loss of sphericity by itself, however, does not necessarily lead to a poor long-term result (175,193,206).

Thompson and Westin (256) confirmed the work of Ferguson and Howorth (68), which demonstrated that, after the femoral head is in the reossification stage of the disease, it will not deform further. For any treatment to influence head deformity, it must be instituted early in the course of the disease, that is, in the initial or fragmentation stage.

CLINICAL PRESENTATION

Patients with Legg-Calvé-Perthes syndrome most commonly present with a history of the insidious onset of a limp. Most patients do not complain of much discomfort, unless specifically questioned about this aspect. Pain, when present, is usually activity-related and relieved by rest. Because of its mild nature, most patients do not present for medical attention until weeks or months after the clinical onset of disease. The pain the patients experience generally is localized to the groin, or referred to the anteromedial thigh or knee region. Failure to recognize that thigh or knee pain in the child may be secondary to hip pathology may cause further delay in the diagnosis. Some children present with more acute symptom onset. Seventeen percent of patients with Legg-Calvé-Perthes syndrome may give a history of related trauma (20,23,257).

PHYSICAL EXAMINATION

The child with Legg-Calvé-Perthes syndrome usually presents with limited hip motion, particularly abduction and medial rotation. Early in the course of the disease, the limited abduction is secondary to synovitis and muscle spasm in the adductor group; however, with time and the subsequent deformities that may develop, the limitation of abduction may become permanent. Long-standing adductor spasm occasionally leads to adductor contracture. The Trendelenburg test in patients with Legg-Calvé-Perthes syndrome is often positive. These children most commonly have evidence of thigh, calf, and buttock atrophy from disuse secondary to pain. This is additional evidence of the long-standing nature of the condition before detection (1,2,3,4 and 5,174,248). Limb length should be measured; inequality is indicative of significant head collapse and a poor prognosis. Evaluation of the patient's overall height, weight, and bone age may be helpful to rule out skeletal dysplasias or growth disorders in the differential diagnosis, and may provide confirmatory evidence of the disorder. Laboratory studies generally are not helpful in Legg-Calvé-Perthes syndrome, although they may be necessary to rule out other conditions.

IMAGING

In Legg-Calvé-Perthes syndrome, the diagnosis is made and the clinical course is assessed by plain radiographs taken in the anteroposterior and frog-leg lateral positions. These radiographs are generally sufficient for the assessment of the patient and subsequent follow-up evaluations. From the plain radiographs, the extent of epiphyseal involvement (e.g., Catterall groups 1 to 4; Salter-Thompson type A or B; lateral pillar type A, B, or C) and the stage of the disease (initial, fragmentation, or reossification) can be determined. According to Salter and Thompson, if appropriate radiographs are taken within 4 months of the clinical onset of the disease, the subchondral radiolucent zone will be detectable (115). Catterall, however, states that this sign is helpful in only 25% of cases, because it is present only transiently in the early phases of the disease (65). It is most important in following the course of the disease that all radiographs be viewed sequentially, and compared with previous, radiographs to assess the stage of the reparative process, and to determine the constancy of the extent of epiphyseal involvement. Additional radiographic or imaging studies are rarely necessary, but may be helpful in the initial assessment and follow-up of the condition (258,259 and 260).

Radionuclide bone scanning with technetium and pinhole columnation (Fig. 24-22) may be helpful in the early stages of the disease, when the diagnosis is in question, particularly if the differential diagnosis is between transient synovitis and Perthes disease. Some investigators consider scintigraphy helpful in determining the extent of epiphyseal involvement and the prognosis (261,262,263,264,265,266,267,268,269 and 270).

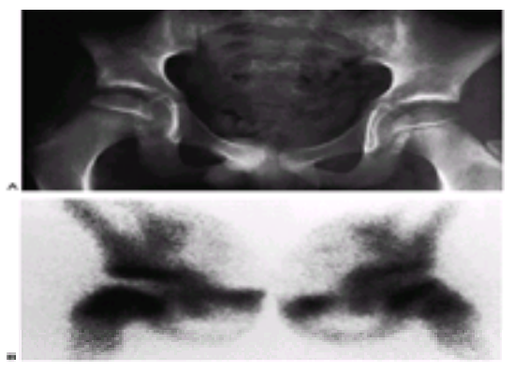

FIGURE 24-22. An 8-year-old boy with right hip pain. **A:** Anteroposterior radiograph demonstrates a slight increase in width and medial joint space; the femoral ossific nucleus is slightly smaller than the opposite side. **B:** Technetium 99 radionuclide scan demonstrates decreased uptake in the entire right femoral head, with increased vascularity in the neck.

Magnetic resonance imaging is widely available in medical centers. It appears to be sensitive in detecting infarction, but cannot yet accurately portray the stages of healing. Its role in the management of Perthes syndrome has yet to be defined. In the future, magnetic resonance imaging may not only help the clinician in the diagnosis, but may shed additional light on the underlying pathology of the condition (93,268,271,272,273 and 274) (Fig. 24-23).

FIGURE 24-23. A 6-year-old boy with Catterall group 3 disease in the early fragmentation stage. **A:** Plain radiograph shows apparent sparing of the posterior head. **B:** Magnetic resonance image demonstrates a complete absence of signal on the affected side. (Courtesy of Peter Scoles, M.D., Case Western Reserve Medical School, Cleveland, Ohio.)

Arthrography is useful primarily in demonstrating any flattening of the femoral head that may not be seen on plain radiographs (Fig. 24-24). It can be used to demonstrate the hinge abduction (Fig. 24-8) phenomenon with abduction of the leg (152,180,181,206,275). Arthrography, in conjunction with plain radiography or computed tomography, also may be useful in the diagnosis of osteochondritis dissecans secondary to Perthes disease. Arthrography is most useful for assessing head shape and the relation to the acetabulum that would be necessary for treatment decisions (Fig. 24-25). With severe flattening of the femoral head, arthrography is helpful in determining containability before any treatment, whether it will be Petrie casts, bracing, or surgery. It is also useful in determining the best position of containment, such as internal or external rotation and abduction or adduction, if surgical management is considered.

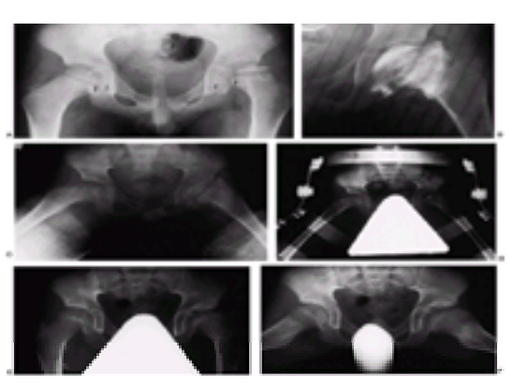

FIGURE 24-24. A 5-year-old boy with Catterall group 4 disease and at-risk status. **A:** Anteroposterior radiograph on presentation. **B:** Anteroposterior arthrogram, in the same position as in **C,** after 10 days of traction. Note the relation between the lateral acetabular margin and the lateral margin of the cartilaginous femoral head, as well as the severe flattening of the femoral head. **C:** Anteroposterior roentgenogram in Petrie broomstick abduction plasters. The patient was maintained in casts for 6 weeks. **D:** Anteroposterior radiograph with pelvis abduction orthosis (weightbearing). **E:** Anteroposterior radiograph at age 13 years. Note residual deformity. **F:** Lauenstein radiograph at age 13 years.

FIGURE 24-25. Arthrogram of a 6-year-old boy with Catterall group 4 disease. **A:** Neutral position. **B:** Abduction, external rotation, and slight flexion (the position that would be maintained by an abduction Scottish Rite–type orthosis). **C:** Abduction and internal rotation (the position that would be maintained by a varus derotation osteotomy). On the basis of the arthrogram, the hip can be contained either by the position that would be maintained by bracing (**B**) or by surgery (**C**).

DIFFERENTIAL DIAGNOSIS

The patient history, physical examination, and plain radiographs are usually sufficient to make a diagnosis of Legg-Calvé-Perthes syndrome (Table 24-5). Diagnosis early in the initial phase of the disease must be differentiated from conditions such as septic arthritis, whether primary or secondary to proximal femoral osteomyelitis,

and toxic synovitis (276,277 and 278). A complete blood count, including white cell differential, erythrocyte sedimentation rate, C reactive protein, and hip joint aspiration and analysis of the fluid, may be necessary to rule out infection. All laboratory studies of Legg-Calvé-Perthes syndrome generally are normal, although the erythrocyte sedimentation rate may be slightly elevated. In early cases, if all of the laboratory and plain radiographic studies are normal, and doubt regarding the diagnosis persists, radionuclide scanning or magnetic resonance imaging may be helpful.

Chondrolysis
Gaucher disease
Hemophilia
Hypothyroidism
Juvenile rheumatoid arthritis
Lymphoma
Mucopolysaccharidosis
Multiple epiphyseal dysplasia
Meyer dysplasia
Neoplasm
Old congenital dysplasia of the hip residuals
Osteomyelitis of the proximal femur
Septic arthritis
Sickle cell disease
Spondyloepiphyseal dysplasia
Toxic synovitis
Traumatic aseptic necrosis

TABLE 24-5. DIFFERENTIAL DIAGNOSIS

In patients with bilateral hip involvement, generalized disorders, such as hypothyroidism and multiple epiphyseal dysplasia, must be considered (279,280). Patients with bilateral involvement, particularly those with atypical radiographic features, must have a careful family history obtained, measurements of height and weight, and a bone survey, to rule out a metabolic or a genetic condition (see Chapter 7 and Chapter 8). Meyer dysplasia, a benign resolving condition, must be considered in children younger than 4 years of age (281).

TREATMENT

For the past 70 years, considerable therapeutic nihilism has been expressed by many authors (14,15,166,189,190,282). Sundt (190) believed that treatment could not prevent degenerative joint disease. Because there is a paucity of long-term natural history data available, the question must be raised whether the outcome of Legg-Calvé-Perthes syndrome can be altered by any particular treatment. As mentioned above, long-term series of treated patients are difficult to evaluate. Long-term series of patients with uniform treatment, and matched for age, gender, stage, and extent of epiphyseal involvement, are necessary to determine the most effective treatment of Perthes syndrome.

Most patients (60%) with Legg-Calvé-Perthes syndrome do not need treatment (65,115,186,214,223,283). Treatment must be considered only for those patients who have an otherwise known poor prognosis based on prognostic factors gleaned from long-term follow-up. It is difficult to formulate specific treatments for patients, because natural history is not well known, and most studies of current treatment methods lack interrater and intrarater reliability of classifications of the extent of epiphyseal involvement and outcome measures, and all lack control groups. These factors, and other variables examined in most series, make it difficult to support a “best” method of treatment.

Standard treatment algorithms are based on radiographic features of the various disease classification schemes. Under these protocols, no treatment is warranted in patients with a good prognosis (i.e., those with Catterall group 1, Salter-Thompson type A, or lateral pillar type A disease) (Table 24-6). Patients with a poor prognosis should be considered for treatment, such as patients with Catterall groups 3 and 4 disease, Salter-Thompson type B disease, and lateral pillar type C disease. There is another large group of patients whose prognosis is indeterminate; these patients require careful follow-up, because they may need treatment. This group includes patients with Catterall group 2 disease (good prognosis in 90% of cases) and patients with lateral pillar type B disease. Because we have learned that the two major prognostic factors in outcome are deformity and age, these two factors must be taken into account in the decision-making process. Patients with deformity (arthrographically and/or clinically documented), younger than 8 years, should be considered for treatment. Patients older than 8 years, especially females, should be considered for treatment even in the absence of deformity, because of their otherwise poor prognosis (240,241,284). All patients should be treated if they manifest clinical at-risk signs (i.e., if they lose range of motion and have pain), or if they demonstrate several of the radiographic at-risk signs, regardless of their extent of epiphyseal involvement. If the patient is already in the reossification or healing stage of the disease, little deformity ensues, and no treatment is indicated (see “Treatment Options in the Noncontainable Hip and the Late-presenting Patient with Deformity ” below).

Poor Prognostic Group: Treatment Indicated
Catterall 3 and 4
Salter-Thompson B
Lateral pillar C
At-risk clinically
At-risk radiographically, regardless of the disease extent
Less than age 8 years with deformity
Over age 8 years (Catterall group 2, 3, and 4, with or without at-risk signs; Lateral pillar B and C; Salter-Thompson B), with or without head deformity
Good Prognosis: No Treatment Necessary
Catterall 1 and 2 (generally good prognosis in 90% of cases)
Salter-Thompson A
Lateral pillar A
Indeterminate Prognosis: May Require Treatment
Catterall 2
Lateral pillar B
In Reossification Stage: May Require Treatment

TABLE 24-6. TREATMENT OF LEGG-CALVÉ-PERTHES DISEASE

The earliest treatment methods used weight relief until the head was reossified. These methods were based on the premise that weight relief would prevent the mechanical deformation of the head and early degenerative joint disease (82,285,286 and 287). These modalities included prolonged, strict bed rest, often in the hospital, and bed rest with or without various periods of traction on special frames or in spica casts. These methods of treatment were associated with disuse atrophy of muscles, osteopenia, shortening of the involved extremity, loss of thoracic kyphosis, urinary calculi, social and emotional problems, and high hospital costs (148,199,200,252,288,289,290,291,292,293,294 and 295).

The concept of weight relief as a treatment for Legg-Calvé-Perthes syndrome was challenged as early as 1927, when Legg stated that, “while the process suggesting weakness of bone structure is going on it is theoretically sound to allow no weight bearing but in practice relief from weight bearing in no way affects the end results” (296). In addition, prolonged immobilization and bed rest do not influence the radiographic course of the disease (214,232,233,297,298 and 299). Harrison and Menon (292) pointed out, as had Pauwels and others (148,300,301), that even at rest, significant forces act on the femoral head with minimal activity.

The cornerstone of treatment for Legg-Calvé-Perthes syndrome is referred to as “containment.” This concept was originally described by Parker (292) and Eyre-Brook (286). The rationale for this concept has been defined further by Harrison and Menon (292), Petrie and Bitenc (254), Salter (114,302), and others (303,304,305,306,307 and 308). The essence of containment is that, to prevent deformities of the diseased epiphysis, the femoral head must be contained within the depths of the acetabulum to equalize the pressure on the head and subject it to the molding action of the acetabulum. Containment is an attempt to reduce the forces through the hip joint by actual or relative varus positioning (309). Containment may be achieved by nonoperative or operative methods. Considering all the methods of containment, the femoral head represents more than three-fourths of the sphere and the acetabulum only half of the sphere. No method of containment can provide for a totally contained femoral head within the acetabulum during all portions of the gait cycle (137,307,308,310).

Patient Management

The primary goals in the treatment of Legg-Calvé-Perthes syndrome are to prevent deformity (Stulberg classes 3, 4, and 5), alter growth disturbance, and thus to prevent degenerative joint disease. Attainment of these goals requires that each patient be assessed clinically and radiographically. Clinically, the patient is evaluated for clinical at-risk signs of loss of motion, joint contracture, and pain. Radiographically, anteroposterior and frog-leg lateral radiographs are evaluated to determine the radiographic stage of the disease, the extent of epiphyseal involvement, and the presence of radiographic at-risk signs. For treatment to have any effect on subsequent deformity, it must be initiated in the initial or fragmentation phase of the disease (68,256).

Treatment is not indicated if the child demonstrates none of the clinical or radiographic at-risk signs; if he or she has Catterall group 1 or 2, Salter-Thompson type A, or lateral pillar type A disease; or if the disease is already in the reossification stage. A child who demonstrates clinical or radiographic at-risk signs, regardless of the extent of epiphyseal involvement, should receive treatment (174). Even patients with Catterall group 2 disease (or lateral pillar type B disease) who are at risk may have poor results without treatment (65,78) (W.J. Cumming, personal communication, 1993).

The first principle of treatment, regardless of the definitive method of treatment chosen, is restoration of motion. Joint motion enhances synovial nutrition and cartilage nutrition (311,312). This tenet of treatment cannot be overemphasized. The most successful reported series of patients treated for extensively involved femoral heads is that of Brotherton and McKibbin (303). These patients were treated with bed rest and containment. End results in these patients were superior to those in another long-term study (199,200) of patients treated with bed rest and containment on a frame. The only difference between the two treatment regimens was that in the former series motion was always maintained. Restoration of motion can be accomplished by bed rest alone, or with skin traction and progressive abduction to relieve the muscle spasms. Occasionally, surgical release of the contracted adductors may be necessary. Restoration of motion allows abduction of the hip, which reduces the forces on the hip joint, and allows positioning of the uncovered anterolateral aspect of the femoral head in the acetabulum. Mobilization of the hip joint also can be obtained by rest followed by the use of progressive abduction plasters to stretch the hip adductor muscles while allowing hip flexion and extension. A full or almost full range of motion is usually obtainable within 7 to 10 days of treatment. Because of early deformity, complete abduction and internal rotation may not always be obtainable. Persistence of an adduction contracture is always associated with a serious femoral head deformity and will not respond to traction (313).

Arthrography is a useful adjunct in determining whether the head actually can be contained and, if so, in what position this is best accomplished (314) (Fig. 24-25). Arthrography can reveal any flattening of the femoral head that may not be seen on plain radiographs. More importantly, it can demonstrate the hinge abduction phenomenon (180,181,206) (Fig. 24-8). Demonstration of the hinge abduction phenomenon, or the inability to contain the hip, is a contraindication to any type of containment treatment. Serious damage to the femoral head and acetabulum may result from trying to contain a noncontainable head (Fig. 24-14). Arthrography should be performed under general anesthesia. This also provides an opportunity to examine whether muscle spasm, contracture, or mechanical deformity is responsible for any apparent fixed deformities.

The treatment of Legg-Calvé-Perthes syndrome remains controversial, and there is disagreement regarding whether operative or nonoperative treatment is beneficial. The shortage of natural history studies for comparison of the results of different modalities of treatment is another reason why it is difficult to resolve this controversy. In addition, the variability of criteria for inclusion of patients in studies, and the use of different measurements to assess outcomes of treatment, lack of interrater and intrarater reliability data, and lack of untreated control groups, make comparisons difficult. The most widely used methods to maintain containment are abduction orthosis, femoral osteotomy, innominate osteotomy, and lateral shelf acetabuloplasty. Interest has grown in combined femoral and innominate surgical procedures, and in the use of procedures originally regarded as salvage procedures in the primary treatment of Perthes disease.

Nonoperative Treatment

In 1971, Petrie and Bitenc (254) reported excellent results from applying the principles of containment, using broomstick abduction long-leg plasters (Fig. 24-24C). This series proved that weight bearing, with the head contained, was not harmful. This method of treatment allows for weight bearing and maintenance of hip range of motion in the contained position. Successful treatment results using this technique have been reported (315). Pietrie casts are used after muscle-release procedures and capsulotomies to reduce heads that are deformed and subluxated (316), to maintain containment before bracing or surgical treatment, or as definitive nonsurgical treatment in situations in which bracing compliance is in question.

To avoid the repeated hospitalizations necessary to regain knee and ankle motion, and to avoid the occasional flattening of the femoral condyles seen in patients treated with broomstick plasters, attention turned to the use of removal abduction orthoses, as typified by the Newington abduction brace (252), the Roberts orthosis (317), the Houston A-frame brace (318), and the Toronto Legg-Calvé-Perthes orthosis (160,319). These devices provide containment in the abducted internal rotation position.

The most widely used abduction orthosis is the Atlanta Scottish Rite orthosis or a modification thereof (Fig. 24-26). These devices were thought to provide for containment solely by abduction without fixed internal rotation (253,255,320,321). These orthotic devices allow free motion of the knee and ankle. Containment is provided by the abduction of the brace and the hip flexion required to walk with the legs in abduction. These devices are less cumbersome than other braces, and are well tolerated by patients. On arthrography, the position of containment that would be maintained by an abduction orthosis of this variety would be demonstrated by abduction, slight flexion, and external rotation (Fig. 24-25). Patients must demonstrate containment on a radiograph in the weight-bearing position while in the brace (Fig. 24-24). At each subsequent visit, the patient must be examined out of the orthosis to be certain that range of motion is maintained. If the range of motion is not adequate, traction should be initiated to restore range of motion, and containability should be reassessed. The brace is worn on a full-time basis until the head is in the reossification stage, when there is no further risk of collapse. Full-time bracing ranges from 6 to 18 months. The negative aspects of bracing include prolonged treatment times and the necessity of having a compliant patient. Some patients may not tolerate the brace for psychological reasons (322). This type of treatment also may be difficult for girls and older patients to accept (323).

FIGURE 24-26. An abduction orthosis.

Although early radiographic anatomic results were comparable with those of previously used containment weight-bearing methods (255,321), follow-up reports of patients treated with these orthotic devices question the efficacy of this method of management (216,324,325). Martinez and colleagues (216) reported on 31 patients, with 34 hips, who had severe Perthes disease (Catterall groups 3 and 4) that had been treated with a weight-bearing abduction orthosis. The mean age of the patients when first seen was 6 years, and the mean duration of follow-up was 7 years. According to the Mose criteria, at follow-up no hip had a good result, 35% had fair results, and 65% had poor results. On the basis of the classification of Stulberg and colleagues, there were 41% class 2 results, 53% class 3 and 4 results, and 6% class 5 results. With respect to the lateral column, of the 20 hips in which collapse occurred, only 10% had Stulberg class 2 results, 35% had class 3 results, 45% had class 4 results, and 10% had class 5 results. By comparison, in the 14 hips in which collapse of the lateral column did not occur, 86% had Stulberg class 2 results and only 14% had class 3 results. No hip in which collapse did not occur had a class 4 or 5 result. The authors concluded that although containment is the most widely accepted principle of treatment of Legg-Calvé-Perthes disease, little clinical information supports the contention that bracing in abduction and external rotation, as provided by the Atlanta Scottish Rite orthosis and its modifications, is effective.

Meehan and colleagues (324) reported on 34 patients with Catterall group 3 or 4 disease, with an average age at diagnosis of 8 years. The average follow-up in this series was 6 years, 9 months. At follow-up, there were no Stulberg class 1 results, 3 class 2 results, 24 class 3 results, 6 class 4 results, and 1 class 5 result. These

authors also arrived at a similar conclusion concerning the use of this orthotic device in the treatment of Perthes disease. In both of these studies the issue of compliance is not documented, and as with all studies of Perthes disease in the literature, control groups other than historic controls are absent. Because the radiographic outcomes in both of these studies were poor, it is questionable whether the orthosis itself adds anything to the treatment other than maintenance of range of motion. As expected, the majority of patients in both series were doing well clinically, as do most patients who have Perthes disease over the short term, regardless of the extent of the deformity. The long-term prognosis, for all but the Stulberg class 1 and 2 hips, is guarded.

Because of these results, many physicians have begun treating patients with only maintenance of range-of-motion programs, including stretching exercises, nighttime abduction splinting, home traction, and other combinations. Long-term follow-up studies of these nonoperative range-of-motion regimens are needed to determine their efficacy.

Surgical Treatment

Surgical methods of providing or maintaining containment are advocated by many investigators. Surgical containment methods offer the advantage of early mobilization and the avoidance of prolonged bracing or cast treatment. In addition, no end point for discontinuing treatment is required, and any improved containment is permanent (316). Surgical containment may be approached from the femoral side, the acetabular side, or both sides of the hip joint. Procedures used to obtain or maintain containment in Legg-Calvé-Perthes syndrome are those that originally were used in the treatment of problems associated with developmental hip dysplasia and dislocation.

Varus Osteotomy

Varus osteotomy, **[➥4.1,4.2]** with or without associated derotation, offers the theoretical advantage of deep seating of the femoral head and positioning of the vulnerable anterolateral portion of the head away from the deforming influences of the acetabular edge (223,313,326,327,328 and 329). The varus position reduces the joint forces on the femoral head (309,326). This procedure also relieves the intraosseous venous hypertension and improves the disturbed intraosseous venous drainage reported in Legg-Calvé-Perthes syndrome, thus speeding the healing process (117,118,134,326,327,330). This belief, however, has been disproved (331,332 and 333).

Prerequisites for varus derotation osteotomy include a full range of motion, congruency between the femoral head and the acetabulum, and the ability to contain the femoral head in the acetabulum in abduction and internal rotation (316,334) (Fig. 24-25). This assessment may require arthrography if the femoral head is well into the fragmentation phase. As with nonoperative treatment, the procedure must be performed early in the initial or fragmentation stage of the disease to have any effect on head deformity (168,212,326).

The negative aspects of this treatment modality must be considered. Varus osteotomy, with or without derotation, usually requires the use of internal fixation and external mobilization in plaster for 6 weeks. The patient must incur the inherent risks and costs associated with at least one surgical procedure, and most likely a second surgical procedure for hardware removal. The limb is temporarily shortened by the procedure. The varus angle must not exceed a neck–shaft angle of less than 110 degrees. The varus angle generally decreases with growth (180,335,336); however, if there has been physeal plate damage secondary to the disease, this remodeling potential may be lost, and the patient may have permanent shortening and temporary or permanent weakness of the hip abductors (134,336,337,338,339 and 340). The proponents of varus osteotomy, with or without derotation, report 70 to 90% satisfactory anatomic results using this method (134,212,326,327,337,339,341,342,343,344 and 345).

Innominate Osteotomy

Innominate osteotomy **[➥3.5]** provides for containment by redirection of the acetabulum, providing better coverage for the anterolateral portion of the femoral head. The head is placed in relative flexion, abduction, and internal rotation with respect to the acetabulum in the weight-bearing position. Any shortening caused by the disease can be corrected, and the need for bracing is eliminated (114,316,334,339,346,347,348 and 349). Prerequisites for innominate osteotomy include restoration of a full range of motion, a round or almost round femoral head, and joint congruency demonstrated arthrographically. Treatment must be performed early in the course of the disease, and the head must be well seated in flexion, abduction, and internal rotation.

Innominate osteotomy is performed in a similar fashion as for residual hip subluxation. The tendinous portion of the iliopsoas muscle is always released at the musculotendinous junction, and any residual contractures of the adductor muscles are released by subcutaneous adductor tenotomy (114,316). The osteotomy is fixed by two or three threaded pins for internal fixation. Partial weight bearing may be resumed in a cooperative child several days after surgery; however, in an uncooperative patient, immobilization in a spica cast for 6 weeks is required.

The disadvantages of innominate osteotomy are the associated risks and cost factors of the surgical procedure and the procedure for pin removal. Additionally, the operation is performed on the normal side of the joint. This procedure may increase the forces on the femoral head by lateralizing the acetabulum and increasing the lever arm of the abductors (326), although this supposition has thus far not been substantiated. Innominate osteotomy also may cause a persistent acetabular configuration change in the face of a previously normal acetabulum, leading to loss of motion, particularly flexion (350). Satisfactory anatomic results from this procedure range from 69 to 94% (316,339,346,347,351,352,353,354 and 355).

There is significant biomechanical evidence to show that neither method of surgical containment, innominate or femoral osteotomy, may effectively stress shield an extensively necrotic segment of the femoral head; the same may also apply for patients treated with bracing (307,308,356,357). Wenger (177) reported a high incidence of complications in surgically treated patients in whom the accepted methods and prerequisites were met.

Varus Osteotomy Plus Innominate Osteotomy

Several short-term results of combined varus osteotomy plus innominate osteotomy have been reported in severely involved Catterall group 3 or 4 disease. This combined procedure has the theoretical advantage of maximizing femoral head containment while avoiding the complications of either procedure alone. The femoral osteotomy directs the femoral head into the acetabulum, while theoretically reducing any increasing joint pressure or stiffness that would result from the pelvic osteotomy. The coverage provided by the innominate osteotomy reduces the degree of correction needed from the femoral osteotomy, thereby minimizing the complications of excessive neck-shaft varus, associated abductor weakness, and limb shortening. Advocates of this procedure also believe that permanent correction of the deformity, early weight bearing, and shortened treatment time are obtained. The disadvantages of the procedure include those mentioned for varus osteotomy and innominate osteotomy alone. Surgical time is increased, potential blood loss is magnified, and the combined procedures are technically more difficult. Satisfactory anatomic results from this combined procedure are reported in up to 78% of patients. As would be expected in short-term follow-up, the clinical results are excellent (358,359,360,361 and 362). The prerequisites for this operation include those for the varus and innominate osteotomies alone, in a patient who probably would not achieve satisfactory coverage from either procedure alone.

Shelf Arthroplasty

Shelf arthroplasty **[➥3.12]** formerly was used only as a salvage procedure. However, recently it has been proposed as a primary method of management in children older than 8 years of age with Catterall groups 2, 3, and 4 disease with or without at-risk signs, lateral pillar types B and C disease, and Salter-Thompson type B disease; if subluxation is present, it must be reducible on a dynamic arthrogram (284,363). Contraindications include hips that do not meet the above criteria and the presence of hinge abduction. Only one intermediate-term follow-up study exists, but proponents believe that containment of the femoral head by shelf arthroplasty, before significant deformity develops, improves femoral head remodeling (284,364). Preliminary risk factors for poor results with this technique are age older than 11 years, female gender, and Catterall group 4 disease. The shelf procedure may cover the anterolateral portion of the head, preventing subluxation and lateral overgrowth of the epiphysis (Fig. 24-27).

FIGURE 24-27. A 9-year-old girl with Catterall group 4 and lateral pillar type C disease treated with lateral shelf arthroplasty. **A:** Note the marked loss of epiphyseal height. **B** and **C:** Anteroposterior (**B**) and Lauenstein (**C**) radiographs 1 year after operation. Note that the femoral head is in the reossification phase. The patient is 1 cm short on the involved side. Abduction and internal rotation are to 15 degrees, external rotation is to 25 degrees, and flexion is to 100 degrees. (Courtesy of Fred Dietz, M.D., University of Iowa, Iowa City, Iowa)

Regardless of the method of containment chosen, any episode indicative of loss of containment, such as recurrent pain or loss of range of motion, must be treated aggressively with rest, traction, and reassessment of containment.

Treatment Options in the Noncontainable Hip and the Late-presenting Patient with Deformity

Patients presenting in the later stages (reossification) of the disease with deformity, those with noncontainable deformities, and those who have lost containment, after either surgical or nonsurgical containment, present a management problem. These patients usually demonstrate hinge abduction on arthrography, and have an extremely poor prognosis without additional treatment (175,193,222,316,365,366). These patients generally present with persistent pain, shortening of the involved extremity, and a fixed deformity, generally 10 to 15 degrees of fixed flexion and 15 to 20 degrees of fixed adduction (222,366). The salvage procedures to be considered at this point include Chiari osteotomy, lateral shelf arthroplasty, cheilectomy, and abduction extension osteotomy (222,316,366,367,368 and 369). These procedures must be viewed as salvage procedures, with each having specific limited aims, which may include pain relief, correction of limb-length inequality, increasing head coverage, and improvement of movement and abductor weakness (366).

Chiari osteotomy **[➥3.11]** improves the lateral coverage of the deformed femoral head, but does not reduce the lateral impingement in abduction, and may exacerbate any existing abductor weakness (222,366). Chiari osteotomy may be useful in the enlarged, poorly covered femoral head that is beginning to develop symptoms of early degenerative joint disease. Although good preliminary results have been reported (368,369,370,371,372,373 and 374), the role of Chiari osteotomy in the treatment of Legg-Calvé-Perthes syndrome has yet to be defined.

In patients in the active stage of the disease with a noncontainable hip, or patients with a painful hip after healing, who demonstrate hinge abduction, abduction extension osteotomy **[➥4.5]** should be considered. Abduction extension osteotomy of the femur is indicated when arthrography demonstrates that joint congruency is improved by the extended adducted position (Fig. 24-28). The preliminary results with this modality of treatment indicate improvement in limb length, decrease in limp, and improvement in function and range of motion (366). This procedure may be applied in either the active or the late stage of the disease, when arthrography demonstrates that joint congruency is improved by the extended adducted position. This modality of treatment allows for realignment of the congruent position of the hip in the neutral weight-bearing position (316,366).

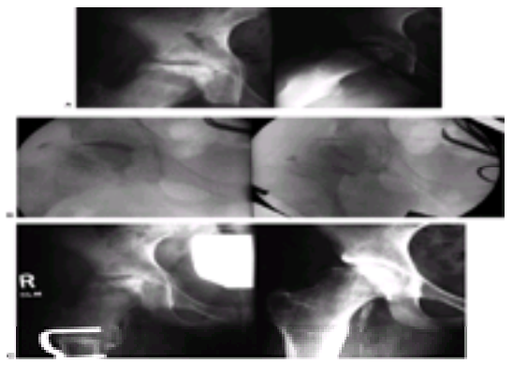

FIGURE 24-28. An 11-year-old girl with Catterall group 4 Perthes disease. Hip range of motion showed marked restriction of abduction (20 degrees) and rotation (10 degrees internal and external). All movement was painful. **A:** Preoperative anteroposterior (**left**) and Lauenstein (**right**) views. **B:** Intraoperative arthrograms demonstrating hinging on the lateral aspect of the acetabulum in abduction (**left**) with good congruity in adduction (**right**). **C:** Six-month (**left**) and 7-year (**right**) follow-up after abduction osteotomy. At 7-year follow-up, the patient was free of pain, with 40 degrees of abduction, 20 degrees of adduction, flexion to 130 degrees, and 20 degrees of internal and external rotation. She has been pain free since her surgery.

Lateral shelf acetabuloplasty **[➥3.12]** may also be used in “salvage” situations, including lateral subluxation of the femoral head, inadequate coverage of the femoral head, and hinge abduction associated with severe Legg-Calvé-Perthes disease (370,371,372,373,374 and 375); use in hinge abduction, however, would not be the author's preference.

Cheilectomy removes the anterolateral portion of the femoral head that is impinging on the acetabulum in abduction (Fig. 24-29). It is indicated only for functionally limiting restricted range of motion. The procedure must be performed only after the physis is closed; otherwise, a slipped capital femoral epiphysis may ensue (367,376). Although cheilectomy may produce gratifying results with regard to improved range of motion, in some cases increasing stiffness may occur secondary to capsular adhesions at the osteotomy site (316). In addition, shortening associated with the femoral head deformity is not corrected.

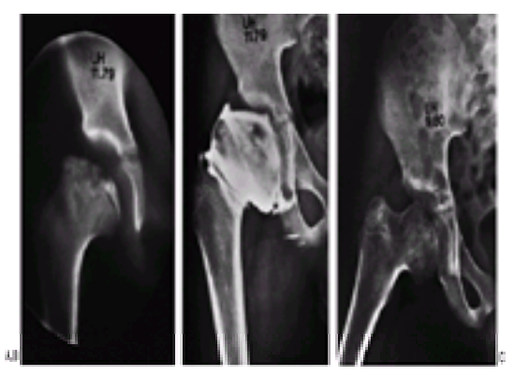

FIGURE 24-29. An 8-year, 6-month-old boy with Catterall group 4 disease. Hip range of motion included flexion of 140 degrees, extension of 0 degrees, abduction of 20 degrees, adduction of 30 degrees, internal rotation of 10 degrees, and external rotation of 30 degrees. **A:** Polytome indicating superolateral growth arrest. **B:** Arthrogram demonstrating femoral head flattening and enlargement, and deformation of the peripheral acetabulum. **C:** Abduction radiograph 7 months after cheilectomy. Range of motion at this time was 130 degrees of flexion, 20 degrees of extension, 50 degrees of abduction, 50 degrees of adduction, 45 degrees of

internal rotation, and 40 degrees of external rotation. (Courtesy of J.G. Pous, M.D., Montpellier, France.)

Osteochondritis dissecans after Perthes syndrome may or may not be symptomatic. If it is symptomatic, the pain may be intermittent. In patients with pain, several treatment options are available. Symptomatic treatment with antiinflammatory agents and protective weight bearing may be used to promote healing. Persistent pain may warrant attempts at revascularization. This may include drilling of the fragment via the femoral neck, and internal fixation, either percutaneously with pins or open with devices such as the Herbert screw. If the fragment becomes detached and cannot be reattached, and causes mechanical catching symptoms, it may require removal (181). There is a paucity of information on the natural history of the condition and the results of treatment.

In patients with Legg-Calvé-Perthes syndrome who have premature physeal arrest, trochanteric overgrowth may ensue (169,178). Such patients may develop a Trendelenburg gait and pain secondary to muscle fatigue. This rarely has been a significant problem in long-term reviews (175). However, distal and lateral advancement of the greater trochanter may be necessary **[➥4.9]** (377,378).

FUTURE DEVELOPMENTS

Long-term series of patients with uniform treatment who are matched for age, gender, degree of epiphyseal involvement, and other diagnostic factors, compared with an untreated control group, will no doubt be required to determine the most effective treatment for Legg-Calvé-Perthes syndrome. As fundamental understanding of Legg-Calvé-Perthes syndrome increases, so does understanding of how various treatment modalities influence this complex growth disturbance.

CHAPTER 25

SLIPPED CAPITAL FEMORAL EPIPHYSIS

DOUGLAS K. KEHL

D. K. Kehl: Department of Orthopaedic Surgery, Emory University School of Medicine, Atlanta, Georgia 30303; Department of Orthopaedic Surgery, Children's Healthcare of Atlanta at Scottish Rite, Atlanta, Georgia 30342.

Slipped capital femoral epiphysis (SCFE) remains one of the most common disorders affecting the hip during adolescence. The condition is characterized by a displacement of the femoral neck from the capital femoral epiphysis through the physeal plate. The femoral head is held securely in the acetabulum, whereas the femoral neck displaces mainly in an anterior direction, creating an apparent varus deformity at the proximal femur. Rarely, femoral neck displacement can be in a posterior direction, creating a proximal femoral valgus deformity (1,2). The physiolysis in SCFE differs from that seen in traumatic physeal fracture. Histologic studies have shown that the separation in SCFE is through a widened zone of hypertrophy, which has become weakened by alterations in chondrocyte maturation and endochondral ossification (3,4).

EPIDEMIOLOGY

The annual incidence of SCFE has been reported to average 2 per 100,000 in the general population. Minomiya and colleagues have reported an incidence as low as 0.2 per 100,000 in the eastern half of Japan (5), whereas Kelsey and colleagues have reported an incidence as high as 10.08 per 100,000 in certain regions of the United States (6). Loder has reported a seasonal predilection for SCFE during the summer months (7).

SCFE is related to puberty, as evidenced by 78% of cases of SCFE occurring during the adolescent growth phase (8). The age range at presentation in boys is most often between 10 and 16 years of age (average, 13.5 years), and in girls it is between 9 and 15 years of age (average, 12.1 years) (6,9,10). When a patient with SCFE presents at an age outside of these ranges the treating physician should strongly consider an underlying endocrine or systemic disorder, to include primary and secondary hypothyroidism, panhypopituitarism, hypogonadal conditions, and renal osteodystrophy (11).

A delay in skeletal maturation commonly is seen in patients with SCFE. In some studies, skeletal age has been found to be as much as 20 months behind chronologic age in up to 70% of affected individuals (8,12). A male predilection for SCFE has been reported at 1.43 to 1, with the left hip being affected twice as often in unilateral SCFE (10,13,14). An increased incidence of SCFE has been reported in the African-American and Polynesian populations (6,14).

Obesity definitely is associated with the development of SCFE. Weight-for-age profiles have been reported by Loder (14) to be over the 90th percentile in 63% of affected individuals. Kelsey and colleagues have also reported weight-for-age profiles over the 95th percentile in 49% of affected individuals (15). Brenkel and colleagues have reported weight-for-height profiles over the 90th percentile in 73% of affected boys and 52% of affected girls (16). Clinically obese patients acquiring SCFE also tend to present at a younger age (14,17).

Bilateral symptomatic involvement with SCFE averages 25% during adolescence (range, 21 to 37%) (13,14,17,18,19 and 20). Approximately 50% of these patients present with bilateral involvement, and the remaining 50% show sequential onset (13,17,18,20). Long-term follow-up studies, however, identify changes of bilateral involvement in as many as 60 to 80% of patients with known unilateral SCFE (19,21,22). This implies that many sequential SCFEs occur asymptomatically, prior to the end of growth. When bilateral symptomatic involvement occurs sequentially, Loder and colleagues have shown the second slip to present by 12 months in 77% of patients and 18 months in 88% of patients (14,17). Bilateral involvement also is reported to have a higher incidence in males, African-American patients, and obese patients with younger age at initial presentation (13,14,17,23).

PATHOANATOMY

Historically the femoral head was believed to displace mainly in a medial direction off of the femoral neck in SCFE, creating a radiographic varus deformity at the proximal femur (24). Most recently, Nguyen and Morrissy have demonstrated that the displacement in SCFE occurs mainly in a posterior direction, as the femoral head rotates around the axis of the femoral neck, with the apparent proximal femoral varus deformity being secondary to radiographic parallax (25). Some cephalad displacement of the femoral neck, bringing it into contact with the acetabulum, can occur in chronic SCFE, but only after the femoral head has slipped to the posterior aspect of the femoral neck (Fig. 25-1). This knowledge becomes extremely important when considering surgical stabilization of a slip, as well as reconstructive procedures about the proximal femur.

FIGURE 25-1. In the early displacement of chronic slipped capital femoral epiphysis, the femoral head is held securely in the acetabulum, whereas the femoral neck initially migrates in an anterior direction (**top left**, **top right**). The resultant posterior displacement of the femoral head around the axis of the femoral neck continues until the femoral head contacts the posterior aspect of the femoral neck (**bottom left**). In this later stage of displacement, the femoral neck may begin to additionally migrate cephalad in relation to the femoral head (**bottom right**). (From ref. 109, with permission.)

Histologic examination of the hip joint and physeal plate, in patients with SCFE, has shown several abnormalities. The synovium demonstrates a hyperplasia with increased vascularity and round cell infiltration, indicative of an inflammatory response (26,27). The physeal plate is noted to be widened. Ippolito and colleagues have shown that this increase in physeal plate width can be as much as twice normal (4). The majority of the change in the physeal plate occurs in the zone of hypertrophy. The hypertrophic zone normally constitutes 15 to 30% of the width of the normal physeal plate. In SCFE, this zone can increase to as much as 80% of the width of the physeal plate (4,5). Abnormal cartilage maturation and subsequent endochondral ossification are implied by the microscopic identification of

disruption of the normal columnar pattern of the cartilage columns into cartilage cell clusters, and the presence of cartilage cell islands extending into the adjacent femoral metaphysis (4,28,29) (Fig. 25-2). The slip cleft is noted to traverse mainly the zone of hypertrophy (4,29,30).

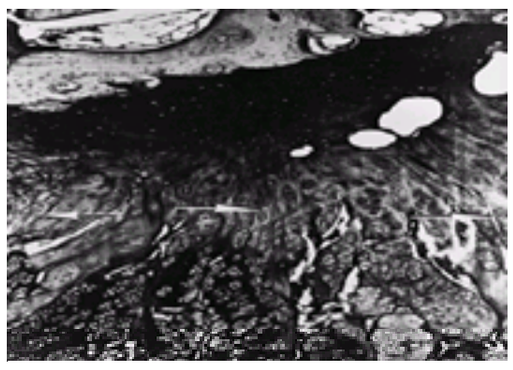

FIGURE 25-2. Photomicrograph of the proximal femoral growth plate of a 13-year-old boy with slipped capital femoral epiphysis. The resting zone is noted to be thinned, and accounts for much less than its normal 60 to 70% of the thickness of the physeal plate. The proliferating zone (*arrows*) demonstrates short columns of chondrocytes enveloped in a compact matrix. The hypertrophic zone is greatly thickened. Large clusters of chondrocytes, separated by deep clefts containing matrix debris, replace the orderly columnar pattern normally seen in this zone. (From ref. 4, with permission.)

Electron microscopic studies demonstrate disorganized collagen fibrils in the physeal plate, with abnormal accumulations of proteoglycans and glycoproteins, particularly adjacent to the slip cleft (4,29,31).

Although several abnormalities in the hip joint synovium and proximal femoral physeal plate have been documented histologically, it remains undetermined whether these changes are primary abnormalities or, more likely, responses secondary to minimal physeal slippage.

ETIOLOGY

The true etiology of SCFE remains unknown. It is unlikely that it is the result of a single factor, but rather is more likely secondary to multiple factors, resulting in a weakened physeal plate that is loaded with a higher than normal shear stress, resulting in a failure of the proximal femoral physeal plate (32,33,34,35 and 36).

Local trauma to the proximal femur frequently is reported as a possible contributing etiologic factor in SCFE (13,37). Wilson and colleagues reported 26% of the patients in their review to have had a history of antecedent trauma (13). Trauma was reported much more frequently in slips that presented with an acute onset and a short duration of symptoms. Although traumatic transphyseal fracture of the proximal femur and SCFE share a similar gender and age-related peak incidence, the amount of force required to cause physiolysis, and the region of the physis through which the slip cleft traverses differ in the two conditions (3,4). The majority of traumatic transphyseal fractures of the proximal femur are the result of high-energy injuries, such as motor vehicle accidents and falls from a height. SCFE presenting with an acute onset, on the other hand, usually follows a minor torsional or low energy injury.

Mechanical factors affecting the proximal femoral physis also have been proposed. Obesity, a decrease in normal femoral anteversion or an actual retroversion of the femoral neck, or a more oblique orientation of the physeal plate during adolescence, have all been shown to be associated with increased shear force generation at the proximal femoral physeal plate, and could be factors associated with physeal plate fatigue (32,36,38). The physeal perichondrial ring, which functions as a stabilizer of the physeal plate, decreases in strength during the growth years. Chung and colleagues have shown experimentally that physiologic forces at the proximal femur generated by normal activities in obese patients can be of adequate magnitude to cause physeal fatigue, if the perichondrial ring is adequately weakened (39).

Inflammatory factors that weaken the physeal plate must be considered in any proposed etiology of SCFE, as evidenced by the almost universal association of synovitis of the hip with SCFE (33). It remains unknown, however, whether the synovitis precedes, or is a secondary response to, the physeal slippage. Eisenstein and Rothchild proposed the etiology of SCFE to be a systemic immunologic condition with a local manifestation at the hip (40). Their work demonstrated an increase in immunoglobulins and C3 component of complement in the serum, as well as the synovium of the hip joint, in patients with SCFE. Other authors disagree, and propose a local immunologic disorder confined to the hip joint. Morrissy and colleagues have shown no serum abnormalities, but did find increased plasma cells, IgG, and C3 component of complement in the hip joint synovium of patients with SCFE (27). Morrissy and colleagues also have demonstrated the presence of immune complexes in the synovial fluid of the hip in 10 of 12 patients with SCFE, but not in the synovial fluid of other conditions associated with synovitis (41).

Endocrine imbalance is known to change physeal plate physiology, and must therefore be considered as a possible etiologic factor in SCFE (35). An association between endocrine function and SCFE is suggested by the majority of SCFE occurring during the adolescent growth phase. This is a period of significant hormonal change, in which SCFE occurs prior to menarche in girls (8), and is more common in boys, who are known to have a longer, more accelerated growth phase and a frequent association with obesity, which may have an underlying hormonal basis. Additional evidence for an association with endocrine dysfunction is suggested by the frequent association of SCFE with primary and secondary hypothyroidism (42,43,44 and 45), panhypopituitarism (44,46,47), hypogonadal conditions (48), renal osteodystrophy (49,50), and growth hormone therapy (51,52 and 53).

Experimental data have confirmed that various hormonal changes affect physeal strength by altering physeal cartilage collagen and matrix production. Estrogens have been shown to thin the physis and increase physeal strength (46), whereas oophorectomy leads to a decrease in physeal strength (46,54). Growth hormone therapy is known to be associated with the development of SCFE (51,53). Growth hormone through somatomedin increases the width of the physis by increasing cell activity and matrix production, which in turn decreases the physeal strength (46,52). Testosterone in low levels has been shown to weaken the physeal plate, whereas high levels for long durations leads to physeal plate narrowing (12). In spite of this association between hormonal alternations and physeal plate physiology, numerous clinical reports have shown no reproducible laboratory endocrine abnormalities in patients with SCFE (16,40,55,56). A recent report by Wilcox and colleagues (57) did show significant changes in the levels of thyroid hormone (T3), testosterone, and growth hormone in a group of patients with SCFE. T3 levels were significantly decreased in 25% of 80 patients reviewed. In 64 patients tested, the levels of testosterone and growth hormone were depressed in 76 and 87%, respectively (57).

Loder and associates (58) have identified an association between pelvic and/or proximal femoral radiation therapy for treatment of childhood neoplasms and SCFE. The amount of radiation averaged 4,420 ± 1,445 rads. Unlike patients with routine SCFE, patients with SCFE following radiation therapy presented at a younger age (average, 10.4 years) and were usually thin (median weight, 10th percentile). The age at SCFE diagnosis was usually younger when the patient's neoplasm was diagnosed and treatment was initiated at a younger age, or when higher amounts of radiation therapy were given.

Although a definite hereditary pattern in SCFE has never been established, there is some evidence that inheritance can be an etiologic factor. Wilson and colleagues reported a 5% incidence of SCFE in family members of 240 patients with SCFE (13). Rennie proposed an autosomal dominant inheritance pattern with incomplete penetrance in SCFE, and reported a 7.1% risk of SCFE to a second family member (59).

CLINICAL PRESENTATION

Patients with SCFE usually present with complaints of pain in the affected hip or groin, a change in hip range of motion, and a gait abnormality. A patient can present with pain perceived in the medial thigh and knee region of the affected limb. This phenomenon represents referred pain along the sensory distribution of the obturator and femoral nerves, and commonly is seen in association with hip pathology. If not recognized as referred pain, it can lead to a significantly delayed or even missed diagnosis (60,61). The intensity and duration of symptoms traditionally have been used to classify SCFE into four patterns of presentation: preslip, acute, chronic, and acute-on-chronic.

The true preslip or prodromal stage of SCFE theoretically occurs prior to any actual slippage through the physeal plate. Whether preslip is an actual phase in SCFE,

or is secondary to a mild synovitis induced by minimal slippage through the physeal plate, remains controversial. The patient provides history of an episodic limp and limb weakness associated with intermittent mild pain in the groin, medial thigh, or knee region, particularly with exertion. On physical examination, the patient may show mild pain with rotation of the affected hip, and a minimal decrease in internal rotation. Plain radiographs may show osteopenia and a minor widening and fuzziness of the physeal plate; however, the physeal plate–femoral neck relation appears normal. The preslip stage in SCFE most likely is not a true prodromal phase, but represents early symptomatology associated with mild physeal slippage that cannot be detected on plain radiographs.

The most frequent pattern of presentation is a chronic SCFE. The patient describes intermittent pain in the groin, the medial thigh, or the anterior suprapatellar region of the knee for longer than 3 weeks. The patient remains ambulatory, but does show an antalgic gait with associated limp. The affected limb positions itself in an externally rotated and mildly shortened position. Range of hip motion shows a decrease mainly in internal rotation and abduction with the amount of limitation being dependent on the severity of the slip. Mild to moderate pain is noted with motion of the hip, particularly at the extremes of motion. There may be some thigh and gluteal muscle atrophy secondary to long-standing symptoms and disuse. A frequently seen sign associated with SCFE can be demonstrated during passive flexion of the affected hip. As flexion is increased from an extended position, the thigh of the affected limb abducts and externally rotates. Radiographs frequently show attempts at bony healing and remodeling along the posterior and medial femoral neck (Fig. 25-3).

FIGURE 25-3. Anteroposterior (**A**) and frog-leg lateral (**B**) hip radiographs of a 13-year, 4-month-old boy demonstrate chronic epiphyseal displacement. The bony resorption on the superior and anterior femoral neck, and the new bone formation on the inferior and posterior femoral neck, indicate a more prolonged process.

The acute-on-chronic presentation in SCFE occurs when a patient with an extended history of symptoms and signs of chronic SCFE presents with an acute increase in pain and loss of motion at the affected hip. This presentation is associated with an acute increase in slip severity from a previous, more mild chronically displaced pattern (Fig. 25-4).

FIGURE 25-4. Anteroposterior (**A**) and frog-leg lateral (**B**) hip radiographs of a 12-year, 4-month-old girl demonstrate an acute-on-chronic epiphyseal displacement. The radiographic changes seen on both radiographic views demonstrate an acute increased displacement of the femoral head from a previous more chronic position of displacement, as indicated by the new bone formation on the inferior and posterior femoral neck.

An acute presentation in SCFE occurs in approximately 10% of patients (18,62). It is manifest by the sudden onset of severe pain and hip dysfunction in a patient who was previously asymptomatic. A few patients may describe prodromal symptoms for a short time preceding the acute onset of pain, which is frequently associated with minimal trauma. Although the literature varies with respect to the duration of painful symptoms prior to presentation, for a SCFE to be classified as acute, most reviews stipulate that the painful symptoms be present for no longer than a 3-week duration (5,62,63,64 and 65). Physical examination demonstrates the affected limb externally rotated and shortened with the patient refusing to bear weight. Active motion of the affected hip is severely limited by muscle spasm, and the patient complains of intense pain with any attempt at passive hip motion. Radiographs document the epiphyseal displacement, and show no evidence of bone healing or remodeling (66,67) (Fig. 25-5).

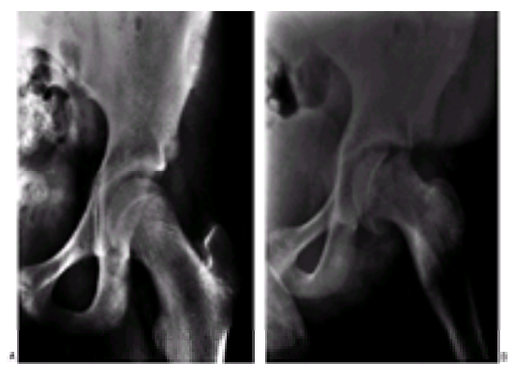

FIGURE 25-5. Anteroposterior (**A**) and frog-leg lateral (**B**) hip radiographs of a 12-year, 10-month-old girl demonstrate acute epiphyseal displacement. There is no evidence of bone healing or remodeling at the femoral neck.

Classification systems are only useful to the treating physician if they assist in the planning of treatment or relate to the outcome of a specific disease process. In SCFE, the classification system of acute, chronic, or acute-on-chronic, with respect to patterns of presentation, traditionally has been used. Loder and colleagues have proposed a more simplified classification system in SCFE, based on physeal plate stability at the time of presentation. A slip is classified as unstable if the patient has such severe pain that walking is not possible, even with crutches, regardless of the duration of symptoms. A slip is classified as stable if walking and weightbearing are still possible, with or without crutches (68,69). Other authors include SCFE that shows reduction at the time of surgical stabilization, either intentional or unintentional, as retrospectively unstable (70,71). Both classification systems in SCFE have been shown to be of assistance in the planning of treatment and the projection of outcome. The more simplified system, however, in which slips are classified as stable or unstable, seems to be more objective in its method of classification, and has the potential to be more useful not only in determining treatment, but also predicting outcome. Loder and colleagues (68) have shown that not all slips classified as acute are unstable, and not all slips classified as chronic are stable. They, as well as other authors (70,71,72,73 and 74), have also shown that slips treated by the same technique and classified as stable have a higher rate of satisfactory results from treatment when compared with unstable slips, which show a

lower rate of satisfactory results primarily because of higher rates of osteonecrosis. Loder reported the development of femoral head osteonecrosis in 14 of 30 patients (46.7%) presenting with an unstable SCFE (68). As experience with the more simplified system of classification continues to be reported, it appears that the simplified system (stable versus unstable) is becoming the more useful form of classification in SCFE.

RADIOGRAPHIC FEATURES

The actual diagnosis of SCFE is confirmed by radiographic examination of the affected hip taken in two orthogonal planes. The anteroposterior radiograph usually demonstrates physeal plate widening and irregularity, and a decrease in epiphyseal height in the center of the acetabulum. A crescent-shaped area of increased density frequently can be identified in the proximal portion of the femoral neck, and is known as the blanch sign of Steel (75). This radiographic finding is created by the double density of the posteriorly displaced femoral head on the femoral neck. The femoral metaphysis of the affected hip also appears to be more laterally displaced from the medial acetabular wall, compared with the unaffected hip (Fig. 25-6). A positive Klein line is identified as the amount of slip increases. Klein line is defined as a straight line drawn along the superior basal margin of the femoral neck on the anteroposterior radiograph (76). Normally this line intersects the lateral aspect of the epiphysis. The amount of femoral head intersected is dependent on the degree of hip rotation, and is greatest when the hip is in maximum internal rotation. As progressive displacement of the epiphysis occurs, the amount of Klein line that intersects the epiphysis decreases, compared with the uninvolved hip. Eventually, the line fully misses intersection with the proximal femoral epiphysis (Fig. 25-7).

FIGURE 25-6. Anteroposterior hip radiograph demonstrates the classic radiographic findings in slipped capital femoral epiphysis, which include physeal plate widening and irregularity, a decrease in epiphyseal height, and a lateral displacement of the femoral neck from the medial acetabular wall. Also of note is a crescentic area of increased density in the proximal portion of the femoral neck adjacent to the physeal plate, known as the blanch sign of Steel.

FIGURE 25-7. Anteroposterior pelvic radiograph of a 15-year, 6-month-old boy demonstrates a positive Klein line measurement. A line drawn along the superior basal margin of the femoral neck (i.e., Klein line) intersects the lateral aspect of the right femoral head, but essentially misses intersection with the left femoral head. This finding indicates displacement of the left femoral head–femoral neck relation, and indicates a slipped capital femoral epiphysis at the left hip.

A true lateral or cross-table lateral radiographic view of the hip better defines the extent of posterior displacement of the femoral epiphysis (Fig. 25-8). This view can be of assistance in diagnosing minimal slips because it better elucidates the posterior displacement. This view, however, remains difficult to obtain in the extremely obese patient.

FIGURE 25-8. True lateral hip radiograph of a slipped capital femoral epiphysis demonstrates the posteriorly displaced femoral head remaining in close contact with the femoral neck. Early secondary resorption and rounding of the posterior femoral neck region are noted.

A frog-leg lateral radiographic view usually demonstrates the posterior displacement and step-off of the epiphysis on the femoral neck (Fig. 25-9). Although the frog-leg lateral view assists in confirming the diagnosis, it should be avoided in the acute (unstable) presentation, because of the potential of increasing the physeal displacement during positioning for the radiograph.

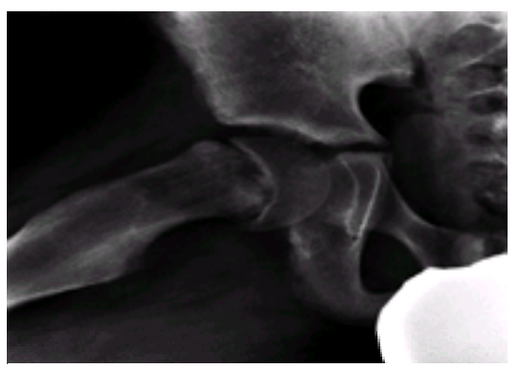

FIGURE 25-9. Frog-leg lateral hip radiograph of a slipped capital femoral epiphysis demonstrates an epiphyseal step-off and posterior displacement of the femoral head on the femoral neck, classically seen in slipped capital femoral epiphysis.

Two radiographic images of the affected hip in SCFE, taken in orthogonal planes, should be obtained when possible to assist in diagnosis and planning of treatment. The anteroposterior and true lateral radiographic views of the affected hip are preferred. If a true lateral view of the involved hip is not technically obtainable, a good compromise in most patients is the frog-lateral view.

Ultrasonography recently has been proposed in the diagnosis and evaluation of SCFE (77,78). Kallio and colleagues used ultrasonography in 26 hips of patients with SCFE to confirm diagnosis and degree of slip by evaluating the step-off in the anterior physeal outline, and by measuring the amount of posterior epiphyseal displacement (79). Although ultrasonography can confirm the diagnosis of SCFE, it offers little if any information compared to conventional radiography in SCFE, and has no additional use in treatment.

Computed tomography scan has been shown to be of assistance in both the diagnosis and treatment of SCFE (80). Computed tomography scan can be used to confirm epiphyseal displacement and accurately measure the amount of displacement in patients with symptoms suggestive of a SCFE, but without documentation on plain radiographs (Fig. 25-10). Currently, a computed tomography scan in SCFE is rarely needed in the diagnosis of SCFE, but can be of assistance in assessing the presence of early physeal plate closure in severe slips, in which positioning for standard radiographic views may be difficult.

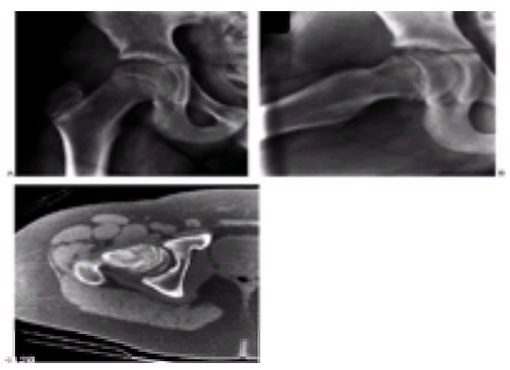

FIGURE 25-10. Radiographs of a 12-year, 2-month-old girl with recent onset of hip pain and a physical examination showing early findings of slipped capital femoral epiphysis. Anteroposterior (**A**) and frog-leg lateral (**B**) hip radiographs demonstrate mild physeal plate-widening and minimal displacement, indicating a mild slipped capital femoral epiphysis. **C:** Computed tomography (CT) image of the same hip more clearly demonstrates the minimal posterior displacement of the femoral head on the femoral neck, consistent with a mild slipped capital femoral epiphysis.

Reports of the use of magnetic resonance imaging studies in hips affected with SCFE remain rare (81,82). The published reports, however, confirm that magnetic resonance imaging can be of assistance in the early diagnosis of SCFE, by identifying morphologic and signal abnormalities around the affected physeal plate at a time when plain radiographs, and even computed tomograph scans, may appear normal. Umans and colleagues (82) performed magnetic resonance imaging on 15 symptomatic hips secondary to SCFE. They reported T1-weighted images to universally show physeal widening, as well as physeal displacement when present. The T2-weighted images demonstrate synovitis and joint effusion, as well as marrow edema in the juxtaphyseal femoral neck metaphysis and femoral epiphysis of the affected hip (Fig. 25-11). Although magnetic resonance imaging has been shown to assist in the diagnosis of minimal SCFE, it is not to be used as a routine radiologic procedure for diagnosis of SCFE, but may be rarely indicated in cases of hip pain associated with a high clinical suspicion of SCFE but negative plain radiographs.

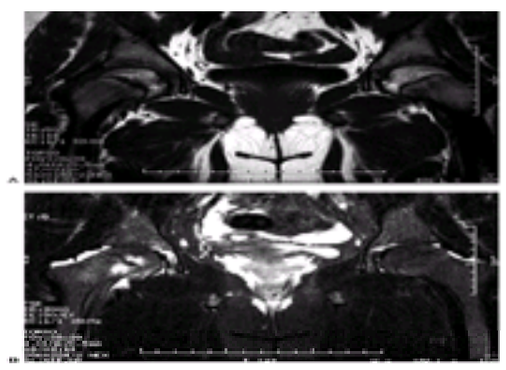

FIGURE 25-11. Magnetic resonance imaging (MRI) of a 12-year, 8-month-old girl with recent onset of right hip pain and a physical examination indicative of a slipped capital femoral epiphysis. **A:** T1-weighted image demonstrates physeal widening and minimal epiphyseal displacement on the right. **B:** T2-weighted image demonstrates marrow edema in the juxtaphyseal femoral neck metaphysis and femoral epiphysis, as well as a joint effusion on the right.

A radiographic classification system based on the maximum anatomic displacement of the femoral head on the femoral neck, as seen on any of the radiographic views of the hip in a patient with SCFE, has been described (83). In this classification system a “minimal slip” is defined as epiphyseal displacement of less than one-third of the width of the femoral neck (Fig. 25-9); “moderate slip” is defined as displacement of one-third to one-half of the width of the femoral neck (Fig. 25-5); and “severe slip” is defined as displacement greater than one-half of the width of the femoral neck (Fig. 25-8). Southwick has recommended that displacement be measured by the angle subtended between the femoral head and the femoral shaft on the anteroposterior and lateral radiographic views (84). Boyer and colleagues have proposed measurement of the maximum difference in the Southwick angles, between the involved and uninvolved hip in SCFE, as a radiographic classification system (62). These authors define a mild slip as a head–shaft angle difference of 30 degrees or less, a moderate slip as a 30- to 50-degree difference, and a severe slip as a difference of more than 50 degrees. The reproducibility of these radiographic classification systems in SCFE remains unproven, but can be used to assist in planning treatment, and more importantly, aid in determining outcome in SCFE with respect to the severity of slip and the future development of degenerative joint disease.

NATURAL HISTORY

The complete natural history of the hip in SCFE remains unknown. Very few long-term studies with untreated pa-tients exist in the current literature, and the studies that do exist deal only with small numbers of patients (18,85,86,87,88 and 89).

The current literature shows that not all hips affected with SCFE are symptomatic during slippage. In fact, the second slip can be asymptomatic in 30 to 40% of patients. In most of these patients the slip shows a very slow minimal progression, with ongoing remodeling during the adolescent growth phase (19,21,22,90). Symptomatic slips, on the other hand, usually show more rapid progressive displacement. Jacobs has shown that the longer the duration of symptoms the more likely the slip will have a greater severity of displacement (83).

Howorth stated that SCFE during adolescence frequently is associated with degenerative joint disease of the hip during middle life (91). Long-term studies of patients

with SCFE do indicate a definite relation between SCFE during adolescence and the subsequent development of degenerative joint disease (18,62,89).

The incidence of degenerative joint disease of the hip associated with previous SCFE remains unknown. Murray reported on 200 patients with degenerative joint disease of the hip, and described the tilt deformity, a sign of femoral neck remodeling believed to be associated with previous SCFE, in 40% of the patients (92). Stulberg and colleagues have reported a pistol-grip deformity at the proximal femur, believed to be secondary to previous SCFE or Perthes disease, in 40% of patients with assumed primary osteoarthrosis undergoing total hip arthroplasty (93). The presence of this postslip morphology at the proximal femur, and its association with osteoarthrosis of the hip, was also reviewed by Goodman and colleagues in 1997 (94). They examined 2,665 adult human skeletons from an osteological collection, and found a prevalence of postslip morphology in 215 skeletons (8%). Severe osteoarthrosis of the hip was found to be more prevalent in association with postslip morphology, when compared to the contralateral normal hip. It was therefore concluded that the presence of postslip morphology was a major risk factor for the subsequent development of severe hip degenerative joint disease. Solomon reviewed 327 patients with degenerative joint disease at the hip, and found only six patients with a history of previous SCFE (95). Resnick refuted the association of the radiographic tilt deformity with previous SCFE, by showing that the remodeling process at the femoral neck was not the result of SCFE, but, rather, was solely related to the osteoarthritis (96).

Long-term studies have confirmed that the prognosis for subsequent development of degenerative joint disease and deteriorating function at the hip affected with SCFE are dependent on the severity of the slip and increasing patient age at follow-up (18,86,87,88 and 89). Oram has demonstrated that severe slips develop earlier degenerative joint disease and poorer hip function than do moderate slips (87). Jerre (86) and Ross and colleagues (88) reported an increase in symptoms and a deterioration in hip function associated with increasing patient age at follow-up in patients with SCFE. Jerre also noted that the clinical symptoms do not always correlate with the changes seen radiographically (86). Carney and colleagues recently reported long-term follow-up on 155 hips in 124 patients affected with SCFE, with a mean follow-up of 41 years from symptom onset (18). Their work represents continued follow-up on the patients previously reported by Boyer and colleagues (62). Carney reported a continued deterioration in Iowa Hip Rating scores with increasing time of follow-up. This deterioration in hip-rating scores was shown to occur in all of the grades of slip severity. An accompanying deterioration in the radiographic grade for degenerative joint disease also was documented.

The current literature suggests that the onset of both symptoms and degenerative joint disease at the hip will be accelerated in most cases of SCFE. This accelerated onset of degenerative joint disease has been shown to be directly related to the severity of the slip. Treatment, therefore, can influence positively the natural history of SCFE, if early recognition and subsequent intervention to prevent progressive deformity are achieved.

TREATMENT

The treatment in SCFE is designed to improve on the natural history of the untreated condition as it is currently understood. The goals of treatment include the prevention of further slipping, by stabilizing the diseased physis and thereby reducing the incidence and onset of osteoarthrosis at the affected hip, and the avoidance of iatrogenically induced osteonecrosis of the femoral head and chondrolysis.

Treatment can be divided into three categories: treatment to prevent further slippage, treatment to reduce the degree of slippage, and salvage treatment.

Treatment to Prevent Further Slippage

After slipping of the proximal femoral epiphysis has been documented, treatment should be directed at prevention of further slippage. This can be accomplished by spica cast immobilization, *in situ* metallic pin and screw fixation, and bone-peg epiphysiodesis.

The treatment rationale for the use of spica cast immobilization in SCFE is based on the following assumptions, not all of which have been proven to be true. The slippage in SCFE is short-lived and will heal spontaneously if immobilized for a long-enough period. Further slipping can be prevented by external immobilization. The treatment process is associated with a low complication rate, because there is no violation of the proximal femur or hip joint. Prolonged joint immobilization in adolescence is without increased complications (18,24,97).

Treatment by spica cast immobilization has been reported mainly in chronic and acute-on-chronic SCFE. The use of spica cast immobilization in acute SCFE has been reported in only a limited number of patients (97,98). Previous authors (97,98) have standardized the method of treatment, which includes an initial phase of bed rest with split Russell or Buck skin traction, until joint irritability has lessened. Traction averages 10 days, but has been reported to last as long as 30 days (97). A one-and-a-half or double-spica cast is then applied without any attempt at epiphyseal reduction. The hip is positioned at the midpoint of comfortable internal and external rotation. Radiographs of the hip are obtained every 4 weeks to document that no additional progression of slip has occurred, and to evaluate healing. Adequate physeal plate healing to allow for discontinuation of the immobilization is determined radiographically, and is present either when physeal plate closure is identified or when the metaphyseal juxtaphyseal lucency (i.e., a radiolucent zone on the metaphyseal side of the physis) (59) is no longer seen on radiographs of the affected hip. The immobilization averages 12 weeks with a range of 8 to 16 weeks. After cast removal, gentle range of motion and muscle-strengthening exercises are initiated.

The results of treatment with spica cast immobilization in SCFE have been reported by several authors (18,97,98 and 99). Successful prevention of further slippage by spica cast immobilization is reported at 82 to 97% (97,98). Associated with this high rate of success in preventing further slippage, Betz and colleagues reported 14 of 17 hips (82%) treated by spica cast immobilization to show premature physeal closure at the affected physis, in comparison with the contralateral uninvolved hip (97).

Complications associated with spica cast immobilization include recurrent slip after cast removal in as high as 18% of patients (98). Betz and colleagues reported only a 3% rate of recurrent slip if the spica cast is maintained until full resolution of the metaphyseal juxtaphyseal radiolucent zone has been radiographically documented (97). Osteonecrosis of the femoral head has been reported by Carney and colleagues to be associated with spica cast immobilization, without reduction in 2 of 27 hips (7%) (18). Meier and colleagues reported full-thickness skin pressure ulcers in 2 of 13 patients (16%) (98). The development of psychosocial complications during prolonged treatment with a spica cast in these generally obese patients also must be considered. The most frequent and serious complication associated with spica cast immobilization in SCFE remains chondrolysis. This complication is reported to occur in 19 to 67% of affected hips treated by spica cast immobilization, and has been shown to have a higher occurrence rate, with more severe degrees of slippage at the time of spica cast placement (18,97,98 and 99).

Although treatment with spica cast immobilization to prevent further slippage has been considered as an alternative in patients with chronic SCFE, abandoning its use, due to the high rate of associated serious long-term complications, is recommended.

In situ fixation of the displaced femoral head, with metallic pins or screws, historically has been and remains the most commonly used method of stabilization in SCFE **[➥3.14]**. The primary rationale behind the use of metallic fixation is that the fixation device, by crossing the diseased physeal plate, provides mechanical support to prevent further slippage. Historically, *in situ* fixation has been associated with some technical difficulties and higher complication rates, arising from a poor understanding of the three-dimensional characteristics of pin placement, inadequate radiographic imaging, a lack of knowledge of the intraosseous vascular supply of the femoral head, and inadequate internal fixation. Currently available surgical techniques, fixation devices, and fluoroscopic equipment, as well as a better understanding of the anatomy and the pathoanatomy found in SCFE, have greatly improved and simplified the performance of the procedure, which has led to improved treatment outcomes. When *in situ* fixation is performed percutaneously or through a minimal incision, it has the advantages of minimal blood loss, avoidance of opening of the hip joint, and minimal requirement for postoperative hospitalization and rehabilitation (67). Certain disadvantages, however, are inherent with the technique, and include the possibility of persistent penetration of the hip joint by the fixation device (100) and increased technical difficulty in some severe slips. The need for subsequent hardware removal has historically been proposed as an additional disadvantage; however, several recent reports have questioned the benefit of routine hardware removal (67,101,102 and 103). Currently, hardware used for stabilization in SCFE that is causing no symptoms is no longer routinely removed.

Review of the historical literature on metallic fixation in SCFE demonstrates previous complication rates as high as 20 to 40%, with the majority of the complications related to hardware placement and hip joint violation leading to osteonecrosis and chondrolysis (104,105 and 106). Proximal femoral fracture, unsuccessful stabilization, and hardware breakage also were reported complications (106,107). The use of multiple pins and screws, improper starting position for the hardware, and inadequate radiography were shown to be associated with this higher incidence of complications (25,108,109,110 and 111). With experience and a better understanding of the actual pathoanatomy of SCFE, the principles of safe and successful *in situ* metallic fixation have been developed, and have been shown to significantly lower the incidence of complications previously associated with metallic fixation.

In situ fixation remains a surgical technique dependent on biplane fluoroscopy to perform properly. With the advent of current fluoroscopic equipment and patient positioning devices, adequate visualization of the femoral head and proximal femur, even in obese patients, is possible, and has greatly improved the simplicity and safety of *in situ* fixation. The proper technique of percutaneous *in situ* fixation in SCFE, to include patient positioning, hardware start-point determination, hardware

placement, and postoperative care, has been described by Aronson and Carlson (66) and Morrissy (112).

The principles of successful *in situ* fixation in SCFE warrant reemphasis. It is imperative that the outline of the femoral head be seen on both the anteroposterior and true lateral (not frog-leg lateral) radiographic projections prior to any attempt at fixation placement.

The central axis of the femoral head remains the only safe position for the fixation device. The farther off the central axis the fixation is, the more likely penetration of the femoral head is to occur. Walters and Simon (104), through the use of mathematical models, have demonstrated what is called the blind spot of the femoral head. In using biplane radiography, it was shown that there is always an area where a pin can violate the femoral head and not be seen radiographically. This blind spot is small in the central axis of the femoral head; however, it increases greatly the farther the position of the fixation device is from the femoral head central axis (Fig. 25-12). Only by positioning the fixation device centrally, and at least 5 mm from the margin of the femoral head, can avoidance of penetration be assured (Fig. 25-13). Because there is only one central axis in the femoral head, the use of multiple pins and screws must position some of the devices off the central axis and increase the incidence of potential femoral head penetration. Blanco and colleagues validated this concept in their report of 114 hips in 80 patients treated with single, double, or multiple pins (108). The authors reported a decrease in pin-related complications from 36% in hips stabilized by multiple pins to 4.6% in hips stabilized by a single pin.

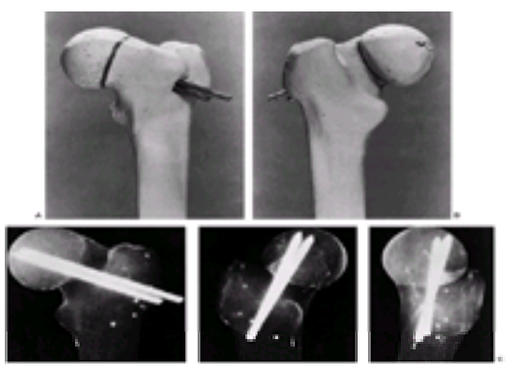

FIGURE 25-12. Models of a moderate slipped capital femoral epiphysis stabilized *in situ* with two threaded pins demonstrate the concept of the radiographic blind spot of the femoral head (**A**) and (**B**). This concept proposes that there will always be an area in the femoral head where a pin may violate the head itself, and yet not be seen on plain radiographs (**C**). The blind spot is smallest in the central axis of the femoral head, and increases greatly the farther the fixation device position is off the central axis. Only by positioning the fixation device centrally, and at least 5 mm from the margin of the femoral head, can avoidance of penetration be assured.

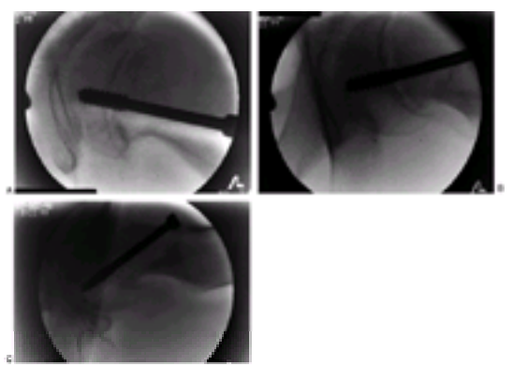

FIGURE 25-13. Anteroposterior (**A**), frog-leg lateral (**B**), and true lateral (**C**) fluoroscopic images of the hip in a 13-year, 6-month-old girl with slipped capital femoral epiphysis taken following *in situ* fixation. All images demonstrate proper hardware placement, with the screw positioned perpendicular to the plane of the femoral head, and centrally within its axis, in all views. The tip of the hardware remains approximately 5 mm from the margin of the femoral head.

The metaphysis of the femoral neck displaces anteriorly from the femoral head, as the femoral head rotates posteriorly around the axis of the femoral neck. For the fixation device to enter and stay central in the femoral head, it must be placed perpendicular to the plane of the proximal femoral physis. This can only be accomplished if the starting position for the fixation is on the anterior femoral neck and not the lateral cortex of the proximal femur (25,109,113) (Fig. 25-14). The proper starting point on the femoral neck is determined by the severity of displacement of the femoral head. In hips with minimal displacement, the starting point is anterolateral at the base of the femoral neck. In hips with more severe femoral head displacement, the starting point moves progressively more medial on the femoral neck (Fig. 25-15).

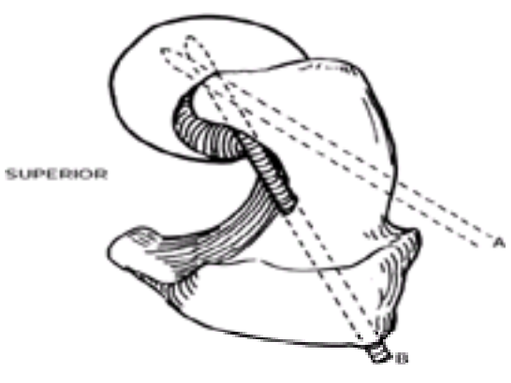

FIGURE 25-14. The metaphysis of the femoral neck displaces anteriorly from the femoral head as the femoral head rotates posteriorly in slipped capital femoral epiphysis. For the fixation device to enter and stay central in the femoral head, it must be placed perpendicular to the plane of the femoral head. This approach necessitates a starting point along the anterior femoral neck (*A*). The more traditional starting point on the lateral cortex of the femur (*B)* is associated with penetration of the cortex of the posterior femoral neck before reentering the femoral head. This route can lead to damage of the posterior retinacular vessels, which provide the major blood supply to the femoral head, and direct the hardware into the more vulnerable anterior femoral head quadrant. (From ref. 106, with permission.)

FIGURE 25-15. Series of frog-leg lateral hip radiographs in slipped capital femoral epiphysis following *in situ* fixation. Each radiograph demonstrates progressive posterior displacement of the femoral head. For the fixation device to stay central in the femoral head, its starting position progressively moves more proximal on the anterior femoral neck as the femoral head displacement becomes more severe.

The internal fixation device should always avoid the superior and anterior quadrant of the femoral head. The terminal branches of the lateral ascending cervical artery traverse this quadrant (114) (Fig. 25-16). These intraosseous vessels are at high risk for injury leading to segmental osteonecrosis of the femoral head if the fixation device is placed in the superior quadrant of the femoral head, as has been shown by Brodetti (115) and Stambough and colleagues (105) (Fig. 25-17).

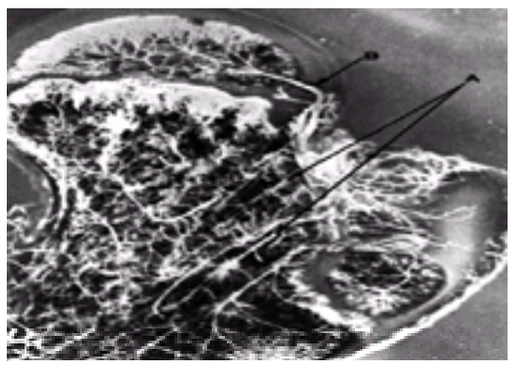

FIGURE 25-16. The blood supply to the femoral neck and proximal femoral epiphysis. The lateral ascending cervical artery gives off metaphyseal branches into the femoral neck (*A*), then continues on to form epiphyseal branches that provide a segmental blood supply to the superior quadrant of the femoral head (*B*). Fixation placed into the superior quadrant of the femoral head could damage this blood supply, leading to osteonecrosis. (From ref. 114, with permission.)

FIGURE 25-17. Frog-leg lateral hip radiograph, in a patient with slipped capital femoral epiphysis, demonstrates multiple pin fixation from a lateral starting position. The hardware is not maintained in the center of the femoral head, but rather is confined to the vulnerable anterosuperior quadrant. Penetration of the femoral head and early segmental osteonecrosis are demonstrated.

Following fixation, radiographic confirmation that the fixation device has not penetrated the joint space is mandatory. This can be accomplished by removing the affected limb from the holding device on the fracture table, and moving the hip through a full range of motion under fluoroscopic examination. The "approach–withdraw" technique of Moseley has been proposed to radiographically confirm avoidance of femoral head penetration (116). This technique employs visualization of the femoral head fluoroscopically, while the fully extended limb is rotated from maximum internal rotation to maximum external rotation. As the hip is ranged, the tip of the fixation device in the femoral head is observed to approach the subchondral outline of the femoral head, then withdraw without ever violating the subchondral bone. If violation of the subchondral bone is noted, then femoral head penetration has occurred.

The metallic device used for femoral head stabilization must be of appropriate strength to avoid failure prior to physeal plate closure. It should also be of such strength to avoid the need for multiple devices that increase the prevalence of penetration and the volume of metal occupying the femoral head. The device should be of a cannulated design to facilitate placement, and have back-cutting threads for ease of removal, if it should be necessary. Doane and colleagues, through the use of biomechanical analysis of bovine proximal slipped femoral epiphyses, reported that a single 5.5-mm–diameter screw provided approximately the structural stiffness of two 4.5-mm–diameter screws, and that a single centrally placed 7.5-mm–diameter screw approached the stiffness of an unslipped epiphysis (117). Karol and colleagues, using mechanical force analysis in cannulated screw fixation of slipped proximal femoral epiphyses in bovine models, reported only a 33% increase in stiffness to failure in specimens secured with double-screw fixation, compared to single-screw fixation (118). Kibiloski and associates (119) created an acute SCFE in 12 pairs of immature bovine femurs, and pinned one side with a single cannulated screw and the opposite side with two cannulated screws. The specimens were then subjected to physiologic shear loads simulating slow and fast walking. The rates of creep were decreased 23% with double screws compared to a single screw at slow walking and 30% at fast walking. These differences, however, were not statistically significant. These authors concluded that the small gain in fixation stiffness and cyclic creep, seen with a second screw, did not offset the potential increase in complications associated with its placement to warrant its routine use.

By adhering to these treatment guidelines and principles, almost all slipped proximal femoral epiphyses should be able to be stabilized with percutaneous placement of a single 6.5- to 7.5-mm cannulated screw. One possible exception is the acute unstable slip in a very obese and unreliable patient in whom the need for a second screw, to give adequate stabilization and to control possible femoral head rotation, has been proposed by Koval and colleagues (120). The need for a second screw remains controversial, with recent reports implying that it is not needed. Aronson and Carlson (66) reported on single-screw fixation in SCFE in 58 hips. Eight of these 58 hips were classified as acute slips with only 1 of the 8 hips showing loss of fixation. Ward and colleagues (67) reported on fixation with a single screw in SCFE in 53 hips. Five of the 53 hips were acute slips with none of the 5 hips showing loss of fixation. More recently, Goodman and colleagues (121) reported on 21 hips (9 acute and 12 acute-on-chronic) treated with a *single in situ* cannulated screw. At physeal plate closure, no hip showed any significant loss of fixation or change in head-shaft angle.

Reports confirm the safety, reliability, and efficacy of the *in situ* single, centrally positioned, cannulated-screw fixation technique for the stabilization of acute and chronic SCFE (66,67,120,121). If these series are combined, 192 hips of acute, acute-on-chronic, and chronic patterns were stabilized by a single screw, of which 34 hips were classified as acute or acute-on-chronic presentations. Following stabilization, there was only one case of osteonecrosis, which was identified in a patient with an acute slip, and no cases of chondrolysis. Five hips were reported to have had transient femoral head penetration, all of which were recognized and adjusted, and none of which developed any complications related to the penetration. There were no reported cases of hardware breakage. Four hips developed fractures in the proximal femur related to the hardware used to treat SCFE (122,123). Three cases of increased slippage around the fixation were reported. One case occurred in a hip in which the fixation was placed outside of the central quadrant of the femoral head, and the other two cases were following single-screw fixation of an acute slip and an acute-on-chronic slip (124).

Reports suggest that *in situ* pin and screw fixation of SCFE can be associated with an accelerated closure of the affected physeal plate. Ward and colleagues, in a review of 53 SCFE hips, reported 49 hips (92%) to have undergone closure following single-screw fixation (67). The time to closure was analyzed in 29 of the 49 hips. Physeal plate closure averaged 13 months (range, 2 to 34 months) and showed no correlation to age at the time of fixation, race, or gender. A longer time to physeal closure was noted in hips with more severe displacement and increasingly eccentric screw placement. Premature closure of the physeal plate in the treated hip, compared with the contralateral normal hip, was demonstrated in 19 of 20 patients treated by single-screw fixation. Stanton and Shelton reported on 26 SCFE hips

treated with *in situ* fixation, and demonstrated the pinned physes to close an average of 10.2 months earlier than the unpinned physes (125). The average time to closure was 12 months in the pinned physes and 22.2 months in the nonpinned physes. Although accelerated physeal plate closure in SCFE treated with *in situ* metallic fixation has been demonstrated, the reason for the early closure has not been established. Physeal damage from placement of the fixation device, or more likely, physeal damage secondary to the slip itself, could be considered as possible etiologies.

In patients whose age at the onset of SCFE is greater than 1 year earlier than the reported mean for the disorder (boys younger than 12.5 years old and girls younger than 11.1 years old), premature closure of the proximal femoral physis, induced by metallic stabilization, may lead to growth disturbances in the proximal femur, including relative greater trochanteric overgrowth, coxa vara, and coxa breva (126). Segal and colleagues demonstrated radiographic sequelae about the proximal femur in 64% of 33 hips in these younger patients at follow-up, who had been stabilized by metallic fixation for SCFE. The authors concluded that stabilization in younger patients with SCFE should be by fixation devices that will not induce early physeal closure, but rather will allow continued proximal physeal plate growth. Hansson has proposed a similar concept for stabilization in SCFE (127). He has recommended the use of the hook pin as the fixation device of choice, and has shown continued growth of the femoral neck along the pin of as much as 15 mm. Despite the large number of patients showing radiographic changes at the proximal femur (126), only two patients demonstrated limb-length discrepancy, both of which measured 1 cm or less, and only three patients demonstrated a Trendelenburg gait. The true clinical significance of these radiographic findings, seen following premature physeal plate closure in these younger patients, remains in doubt.

In hips in which physeal closure is not induced, femoral head overgrowth off the fixation device is possible. This was reported by Ward and colleagues in 3 of 53 hips treated by single-screw fixation (67). No slip progression or detrimental consequences were noted in these patients.

Carney and colleagues reported long-term follow-up of SCFE patients treated by various techniques, and with a mean follow-up of 41 years after onset of symptoms (18). They concluded that, regardless of the slip severity in SCFE, pinning *in situ* "provides the best long-term function with a low risk of complications and most effectively delays the development of degenerative arthritis" (18). Other recent studies have also demonstrated that fixation with a single 6.5- to 7.5-mm screw provides safe and reliable epiphyseal stabilization, and promotes premature physeal fusion in patients with SCFE, while decreasing the rate of complications historically associated with multiple-pin fixation (66,67,108,120,121,128).

The use of open bone-peg epiphysiodesis **[➥3.15]** for stabilization in SCFE was first described by Ferguson and Howorth in 1931 (26). The rationale behind the use of this technique in the stabilization of SCFE is based on the assumption that open bone grafting of the proximal femoral physis should lead to a more rapid physeal closure as a result of the curetting of a large portion of the physeal plate, with subsequent placement of bone graft bridging the physeal plate, and a lower rate of complications as a result of direct visualization of the femoral neck and head (129,130 and 131).

The disadvantages associated with open bone-peg epiphysiodesis include its more demanding and extensive surgical approach, longer operative times, increased blood loss, and the potential for continued femoral head displacement prior to physeal plate closure. Ward and Wood reported operative times averaging 3 h (range, 2 to 5 h), and blood loss averaging 800 mL (range, 250 to 2,400 mL) in association with 17 hips treated by bone-peg epiphysiodesis (132). Irani and colleagues reported an average operative time of 3 h and 40 min, and average blood loss of 750 mL, in 48 hips treated by open bone grafting (133). More recently, Rao and colleagues (134) reported on 64 open bone-peg epiphysiodeses for SCFE. The average operative time was 122 ± 34 minutes, and blood loss was 426 ± 238 mL. Longer hospitalization times—a mean stay of 12.5 days as reported by Rao and colleagues (134)—and the need for more extensive postoperative rehabilitation seen in bone-peg epiphysiodesis, make it a more costly form of treatment. The minimal stability created by the bone graft itself makes the potential for continued femoral head displacement prior to physeal plate closure a definite risk. This potential instability necessitates the additional inconvenience and requirement for spica cast immobilization in most patients, particularly in slips with an acute or unstable presentation. It also necessitates the need for extended limited weightbearing on the affected hip until physeal plate closure has occurred (135).

The recommended surgical technique used in bone-peg epiphysiodesis has been described (132,135) **[➥3.15]**. Historically, an anterior iliofemoral approach to the hip joint has been used, but Weiner and colleagues have recommended an anterolateral approach, which they report is associated with reduced operative time, less blood loss, and improved wound healing, compared with the anterior iliofemoral approach (136). After the hip capsule is opened, a tunnel is created between the femoral neck and the central femoral head with drills and curettes. Corticocancellous iliac bone graft is then obtained and packed tightly into the tunnel (Fig. 25-18). Unfortunately, no standardized dimensions or cross-sectional area for the size of the bone graft, needed to avoid graft failure, have been documented. Weiner and colleagues recommended sandwiching multiple corticocancellous slips into the bone tunnel to a width of approximately 1 cm (135). Ward and Wood recommended using a single rectangular bone graft, measuring 5 cm in length and 6 mm in height by 6 mm in width, which is impacted tightly across the physis (132). Postoperatively, a spica cast is placed on all patients with acute slips, as well as any chronic slip demonstrating physeal instability at the time of surgery.

FIGURE 25-18. Technique used in open bone-peg epiphysiodesis in slipped capital femoral epiphysis. **A:** Using an anterolateral approach to the hip, the hip capsule is opened and the proximal femoral physis is identified. A small anterior metaphyseal cortical window is formed in the femoral neck immediately distal to the physis. **B:** A 1-cm hollow mill drill is then passed through the window into the center of the femoral head under fluoroscopic image intensification. **C:** The physeal plate is thoroughly curetted adjacent to the cylindrical bone tunnel. **D:** Cortical cancellous grafts are obtained from the adjacent ilium, and packed tightly into the bone tunnel bridging the physeal plate. The cortical window of bone from the anterior femoral neck is replaced. (From ref. 137, with permission.)

A limited number of reports are available concerning the use of bone-peg epiphysiodesis in SCFE (63,131,132,134,135). Osteonecrosis and chondrolysis rarely are reported in association with this form of treatment. Weiner and colleagues reviewed 185 hips treated with bone-peg epiphysiodesis, including 26 acute slips and 159 chronic slips (135). A total of only three cases of osteonecrosis and one case of chondrolysis were reported. In the review by Rao and colleagues (134) on 64 open bone-peg epiphysiodeses for SCFE, four hips developed osteonecrosis and three hips developed chondrolysis. Other reported complications associated with bone-peg epiphysiodesis include failure to achieve physeal fusion, bone graft insufficiency with continued slippage, delayed wound healing, heterotopic bone formation, and lateral femoral cutaneous nerve dysesthesia (134).

The time to physeal plate closure following bone-peg epiphysiodesis averaged 2.5 months, as reported by Weiner and colleagues (135); 4.8 months (range, 3 to 15 months), as reported by Irani and colleagues (133); and 17 weeks, as reported by Rao and colleagues (134). Ward and Wood reported physeal closure in 12 of 17 hips treated by bone-peg epiphysiodesis (132). Eight of the 12 hips achieving physeal closure did so by 16 weeks. Two hips, however, required between 24 and 36 weeks for closure.

Bone graft insufficiency, defined as bone graft breakage, displacement, or resorption, was noted in 8 of the 17 hips (47%) reported by Ward and Wood (132). Three of these hips went on to physeal closure, whereas five hips required additional stabilization by metallic pin fixation. Continued radiographic displacement of the femoral head after bone graft epiphysiodesis, but prior to physeal closure, was reported in all patients demonstrating bone graft insufficiency, but also was noted in three of nine hips in which no insufficiency was noted. Rao and colleagues (134) identified one hip with an acute displacement of the bone graft that was then treated by closed reduction and pinning, and 12 hips with continued displacement without bone graft insufficiency, showing greater than or equal to 5 degrees of increase in the lateral head–shaft angle (range, 5 to 36 degrees) at physeal plate healing, in their 64 hips treated by bone-peg epiphysiodesis.

The more extensive surgical approach, greater blood loss, longer hospitalization, and reported problems with bone graft insufficiency, and continued femoral head

displacement associated with bone-peg epiphysiodesis, preclude this technique from being recommended for the routine stabilization of the physeal plate in SCFE.

Treatment to Reduce the Degree of Slippage

Natural history studies as well as long-term follow-up studies on *in situ* fixation, have shown a direct relation between the degree of displacement in SCFE and the affected hip's final outcome, including the development of degenerative joint disease (18,87,138). Treatment methods that reduce the degree of slip, and create a more anatomic relation of the femoral head with the remainder of the femur, should lead to improved function and motion, as well as delay the onset of degenerative joint disease. To truly have a beneficial effect on the natural history, however, these treatment methods must not be associated with a significant increase in complications, particularly osteonecrosis and chondrolysis of the femoral head. Techniques to reduce the degree of slip include closed manipulation prior to physeal plate stabilization and osteotomies of the proximal femur, performed either concurrently with physeal stabilization or after physeal closure.

The potential need for closed manipulation of femoral head displacement in SCFE is based on the concept that spontaneous remodeling at the proximal femur, following physeal stabilization, will not be adequate to restore femoral head–femoral neck and femoral head–femoral shaft relations to near-normal alignment. Several authors have implied that remodeling following *in situ* fixation in SCFE has the ability to correct proximal femoral deformity and secondarily to improve hip motion. Key (34), Billing and Severin (21), Bellemans and associates (139), and Wong-Chung and Strong (140) have reported on bony remodeling of the contour of the proximal femur that occurs in SCFE. These authors defined remodeling as the radiographic appearance of new bone formation between the overhanging femoral head and the posteroinferior femoral neck, in association with a rounding off of the prominent anterosuperior margin of the femoral neck. Lacroix and Verbrugge have demonstrated histologically that these radiographic changes are secondary to appositional new bone formation on the inferior margin and osteoclastic resorption on the superior margin of the femoral neck (141). O'Brien and Fahey, in a review of 12 hips of moderate to severe displacement in SCFE treated by *in situ* fixation, suggested that femoral neck remodeling leads to an associated improvement in hip motion to essentially normal values, except for a mild residual loss of internal rotation (142). They reported the probability of sufficient femoral neck remodeling to increase with an open triradiate cartilage, but to decrease with greater severity of slip (142,143).

Siegel and colleagues recently have confirmed that hip motion significantly improves following *in situ* fixation in SCFE, but that remodeling at the proximal femur is insufficient to restore normal hip alignment (20). Their study employed a quantitative evaluation of hip motion and proximal femoral remodeling following *in situ* fixation in 39 patients with SCFE, with 2 or more years follow-up. Hip motion was found to improve most rapidly in the first 6 months after treatment, mainly as a result of resolving muscle spasm, pain, and synovitis. Although hip motion continued to show improvement over the entire period of follow-up related to continued soft tissue stretching and bone resorption from the anterolateral femoral neck, it never approached the motion of the unaffected hip. Plain radiography and computed tomography scans demonstrated femoral neck remodeling, which produced an apparent improvement in the displaced femoral head and femoral neck relation, but did not confirm any significant change in the more critical relation between the displaced femoral head and the femoral shaft. The authors concluded that the improvement in hip motion, seen following *in situ* fixation in SCFE, was not directly related to significant osseous remodeling.

Although motion at the affected hip in SCFE after *in situ* fixation can be expected to improve as synovitis and protective spasm resolve, the bony deformity created by the slip shows little if any true realignment through remodeling. Closed manipulation to reduce the degree of displacement prior to stabilization in SCFE, therefore, has a potentially beneficial effect on the natural history, if it can be performed without increased complications. The major complication seen in association with closed manipulation in SCFE remains osteonecrosis of the femoral head, which leads to rapid deterioration in hip function. Although the incidence of osteonecrosis following closed manipulation in SCFE varies, most studies confirm an increase in the incidence in manipulated hips over nonmanipulated hips (18,21,72,144). Carney and colleagues reported that osteonecrosis developed in 12 of 39 hips (31%) in which reduction of the slippage was attempted, whereas osteonecrosis occurred in only 6 of 116 hips (6%) in which no reduction had been attempted (18). A recent study by Rhoad and colleagues (74), however, implies that the osteonecrosis seen in unstable SCFE treated by gentle manipulation is, more likely, secondary to the initial displacement associated with the unstable slip, and not the reduction maneuver. Vigorous reductions, multiple attempts at reduction, and overreduction continue to be associated with an increased incidence of osteonecrosis (64,145).

Closed manipulation can be considered in patients presenting with acute or acute-on-chronic presentations with severe displacement, in which the risk of significant limitation in range of motion and accelerated degenerative arthritis, associated with fixation *in situ,* outweighs the risk of potential complications from reduction. Closed manipulation is never indicated in patients presenting with chronic or stable slips, or in slips with displacement of a mild to moderate degree.

If closed manipulation is to be attempted, it can be performed by either slow reduction with skeletal traction through a distal femoral pin over a period of days prior to stabilization, or by a gentle reduction performed at the time of surgical stabilization. Neither method, properly performed, has been statistically proven to be safer or more beneficial than the other (64,69,145).

If traction is employed, it is applied through longitudinal skeletal traction, allowing for slow reduction of the femoral head over a few days. The use of skeletal traction is necessitated by the generally larger body weights of these patients, which require the generation of greater forces than can be safely achieved through skin traction. The addition of an internal rotation force, applied to the lateral aspect of the femoral pin to assist in reduction, also can be used (146).

If reduction under anesthesia is performed, it should be done without force or repeated attempts. The accepted reduction is what is obtained when the patient is placed onto the fracture table and the affected limb is rotated to neutral while the hip is maintained in extension—so-called “unintentional reduction.” No forced internal rotation or flexion should be performed at the affected hip, because of the increased potential for vascular injury associated with these maneuvers (145).

In the treatment of acute and acute-on-chronic SCFE, a question remains as to the urgency of operative stabilization and the avoidance of complications, particularly osteonecrosis. Should operative stabilization, with or without gentle manipulation, be performed as an emergency, or is it safer to employ a more delayed approach, with the affected hip temporarily treated at rest in traction? Loder and associates (68) reviewed acute SCFE in 30 hips, with respect to the time interval between the onset of symptoms and operative stabilization. In eight hips with treatment initiated less than 48 h after the onset of symptoms, osteonecrosis developed in seven hips (87.5%). In 22 hips with treatment initiated after 48 h from onset of symptoms, osteonecrosis was identified in seven hips (31.8%). Although these numbers are small, these data imply that delay in operative stabilization in acute SCFE may decrease the incidence of osteonecrosis. Peterson and colleagues (71), in a similar study of acute unstable SCFE in 91 hips, reviewed the timing of reduction and operative stabilization with respect to the development of osteonecrosis. Gentle manipulative reduction and stabilization were performed in 42 hips less than 24 h from presentation, in which three hips (7.2%) developed osteonecrosis. Reduction and stabilization were performed in 49 hips after 24 h from presentation with 10 hips (20.4%) developing osteonecrosis. The authors concluded that gentle reduction and operative stabilization, performed prior to 24 h from presentation in acute SCFE, does not increase the risk of osteonecrosis, and may actually reduce its risk. Although further prospectively randomized and treatment-standardized research concerning the urgency of reduction and stabilization in acute unstable SCFE will be needed to clarify this issue, the author currently recommends gentle reduction and operative stabilization within 24 h of presentation.

Osteotomies about the proximal femur in SCFE are designed as realignment procedures through which restoration of a more normal relation among the femoral head, the femoral neck and shaft, and the acetabulum, can be achieved. The various osteotomies accomplish this goal by creating a compensatory deformity through which the primary deformity created by the original femoral head/femoral neck displacement is realigned. Realignment of the proximal femur by osteotomy, when indicated, should result in an improved range of hip motion and a delay in the development of degenerative joint disease. The complications of femoral head osteonecrosis and chondrolysis must be avoided. Osteotomies in SCFE can be performed at the time of physeal stabilization, although most are performed as delayed procedures in patients in whom residual hip function remains inadequate.

Several osteotomies, performed at various levels along the femoral neck and proximal femur, have been described in SCFE (84,147,148,149,150,151,152,153,154,155,156,157 and 158). In general, as the location of the osteotomy proceeds distally along the proximal femur, the amount of correction achieved at the primary site of deformity decreases. Conversely, as the location of the osteotomy proceeds proximally along the proximal femur, the risk of osteotomy-induced osteonecrosis of the femoral head increases. Procedures performed in the proximal femoral neck can achieve almost anatomic correction of the primary deformity; however, they are associated with a high incidence of osteonecrosis of the femoral head. More distal osteotomies, performed at the intertrochanteric region, have a very low incidence of osteonecrosis of the femoral head, but are limited in the amount of correction of the primary deformity that they can achieve. The use of osteotomies in SCFE is limited to patients with displacement of the femoral head in the severe range, in whom motion at the affected hip after initial treatment remains significantly limited and restricts activities of daily living. In long-term follow-up of hips treated for SCFE using realignment procedures, Jerne and colleagues (159) recognized a high rate of serious complications in 7 of 22 hips (31.8%) treated with subcapital osteotomy, and 3 of 11 hips (27.3%) treated by intertrochanteric osteotomy. At follow-up examination averaging 33.8 years, these hips showed very low rates of excellent and good clinical and radiographic results. The authors concluded that the realignment procedures had not significantly improved on the condition's natural history, and therefore discouraged their use in the routine treatment of chronic SCFE. The needs of the patient must be weighed against the potential complications when realignment osteotomies are considered. The osteotomy that fulfills the patient's needs at the lowest potential risk should always be chosen.

The use of cuneiform osteotomy of the femoral neck in SCFE has been described by several authors (148,151,152,153 and 154,160,161 and 162). Cuneiform

osteotomy at the level of the proximal femoral physis is the only procedure that has the ability to restore an anatomic relation of the femoral head with the femoral neck, as well as the femoral shaft. The procedure should be performed only in patients with an open proximal femoral physeal plate (151,152,160). Cuneiform osteotomy performed by the method reported by Fish is preferred (152,160). The hip capsule is opened anteriorly, and the procedure is performed under direct visualization. The physeal plate is removed in conjunction with a wedge resection of bone from the juxtaphyseal femoral neck. The size of the wedge to be removed is determined by the severity of the displacement being corrected. The wedge resection shortens the femoral neck, which allows for reduction of the femoral neck onto the femoral head without excessive tension. Care must be taken throughout the procedure not to damage the periosteum and the vasculature running along the posterior femoral neck (Fig. 25-19). The reduced femoral head is then stabilized with pin or screw fixation.

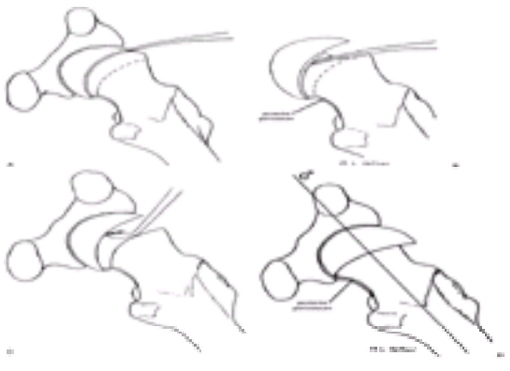

FIGURE 25-19. Technique used in performing a cuneiform osteotomy in slipped capital femoral epiphysis. **A:** The hip capsule is opened anteriorly, and the location of the physeal plate is carefully identified. **B:** A wedge of bone of predetermined size is removed in small pieces from the juxtaphyseal femoral neck. The physeal plate cartilage is identified continuously as the bone wedge is resected. Extreme care is taken not to damage the posterior periosteum. **C:** After the bone wedge has been removed, the physeal plate cartilage is curetted. Adequate bone must be excised from the posterior corner to allow for reduction of the femoral head without tension on the posterior periosteum and vasculature. **D:** The femoral neck is reduced onto the femoral head, recreating more normal proximal femoral alignment. The reduction is stabilized with pin or screw fixation. (From ref. 152, with permission.)

Although anatomic correction of the deformity is possible, when considering the results reported by a large group of orthopaedic surgeons, a high incidence of femoral head osteonecrosis remains associated with this procedure. Gage and colleagues reviewed the literature and reported the average incidence of femoral head osteonecrosis in association with cuneiform osteotomy to be 21% (153). Other series demonstrate the rate of femoral head osteonecrosis following cuneiform osteotomy to be between 12 and 35% (13,85,151,153,161,162). More recently, a lower incidence of osteonecrosis of the femoral head has been reported following cuneiform osteotomy performed by the subcapital wedge-resection technique. Fish reported osteonecrosis of the femoral head in 3 of 66 hips (4.5%) (160), and Nishiyama and colleagues reported osteonecrosis in 1 of 18 hips (5.5%) treated by the technique of cuneiform osteotomy (154). Chondrolysis also has been reported in association with cuneiform osteotomy, but usually is in association with osteonecrosis (153,162). Fish reported an 11% incidence of pin-related complications due to hardware violation of the hip joint in cuneiform osteotomy (160).

Realignment of the femoral head by cuneiform osteotomy remains a technically demanding procedure, and although a lower incidence of osteonecrosis recently has been reported, the potential for severe complications remains very high.

Osteotomy at the base of the femoral neck has been described by several authors (147,149,153,163). Intracapsular (153,163) and extracapsular (147,149) techniques have been reported **[➥4.8]**. The base of the femoral neck is exposed, and an anterosuperior-based wedge of bone is removed. Care is taken not to place retractors posterior to the femoral neck. The posterior cortex of the femoral neck and its periosteum are not cut, but are “greensticked” during closure of the osteotomy. This avoids injury to the vasculature running along the posterior femoral neck. The osteotomy is stabilized by pins or screws (Fig. 25-20). The procedure has a lower reported incidence of osteonecrosis of the femoral head than is found in cuneiform osteotomy, but its ability to correct the more proximal femoral deformity is more limited. A maximum correction of 35 to 55 degrees is reported with base-of-neck osteotomies (147,164). The osteotomy secondarily creates a coxa breva, which can cause the greater trochanter to impinge on the acetabulum during hip motion (163).

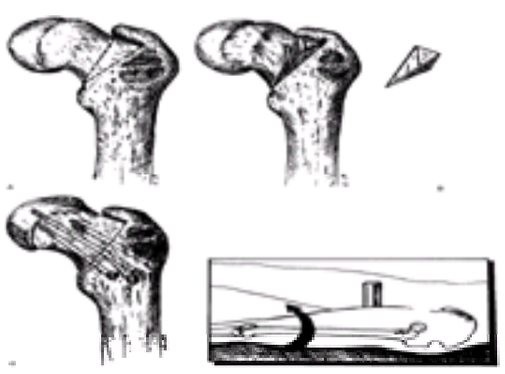

FIGURE 25-20. Technique for performing a base-of-the-neck osteotomy in slipped capital femoral epiphysis. **A:** The base of the femoral neck is exposed through an anterolateral approach to the hip. The outline of an anterosuperior-based wedge of bone of predetermined size is marked on the base of the femoral neck. **B:** The bony wedge is then cut and excised in such a manner that a triangular segment is created that contacts, but does not penetrate, through the posterior cortex. This avoids injury to the vasculature running along the posterior femoral neck. **C:** The gap in the femoral neck is closed by internally rotating the limb while maintaining traction, which “greensticks” the posterior cortex of the femoral neck. The reduction is stabilized by pins or screws. (From ref. 147, with permission.)

Transtrochanteric rotational osteotomy originally was described by Sugioka (157). This osteotomy represents a transtrochanteric osteotomy proximal to the abductor insertion on the greater trochanter. Rotational correction of severe deformities of the proximal femur is possible with this procedure, without disturbing abductor muscle mechanics or limb length. Reports of the use of the procedure in SCFE, however, are limited. Sugioka reported osteonecrosis in one of nine hips (11%) treated with this procedure (157). Masuda and colleagues reported osteonecrosis in one of five hips (20%) treated by transtrochanteric osteotomy (165). The use of transtrochanteric rotational osteotomy has rarely been reported in SCFE, and is not recommended for routine use.

Intertrochanteric osteotomies remain the most frequently used procedures for realignment in SCFE. The surgical technique was originally described by Southwick (84) **[➥4.7]** and has since been slightly modified by several authors (150,155,156,166,167 and 168). Intertrochanteric osteotomy can be performed in a single-plane, biplane, or multiplane technique. A derotational osteotomy of the proximal femur **[➥4.6]** represents a single-plane intertrochanteric osteotomy, and serves only to adjust internal and external rotation at the affected hip. The biplane and multiplane intertrochanteric osteotomies remove a wedge of bone of varying size from the anterior and lateral cortices of the affected femur at the level of the lesser trochanter. When this osteotomy is reduced and coupled with internal rotation of the femoral shaft, a realignment of the proximal femoral deformity occurs as a secondary deformity in the intertrochanteric region is created (Fig. 25-21). The correction achieved by osteotomy at this level is limited to deformities equal to or less than 45 degrees on the anteroposterior radiograph and 60 degrees on the lateral radiograph, as measured by the Southwick method (84,155,156).

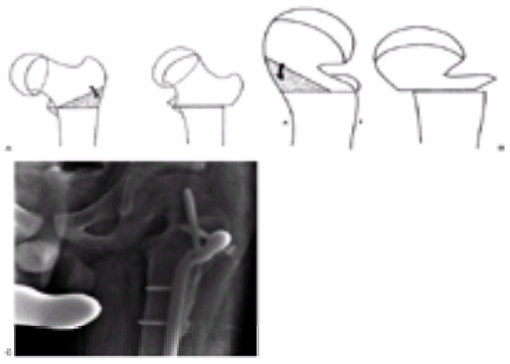

FIGURE 25-21. Technique used in performing a biplane intertrochanteric osteotomy in slipped capital femoral epiphysis, as described by Southwick. Following surgical exposure of the proximal femur, a transverse line is marked on the anterior (**A**) and lateral (**B**) surfaces of the proximal femur at the level of the lesser trochanter. This line acts as the base of the subsequent bony wedge resections. The predetermined size of the anterior and lateral wedges to be removed are marked on the respective femoral surfaces. The biplane wedge of bone created is excised, and the transverse osteotomy at the level of the lesser trochanter is completed. The distal femoral segment is derotated, and the osteotomy is closed into the corrected position, as demonstrated. The osteotomy is stabilized with a plate and screws. (**A** and **B** from ref. 150, with permission.) **C:** Anteroposterior hip radiograph of a 14.5-year-old boy following biplane intertrochanteric osteotomy for correction of residual deformity in slipped capital femoral epiphysis.

Another intertrochanteric osteotomy used for realignment in severe chronic SCFE is the flexion intertrochanteric osteotomy described by Imhauser (158). The justification for this osteotomy is based on the concept that the majority of the deformity in SCFE is a posterior displacement of the femoral head around the axis of the femoral neck, and not a true varus displacement (25,169). Correction of this deformity would therefore be most efficiently performed by a flexion osteotomy realigning the plane of the proximal physis perpendicular to the femoral shaft. Millis and colleagues (170) have recently described their method for flexion intertrochanteric osteotomy of the proximal femur in severe chronic SCFE. Following exposure of the proximal femur, an extensive anterior capsulotomy is performed. This capsulotomy facilitates placement of a cancellous bone screw to stabilize the proximal femoral epiphysis, if the physis remains open, as well as placement of subsequent internal fixation used to stabilize the intertrochanteric osteotomy. It also allows for improved extension of the head/neck fragment following osteotomy, and avoids an unacceptable flexion contracture of the hip. A transverse intertrochanteric osteotomy is performed just proximal to the lesser trochanter. The distal fragment is displaced anteriorly, and flexed adequately to realign the plane of the proximal femoral physis perpendicular to the femoral shaft. A wedge resection at the osteotomy site to improve bone apposition is usually not needed. When necessary, inward rotation of the distal fragment, to correct rotational malalignment, can also be performed prior to final fixation. Internal fixation is achieved with a blade plate avoiding the need for a spica cast, and allowing for the earlier initiation of hip motion. Correction of up to 90 degrees of posterior displacement of the femoral head is theoretically possible with this osteotomy. If flexion correction is greater than 55–60 degrees, a separate osteotomy of the greater trochanter should be performed, creating a three-part osteotomy prior to fixation. This is done to avoid excessive anterior displacement of the trochanter, which could potentially impair proper abductor muscle function.

Intertrochanteric osteotomy enjoys a very low incidence of osteonecrosis of the femoral head compared with femoral neck osteotomies. This is secondary to the intertrochanteric osteotomy being performed in an area of the proximal femur that is not in direct proximity to the blood supply of the femoral head. An increased incidence of chondrolysis with joint space narrowing and stiffness, however, has been reported to be associated with intertrochanteric osteotomy. Southwick, in his original description of the procedure, noted 6 of 55 hips (11%) that showed the development of chondrolysis (84). More recent series have reported the development of chondrolysis of the hip in SCFE, following corrective intertrochanteric osteotomy, to range from 6 to 56% (155,156,166). Although Imhauser did not report on osteonecrosis or chondrolysis of the femoral head associated with flexion intertrochanteric osteotomy, Tokarowski and associates (171) reported no cases of osteonecrosis, but reported an 18.2% incidence of chondrolysis in 33 hips treated for moderate or severe SCFE by the Imhauser osteotomy.

The reason for the increase in chondrolysis, seen in association with intertrochanteric osteotomy in SCFE, remains unknown. The author believes that the development of chondrolysis is related to increased pressure at the femoral head, which is created as the osteotomy is closed and the limb is lengthened. A simple femoral shortening, from the distal segment of the femur at the osteotomy site, should relieve femoral head pressure and thereby reduce the incidence of chondrolysis. The deformity created in the intertrochanteric region of the proximal femur by this osteotomy also can have a potentially deleterious effect on later total hip arthroplasty (172). The wedge resections of bone create an angular deformity in the intertrochanteric region that results in a tortuous proximal femoral canal. This could necessitate the need for excessive bone resection from the femoral neck calcar, and make for difficult passage and seating of the femoral component during future total hip arthroplasty.

Salvage Procedures

If the femoral head in SCFE becomes severely deformed and the joint becomes stiff and painful as a result of osteonecrosis or chondrolysis, salvage procedures are indicated to relieve pain and improve function. The procedure of choice in adolescents and young adults remains arthrodesis **[➥3.13]**. Sponseller and colleagues reported on 53 patients who had a hip arthrodesis and had been under 35 years of age at the time of the procedure (173). At an average follow-up of 38 years, 78% of the patients remained satisfied with the arthrodesis, and all remained employable. Only 13% who had the arthrodesis converted to a total hip arthroplasty. Callaghan and colleagues reviewed 28 patients who had a hip arthrodesis as an adolescent or young adult (174). At an average 35-year follow-up, some pain in the ipsilateral knee, the lower back, or the contralateral hip frequently was reported, but had not become symptomatic until an average 20 years or longer following the procedure. Only one patient (4%) was unemployed because of pain, and only six patients (21%) had undergone conversion to a total hip arthroplasty. Hip arthrodesis, therefore, remains a very successful salvage procedure for relief of severe pain in young patients who develop complications in SCFE.

The procedure relieves pain and allows the patient a high level of activity and employment at most occupations. Some pain at the ipsilateral knee, the lower back, or the contralateral hip commonly occurs, but usually only many years following the procedure. Proper positioning of the femur in relation to the pelvis is extremely important to function as well as avoidance of future back and knee pain. The proper position for the hip during arthrodesis is 20 degrees flexion with neutral rotation and neutral to slight adduction. Abduction at the hip is to be avoided secondary to it being associated with accelerated ipsilateral knee pain (174). A take-down of the arthrodesis and conversion to a total hip replacement is possible, if painful back and knee symptoms become too severe (173,174,175 and 176). Also, the abductor muscles should not be injured, in order to facilitate future hip function following total hip arthroplasty. The method of arthrodesis described by Mowery and colleagues is preferred (177). This technique offers many advantages, which include a familiar anterior approach to the hip, a large surface area for fusion, a relatively simple technique of compression arthrodesis using minimal hardware, no disturbance of the greater trochanter and abductor muscles, no additional loss of limb length, and an upper femoral osteotomy that reduces the lever arm force on the fusion area, and allows for adjustment of limb position postoperatively (Fig. 25-22). The main disadvantage associated with this technique remains the need for postoperative immobilization in a spica cast for 6 to 8 weeks.

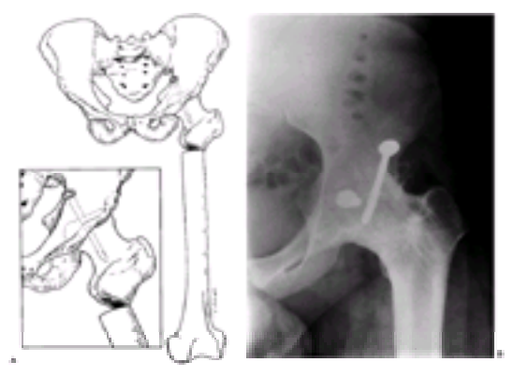

FIGURE 25-22. A: Hip arthrodesis is performed through an anterior approach. The abductor muscles are not disturbed. Compression arthrodesis is achieved with minimal hardware. A proximal femoral osteotomy reduces force on the fusion area, and allows for adjustment in limb position postoperatively. (From ref. 177, with permission.) **B:** Anteroposterior hip radiograph of a 16-year, 4-month-old boy demonstrates a solid hip arthrodesis performed by the previously described technique. Femoral head osteonecrosis had occurred following treatment for slipped capital femoral epiphysis.

Schoenecker and colleagues (178) have recently reported on the successful use of hip arthrodesis in 25 patients age 11 to 19 years with severe unilateral osteoarthrosis of the hip. The authors describe a two-incision surgical approach utilizing an intraarticular fusion technique with internal fixation with avoidance of dissection of the abductor hip musculature. The technique avoids the need for a proximal femoral osteotomy by precise positioning of the extremity at the time of arthrodesis.

Arthroplasty of the affected hip is not recommended for most adolescents and young adults, with severe unilateral hip osteoarthritis associated with SCFE (179,180). The potential for early component loosening and wear in active young adults remains very high. The need for several revisions over the patient's lifetime, and the subsequent risk of chronic infection, preclude total hip arthroplasty as the recommended procedure in these younger patients. Chandler and colleagues reported on 29 patients who had been treated with a total hip arthroplasty at an average age of 23 years (range, 14 to 30 years) (180). At 5-year follow-up, 57% of the patients showed evidence of loosening of at least one of the components of the implant. Seven patients (24%) had already undergone revision surgery. The factors of associated osteonecrosis of the femoral head, heavy activity, and excessive weight, all commonly seen in patients with SCFE, were associated with poorer results from arthroplasty. One exception in SCFE is the patient with bilateral disease. Although no universally good method of treatment for bilateral disease has been documented, one option is an arthrodesis of one hip and an arthroplasty of the contralateral hip, which would provide a better balance of function and durability.

Osteoplasty of the femoral neck has been reported as a means of improving function in hips with severe displacement of the femoral head and secondary deformity (130,181). The prominent bony projection on the superior and anterior segments of the femoral neck can be excised to eliminate the mechanical block to motion between the bony prominence and the acetabulum. Although early improved motion has been documented, mainly in abduction and internal rotation, the long-term results of this procedure remain unpublished. Remodeling of the femoral neck can have a similar result on motion over time. Osteoplasty also leaves a large area of denuded bone surface in the weight-bearing area of the hip, which can lead to accelerated degenerative joint disease.

PROPHYLACTIC PINNING OF THE CONTRALATERAL HIP

The controversy over prophylactic pinning of the uninvolved hip in SCFE remains unanswered. Proponents of prophylactic pinning emphasize the rate of bilateral disease and the higher risk of osteoarthritis associated with increasing slip severity (19,182). Opponents of prophylactic pinning stress the fact that *in situ* pinning can be associated with severe complications that can be more devastating to hip function than the slip itself (109). Symptomatic bilateral SCFE averages 25% (range, 21 to 37%) during growth (13,17,18,19 and 20). One-half of these patients (12.5%) develop the second symptomatic slip prior to skeletal maturity (13,17,18,20). Asymptomatic slipping of the contralateral hip prior to maturity has been proposed in as high as 40% of patients (19,21). If all contralateral hips in SCFE were pinned prophylactically, 50 to 80% of contralateral hips would be treated unnecessarily.

After a patient has had treatment for unilateral SCFE, the patient is under established medical follow-up until maturity. The patient also is aware of the prodromal symptoms of a second slip, and should it develop, the patient is instructed to return immediately for evaluation and treatment. In this situation, only acute unstable slips should have the potential for significant initial displacement. With acute slips representing only 10% of SCFE, 90% of symptomatic slips should be able to be treated prior to the development of more significant displacement.

Observation of the unaffected hip rather than prophylactic pinning remains the most appropriate treatment in patients presenting with unilateral SCFE (90,109). Exceptions to this treatment include patients with an inability to obtain appropriate and timely follow-up, due to personal or family circumstances, and patients who have SCFE associated with known metabolic or endocrine disorders, in which the risk of a contralateral slip is extremely high. In these situations, prophylactic pinning of the contralateral hip is appropriate.

COMPLICATIONS

The two major complications in SCFE, which are associated with the development of accelerated degenerative joint disease and motion loss at the affected hip, are osteonecrosis of the femoral head and chondrolysis.

Osteonecrosis of the femoral head has been reported to occur in 10 to 15% of patients with SCFE (18,62,71,85,183). More recent reviews of *in situ* fixation in SCFE using cannulated screws, and strict attention to technical detail, report a much lower incidence of osteonecrosis: 0 to 5% (67,120,184,185). Osteonecrosis of the femoral head was once believed to be a complication of treatment, because it was reported only rarely in untreated SCFE (18,62). It has recently been shown that osteonecrosis of the femoral head is more frequently associated with acute and unstable slips (18,68), and is most likely secondary to vascular injury associated with the initial femoral head displacement, and not tamponade from joint effusion or injury from gentle repositioning at the time of surgical stabilization (70,73) (Fig. 25-23). Rhoad and associates (74) reviewed 62 consecutive patients with 73 SCFE, who had a pretreatment technetium 99m bone scan with pin hole and single photon emission computed tomography (SPECT) imaging. The patients were followed for a minimum of 12 months following treatment by spica cast or cannulated screw fixation across the physis. None of the 63 stable SCFE hips showed evidence of ischemia by bone scan, and none developed osteonecrosis at follow-up. Ten SCFE hips were unstable at presentation with six of these hips showing ischemia on bone scan. Five of the six hips subsequently developed osteonecrosis at follow-up. Spontaneous reduction of varying degrees in the unstable SCFEs was noted in eight of the ten hips following treatment. Reduction of the unstable SCFE, in patients with normal bone scan pretreatment, did not result in osteonecrosis. In the five patients with initial ischemia on bone scan and subsequent development of osteonecrosis, the osteonecrosis developed independent of the presence or absence of reduction. Although the author's numbers are small, they do imply that the osteonecrosis seen in acute unstable SCFE more likely occurs at the time of the initial slip, and not during its treatment.

FIGURE 25-23. Anteroposterior hip radiograph of a 14-year, 4-month-old girl with osteonecrosis of the femoral head, following treatment for slipped capital femoral epiphysis.

The etiology of osteonecrosis is related to vascular injury to the extraosseous or intraosseous circulation of the femoral head. An increased incidence of osteonecrosis of the femoral head has been reported with increasing severity of the slip (18,62). Carney and colleagues, in a review of 155 hips, reported an incidence of femoral head osteonecrosis of 12% (18). Osteonecrosis was noted in 2% of 65 mild slips, 20% of 50 moderate slips, and 20% of 40 severe slips. Acute slips have a higher incidence of femoral head osteonecrosis, which is secondary to the rapid and excessive stretch of the extraosseous epiphyseal vessels that can occur during the acute displacement (18,62,71). Iatrogenic injury to the extraosseous epiphyseal vessels may occur during aggressive manipulation of the femoral head; stabilization of the femoral head, if the fixation device violates the posterior cortex of the femoral neck; and realignment of the femoral head through osteotomy of the femoral neck (18). Iatrogenic injury to the intraosseous circulation of the femoral head usually is related to hardware placement into the vulnerable superior quadrant of the femoral head, as previously discussed (115).

After osteonecrosis of the femoral head has been established, treatment must be directed at maintaining motion and preventing collapse by decreasing the magnitude of the forces at the affected hip, through relieved weightbearing until healing occurs. Any hardware in the zone of collapse of the femoral head must be withdrawn and replaced, to avoid joint injury. The use of vascularized bone graft and redirectional intertrochanteric osteotomy, with bone grafting to the femoral head, has been

proposed to improve outcome in osteonecrosis of the femoral head (186). No large report directly addressing treatment of osteonecrosis associated with SCFE has been published.

Long-term reviews of SCFE show that hips affected with osteonecrosis have a poorer outcome that continues to deteriorate over time (18,62,187).

Acute cartilage necrosis of the femoral head or chondrolysis was first described by Elmslie, in 1913 (188), and was later reported in association with SCFE by Waldenstrom (189). Chondrolysis is defined as an acute dissolution of articular cartilage in association with rapid progressive joint stiffness and pain.

The etiology of chondrolysis in association with SCFE remains unknown. Historically, the condition was believed to be a result of synovial malnutrition (189), ischemic injury of articular cartilage (85), or excessive cartilage pressure (190). Modern theory suggests an etiology associated with an immunologic and an autoimmune disorder within the hip joint (27,40,191). A genetic factor is implied by the increased incidence of chondrolysis in female patients in spite of SCFE being more prevalent in males patients.

The incidence of chondrolysis of the hip in SCFE has been reported in the literature to average 16 to 20% (range, 1.8 to 55%) (18,188,192). Recent reviews of the association of chondrolysis with treatment of SCFE by *in situ* stabilization with a single cannulated screw have been reported (67,120). Ward and colleagues reported no chondrolysis in 53 treated hips with at least 24-month follow-up (67). Koval and colleagues reported no cases of chondrolysis to have developed postoperatively in any of 60 hips with at least 2 years follow-up (120). Modern techniques of stabilization and attention to detail during treatment seem to be associated with a lower incidence of chondrolysis than has been previously reported.

Ingram and colleagues have reported on 79 hips in SCFE affected by chondrolysis (192). The authors found the incidence of chondrolysis to be higher in female patients, patients with acute slips, and patients with slips with increased severity of displacement. Similar results have been reported by additional authors (18,99,188). Historically, African-American patients and patients of Hawaiian ancestry have been reported to have a higher incidence of chondrolysis of the hip in association with treatment of SCFE (13,99,192,193 and 194). Recent reports of treatment in SCFE by modern techniques of *in situ* stabilization have shown the incidence of chondrolysis in the African-American population to be no higher than in the general population (111). Kennedy and Weiner reported on *in situ* stabilization of SCFE in 44 African-American children with an incidence of chondrolysis of 2.3% (195). Spero and colleagues reported an incidence of chondrolysis of 6.8% in 44 hips in 29 African-American patients treated by *in situ* pinning (185). Aronson and Loder reviewed *in situ* stabilization of 97 SCFE hips in 74 African-American children, and reported the development of chondrolysis in only 3% (184).

Although chondrolysis of the hip in SCFE can occur in the untreated hip (18,196), the majority of chondrolysis in SCFE has been reported to follow treatment. The treatment modalities shown to be associated with an increased incidence of chondrolysis include manipulative reduction (18), prolonged immobilization (97,98), and realignment osteotomies of the proximal femur (18,153,156). Persistent pin penetration of the femoral head has been shown to be associated with the development of chondrolysis (104,196). Transient penetration of the hip joint in SCFE by stabilizing hardware also was believed to be associated with the induction of chondrolysis. Zionts and colleagues (197), Koval and colleagues (120), and Vrettos and Hoffman (196) have shown that a single episode of transient penetration of the hip joint by a pin or screw, with immediate recognition and removal, is not associated with an increased incidence in the development of chondrolysis.

The diagnosis of chondrolysis is confirmed in a patient with clinical symptoms of progressive hip stiffness and pain by radiographic confirmation of joint space narrowing at the hip to 3 mm or less (192,198). If chondrolysis does develop, it usually appears within the first year following the SCFE. If chondrolysis follows surgical treatment of SCFE, a septic process mimicking chondrolysis must always be ruled out by hip aspiration. Mandell and colleagues have reported radiographic premature closure of the greater trochanteric physis to be a predictive sign of chondrolysis (199). The authors demonstrated that decreased activity on bone scintigraphy at the greater trochanteric physis was associated with concurrent or developing chondrolysis in 16 patients with SCFE.

The recommended early treatment of chondrolysis in SCFE has not been standardized, but should include elements of relieved weightbearing, antiinflammatory medication, and passive as well as active hip motion (83,200). In the early stages of chondrolysis, and during recurrent episodes of synovitis and pain, therapeutic doses of nonsteroidal antiinflammatory medications should be initiated and maintained. Periodic hospitalization for enforced bed rest, traction, and frequent physical therapy can be used during episodes of increased pain and motion loss. Physical therapy, consisting of aggressive passive and active motion to the affected hip, should be initiated early. The use of continuous passive motion equipment can be of assistance in maintaining reacquired motion. If pain during physical therapy remains excessive, continuous epidural anesthesia can be of benefit. Ambulation should remain protected, with non-weightbearing and limited-weightbearing crutch use continued until pain has resolved and joint space narrowing radiographically has ceased.

A fibrous ankylosis of the hip joint often can be the final outcome in hips affected by chondrolysis (13,201). However, spontaneous partial cartilage recovery from chondrolysis following SCFE has been reported (190). The prognosis for the hip developing chondrolysis following SCFE is not invariably bad, as had been supposed. Hartman and Gates reported partial restoration of the cartilage space at the hip joint and hip motion in 9 of 28 hips (32%) with chondrolysis (188). At follow-up of 2 to 5 years, 6 of the 9 hips showing recovery were classified as good results. Vrettos and Hoffman confirmed partial reconstitution of the joint space to an average of 2.6 mm (range, 1 to 5 mm) in 14 hips with chondrolysis following SCFE (196) (Fig. 25-24). This reconstitution of joint space occurred as late as 3 years after maximum joint involvement. At an average follow-up of 13.3 years, a good functional outcome was reported in 64% of the patients with chondrolysis. Although this information allows for a more optimistic attitude in reference to the early outcome of chondrolysis associated with SCFE, Carney and colleagues, at a mean follow-up of 41 years, have reported that the hip affected by chondrolysis in SCFE eventually shows a continued deterioration in hip function over time (18).

FIGURE 25-24. Anteroposterior hip radiographs of a 12-year, 2-month-old girl with a chronic stable slipped capital femoral epiphysis. **A:** Hip radiograph at presentation. **B:** At 4 months after uncomplicated *in situ* screw fixation, the patient demonstrates progressive hip pain and stiffness with hip radiograph documenting chondrolysis with the cartilage joint space narrowed to 1–2 mm. **C:** Patient treated with relieved weightbearing, antiinflammatory medication, and range of motion to the affected hip. At 2-years, 6-month follow-up, the physical examination demonstrated painless hip motion, with a hip radiograph showing restoration of the cartilage joint space to near-normal values.

CHAPTER 26

DEVELOPMENTAL COXA VARA, TRANSIENT SYNOVITIS, AND IDIOPATHIC CHONDROLYSIS OF THE HIP

DOUGLAS K. KEHL

D. K. Kehl: Department of Orthopaedic Surgery, Emory University School of Medicine, Atlanta, Georgia 30303; Department of Orthopaedic Surgery, Children's Healthcare of Atlanta at Scottish Rite Children's Medical Center, Atlanta, Georgia 30342.

This chapter addresses three conditions affecting the juvenile and adolescent hip: developmental coxa vara, transient synovitis, and idiopathic chondrolysis of the hip. Developmental coxa vara and idiopathic chondrolysis of the hip remain relatively uncommon, but continue to present challenging dilemmas in diagnosis and treatment. Transient synovitis remains the most common condition causing hip pain in childhood. A knowledge of this condition's presentation, diagnosis, and treatment is crucial for any physician treating musculoskeletal problems in pediatric patients.

DEVELOPMENTAL COXA VARA

“Coxa vara” is defined as any decrease below the normal values of the neck–shaft angle of the proximal femur, which is the angle subtended by the femoral neck and shaft in the coronal plane (Fig. 26-1). However, instead of referring to a specific clinical disease entity, coxa vara comprises a group of conditions occurring during childhood with different causes and natural histories that ultimately produce a specific deformity in the proximal femur.

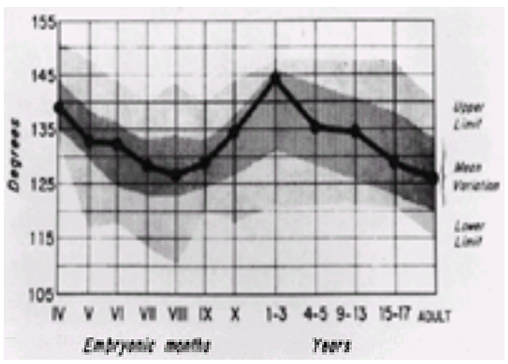

FIGURE 26-1. Variation of the normal neck–shaft angle with age. (From ref. 1, with permission.)

Elmslie (2) proposed a classification system for coxa vara that was later expanded by Fairbank (3). This classification system grouped coxa vara on the basis of proposed etiology, and included the congenital, rachitic, infantile or cervical, adolescent (i.e., slipped capital femoral epiphysis), traumatic, inflammatory, and metabolic types. These multiple categories have subsequently been condensed into three: congenital coxa vara, acquired coxa vara, and developmental coxa vara.

Congenital coxa vara is present at birth, and is assumed to be caused by an embryonic limb-bud abnormality. Significant proximal femoral varus is present at birth, but usually shows minimal progression in the degree of varus during growth. Associated congenital musculoskeletal abnormalities and significant limb-length inequality, secondary to femoral segment shortening, are common. This category includes cases of proximal femoral focal deficiency, congenital short femur, and congenital bowed femur (Fig. 26-2).

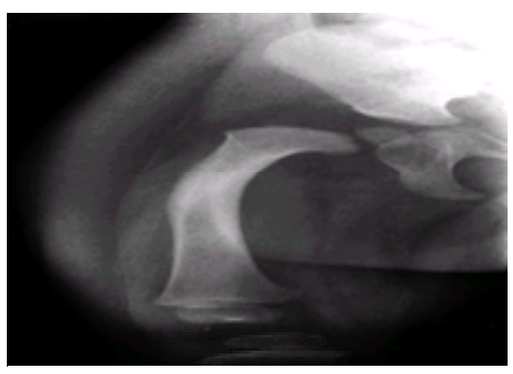

FIGURE 26-2. The radiographic appearance of congenital coxa vara in a 14-month-old girl with a congenital short femur.

Acquired coxa vara includes all clinical entities in which the deformity of the proximal femur is secondary to an underlying metabolic, tumorous, or traumatic condition. This classification includes coxa vara secondary to rickets, fibrous dysplasia, and early traumatic proximal femoral epiphyseal plate closure (Fig. 26-3).

FIGURE 26-3. The radiographic appearance of acquired coxa vara in a girl 7 years, 2 months of age who had fibrous dysplasia and a shepherd-crook deformity of the proximal femur.

Developmental coxa vara, also known as cervical or infantile coxa vara, represents coxa vara not present at birth, but that develops in early childhood and produces progressive deterioration of the proximal femoral neck–shaft angle during growth. Classic radiographic changes accompany the physical findings. There is no significant increase in associated musculoskeletal anomalies. A minimal limb-length inequality develops secondary to the progressive varus deformity of the proximal femur, but not because of a significant true decrease in the femoral segment length (Fig. 26-4).

FIGURE 26-4. Radiographic appearance of developmental coxa vara in a girl 3 years, 9 months of age.

More complete discussions on the various forms of congenital and acquired coxa vara are reviewed in chapter 7 and chapter 8 in this textbook. The remainder of this section is devoted to a review of developmental coxa vara.

Developmental coxa vara is a specific deformity of the proximal femur, manifesting in the pediatric patient with characteristic behavior during growth and associated radiographic findings that differentiate it from other forms of childhood coxa vara.

Historical Review

The initial clinical description of coxa vara was presented in 1881 by Fiorani, who described a “bending of the femoral neck” in adult patients (4). In 1888, Muller (5) confirmed Fiorani's description by anatomic dissection. The first radiographic confirmation of a decreased neck–shaft angle was described by Hofmeister in 1894 (4). He has also been credited with first using the term “coxa vara” in the clinical description of this entity. In 1905, Hoffa (5) was the first to report the microscopic pathologic findings associated with coxa vara.

Coxa vara occurring during childhood was first described by Kredel in 1896 (4). He proposed that childhood coxa vara had a congenital origin. In 1907, Elmslie (2) proposed the childhood form of coxa vara to be a separate entity from that seen in the adult, and recommended the term “infantile coxa vara.” A progressive tendency to the proximal femoral deformity during growth was described in childhood coxa vara by Fairbank in 1928 (3). In 1938, Duncan (6) disagreed with Kredel's congenital origin theory, and proposed that progressive childhood coxa vara represented a deformity that appeared during the early years of growth. He coined the term “developmental coxa vara.”

Despite Duncan's developmental theory for progressive coxa vara of childhood being well documented by his series, his theory was not generally accepted. It was not until 1970 that the confusion about the developmental theory was clarified by Amstutz (7), when he reported two patients with documented normal hip radiographs during the first year of life, who subsequently developed typical clinical and radiographic manifestations of developmental coxa vara by 2 and 3 years of age, respectively. Amstutz documented the presence of a childhood developmental form of coxa vara, and drew attention to the differentiation of this form of coxa vara from the true congenital and acquired varieties.

Incidence

Developmental coxa vara is a rare entity with a reported incidence of 1 in 25,000 live births worldwide (8). Compared with developmental hip dislocation, this represents a ratio of approximately 1 developmental coxa vara case for every 20 developmental hip dislocations. The reported rates of male to female and right to left involvement are essentially equal. Bilateral involvement occurs in 30 to 50% of patients (9,10 and 11). Although previous reports have shown developmental coxa vara to occur among white and those of African descent, later reports demonstrated a preference for the latter group (6,9). Although most investigators have not been able to prove a definite hereditary inheritance pattern for developmental coxa vara, reports by Fisher and Waskowitz (12) and Say and colleagues (13) demonstrated a familial pattern in a limited number of cases, which they propose follows an autosomal dominant pattern of genetic transmission.

Etiology

The cause of developmental coxa vara remains unknown. Several investigators have proposed hypotheses about the cause of the varus deformity. A metabolic abnormality causing a deficient production of, or a delay in, the normal ossification process of the proximal end of the femur has been proposed (4). Hoffa and Alsberg proposed a mechanical abnormality occurring during hip development in which excessive intrauterine pressure on the developing hip results in a depression in the neck of the femur (4). A partial vascular insult, causing an arrest in the early development of the femoral head and neck has been proposed by Nillsone (14). Duncan proposed that the varus deformity occurred secondary to a developmental error, resulting in faulty maturation of the cartilage and metaphyseal bone of the femoral

neck (6).

Biopsies of the proximal femoral growth plate and femoral neck, in patients with developmental coxa vara, have been reported by Pylkkanen (11), Chung and Riser (15), and Bos and colleagues (16). Histopathologically confirmed abnormalities exist in cartilage production and secondary metaphyseal bone formation in the inferior portion of the proximal femoral physeal plate and adjacent femoral neck. Biopsies of the involved segment of the femoral neck have shown an increase in the width of the true growth plate, with irregularly distributed germinal cells in the resting zone, an absence of normal orderly progression of the cartilage columns, and a poorly defined or absent zone of provisional calcification. Associated nests of cartilage have been found to extend deeply into the metaphyseal region. The metaphyseal bone is osteoporotic, with an increased vascularized fibrous element between bony spicules (Fig. 26-5). There was no evidence of aseptic necrosis in the reported biopsy specimens. These histopathologic findings are similar to those previously reported from biopsy specimens of the proximal tibias of patients with Blount disease (17,18), and biopsy specimens of the proximal femoral physeal plates of patients with metaphyseal chondrodysplasia (Schmid type) (16). The significance of these histopathologic similarities, and of any possible association between the cause or pathogenesis of developmental coxa vara and infantile Blount disease or metaphyseal chondrodysplasia, remains undetermined.

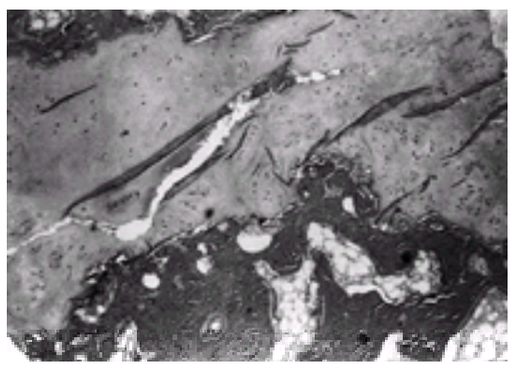

FIGURE 26-5. Photomicrograph of a biopsy specimen of the proximal femoral physeal plate, from a patient with developmental coxa vara, demonstrates irregularly distributed germinal cells in the resting zone; an absence of normal, orderly progression of the cartilage columns; and a poorly defined zone of provisional calcification. Nests of cartilage cells reside at the margin of the metaphyseal bone. (From ref. 16, with permission.)

In 1960, Pylkkanen (11) proposed what remains as the most widely accepted theory about the cause of developmental coxa vara. He postulated that the deformity in the proximal femur is the result of a primary ossification defect in the inferior femoral neck, on which physiologic shearing stresses, applied during weight bearing, cause fatigue of the local dystrophic bone, resulting in the progressive varus deformity seen clinically. Bos and associates (16), after reviewing biopsy specimens and magnetic resonance imaging studies of hips affected by developmental coxa vara, concurred with Pylkkanen's theory. In particular, their studies found no evidence of slippage of the proximal femoral physeal plate as the cause of the progressive proximal femoral varus deformity.

Clinical Presentation

Most patients affected with developmental coxa vara present sometime between the initiation of ambulation and 6 years of age (9,19). Their most frequent complaint is a progressive gait abnormality; pain is rarely reported. In patients with unilateral involvement, the gait abnormality is caused by combined abductor muscle weakness and limb-length inequality. As the neck–shaft angle of the proximal femur decreases in developmental coxa vara, the articulotrochanteric distance between the femoral head and greater trochanter also decreases, which affects normal hip joint mechanics. As the articulotrochanteric distance decreases, the normal length–tension relation of the abductor muscles is lessened, and the ability of the abductor muscles to control the pelvis in one-legged stance is weakened. The functionally weaker abductor muscles produce the gait abnormality seen in patients with developmental coxa vara. Patients with bilateral involvement present with a waddling gait pattern associated with increased lumbar lordosis, similar to that seen in bilateral developmental hip dislocation (3,6,9,20,21 and 22).

Physical examination usually reveals a somewhat prominent and elevated greater trochanter, which is often associated with an abductor muscle weakness and positive Trendelenburg testing. An associated limb-length inequality is commonly identified, but this is usually mild and averages only 2.5 cm (9,11). The range of motion of the affected hip is usually restricted in all planes of motion, with the most significant limitations occurring in abduction and internal rotation (9,11). The loss of abduction is associated with a decrease in the neck–shaft angle of the proximal femur. The loss of internal rotation is secondary to the progressive decrease in femoral anteversion seen in developmental coxa vara (9,23). An associated hip flexion contracture is often identified. Associated musculoskeletal anomalies are rare (5).

Radiographic Findings

The diagnosis of developmental coxa vara, and its differentiation from other forms of coxa vara, depends on the identification of certain classic radiographic findings. These radiographic features include a decreased femoral neck–shaft angle, often to values below 90 degrees; a more vertical position of the physeal plate; a triangular metaphyseal fragment in the inferior femoral neck, surrounded by an inverted radiolucent Y pattern; a decrease in normal anteversion of the proximal femur, which may become true retroversion; coxa brevia; and, in some patients, mild acetabular dysplasia (3,4,6,19,23,24) (Fig. 26-6).

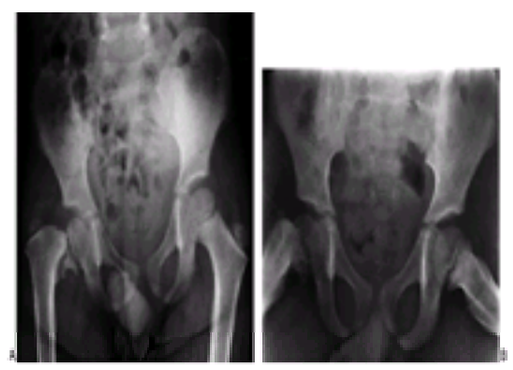

FIGURE 26-6. A: Anteroposterior pelvic radiograph demonstrates the classic radiographic findings in developmental coxa vara, which include a decreased femoral neck–shaft angle, a more vertical physeal plate, an inferior triangular metaphyseal fragment surrounded by an inverted radiolucent Y, and coxa brevia. **B:** Lateral pelvic radiograph demonstrates changes in the posterior segment of the proximal femoral neck.

The more vertical position of the physeal plate is measured by the Hilgenreiner physeal angle, which is defined by the angle subtended by the planes of the physeal plate and the Hilgenreiner line (25) (Fig. 26-7). This angle is normally 25 degrees or less, but in developmental coxa vara, it is usually in the range of 40 to 70 degrees (9).

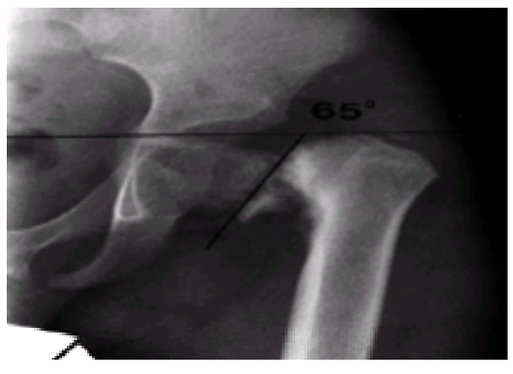

FIGURE 26-7. The anteroposterior view of a hip affected with developmental coxa vara demonstrates the method of measurement of the Hilgenreiner physeal angle. The physeal angle represents the angle subtended between the planes of the Hilgenreiner line and the physeal plate, which measures 65 degrees in this example.

The inverted Y pattern seen in the inferior femoral neck remains the *sine qua non* of this condition. The inverted Y radiolucency was once postulated to be a true double physeal plate. Biopsy specimens and magnetic resonance imaging studies, however, have shown that the radiolucent area actually represents a zone of widening of the inferior portion of the physeal plate, with associated abnormal ossification and an interposed triangular segment of dystrophic bone (15,16).

Natural History

Historically, untreated developmental coxa vara was viewed as a condition in which a pattern of progressive varus deformity of the proximal femur ultimately resulted in the development of a stress fracture–related nonunion of the femoral neck and premature degenerative arthritic changes within the hip joint (5). These changes led to progressive pain and disability for the patient, and were thought to occur universally after the condition was established. Weinstein and colleagues (25) and Serafin and Szulc (23) showed that not all patients with developmental coxa vara follow such a progressive course. Their studies demonstrated that the determining factor for progression of the varus deformity was the Hilgenreiner physeal angle. Patients demonstrating a physeal angle that remained less than 45 degrees more commonly had spontaneous healing of the femoral neck defect and an associated arrest in progression of the varus deformity. Patients with a physeal angle greater than this value were found to more commonly manifest the more classic progressive pattern.

Treatment

As long as the actual cause of developmental coxa vara remains unknown, treatment of the condition must continue to concentrate on prevention of the secondary deformities of the proximal femur created by the condition's natural history, instead of on prevention of the disease itself. Borden et al. (26) identified the main objectives of current treatment to include correction of the varus angulation into a more normal physiologic range, changing the loading characteristics seen by the abnormal femoral neck from shear to compression, correction of limb-length inequality, and reestablishment of a proper abductor muscle length–tension relation.

Nonoperative treatment during childhood has historically been unsuccessful in achieving the objectives of proper treatment. Jones and Lovett (3) and Barr (27) previously proposed spica cast immobilization, with the affected limb in abduction for 6 to 12 months. Although Barr was able to demonstrate closure of the femoral neck defect, neither group found any improvement in the neck–shaft angle of the proximal femur with this form of treatment. Nillsone (14) and Le Mesurier (22) investigated the use of heavy skeletal traction and bed rest, but they could not identify any beneficial effects from such treatment. Zadek (4), in a review of conservative treatment of developmental coxa vara, concluded that the previously attempted nonoperative methods had universally poor or no value.

Surgical derotational valgus-producing proximal femoral osteotomy has been shown to be the most effective form of treatment in the restoration of more normal hip joint mechanics in developmental coxa vara (3,9,11,22,26,28,29 and 30) **[➥4.4]**. Historically, femoral osteotomies at the level of the neck and intertrochanteric and subtrochanteric regions have been proposed. Brackett and New (31) recommended a femoral neck procedure in which the dysplastic neck was resected, with the remaining proximal shaft inserted into the femoral head, coupled with advancement of the greater trochanter. In general, this and other femoral neck procedures have higher morbidity rates and poorer clinical results than the intertrochanteric–subtrochanteric osteotomies, which remain the treatments of choice (10). Pauwels' Y-shaped osteotomy (32,33) and Langenskiold's valgus-producing osteotomy (11) are examples of intertrochanteric corrective osteotomies that have produced good results. Unfortunately, Pauwels' Y-shaped osteotomy does not allow rotational correction of the upper femur. Subtrochanteric valgus-producing osteotomies, as described by Fairbanks (3), Borden et al. (26), and Amstutz and Wilson (28), also remain well-proven forms of successful therapy in achieving the goals of surgical treatment (Fig. 26-8).

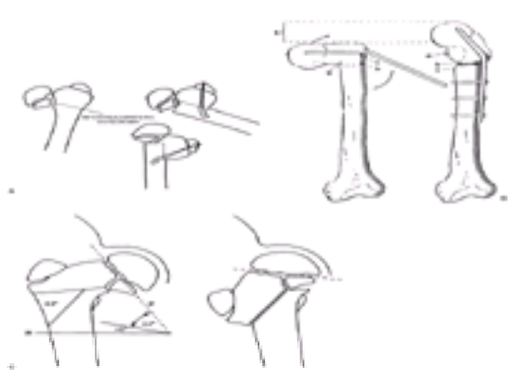

FIGURE 26-8. Surgical methods of valgus-producing proximal femoral osteotomy. **A:** The Langenskiold intertrochanteric osteotomy. (From ref. 11, with permission.) **B:** The Borden subtrochanteric osteotomy. (From ref. 26, with permission.) **C:** The Pauwels Y-shaped osteotomy. *P* represents the plane of the growth plate, and *H* represents the horizontal plane. In this example, a 44-degree closing-wedge osteotomy can correct the physeal angle to 16 degrees. (From ref. 32, with permission.)

Additional principles of proper surgical treatment include a concomitantly performed adductor tenotomy that allows less-forceful correction of the bony deformity and improved stability at the osteotomy site, when the femur is put into valgus (30). A proximal femoral shortening procedure at the level of the osteotomy can be employed to facilitate correction of the varus deformity and unload the femoral head, in situations in which difficulty in reduction of the osteotomy and excessive femoral head pressure are realized as proximal femoral valgus is recreated (34). To prevent loss of the surgical correction achieved before healing of the osteotomy, firm internal fixation, by a tension band technique, blade plate, or nail-plate system, is recommended. Violation of the physeal plate by the internal fixation device should be avoided, if possible. A spica cast may or may not be applied, depending on the stability of the internal fixation and patient compliance.

It is important to include internal rotation of the distal segment at the time of osteotomy, to correct the loss of internal rotation seen in developmental coxa vara and reestablish more normal rotational arcs at the hip, postoperatively. The goal of surgical treatment is to produce a valgus overcorrection of the neck–shaft angle of the proximal femur, regardless of the patient's age. Several researchers have demonstrated that the neck–shaft angle of the proximal femur should be corrected to a value of 160 degrees or greater, and that the Hilgenreiner physeal angle should be corrected to 30 to 40 degrees, or less at the time of osteotomy, to significantly decrease the potential for varus deformity recurrence (9,25,32,35) (Fig. 26-9). In 1997, Carroll and colleagues (36) reemphasized the importance of adequate correction of the Hilgenreiner physeal angle in the prevention of recurrent varus during treatment of coxa vara. Ninety-five percent of their operative hips, with a postoperative correction of the physeal angle to less than 38 degrees, had no recurrence of the coxa vara during growth. In contrast, 93% of the osteotomies that retained a physeal angle greater than 40 degrees required revision for recurrent varus.

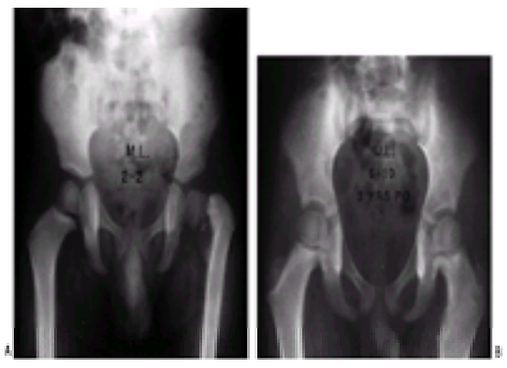

FIGURE 26-9. Anteroposterior pelvic radiographs of a boy 2 years, 2 months of age, with developmental coxa vara. **A:** Preoperative radiograph. **B:** Postoperative radiograph. A subtrochanteric derotational proximal femoral osteotomy successfully achieved the objectives of surgical correction, including correction of the varus angulation into a physiologic range, changing the loading characteristics of the femoral neck from shear to compression by achieving a physeal angle of 30 degrees or less, and reestablishing a proper abductor muscle length–tension relation.

Zadek (4) and Le Mesurier (22) proposed drilling and supplemental bone grafting of the femoral neck at the time of osteotomy, to facilitate healing of the femoral neck defect and restrain recurrent deformity. The need for these additional procedures at the time of osteotomy has subsequently been shown to be unnecessary.

The criteria for surgical intervention, in a patient with developmental coxa vara, include one or more of the following clinical and radiographic findings: the proximal femoral Hilgenreiner physeal angle is greater than 45 to 60 degrees, the proximal femoral neck–shaft angle is progressively decreasing or measures less than or equal to 90 to 100 degrees, or the patient with developmental coxa vara develops a Trendelenburg gait (9,25,28).

Duncan (6) and Weinstein and colleagues (25) recommended delaying surgical intervention until after the patient is 5 to 6 years of age. Weighill (30) proposed performing surgery on all patients after 18 months of age, as soon as the proper diagnosis has been made. Pylkkanen (11) and Serafin and Szulc (23) demonstrated improved results from surgery in younger patients. Corrective osteotomy is best performed, not at a particular age, but as soon as the criteria for surgical intervention are apparent. If the proper indications are unambiguous, a delay in surgical intervention until an older age, in hopes of achieving better internal fixation, is not justified. The progressive proximal femoral deformity and dysplastic changes at the femoral head, neck, and acetabulum, which occur with time, make complete and lasting correction much more difficult or impossible to achieve.

Results

The triangular metaphyseal defect in the femoral neck spontaneously closes by 3 to 6 months postoperatively, in the majority of cases of developmental coxa vara, if adequate valgus has been created (9) (Fig. 26-10). Between 50 and 89% of operated hips demonstrate a premature closure of the proximal femoral physeal plate. This usually occurs within 12 to 24 months after surgery (9,24) (Fig. 26-11). This premature physeal plate closure is not related to surgical trauma, patient age, or degree of valgus correction. It more likely represents a possible surgically induced acceleration of natural physeal plate closure. Premature physeal plate closure may also be a manifestation of an inherently abnormal proximal femoral physis in developmental coxa vara, which is stimulated to undergo closure as the stresses across the plate change from shear to compression after surgical realignment of the proximal femur.

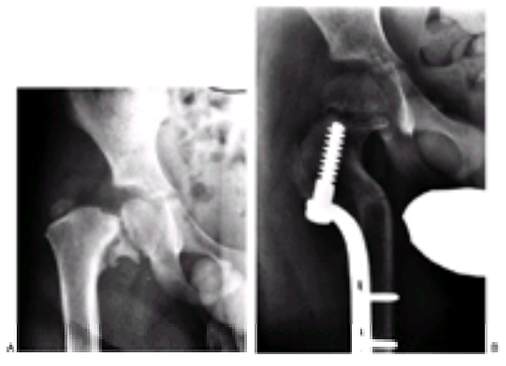

FIGURE 26-10. Anteroposterior radiographs of a hip affected with developmental coxa vara. **A:** The preoperative radiograph demonstrates a classic inferior femoral neck triangular fragment. **B:** Three months postoperatively, the radiograph demonstrates correction of the physeal angle, with spontaneous closure of the femoral neck triangular metaphyseal fragment.

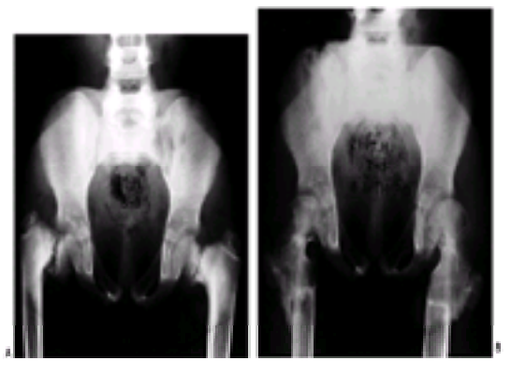

FIGURE 26-11. The anteroposterior pelvic radiographs of a boy 6 years, 3 months of age demonstrates bilateral developmental coxa vara. **A:** Preoperative radiograph. **B:** The postoperative radiograph, 8 months after the subtrochanteric proximal femoral derotational osteotomies, demonstrates bilateral spontaneous closure of the proximal femoral epiphyseal plates, and the greater trochanteric apophyses remain open. (From ref. 34, with permission.)

If premature closure of the proximal femoral physeal plate occurs, the patient must be monitored closely for the development of a growth-related recurrent varus deformity of the proximal femur, and for development of a significant limb-length inequality secondary to closure of the proximal femoral physis, which accounts for approximately 13% of the growth of the lower limb.

Historically, recurrence of the proximal femoral varus after surgical correction was a frequent complication as patient growth continued. This recurrence of the varus deformity was thought to be secondary to the underlying pathologic process associated with developmental coxa vara. However, Weighill (30), Weinstein and colleagues (25), Kehl and associates (9), Desai and Johnson (35), and Cordes' group (32) have all demonstrated that true varus recurrence, secondary to the underlying pathologic process, is rare if adequate proximal femoral valgus is reestablished and maintained by stable internal fixation.

The proximal femoral physeal angle must be corrected to 30 to 40 degrees or less, to facilitate the conversion of shear to compression forces on the proximal femoral growth plate. It is equally important that stable internal fixation be used to maintain the valgus correction until full osseous healing has occurred, and that the internal fixation device does not violate the physeal plate. If premature proximal femoral epiphyseal plate closure occurs, it creates a situation of unbalanced growth about the

proximal femur, with secondary trochanteric overgrowth and recurrent coxa vara and coxa brevia (Fig. 26-12). To prevent this recurrent deformity, it is recommended that after premature closure of the proximal femoral epiphyseal plate has been documented, greater trochanteric apophyseodesis, or advancement **[➥4.9]** be performed before the development of a recurrent deformity (9). If the varus deformity does recur, a repeat valgus-producing femoral osteotomy can be performed.

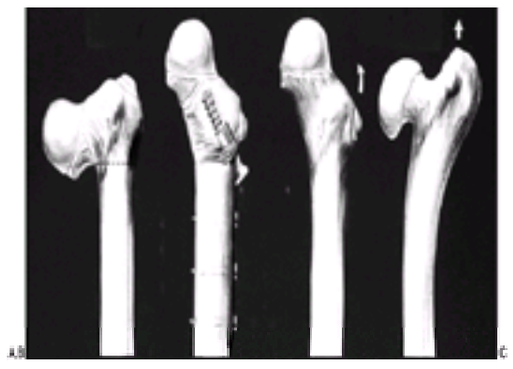

FIGURE 26-12. Illustration of recurrent coxa vara secondary to premature proximal femoral epiphyseal plate closure and secondary greater trochanteric overgrowth. **A:** Preoperatively, the proximal femoral physeal plate is open. **B:** Postoperatively, adequate surgical correction has been achieved. **C:** Premature closure of the proximal femoral physeal plate, with the greater trochanteric apophyseal plate remaining open. **D:** Recurrent coxa vara secondary to unbalanced growth about the proximal femur. *Arrows* in **C** and **D** indicate the direction of subsequent growth. (From ref. 34, with permission.)

Proper and timely treatment of developmental coxa vara can result in a hip joint that is painless, has a functional range of motion, and demonstrates a negative Trendelenburg gait at maturity. Although most patients continue to show a mild residual limb-length inequality, it rarely is significant enough to require a shoe lift (9,11).

Through compliance with the outlined surgical indications and proper technique, the objectives of treatment of developmental coxa vara can be accomplished, with a predictable conversion of the condition's natural history—development of degenerative arthritis and pain in late adolescence or early maturity—to a hip joint that is painless and has a much-improved long-term functional outcome (9,32,35).

TRANSIENT SYNOVITIS OF THE HIP

Transient synovitis of the hip represents the most common cause of hip pain in childhood (37,38). Although the condition's true cause remains unknown, the associated signs and symptoms, natural history, and ultimate patient outcome have been well documented. Transient synovitis is usually characterized by the acute onset of monarticular hip pain, limp, and restricted hip motion, in a patient who is otherwise not systemically ill. The symptoms generally show a gradual but complete resolution over several days to weeks, and are rarely associated with recurrences or late sequelae.

This clinical entity has been previously described by numerous names because of confusion about its cause. Some of the previously used terms include transitory synovitis, transitory coxitis, acute transient epiphysitis, coxitis fugax, coxitis serosa seu simplex, phantom hip, toxic synovitis, and observation hip. Transient synovitis is most commonly used to describe this clinical condition. Transient synovitis also remains the most descriptive term, because of its reference to the condition's short duration and associated pathology.

There remains no diagnostic test to confirm the disease transient synovitis. The several variable patterns of presentation and courses of illness associated with transient synovitis raise the question whether this disease has many different phases and features, or represents a number of diseases that appear clinically alike.

Historical Review

In 1892, Lovett and Morse (39) first described transient synovitis of the hip, and differentiated it from tuberculous synovitis, when they referred to the condition as “a short-lived and ephemeral form of hip disease that presents at first the characteristics of common hip disease, but the symptoms of which disappear within a few weeks or months instead of continuing for years” (39). Bradford and Lovett (40), Todd (41), Fairbank (42), and Belmonte (43) subsequently described a similar painful condition of the hip that was characterized by a transient course of symptoms with rapid resolution and permanent recovery. In 1933, Butler (44) described children admitted to the hospital with painful hip symptoms but normal radiographs, who subsequently demonstrated a self-limiting and rapidly resolving clinical course. He coined the term “observation hip” for this condition. In 1936, Finder (45) confirmed, through biopsy specimens, that the condition was characterized by a nonpyogenic inflammatory response of the synovium of the hip joint.

Etiology

Although the cause of transient synovitis of the hip remains undefined, the more popular hypotheses proposed imply an association between transient synovitis and one or more of the following: active or recent infection, trauma, or allergic hypersensitivity (38,41,42,44,46,47,48,49 and 50).

The concept of a possible infectious cause is given credence by the frequent association of transient synovitis with current or antecedent illness. A nonspecific upper respiratory infection, pharyngitis, and otitis media have been associated with the occurrence of transient synovitis in as many as 70% of cases (38,47,51). Fairbank (42), Miller (48), Butler (44), and Spock (38) have proposed a definite causal association between transient synovitis and a concomitant viral or bacterial infection. Spock reported isolating an increased incidence of b-hematolytic streptococci from the nose and throat of patients with transient synovitis, compared with asymptomatic pediatric patients. He also found elevated viral titers in 50% of the patients tested (38). Hardinge (52), however, could find no definite correlation between infectious sources and transient synovitis, when comparing parameters of infection found in involved patients with age-matched controls. Tolat and associates (53) demonstrated elevated interferon levels in the systemic circulation, normally negligible in healthy individuals, in 43% of 65 patients with acute transient synovitis. Fifteen of 16 of these patients, with fluid aspirated from the involved hip, also showed elevated interferon levels in the synovial fluid. Although viral cultures of the same synovial fluid were all negative, the authors concluded that elevated interferon levels in the joint and blood of several patients with acute transient synovitis indicated an activated interferon system, possibly secondary to a viral etiology. Blockey and Porter (54) and Lockhart and colleagues (51), however, were unable to confirm any correlation with viral infections through detailed virologic studies of patients with transient synovitis.

A history of preceding local trauma to the involved hip in transient synovitis has been reported in 17 to 30% of patients (38,43). In 1925, Todd (41) proposed that trauma was a frequent factor associated with transient synovitis of the hip, and thought that the condition was nothing more than a simple “contusion of the hip.” Rauch (49) proposed injury to be the leading cause of transient synovitis, and Gledhill and McIntyre (47) also found trauma frequently was associated with the condition.

An association between an allergic predisposition and the development of transient synovitis of the hip has been reported for 16 to 25% of symptomatic patients (38,43). Edwards thought the condition represented an allergic hypersensitivity response manifesting itself within the hip joint, as evidenced by the dramatic clinical improvement seen in symptomatic patients given antihistamines (46). Rothschild, Russ, and Wasserman (50) supported an allergic cause, based on the rapid clinical improvement seen in their patients with transient synovitis, when given intramuscular steroid injections. Nachemson and Scheller (55) reported on 12 patients (16.4%) of a 73-patient study group with transient synovitis of the hip, who demonstrated an association between a hyperallergic state and a history of transient synovitis of the hip. This association, however, was also discredited when the investigators demonstrated that the percentage of patients in the general population reporting allergic hypersensitivity was essentially equal to that found in patients with previous transient synovitis.

Spock (38) proposed that body size in the child may predispose to the development of transient synovitis. He demonstrated a three times greater incidence of the condition in patients of a stocky and obese physique than in a randomly selected group of children with similar ages. Biopsy specimens from hip joints of patients with transient synovitis have universally demonstrated synovial hypertrophy secondary to a nonspecific nonpyogenic inflammatory reaction (45,56,57). Hip joint aspiration

has shown an associated culture-negative synovial effusion, usually measuring 1 to 5 mL (58,59 and 60).

Incidence

Transient synovitis has been reported to be the most common cause of hip pain in children. The diagnosis of transient synovitis has historically accounted for 0.4 to 0.9% of annual pediatric hospital admissions (37,38). The actual incidence of the condition, however, is likely to be higher than that reported, because many patients with the condition never seek medical attention, and few patients are hospitalized once the diagnosis has been established. Landin and colleagues (37) reported that the risk for a child to have at least one episode of transient synovitis of the hip is 3%. A seasonal preference for the condition has not been demonstrated other than by Landin and associates (37), who showed a slightly higher rate of occurrence during the autumn months.

Right and left involvement is essentially equal, with simultaneous bilateral involvement never having been reported. There is an approximately 2:1 male to female ratio, and a much lower incidence among African-Americans (58).

Clinical Presentation

The condition has been reported in patients as young as 9 months of age through adolescence. The average age of symptom onset is 6 years, with most cases occurring between 3 and 8 years of age (43,47,58,61). The most frequent presenting complaint is the acute onset of unilateral hip pain in an otherwise healthy patient. The pain is usually confined to the ipsilateral groin and hip area; however, it may present as anterior thigh or knee pain. An associated limp and antalgic gait are usually seen, with some patients refusing to bear weight on the involved extremity. The involved extremity is held in a flexed and externally rotated position, and has a restricted range of hip motion, especially abduction and internal rotation. Protective muscle spasm and an associated flexion contracture are frequently identified. The patient may have a low-grade temperature that is rarely greater than 38°C (38,43,58). Ipsilateral muscle atrophy is rarely seen, but when present, it usually implies a long-standing duration of symptoms, and a diagnosis other than transient synovitis should be considered.

Laboratory values are nonspecific and are usually within normal limits, despite the wide range of values that have been reported. The peripheral blood smear includes a white blood cell count averaging 10,000 to 14,000 cells/mm ^{3} (range, 3,000 to 28,000 cells/mm^3) and a Westergren erythrocyte sedimentation rate averaging 20 mm/h (range, 1 to 63 mm/h) (58). Urinalysis, blood culture, febrile agglutinins, serum electrophoresis, rheumatoid factor, and tuberculin skin test results are usually within normal limits.

The diagnosis of transient synovitis of the hip remains a diagnosis of exclusion. Although routine laboratory and radiographic studies have not been of specific value in making the diagnosis, they do assist in eliminating other conditions of the hip that may have features similar to those of transient synovitis. The differential diagnosis of transient synovitis includes pyogenic arthritis, osteomyelitis in the adjacent femoral neck or pelvis, tuberculous arthritis, juvenile rheumatoid arthritis, acute rheumatic fever, Perthes disease, tumor, and slipped capital femoral epiphysis.

Pyogenic arthritis of the hip, with or without associated osteomyelitis of the femoral neck, differs from transient synovitis of the hip, in that the patient is usually systemically ill with a high fever. Pain at the affected hip is usually more intense than is seen in transient synovitis, with voluntary guarding allowing little or no hip motion. Unlike transient synovitis, the symptoms of pyogenic arthritis do not improve significantly with rest, and are progressive. Laboratory studies of pyogenic arthritis show a higher elevation in the white blood cell count, usually with a left shift; a higher elevation of the erythrocyte sedimentation rate; and purulent fluid on aspiration of the hip joint (62).

The synovitis associated with acute rheumatic fever and poststreptococcal reactive arthritis usually occurs 2 to 4 weeks after a group A streptococcal infection. The affected joint is warm, erythematous, and exquisitely tender to any attempt at motion. Unlike transient synovitis, the joint symptoms in these two conditions may be migratory and can be associated with a transient rash (63).

The pain and synovitis associated with juvenile rheumatoid arthritis (64), tuberculous arthritis (65), and Perthes disease (66) usually are more insidious in onset, and more protracted in duration, than is seen in transient synovitis. Hip motion at the onset of symptoms tends be limited to a lesser degree than is seen in transient synovitis. Skin testing results are positive in tuberculous arthritis, and radiographic changes subsequently develop in Perthes disease and tuberculous arthritis.

Radiographic Findings

Radiographs of the pelvis and hip of a patient with transient synovitis are usually normal. Their main purpose is to exclude other diseases that may involve the hip joint. Drey (67) and Hermel and Sklaroff (68) previously proposed the use of plain radiographs in diagnosing hip joint effusion in transient synovitis. They proposed that capsular distension resulted in measurable displacement of the muscle shadows of the iliopsoas, obturator internus, and gluteus minimus. They also proposed that local inflammation could lead to the loss of the intermuscular fat planes lateral to the hip joint. Subsequent investigators have reported demonstrating these soft tissue changes in as many as 60% of patients with transient synovitis (47). In 1975, Brown (69) refuted this finding, by showing that the previously reported soft tissue changes lateral to the hip on plain radiographs were unreliable in determining true hip joint effusion. He demonstrated that the displacement of the muscle planes was related to positioning of the limb, and was not the result of true capsular distension.

Wingstrand (70), Bickerstaff and colleagues (71), Futami and associates (72), and Terjesen and Osthus (73) have used ultrasound for patients with transient synovitis, to document the presence of a hip joint effusion and determine its natural history (Fig. 26-13). Bickerstaff and colleagues documented joint effusions with ultrasound in 71% of 111 patients presenting with an acutely irritable hip. Serial ultrasound studies showed the effusions to decrease steadily in size, with resolution in a mean time of 9 days. Symptoms resolved in these same patients in a mean period of 5 days. Larger effusions at presentation were associated with a longer duration of symptoms and a longer time to effusion resolution. Thirty-two (29%) symptomatic patients had no documented joint effusion at presentation or at follow-up, implying that the joint effusion in transient synovitis may not always be the source of symptoms. Although ultrasound can be useful in documenting and following a hip joint effusion in transient synovitis, it is not in and of itself diagnostic of the condition, and is not routinely required in making the diagnosis.

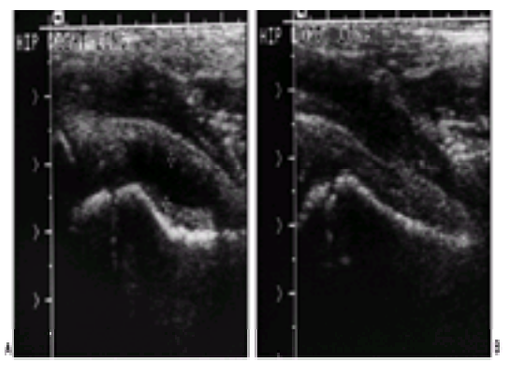

FIGURE 26-13. Longitudinal linear ultrasonographic view of the hips in a boy 5 years, 4 months of age, who had transient synovitis of the right hip. **A:** Ultrasound scan of the symptomatic right hip demonstrates a large joint effusion, as indicated between the cursor markings. **B:** Ultrasound scan of the asymptomatic left hip, for comparison, demonstrates no joint effusion.

Wingstrand and colleagues (74), Kloiber and associates (75), and Hasegawa et al. (76) evaluated pin-hole collimation scintigraphy of the hip involved with transient synovitis, and showed a variety of possible patterns of isotope uptake. Hasegawa and colleagues demonstrated that 49% of femoral heads of 55 patients involved with transient synovitis appeared normal on the scan. Twenty-four percent of femoral heads demonstrated decreased activity, and increased regional activity about the femoral head was found in 27%. It was observed that the patients with decreased femoral head activity on scintigraphy had an average of 5 days from the onset of symptoms, and the patients with increased femoral head activity averaged 23 days. When follow-up scintigraphy was performed on five of the patients initially demonstrating decreased uptake in the femoral head, all five patients demonstrated normalization or increased isotope activity in the femoral head.

These findings demonstrate that there can be a transient decrease in vascular perfusion of the femoral head during the early stages of transient synovitis. The decrease in perfusion, however, was never severe, and seemed to resolve spontaneously, with femoral head perfusion subsequently returning to a normal or increased pattern (48,76). The role of bone scanning in transient synovitis remains undetermined, and until the proposed therapeutic benefits afforded by early bone scintigraphy in the patient with transient synovitis have been documented, its routine use is not recommended.

Natural History

As its name implies, transient synovitis usually demonstrates a limited duration of symptoms. The average duration of symptoms is 10 days, but some patients have remained symptomatic for as long as 8 weeks (47,58). Haueisen and colleagues (58), in reviewing a large number of cases, reported the duration of symptoms to be less than 1 week for 67% of patients, and less than 4 weeks for 88% of patients. Although most episodes of transient synovitis are isolated to a single event, recurrence of the symptoms in the same or contralateral hip has been reported for approximately 4 to 17% of patients (58,77). Illingworth has shown that recurrences can develop at any time, but are most likely to occur within the first 6 months after the initial episode (77).

Most short-term retrospective reviews on transient synovitis report complete resolution of all signs and symptoms in the affected hip, with no immediate residual clinical or radiographic abnormalities (38,42,43). Although most patients remain asymptomatic, long-term studies have demonstrated mild radiographic changes in the involved hip.

Kallio reported asymptomatic coxa magna of 2 mm or more in 32% of 109 patients with transient synovitis of the hip, after a follow-up period of 1 year (59). He questioned if this high frequency of coxa magna seen after transient synovitis could play a role in the development of degenerative joint disease in adulthood. De Valderrama (78) reported 23 patients who had had transient synovitis and were reviewed at an average of 21 years later. He reported a 50% incidence of radiographic changes in the involved hip, consisting of various degrees of coxa magna, degenerative joint disease, and femoral neck widening. He thought these changes were secondary to the local hypervascularization of the hip that had been associated with the initial inflammatory synovitis. Nachemson and Scheller (55) described 73 patients with 20- to 22-year follow-up periods. When the clinical and radiographic sequelae of transient synovitis occurred, they were described as “few and mild.” Although the researchers described a few patients with mild decreases in hip motion, the change was not associated with any functional disability. Coxa magna and femoral neck density changes were increased over normal values, but these changes were unassociated with functional limitations. Nachemson and Scheller (55) found no radiographic changes of degenerative joint disease in their patients at follow-up.

The full importance of these radiographic changes occurring about the hip previously involved with transient synovitis remains unknown. Although very few of the patients whose radiographs showed mild changes have been found to be symptomatic, with longer follow-up, it is possible that the incidence of symptoms may change.

Several investigators have reported cases of Legg-Calvé-Perthes disease developing several months after an episode of transient synovitis (37,38,47,71,73,79). Jacobs (57) and Bickerstaff and colleagues (71) thought that there was a definite correlation between the two conditions, and that patients with transient synovitis who had a more slowly resolving or recurrent clinical pattern were much more likely to develop Legg-Calvé-Perthes disease. Spock's survey of the modern literature demonstrates an association of the two conditions in an average of 1.5% of patients (range, 0 to 17%) (38,57,80). Gledhill and McIntyre (47) reported an association in 0.9% of patients with transient synovitis. A direct causative correlation, however, between transient synovitis and the subsequent development of Legg-Calvé- Perthes disease, secondary to an induced vascular insult to the femoral head, has never been documented. It is more reasonable to conclude that the small percentage of patients demonstrating this association were patients with Legg-Calvé-Perthes disease who manifested an early synovitis that was indistinguishable from that seen in transient synovitis.

Treatment

Treatment of transient synovitis of the hip is directed at rapidly resolving the underlying inflammatory synovitis with its associated symptomatology. Bed rest and full relief of weight bearing on the involved joint, until pain resolves and full motion returns, is the initial treatment of choice (38,43,47,58). This is followed by a period of continued cessation of all strenuous activities involving the hip. If an asymptomatic limp persists, continued bed rest for younger patients, or partially relieved weight bearing for patients capable of crutch ambulation, should be used until a normal gait pattern has returned. Failure to enforce joint rest, and a too-early return to activities, were shown by Hermel and Albert to result in a doubling of the time required for initial symptomatic relief, and an increased rate of symptom recurrence (43).

During the initial treatment of transient synovitis, the routine use of skin traction on the involved limb is no longer recommended. Skin traction is mainly used in patients with recalcitrant or recurrent symptoms. It can also be of assistance for the younger child in whom enforcement of bed rest cannot otherwise be easily achieved. If traction is to be employed, the position of the involved limb and hip during traction has potential significance. Wingstrand and associates (81), Kallio and Ryoppy (82), and Kesteris and colleagues (60), through the use of ultrasound scanning and intraarticular pressure measurements of patients with transient synovitis and an associated joint effusion, demonstrated that hip joint pressure measurements are at a maximum when the hip is positioned in extension, and can reach potentially critical values with respect to capillary blood flow. Minimum pressure measurements are recorded when the hip is placed in 30 to 45 degrees of flexion. To avoid potential vascular complications, the involved limb and hip should not be positioned in extension when skin traction is used during bed rest; the limb and hip should be placed in 30 to 45 degrees of flexion, and subsequently lowered, as determined by patient comfort.

To aid in resolution of the inflammatory synovitis, oral nonsteroidal antiinflammatory medication, given in therapeutic doses, can be used. The use of aspirin is avoided in the child with an active viral infection, because of the association of aspirin and Reye syndrome in children with acute viral illnesses. The routine use of antibiotics and systemic steroid preparations is not indicated.

Routine aspiration of the hip joint is of no proven short-term or long-term therapeutic value in transient synovitis, and is recommended only to assist in diagnosis (79,80). Wingstrand and associates (81), Terjesen and Osthus (73), and Kesteris and colleagues (60) demonstrated by ultrasound scans that intracapsular hip joint effusions and secondary hip capsular distension in this condition are only minimally reduced by aspiration, and that they recur rapidly after aspiration.

IDIOPATHIC CHONDROLYSIS OF THE HIP

Chondrolysis represents a process characterized by progressive destruction of the articular cartilage from both surfaces of the involved joint, resulting in secondary joint space narrowing and stiffness. Chondrolysis involving the hip joint has followed infection, trauma, prolonged immobilization (83), and severe burns about the lower extremities (84). It is most frequently reported as a complication associated with the treatment of slipped capital femoral epiphysis (83,85,86). An acute form of rapidly progressive chondrolysis, occurring most frequently during adolescence, with isolated involvement of the hip joint, but without a demonstrable cause, has also been reported. This condition is referred to as “idiopathic chondrolysis of the hip.” The rapid loss of articular cartilage from the femoral head and the acetabulum in this condition is unique, and differs from that usually seen in other noninfectious inflammatory conditions affecting the hip joint in this same age group.

Historical Review

Chondrolysis involving the hip joint was originally referred to by Elmslie (86) in 1913 as a potential complication after the treatment of slipped capital femoral epiphysis. The association between chondrolysis and slipped capital femoral epiphysis was documented by Waldenstrom in 1930 (87). In 1971, Jones (88) reported a series of nine adolescent black African girls who had no clinical or radiographic evidence of slipped capital femoral epiphysis or hip joint infection, who spontaneously developed the symptoms and signs of classic chondrolysis of the hip. Jones' series represents the first clinical description of idiopathic chondrolysis of the hip joint. Several articles since that time have documented the condition's existence, clinical presentation, suggested treatment, and prognosis (83,89,90,91,92,93,94 and 95).

Etiology

As the name implies, the cause of idiopathic chondrolysis of the hip remains unknown. Previously proposed theories about the cause of idiopathic chondrolysis of the hip include nutritional abnormalities (85,87), mechanical injury (96), ischemia (97), abnormal intracapsular pressure (97), and an inherent abnormal chondrocyte metabolism within the articular cartilage (98). Waldenstrom (87) proposed that an alteration in the normal synovial supply of nutrition to the articular cartilage led to chondrolysis. Cruess (85) agreed with this theory, and proposed that a fibrosis of the synovial membrane led to a decrease in synovial fluid production within the hip joint that resulted in inadequate nutritional support of the articular cartilage, with subsequent chondrocyte death and secondary cartilage resorption. Jacobs (96) proposed that chondrolysis was the result of a mechanical insult to the articular cartilage or synovium that resulted in a release of lysosomal chondrolytic enzymes

that led to cartilage destruction. Kozlowski and Scougall (98) proposed that idiopathic chondrolysis represents a form of articular cartilage dysplasia in which the chondrocytes of articular cartilage have an inherent abnormality in metabolism that can be triggered into a disease state by an unknown environmental event in susceptible individuals.

The most plausible theory concerning the cause of chondrolysis remains that proposed by Golding in 1973 (93), Mankin et al. in 1975 (99), and Eisenstein and Rothchild in 1976 (97), in which they postulated articular cartilage resorption to be secondary to an autoimmune response within the hip joint in genetically susceptible individuals. Microscopic evaluation of the synovial tissue from hip joints involved with idiopathic chondrolysis give credence to the autoimmune theory by routinely demonstrating an increase in chronic inflammatory cells consisting of lymphocytes, plasma cells, and monocytes concentrated in a perivascular pattern (88,92,100,101).

Eisenstein and Rothchild (97) demonstrated significant elevations of serum and synovial fluid immunoglobulins, and of the C3 component of complement, in patients with slipped capital femoral epiphysis and associated chondrolysis. In particular, the levels of the IgM fraction of the serum immunoglobulins showed the greatest elevations in patients with associated chondrolysis. Morrissy et al. (101) evaluated 16 patients with slipped capital femoral epiphysis. Although they did not demonstrate an increase in the serum immunoglobulin levels above normal values, they did document 3 of the 16 patients to have positive immunofluorescence for immunoglobulin G (IgG) and the C3 component of complement in the synovial tissue of the hip, with two of these patients subsequently developing chondrolysis. Van der Hoeven and colleagues (102) demonstrated immunocomplex deposition of IgM and the C3 component of complement in the synovium of 3 of 4 patients with idiopathic chondrolysis.

Minimal information has been reported concerning similar evaluations of the serum or synovial factors of the autoimmune system in patients with idiopathic chondrolysis of the hip. Bleck reviewed nine patients with idiopathic chondrolysis of the hip, and reported normal levels of serum immunoglobulins in all (89). In 1983, a case report by Smith et al. (103) demonstrated normal immunofluorescence studies of the synovium and cartilage in a single patient with idiopathic chondrolysis of the hip.

Incidence

The incidence of idiopathic chondrolysis of the hip remains unreported. The condition, however, is relatively uncommon, with only 42 patients having been recorded in the literature through 1989 (90).

Clinical Presentation

Idiopathic chondrolysis of the hip occurs five times more frequently in female patients than in male patients. The reported age at the onset of symptoms averages 12.5 years for girls (range, 9 to 18 years) and 14.8 years for boys (range, 13 to 20 years). The right hip is involved at a slightly higher frequency than the left (104). Bilateral hip involvement has been reported for seven patients (89,90 and 91,95,105). Following Jones' original description of idiopathic chondrolysis of the hip in nine adolescent black African females, the condition was regarded as an affliction primarily of persons of African descent. Since that time, idiopathic chondrolysis has been recorded in white, Hispanic, and American Indian patients. As of 1989, 52% of the recorded patients were of African descent and 38% were white (90).

The most frequent presenting complaint is the insidious onset of pain in the anterior or medial side of the affected hip in an afebrile patient. The pain is associated with progressive joint stiffness and a limp. Patients often complain of the development of a limb-length inequality secondary to contractures about the affected hip with secondary pelvic obliquity. Examination of the involved hip demonstrates significant restriction of motion in all planes, and associated muscle spasm. Variable patterns of contracture about the affected joint, in idiopathic chondrolysis of the hip, have been reported; the most common presenting pattern is that of a fixed flexion, abduction, and externally rotated position (88,89 and 90,93,95,104).

Laboratory values for complete blood count, urinalysis, rheumatoid factor, antinuclear antibody, HLA-B27 marker, blood culture, and tuberculin skin testing are usually within normal limits. The Westergren erythrocyte sedimentation rate is also usually within normal limits. It can be slightly elevated, but rarely exceeds 30 mm/h (102,104).

The differential diagnosis for idiopathic chondrolysis of the hip includes such entities as pyogenic arthritis, tuberculous arthritis, juvenile rheumatoid arthritis, seronegative spondyloarthropathy, and pigmented villonodular synovitis. Pyogenic arthritis of the hip differs from idiopathic chondrolysis in that the patient is systemically ill with high fever. Hip pain is usually of a more acute onset, and is associated with intense guarding against hip motion. Laboratory studies in pyogenic arthritis show a significant elevation in the white blood cell count and erythrocyte sedimentation rate, which are usually not seen in idiopathic chondrolysis (62).

The chondrolysis associated with juvenile rheumatoid arthritis (64) and tuberculous arthritis (65) occurs only after an extended period of symptoms. Although hip motion is limited in these conditions, it rarely reaches the degree of restriction seen in idiopathic chondrolysis. Skin testing is positive in tuberculous arthritis.

Seronegative spondyloarthropathy can present as isolated involvement at the hip, but usually has additional joint involvement later in the course of the disease. Unlike idiopathic chondrolysis of the hip, seronegative spondyloarthropathy has a male predominance, and is frequently seen in patients who are positive for the HLA-B27 marker (106).

Pigmented villonodular synovitis of the hip has an insidious onset, with progressive motion loss as in idiopathic chondrolysis. The course of the disease leading to chondrolysis in pigmented villonodular synovitis tends to be more chronic and prolonged than in idiopathic chondrolysis. Radiographs of the hip in pigmented villonodular synovitis show more cystic erosions in the subchondral bone on both sides of the joint. Aspiration of the hip of a patient with pigmented villonodular synovitis usually produces a moderate amount of bloody fluid (107).

Radiographic Findings

The recognition of certain abnormalities on the plain radiographs of the affected hip, in conjunction with the presence of appropriate clinical findings, establishes the correct diagnosis of idiopathic chondrolysis. The radiographic hallmark of the condition remains a narrowing of the joint space of the involved hip from its normal 3 to 5 mm to a value less than 3 mm (89,90). Complete obliteration of the joint space rarely or never occurs. There is usually associated osteopenia of the periarticular osseous structures, an irregular blurring of the subchondral sclerotic lines at the femoral and acetabular joint surfaces, and an enlargement of the fovea capitis femori. With time, the involved femoral head develops a mild coxa magna, and the femoral neck widens slightly (88,89 and 90,93,104,105,108) (Fig. 26-14). Moule and Golding reported that the femoral neck may occasionally demonstrate a limited area of periosteal new bone formation (108) (Fig. 26-15).

FIGURE 26-14. Anteroposterior hip radiograph of a girl 14 years, 2 months of age. The classic radiographic findings in this case of idiopathic chondrolysis of the hip include a narrowing of the joint space to less than 3 mm, diffuse osteopenia, blurring of the subchondral sclerotic lines on both sides of the joint, and an enlargement of the fovea capitis femori. The hip is also in a position of abduction, which is commonly seen in this condition.

FIGURE 26-15. Anteroposterior tomographic view of the hip in a girl 12 years, 3 months of age with idiopathic chondrolysis demonstrates a limited area of periosteal new bone formation along the inferior femoral neck.

With time, the hip involved with idiopathic chondrolysis frequently demonstrates a premature closure of the proximal femoral physis and the trochanteric apophysis. This rarely results in any major growth abnormality or significant architectural change at the proximal femur, because of the limited growth remaining at these growth centers. A mild protrusio acetabuli, assumed secondary to hyperemic softening of the bony acetabular floor, associated with a buttressing osteophyte at the lateral margin of the acetabulum, has been reported in up to 50% of cases (89,90,95,104,105,109).

Arthrography of the hip of a patient with idiopathic chondrolysis can be used to document articular cartilage loss and secondary joint space narrowing (Fig. 26-16). Moule and Golding (108) have described a “dappled” pattern of contrast outlining the femoral head and acetabulum in idiopathic chondrolysis, secondary to the patchy loss of articular cartilage that is associated with the condition. Although not routinely required, arthrography allows for aspiration of the hip to rule out an infectious etiology.

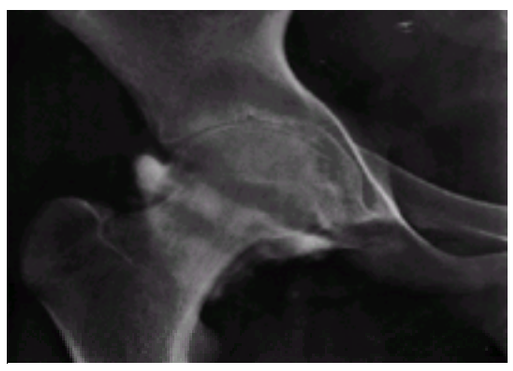

FIGURE 26-16. Arthrographic appearance of a hip involved with idiopathic chondrolysis, demonstrating articular cartilage loss on the femoral head and acetabulum.

Scintigraphic evaluation of the hip in the active stage of idiopathic chondrolysis demonstrates a generalized increase in uptake on both sides of the affected joint. This is secondary to the local inflammatory and hyperemic response associated with the early stage of the condition (Fig. 26-17). Mandell and colleagues (110) have shown that decreased activity on bone scintigraphy around the physis of the greater trochanter, in patients with slipped capital femoral epiphysis, is frequently associated with concurrent or developing chondrolysis. Whether this scintigraphic finding is of prognostic value in idiopathic chondrolysis has not yet been determined.

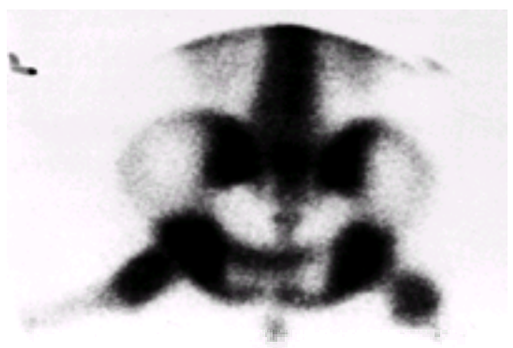

FIGURE 26-17. The scintigraphic appearance of a technetium 99m bone scan of a hip with idiopathic chondrolysis demonstrates a diffuse increased uptake of the isotope by both sides of the affected hip.

Axial computed tomography scans of the pelvis can be used to document local changes in the subchondral bone, cartilage loss, and secondary narrowing of the joint space at the involved hip (Fig. 26-18). The use of magnetic resonance imaging as a method of assessing the local bone and cartilage changes at the hip may also be of benefit, but no large volume of experience has been recorded.

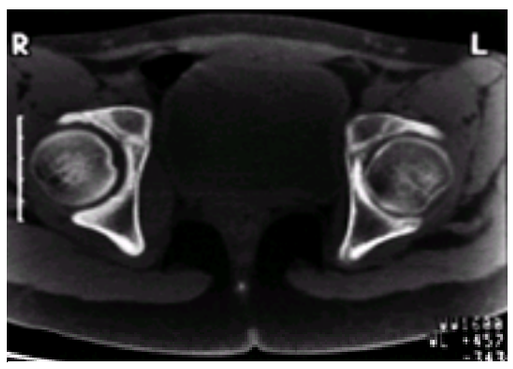

FIGURE 26-18. Axial computed tomographic view of the pelvis and hips in a patient with idiopathic chondrolysis demonstrates osteopenia and narrowing of the involved joint space of the affected hip.

In the majority of cases, the diagnosis of idiopathic chondrolysis of the hip can be made by the patient's clinical presentation and plain radiographs. The routine use of

arthrography, scintigraphy, axial computed tomography, and magnetic resonance imaging in this condition is not recommended. Selected use of these modalities, however, can be of assistance in making a proper diagnosis, when the diagnosis is clinically suspected, but cannot be confirmed by plain radiographs alone.

Pathology

Exploration of the hip joint involved with idiopathic chondrolysis demonstrates numerous abnormalities. The capsule is routinely thickened. The quantity of synovial fluid is decreased, producing a “dry joint” (103). The synovial tissue can be edematous and hypertrophic in the early stages of the disease, but with more prolonged involvement, the synovium becomes thinned and fibrotic. The articular cartilage shows changes on both sides of the joint, with the more significant alterations occurring on the femoral head. The cartilage has a lusterless appearance, with irregular thinning, fibrillation, and fragmentation seen in the surface layers. Areas of erosion in the articular cartilage of various sizes tapering down to subchondral bone, are identified mainly in the weightbearing region of the femoral head and acetabulum (88,92,97,100,103,104,108) (Fig. 26-19).

FIGURE 26-19. The clinical photograph of the femoral head of a girl 12 years, 3 months of age with idiopathic chondrolysis demonstrates the lusterless appearance of the articular cartilage, and areas of irregular erosion, fibrillation, and fragmentation.

Microscopic review of biopsy specimens of the synovium consistently demonstrates a nonspecific chronic inflammation. An increased infiltration of plasma cells, lymphocytes, and monocytes is interspersed throughout a stroma, exhibiting an increased vascular and fibrotic pattern. Specimens of the involved articular cartilage demonstrate frayed and fragmented superficial layers with areas of necrotic chondrocytes. The more basal layers of chondrocytes are usually viable, which may be important in the subsequent regeneration of articular cartilage. The subchondral bone is histologically normal, and often demonstrates a mild increase in vascularity. No evidence of bone necrosis has been identified (86,88,90,91 and 92,100,102,104) (Fig. 26-20).

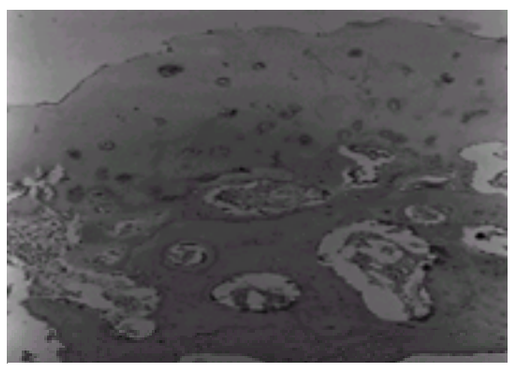

FIGURE 26-20. The photomicrograph of a biopsy specimen of the femoral head from a patient with idiopathic chondrolysis demonstrates a frayed and fragmented superficial layer of articular cartilage, with viable chondrocytes remaining in the more basal layers. The subchondral bone appears histologically normal.

Ippolito and associates (111) reported the electron microscopic ultrastructural findings in the articular cartilage from the femoral head of a patient with idiopathic chondrolysis. The superficial zone I of normal articular cartilage was found to be missing (112). The normally deeper zone II had become the most superficial layer. The collagen fibrils of this zone showed abnormalities in alignment and architecture. Degenerated chondrocytes and debris were found to be interspersed among viable chondrocytes within the extracellular matrix of this layer.

Natural History

At one time, idiopathic chondrolysis of the hip was viewed as a universally progressive disorder with an inevitable outcome of joint destruction, pain, and stiffness. Additional information concerning the condition's natural history changed this pessimistic point of view. In 1971, Jones (88), in his original description of idiopathic chondrolysis of the hip, recorded a very poor prognosis for the condition. All nine patients he described ultimately developed significantly stiffened hips, with most also showing significant dysfunction secondary to hip pain and joint malposition. In 1982, Sparks and Dall (113) reexamined six of Jones' original nine patients and found no significant change in their conditions. They concluded that idiopathic chondrolysis inevitably results in the development of a malpositioned fibrous ankylosis of the involved hip joint.

In 1970, Lowe (86) reported six cases of chondrolysis complicating slipped capital femoral epiphysis. Before his review, the prognosis for this form of chondrolysis was also poor. Lowe demonstrated that after 2 to 9 years all six patients showed improved function, range of motion, and radiographic widening of the involved joint space. He therefore concluded that, at least in some cases of chondrolysis of the hip, the articular cartilage has the ability to recover partially with time. In 1983, Bleck (89) demonstrated a similar favorable outcome for patients affected with idiopathic chondrolysis of the hip. At a mean follow-up of 6.2 years, 6 of the 9 patients had become essentially asymptomatic, with an improved range of hip motion and a partial restoration of joint space width. In 1989, Daluga and Millar (90) reported 14 patients (16 hips) with idiopathic chondrolysis of the hip, after a mean follow-up period of 84 months. Although no patient showed full restoration of the joint space, eight hips showed partial joint space restoration up to 2 mm. Nine hips demonstrated improved range of motion, and five of these hips had a full return of motion.

Idiopathic chondrolysis of the hip appears to have two separate stages. The acute stage is initiated at the condition's onset, and lasts for 6 to 16 months. This stage is characterized by an inflammatory response within the affected hip joint, leading to a painful hip with a decreasing range of motion and loss of articular cartilage. During the latter portion of this stage, the degree of synovial inflammation decreases, with the synovium showing an increase in fibrous tissue deposition. The acute stage is followed by the chronic stage, which may last for 3 to 5 years. During this stage, the hip joint manifests one of three possible outcomes. The involved hip may continue to deteriorate to an ultimately painful and malpositioned ankylosis. The involved hip may become painlessly ankylosed in a position that causes some limitation of hip function for the patient. Alternatively, the involved hip may have a resolution of pain, with a partial or complete return of motion and improved joint space width shown on radiographs (Fig. 26-21).

FIGURE 26-21. Anteroposterior pelvic radiograph of a girl 12 years, 3 months of age, with idiopathic chondrolysis of the hip. **A:** A radiograph made at the time of diagnosis demonstrates significant joint space narrowing at the involved hip. **B:** A radiograph of the same patient 2 years after diagnosis demonstrates partial regeneration of the joint space width at the affected hip.

Although this new information concerning idiopathic chondrolysis of the hip allows a more optimistic prognosis, the full understanding of the condition's natural history and outcomes awaits further investigation. Questions about the condition's cause, variable severity of involvement, and inherent factors, such as race, age, and gender and how they may influence outcome need to be answered before the optimum recommendations for treatment can be determined.

Treatment

As knowledge about the natural history of idiopathic chondrolysis is gained, a change in philosophy concerning the condition's treatment will follow. Previously, the prognosis of idiopathic chondrolysis was viewed as universally poor, with ultimate hip joint function rapidly declining and symptoms rapidly increasing. Recommended treatment included early definitive intervention with corrective osteotomy, bony fusion, or joint arthroplasty for the involved hip. As knowledge has been gained, a less pessimistic treatment approach was developed. As many as 50 to 60% of involved hip joints have the potential to achieve satisfactory function and motion (89,90,104).

In 1979, Duncan et al. (91) reviewed eight patients with idiopathic chondrolysis of the hip. Assuming that the hip involved with idiopathic chondrolysis would inevitably undergo ankylosis, and that many previously reported patients who had been treated with range of motion had undergone ankylosis of the hip in a nonfunctional position, the investigators proposed early and prolonged spica cast treatment, with the affected hip held in a functional position until fibrous ankylosis was achieved. They reported that all patients so treated were functioning well, with an ankylosed pain-free hip and satisfactory gait at last evaluation. Treatment to attempt to maintain motion was only recommended for patients with hip involvement of a “milder degree” (91).

In the 1980s, Bleck (89) and Daluga and Millar (90) reported a much more favorable prognosis for idiopathic chondrolysis of the hip, with respect to ultimate function, persistent joint pain, partial restoration of the radiographic joint space, and range of motion of the involved joint. The researchers employed a treatment protocol that included therapeutic doses of nonsteroidal antiinflammatory medications, aggressive physical therapy, periodic traction and bed rest, and prolonged non-weight-bearing or limited weight-bearing crutch activities for the involved hip.

In 1985, Hughes (104) reported the use of continuous passive motion in the acute stage of idiopathic chondrolysis of the hip for one patient, who demonstrated the maintenance of an improved range of hip motion throughout early treatment. In 1993, Canadell and associates (114) proposed joint distraction (arthrodiastasis) with a hinged unilateral external fixator as treatment for residual hip stiffness in adolescent patients resulting from various etiologies of hip disease. Although at 39-month follow-up most hips demonstrated significantly less pain, improved motion, and radiographic articular space widening averaging 2.8 mm, only one patient in the study had the diagnosis of idiopathic chondrolysis, and that patient demonstrated a much less favorable result in comparison to the results reported for patients with other etiologies of hip disease.

The potential benefit of aggressive surgical treatment, within the first year after the onset of symptoms of idiopathic chondrolysis of the hip, has only recently been investigated. Bleck reported one patient who underwent surgical release of tendon contractures and a limited anterior capsulotomy. This patient at follow-up was asymptomatic, with a functional range of motion and an improved radiographic joint space width. In 1988, Roy and Crawford (115) reported three patients with idiopathic chondrolysis of the hip, who were treated with a subtotal circumferential capsulectomy and release of tendons at the involved hip. The surgical procedure was followed by a period of traction, continuous passive motion, and an aggressive program of physical therapy. The patients were subsequently allowed crutch ambulation with partial weight relief for a prolonged period. At an average follow-up time of 3 years, the investigators reported all patients to be asymptomatic, with a full return of hip motion and an improved joint space width on radiograph. In 1999, Del Couz Garcia and colleagues (95) reported on eight hips with idiopathic chondrolysis treated by capsulectomy and tendon release with an average 13.2 year follow-up. Although the initial surgical outcome appeared to be more favorable, long-term follow-up showed no significant difference in pain, range of motion, or radiographic appearance, when comparing surgically treated hips to nonsurgically treated hips.

Although some limited reports demonstrate favorable outcomes for aggressive surgical release, many questions remain unanswered. What are the specific clinical indications for an aggressive surgical release to be considered for an individual patient? Does the degree of radiographically demonstrated involvement affect outcome? Is the procedure best performed early or late within the actively evolving pathophysiology of the disease process? Were the favorable results attributable to the surgical intervention or to the aggressive joint motion and prolonged joint unloading after surgery? Will the favorable results from surgical intervention be lasting or will they deteriorate in long-term follow-up? The answers to these questions can only be obtained through further investigations.

The current recommendations for treatment of idiopathic chondrolysis of the hip embrace the philosophy of a more favorable long-term prognosis for improved motion and function in most patients. The principles of early treatment include control of synovial inflammation, maintenance of hip motion, and prolonged relief of weight bearing on the involved joint. For most patients, these principles are achieved through the administration of nonsteroidal antiinflammatory medications at therapeutic doses, the periodic use of skin traction and bed rest during periods of acute exacerbation of joint pain and motion loss, surgical release of unresolving contractures, and an aggressive program of passive and active physical therapy for the involved joint. The patient is also maintained on non-weight-bearing or limited-weight-bearing crutch ambulation for the involved hip, until all pain has resolved and progressive loss of joint space radiographically has ceased. The use of prolonged spica casting, with the involved hip in a position of function in an attempt to achieve fibrous ankylosis, is mainly of historical interest, and should only be considered for patients who do not respond to the described protocol. Hip arthrodesis is the more appropriate treatment for relief of pain and malalignment in young patients recalcitrant to nonoperative treatment. Although the early reports on the use of aggressive subtotal capsulectomy and tendon release indicated very favorable initial results, more recent long-term follow-up indicates the favorable results may be only temporary. For this reason, the routine use of this procedure cannot yet be recommended in the treatment of idiopathic chondrolysis of the hip.

ROTATIONAL VARIATION

Definition

Rotational profiles vary widely among normal children (1,2 and 3). Differences in appearance during walking or running are most often just that—differences—not pathologic conditions. Foot position is described by the direction of the foot, relative to the body's line of progression during the gait cycle. This is referred to as torsion. It is produced by the summation of factors that include version of the bones, capsular laxity or tightness, and muscle control (3,4). Parents are more often concerned about a relatively intoed position than an out-toed position.

Rotational variations, although a frequent concern, are most often variations of a normal exam. The foot's line of progression relative to the body during walking describes rotational alignment, internal, external, or neutral. It is a result of rotational forces applied relative to the axis of the lower limb. These torsional forces include the effects of version, soft tissue flexibility, and muscular control (1,3,4 and 5). “Version” is tilt or inclination within a bone, such as the relationship of the femoral head/neck to the shaft of the femur. Contracture of a joint capsule may restrict rotation. Similarly, capsular laxity may allow a greater than normal arc of motion. Arthrosis or incongruity may also restrict motion. Balance between opposing muscle groups is also a determinant of foot position, and may introduce a significant dynamic component to the rotational profile. Age is another important variable since version, soft tissue pliability, and muscle coordination change as the child matures (1,2,3,4,5,6,7 and 8).

Assessment

Assessment of rotational alignment includes static and dynamic components. The static exam describes the available range of rotational motion. The dynamic exam displays the effect of various torsional forces at play during the walking cycle (Fig. 27-1). The static exam is best performed on a firm examining table, with the child in comfortable, loose clothing, such as shorts or a diaper. Rotation is best assessed with the child in the prone position, keeping the pelvis flat and level on the exam table (3,4 and 5). Flexion of the knee to 90 degrees allows the leg to be used like a goniometer relative to the thigh. Some children will not allow examination other than on a parent's lap. This is usually adequate, although not as controlled as in the prone position. The arc of rotation may be more generous if measured with the hip flexed (sitting position) (5).

FIGURE 27.1. How the rotational profile measurements are made. **A:** The foot-progression angle (FPA) is estimated by observing the child's gait. It is defined as the

angular difference between the axis of the foot and the line of progression. This child's FPA is 0 degrees. **B:** The thigh–foot angle (TFA) is the angular difference between the axis of the foot and thigh, as viewed from above. The TFA in this child is 18 degrees. From this view the shape of the foot is apparent. **C:** Medial hip rotation is the maximum angular difference between the vertical and the axis of the tibia. In these hips, this measurement is 70 degrees. **D:** Lateral hip rotation is the corresponding measurement. On this patient the angle is 10 degrees.

Rotation of the foot laterally or medially is used to assess the degree of available hip rotation. When there is a greater degree of internal or medial rotation (outward movement of the foot) than external or lateral rotation, a toed-in gait is more likely to be observed. Similarly, if there is greater external rotation than internal rotation, the gait pattern is usually toed-out. A greater ability to internally rotate than externally rotate the thigh is frequently referred to as " *anteversion*." It should correctly be called "*antetorsion*" because hip rotation is the combined effect of version of the femur, joint mobility, and muscular contracture (1,3,5).

Medial hip rotation is generally greater in girls than boys. Variability is greater in younger children. Static medial hip rotation averages 40 degrees (range 10 to 60) in infants and 40 degrees (range 15 to 60) by age 10 years in girls and 50 degrees (range 25 to 65) by age 10 years in boys (1,2 and 3,5,7,9,10). Lateral hip rotation is greater in infants: an average of 70 degrees (range 45 to 90), compared to children over age 10 years, who average 45 degrees (range 25 to 65) (1,2 and 3,5,9,10).

Observation of the alignment of the sole of the foot, relative to the thigh, which is held in neutral rotation, determines the thigh–foot angle. This relationship also describes the contribution of the leg segment or the degree of tibial torsion. Foot deformity, which may contribute to rotational abnormalities, can easily be assessed in this position. Forefoot adduction/abduction and hindfoot varus or valgus should be noted. Many young children have significant internal/external rotation laxity through the knee. Rotation of the tibia, internal and external, demonstrates the degree of knee joint laxity, which may contribute to variation in foot position. Average thigh–foot angle is 5 degrees internal in infants (range -30 to +20) and 10 degrees external by age 8 years (range -5 to +30) (1,2,3,4 and 5). Thigh–foot angle changes very little after age 8 years.

Correlation of the static exam with the dynamic exam is important. The child's walking pattern should be observed in an area large enough to allow comfortable, safe walking and running. The child should be able to walk alone (not holding someone's hand). It is often helpful to observe the child in shoes, as well as barefoot. Variations are common with change in speed or direction of walking. Foot and knee position should be observed over several cycles of gait. The relationship of foot position to an imaginary line along the path being walked describes the *foot-progression angle.* Variability is tremendous in children up to age 5 years. Out-toed position predominates. Once a mature gait pattern is established, foot-progression angle changes very little (1,2,3,4,5 and 6,9,10).

The child's rotational profile includes the contribution of each of these components to the gait pattern. The position of the foot relative to the line of walking progression (foot-progression angle), alignment of the foot relative to the body (thigh–foot angle), and knee relative to the body (femoral torsion), all contribute to the sum of rotational factors. Each area needs to be assessed along with its contribution, either positive (internal rotation) or negative (external rotation), to the overall gait pattern. Those children whose rotational profiles are beyond two standard deviations of the mean, are considered to be abnormal according to Staheli et al.'s criteria (3,4).

Differential Diagnosis

Infrequently, pathologic conditions will cause a rotational abnormality. Residual foot deformity, disorders of the hip, and neuromuscular disease are the most common causes of pathologic intoeing or out-toeing. Intoeing may be caused by residual foot deformity from metatarsus adductus, clubfoot and/or skew foot (1,4,5). These conditions are discussed in greater detail in Chapter 29 of this text. Intoeing, which is only apparent during swing phase, may be the result of over pull of the posterior tibial tendon, often seen in spastic hemiplegia (11).

Femoral antetorsion may be seen in spastic diplegia or quadriplegia. This may be a combination of excess femoral anteversion with contracture of the adductor and medial hamstring muscles (4,5,12). Excess valgus and pronation of the foot, which contribute to an out-toed foot progression, may also be seen (12). For some children with spasticity, extremes in rotational posture are a compensatory mechanism for limited hip, knee, and/or ankle motion. The combination of excess internal femoral rotation and external tibial rotation is often observed in children with spasticity, who also have lower-extremity weakness. As the foot is constantly dragged along the floor rather than swinging through, external torsional force is applied to the foot, pushing it out, leaving the knee internally rotated.

Pathologic out-toeing may result from severe pes planovalgus often associated with external tibial torsion (13) (Fig. 27-2). This may be secondary to tarsal coalition. It can also be seen in adolescents with rigid flat feet, without tarsal coalition. It is unclear whether the external tibial rotation is an adaptation to a rigid flat foot, or whether the lack of foot flexibility encourages external rotation. Slipped capital femoral epiphysis should be considered in the differential diagnosis of out-toeing, particularly when the gait deviation is asymmetric or of recent onset (4,14).

FIGURE 27.2. Excess external rotational deformity may not resolve. It may be associated with symptomatic flat foot, with or without tarsal coalition. The use of medial support orthotics may reduce symptoms, but will not alter rotation.

Developmental hip dysplasia can alter rotation, but is highly variable (7). An asymmetric hip exam may be apparent, but is not always reliable in detecting hip dysplasia. In such instances, further evaluation with radiographic hip examination is warranted (3,4). Coxa vara may also present as an out-toed gait.

Radiographic Evaluation

It is recommended that any child who presents to an orthopaedic surgeon with concerns of a gait abnormality should have a single anteroposterior (AP) pelvis radiograph. Although the incidence of otherwise occult pathology is low, the consequence of a missed diagnosis, such as developmental dysplasia of the hip (DDH) or a slipped capital femoral epiphysis, may be significant for the child. Radiographs should also be obtained if there has been a significant change in the gait pattern, particularly if there is asymmetry or if pain is present (3,4,14). Cross-table lateral films are essential for the diagnosis of a minimally displaced slipped capital femoral epiphysis.

It is not necessary to obtain serial radiographs of the hips or lower extremities to follow the course of normal rotational development (4,5). Special views to quantify version of the femur or tibia are not indicated in the routine evaluation of rotation (3,4 and 5). Three-dimensional imaging studies (CT or MRI) are rarely indicated in the assessment or follow-up of rotational variations, but are more accurate than clinical exam or bi-plane radiography (15).

Natural History

Most children brought in for concerns of intoeing or out-toeing are normal. Rotational profiles are highly variable, particularly in toddlers who have not mastered the basic skills needed for normal walking, which is just about every child under 2 years of age, and many of those 2 to 5 years of age (1,2,6,10). Internal and external

rotation variations should be considered just that; these are variations of normal, not pathologic disease or disorder. The natural history of rotational variations is gradual normalization, usually accomplished by 5 to 6 years of age. There are no compelling studies to show that any nonsurgical intervention speeds or assures the normalization of gait (4,5,16).

Internal tibial torsion is more common than external tibial torsion in toddlers (4,5). It is often associated with physiologic genu varum, and decreases 1 to 2 years after resolution of the bowing. Occasionally, it will persist into preadolescence. External tibial torsion is less common, and more likely to persist through adolescence (4,5). Neither has been shown to be a risk factor for degenerative joint disease.

The assessment of hip range of motion in newborns and infants is highly variable (2,3,5,7). Most normal infants have an external rotation contracture about the hip, likely a result of intrauterine positioning. This may not fully resolve until they become established walkers at 18 to 24 months. An intoed gait may then be more apparent. Lateral hip rotation gradually decreases as medial rotation increases. Paradoxically, anteversion in the femoral neck typically decreases from 30 degrees (range 15 to 50) at birth, to 20 degrees (range 10 to 35) by age 10 years (1,2,3,4 and 5,7,8). A decrease in anteversion of the femoral neck would be expected to produce greater external rotation of the hip. A child who toes-in while walking, but has at least 20 degrees of hip external rotation, is within normal limits. Similarly, a child who toes-out while walking, but has at least 20 degrees of hip internal rotation, has motion within a normal range (4,5,10).

Internal rotation variations have not been shown to cause degenerative joint disease (9,10,17,18,19 and 20). Hip pain is rarely a complaint (17,19). Anterior knee pain may be associated with increased medial rotation of the femur, but not generally with patellofemoral changes (19,21). Although the presence of hip external rotation may augment posterior shear loads, an increased incidence of slipped epiphysis has not been found in patients with femoral retroversion without other contributory factors being present (14). Athletic ability does not correlate with the position assumed during normal walking, although some activities may be hindered by rotational variations (22,23 and 24). High-performance sprinters do, however, tend to adopt a toed-in position during running, regardless of their walking style (24). Functional impairment, such as tripping, clumsiness, or lack of running ability, although often attributed to rotational differences, has not been shown to correlate with rotational profile (22).

There are some children with such extreme variation in rotation that their appearance is unacceptable to the child, the parents, and/or families (usually grandparents). The natural history of rotational variations, the lack of evidence for musculoskeletal sequelae, and absence of objective functional disability must be kept in mind, and these individuals educated in this regard (1,3,4 and 5). The natural history of rotational variations should be clearly communicated and understood prior to any recommendation for active treatment.

Treatment

The natural history of rotational variations is gradual normalization, which cannot be altered by nonsurgical means. The use of shoe modifications, orthotics, or positioning devices is ineffective (5,16). Although not harmful, there is little to show any positive effect. Their use reinforces the errant notion that intoeing or out-toeing is an abnormal condition or disorder that requires treatment. The cost of orthopaedic shoes and orthotics can be considerable.

For those otherwise normal children, who have persistent rotational abnormality into adolescence and find the appearance of their gait unacceptable, corrective osteotomy may be considered (4,5,25,26). An awkward gait may appear less so following rotational osteotomy. However, it should be clearly understood that function may change little, if at all. Pain, while rarely a complaint, may be improved following surgical treatment (21). Treatment options for foot and ankle abnormalities are covered in Chapter 29.

Supramalleolar rotational osteotomy of the tibia and fibula **[➥6.8]** has less potential for serious neurovascular complication than proximal tibial osteotomy (25,27). The author's preferred technique uses fixation with crossed K-wires, supplemented with a long leg cast for 6 weeks. The tibia should be cut 2 to 3 cm above the physis and parallel to the ankle. Rotation through an oblique cut can tilt the articular surface of the tibia. Sectioning of the fibula also allows easier rotation of the tibia without displacement. The degree of correction is determined by aligning the foot and ankle, such that the second toe is in line with the tibial tubercle and the center of the patella. As the foot is dorsiflexed and the knee bent, the foot should remain in line with the lateral thigh. Two or three stainless steel wires (0.062 is sufficient) are inserted, one from proximal medial to distal lateral, and the second from distal medial to proximal lateral. A long-leg bent-knee cast is used for 6 weeks. Healing is usually sufficient at that time for pin removal and application of a short-leg weight-bearing cast for 4 to 6 weeks more.

Correction of excess femoral internal or external rotation is obtained by equalizing the degree of internal versus external rotation. The amount to be rotated can be estimated from the prone exam, comparing internal and external hip rotation, preoperatively (5). Femoral osteotomy may be proximal **[➥4.6]** or distal, **[➥4.18]** depending on the surgeon's preference and the type of fixation to be used (26,28). Proximal femoral osteotomy may be considered if there is also proximal femoral varus or valgus deformity. A standard lateral approach to the proximal femur is used. A pediatric or adolescent blade plate is used for fixation. If a distal femoral osteotomy is performed, a lateral approach is preferred. In skeletally immature patients, a small compression plate is used. Blade plate fixation may be used in skeletally mature individuals. Use of additional cast or brace immobilization is at the discretion of the surgeon. Alternatively, a medial approach can be used along with K-wire fixation (26). This latter technique should be reserved for smaller children, and must be supplemented with a spica cast. The amount of rotational correction sought is an equal amount of internal and external rotation.

Intramedullary fixation can be used for either the tibia or the femur. Supplemental fixation is generally not necessary. Locking screws or similar mechanisms are needed proximal and distal to the osteotomy, because the osteotomy has no intrinsic stability. In the skeletally immature, and for those with a relatively narrow medullary canal, the osteotomy is generally performed by open technique. The proximal femoral entry site is made lateral and distal to the tip of the greater trochanter. Great care is taken in avoiding any dissection (including penetration) on the medial side of the trochanter. Recent modification in femoral nail design (proximally angulated 15 degrees) enhances nail placement with this approach. In skeletally mature patients with relatively larger bony anatomy, the femur can be sectioned using an intramedullary saw. Because of the technical demands of this technique, it is recommended only for those with considerable experience with intramedullary fixation in children.

External fixation can be used, but effective rotation may be hindered by pull of the soft tissues (30,31). Acute correction with unilateral frame can be used. Pins should be inserted, taking into account the rotation to be accomplished. This can be a difficult technique, particularly in large adolescents. The amount of change in rotation can be reassessed in the early postoperative period, and adjusted if needed. Gradual rotation is not necessary in these normal children.

Increased femoral internal rotation and tibial external rotation may coexist, producing a rotational malalignment (21) (Fig. 27-3). Knee pain, which is usually diffuse, may be present. Patellar maltracking usually is not present. Because the deformities are complementary, foot progression may be normal, but the static exam will demonstrate the abnormality. Combined osteotomy of the femur and tibia may be necessary to correct symptomatic malrotation (4,21). Femoral rotation is corrected as the first step of the procedure. The foot is aligned with a tibial osteotomy to complete the correction.

FIGURE 27.3. A: This 10-year-old girl is attempting to stand with the knees directly forward. The patellae face medially, and, with effort, she can direct the feet straight ahead. **B:** Examination in the prone position demonstrates nearly 80 degrees of internal rotation of the thigh, or medial femoral torsion. **C:** The relationship of the foot position to the thigh, with knees extended, is shown here. Marked external rotation of the foot, relative to the thigh, is seen. **D:** With knees flexed, the outward direction of the foot can also be appreciated. If the rotational deformities are complementary, foot progression may be deceptively normal. The combination of increased medial thigh rotation and external rotation of the lower leg segment may result in symptomatic torsional malalignment. This deformity may be a cause of

nonspecific knee pain in adolescents, because of the increased shear forces through the knee.

Complications

Any of these techniques can be used to alter rotation. Choosing a technique with which the surgeon is most familiar can reduce technical errors and complications. Proximal femoral osteotomy is preferred over distal osteotomy by some, because proximal osteotomy is more forgiving of any inadvertent varus or valgus angulation resulting from an oblique osteotomy (26,28). Scars may be less apparent with proximal osteotomy. Asymmetric growth arrest can occur from periosteal stripping and injury to the lateral distal femoral physis. Injury to the greater trochanteric apophysis can produce valgus deformity in the proximal femur. These risks may be minimized by choice of a technique with which the surgeon is familiar, appropriately sized internal fixation devices, and consideration of the patient's level of skeletal maturity. Osteotomy performed in adolescence has less potential for serious growth disturbance than that performed in young children.

The risks and complications of intoeing and out-toeing are related to its treatment, not its presence (3,4 and 5,15,17,18,22). Therefore any recommendation for surgical treatment carries greater risk than no treatment. Because most patients who have surgical alteration of their rotation do so for a change in the appearance of their gait, the surgical procedure should accomplish the desired change in rotation. Function may not be altered.

Complications of rotational osteotomy are the same as for other osteotomies. Problems related to nonunion, infection, blood loss, joint stiffness, scarring, and anesthesia are the most serious (21,25,26 and 27). Distal tibial osteotomy has less risk of compartment syndrome and peroneal nerve injury than proximal osteotomy.

Use of intramedullary fixation of the femur carries with it the risk of avascular necrosis of the femoral head, which is not a concern with other types of fixation (29,32,33). Recent changes in pediatric intramedullary nail design permit safer entry through the greater trochanter. The availability of appropriately sized locked nails for the femur may limit the feasibility of this technique in small femurs.

GENU VARUM

Physiologic Bowing

Definition

Infants and children frequently present to the orthopaedic surgeon for evaluation of bowleg deformity (34). Typically, these children are early walkers, achieving independent ambulation before the first year of life (35,36 and 37). The normal knee alignment at birth is 10 to 15 degrees of varus, which remodels to a neutral femoral–tibial alignment at approximately 14 months of age (38,39 and 40) (Fig. 27-4). Levine and Drennan (41) have defined physiologic bowing as more than 10 degrees of bilateral varus noted after the age of 18 months.

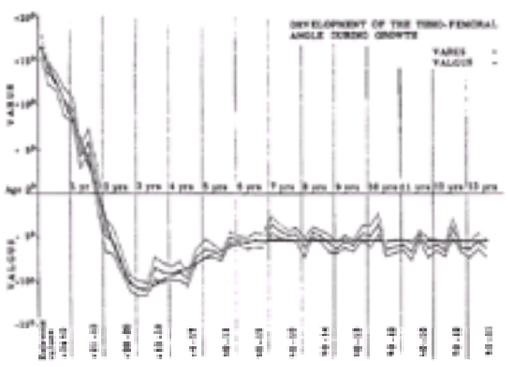

FIGURE 27.4. The graph depicts the expected change in genu varum and genu valgum with age. Children with bowlegs after 2 years of age are outside the normal range, and should be thoroughly evaluated. (From ref. 38, with permission.)

Clinical Features

Parents are concerned with both the cosmetic appearance of the bowing deformity and the seemingly associated problems of excessive tripping. A family history of bowing is common (34,42). Examination typically reveals bowing of both lower extremities with intoeing. Although the bowing deformity is bilateral, it can vary in relative severity of left versus right. Despite their bowlegged, toed-in gait deformity, these infants characteristically are very agile walkers. The child should be observed walking, both coming and going, to assess the severity of the dynamic varus and associated internal rotation deformity. Internal rotation of the extremity seemingly permits maintaining the foot contact point along the body-centered line of progression with the child standing. It should be noted whether or not there is a lateral thrust, a characteristic brief dynamic lateral knee joint protrusion that occurs in stance.

The degree of varus deformity of lower extremity is measured with a goniometer. Standing photographs are helpful in documenting the deformity noted on initial clinical exam. Subsequent photos can be compared with the originals to determine the degree of resolution or progression of the bowing deformity. The “bench exam” is performed with smaller children on the parent's lap and older children on the examining room table.

Angulatory and rotational alignment and joint range of motion for the entire lower extremity is assessed. Knee joint laxity typically is not present. More than likely, the clinical diagnosis will be physiologic bowing and, because the children present at a slightly older age, possibly infantile tibia vara (Blount disease). In the child less than 15 months of age, radiographs document the degree and location of the varus deformity, but usually will not distinguish between physiologic bowing and early Blount disease. Radiographs become a more essential part of the evaluation as the child grows older (>15 months of age), for more relatively pronounced deformities (>20 degrees), if a lateral thrust is observed, if the child is relatively short in stature (<20 percentile), or a metabolic bone disease is suspected (Fig. 27-5). Preferably, the x-ray is taken with the patient standing and the patella pointed straight ahead. The relative degree of varus deformity is noted, observing the shaft-shaft angle of the femur and tibia (41,42). More importantly (43), the distribution of bowing deformity is noted. In physiologic bowing, it occurs diffusely at the distal femur, proximal tibia, and distal tibia, and, in early Blount disease, more focally at the proximal tibia.

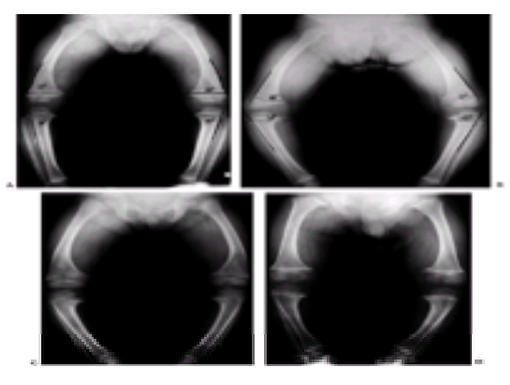

FIGURE 27.5. Standing AP films of both lower extremities help distinguish physiologic bowing from pathologic causes. **A:** Tibial metaphyseal–diaphyseal (M-D) angles are typically 11 degrees or less. A similar angle constructed in the distal femur is the same or greater, indicating that the femur and tibia contribute similarly to the

bowing. The ratio of femoral to tibial M-D angle is ³1. **B:** Early Blount disease may be difficult to distinguish from severe physiologic bowing. The M-D angle in Blount disease is usually greater than 16 degrees, and the ratio of femur to tibia is £1. Fragmentation of the medial tibial metaphysis may not be evident. **C:** This patient with X-linked hypophosphatemic rickets (XLH) has multiple widened physes. Osteopenia is evident in the adjacent metaphysis, which is also flared. Bowing tends to be more diffuse throughout the bone, rather than focal in the proximal tibia. **D:** Skeletal dysplasia, such as chondrometaphyseal dysplasia, may cause genu varus. These children are usually of short stature. Skeletal abnormalities are multifocal, as in this example of Schmid-type metaphyseal chondrodysplasia. The proximal and distal metaphyses of the femur and tibia are all abnormal. The epiphyses, physes, and bone density are normal.

Differential Diagnosis

The differential diagnosis of bowing in the young child includes physiologic bowing and pathologic bowing. Pathologic bowing occurs in infantile tibia vara (Blount disease), metabolic bone disease, and skeletal dysplasias. The clinical and radiologic features associated with metabolic bone disease or skeletal dysplasia can be readily differentiated from physiologic bowing. Most often, the differentiation is between physiologic bowing and infantile Blount disease. If the bowing is physiologic, the entire lower extremity will appear to be bowed. If the varus alignment results in relative greater deformity of the proximal tibia, infantile tibia varus, or Blount disease, may be present. Children with either physiologic bowing or Blount disease usually are early walkers, and typically present for evaluation at 15 to 18 months of age. It is not uncommon for siblings to be affected with either physiologic bowing or Blount deformity (34,35,42,43). No doubt, physiologic bowing and Blount disease ought to be perceived as two different points on the same spectrum, as the end results of the persistence of infantile bowing (35,41,44). Radiographic distinction between physiologic bowing and Blount disease may not be initially obvious, because Langenskiöld changes diagnostic of Blount disease typically are not distinctive until 2 to 3 years of age (36,39,41,43,45) (Fig. 27-6). Measuring the metaphyseal–diaphyseal (M-D) angle of both the proximal tibia and distal femur further helps to identify the specific location and relative severity of varus deformity (41,45,46) (Fig. 27-5A and Fig. 27-5B). Although an absolute M-D angle is not diagnostic, it does serve as a more specific guide in differentiating Langenskiöld stage I infantile Blount disease from physiologic bowing (39,43) (Fig. 27-6). The authors' study of the proximal tibial M-D angle, in patients with physiologic bowing and Blount disease, identifies two distinct bell curves with considerable overlap (45) (Fig. 27-7). From this one concludes that if the M-D angle is less than 10 degrees, chances are (95% probability) that the diagnosis is physiologic bowing. Conversely, if the M-D angle is >16 degrees, then chances are (95% probability) that the diagnosis is Blount disease. The initial indeterminate patient, those between 10 and 16 degrees, often need follow-up for at least 1 to 2 years to note whether progressive remodeling or the occurrence of Blount disease occurs. The ratio of the M-D angle of the distal femur, relative to the same angle of the proximal tibia, can be helpful in attempting to differentiate physiologic bowing from early Blount disease. A ratio of greater than 1 suggests the bowing is physiologically proportioned to the femur and tibia, and remodeling will typically occur (46). If, however, this ratio is <1, the bowing probably will evolve into Blount disease.

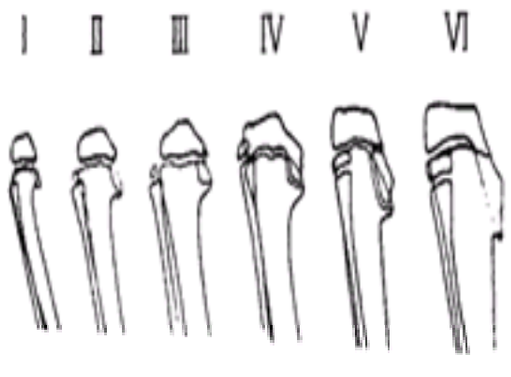

FIGURE 27.6. Depiction of the six stages of radiographic changes seen in Langenskiöld classification of tibia vara. (From ref. 56, with permission.)

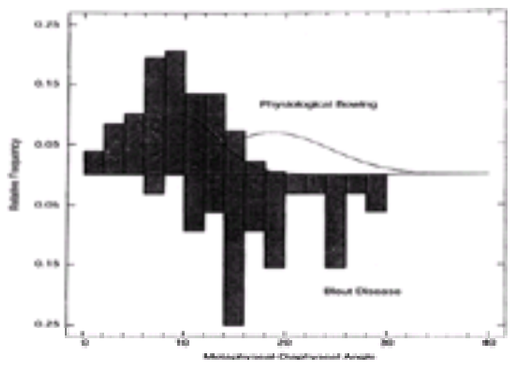

FIGURE 27.7. The relative frequency of metaphyseal–diaphyseal (M-D) angle, measured in children with physiologic and Blount disease, is presented. The M-D angle in physiologic bowing is graphed above the horizontal line; similar measurements in Blount disease are graphed below. The bell curve to the left shows the distribution in physiologic bowing. The bell curve to the right is the distribution in Blount disease. Although peak distributions are clearly separate, there is significant overlap between M-D angles of 10 and 16. Below 10, there is a 95% probability that the bowing is physiologic. Above 16, there is a 95% probability that the bowing observed is in fact Blount disease. Angles in between are indeterminate. Additional risk factors, such as obesity, instability (lateral thrust), and family history, must be considered.

Less often, physiologic bowing must also be differentiated from the pathologic bowing associated with metabolic bone disease or skeletal dysplasia. Rickets is the most likely metabolic bone disease presenting in the toddler with bowed-leg deformity (47,48) (Fig. 27-5C). In this age group, rickets (most likely X-linked hypophosphatemic rickets, or XLH) is the most likely metabolic bone disease to initially present with a lower-extremity bowing deformity. Infants presenting with rickets are very short, the measured height being less than the tenth percentile. Radiographs of infants with bowing deformity secondary to rickets should not be mistaken for physiologic bowing (43). In patients with XLH, the physis will appear abnormally wide, with the metaphysis flared out and around the physis in a trumpet shape. Similar changes will be noted at all metaphyseal/physeal areas. Overall, bone density will be diminished, with particularly poorly defined diaphyseal/ metaphyseal cortices. The severity of both bone morphological and osteomalacia changes varies considerably. The diagnosis of XLH is definitively made by analyzing serum calcium and phosphate and urine calcium and phosphate (47,48). Patients suspected of having rickets should be referred to an endocrinologist for a definitive metabolic workup.

Skeletal dysplasias can initially present as a bowing deformity of the lower extremity (see chapter 8 in this text). Metaphyseal chondrodysplasia (Schmid or McKusick type) typically presents with persistent bowing and short stature, in an otherwise normal child (Fig. 27-5D). The child presenting with bowing deformity, in association with a skeletal dysplasia, will be very short, typically in the <5th percentile. Morphologically, the radiographic changes about the physis and metaphysis will not appear pathologically flared, the physes are not abnormally widened, and bone density will appear to be normal. Achondroplasia often presents with bowing. The distinctive physical findings of achondroplasia should allow for differentiation. Patients with pseudoachondroplasia may initially present with a varus or valgus deformity, in association with ligamentous laxity. Again, these patients can present with very short stature and distinctive physical findings.

Focal fibrocartilaginous dysplasia is a very uncommonly occurring, progressive, unilateral focal dysplasia of the proximal medial tibial metaphysis (49,50,51 and 52). The clinical presentation is very similar to unilateral infantile Blount disease. The diagnosis is made radiographically. A characteristic focal indentation is noted into the medial metaphyseal–diaphyseal cortex, with associated varus of the tibia (Fig. 27-8). The epiphysis will appear normal.

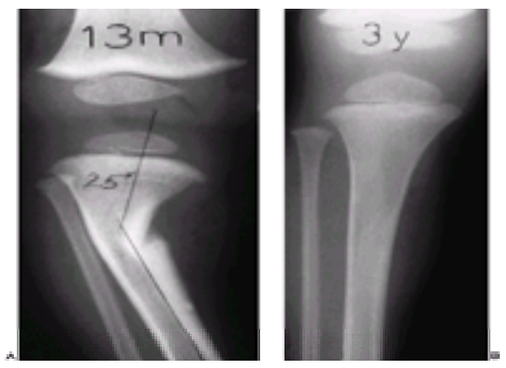

FIGURE 27.8. Focal fibrocartilaginous dysplasia. **A:** Initial radiograph of the patient at 6 months of age shows anterior and lateral bowing of the tibia, but is more proximal than in congenital pseudarthrosis **B:** The deformity resolved spontaneously, as seen in a radiograph made at 3 years of age.

Natural History of Physiologic Bowing

Physiologic bowing in the vast majority of patients will resolve with growth, as predicted by the Salenius plot (Fig. 27-4) of the natural changing frontal plane alignment of the lower extremities (38,40). Parents should be properly informed that spontaneous correction of this physiologic varus is anticipated to occur within 1 to 2 years. Additional effort should be made to explain the futility of nonoperative treatment (be it orthotic shoe insert, shoe modification, or nighttime orthoptic splinting, etc.), in attempting to expedite the anticipated remodeling. Follow-up visits may not be necessary in milder physiology deformities, because the bowing and associated internal torsion predictably resolve. For the relatively more pronounced or persistent deformities, follow-up visits are scheduled at 4 to 6 month intervals. Correction or progression of varus that occurs with growth can be documented with subsequent physical examination and both radiography and photography. Occasionally, physiologic varus may persist into late childhood, warranting longer follow-up.

Infantile Blount Disease

Definition

In 1937, Walter Blount published his classic review of tibia vara or osteochondrosis deformans of the proximal tibia, noting its progressive course of both clinical deformity and correlative radiographic pathology (53). The radiographic and pathologic changes described by Blount, and histopathologic changes by Langenskiöld (36,54,55 and 56), were felt to be secondary to a disruption of normal growth of cartilage and bone from excessive abnormal weight-bearing pressure on the growth plate and adjacent bone. Avascular necrosis of bone has not been observed (56). The inherent progression of this developmental, pathologic tibia vara can be definitively corrected with treatment (53,55,57,58 and 59).

Etiology

Like physiologic bowing, infantile Blount disease is usually bilateral (35,37,42). In the early presentation of the infant bowed-leg deformity, there is no clear distinction between Blount disease and physiologic bowing (35,37,42,44,60,61 and 62). Rather, physiologic bowing is a continuum with Blount disease. When unilateral infantile Blount deformity is noted, it is not uncommon for the contralateral extremity to be physiologically bowed and often indistinguishable from early infantile Blount disease (Fig. 27-9A and Fig. 27-9B). They share the common etiologic factor of early weight-bearing by a child who may or may not be overweight (34,35,37,39,41,43,44,53,54). Early walking results in a variable increase in physeal shear stress and eventual disruption in medial physeal and bony growth (35,36,63). Obesity increases the potential for chronic growth plate injury.

FIGURE 27.9. A: This 30-month old girl shows clinically asymmetric bowing. She is large for her age (>95% weight). **B:** The M-D angle on the right is 20 degrees, compared to 10 degrees on the left. This is consistent with stage II changes of Blount disease on the right and physiologic bowing on the left. **C:** Intraoperative films of a right proximal tibial osteotomy show slight over correction to valgus. A Bovie cord, centered over the hip and ankle, is an easy method to assess mechanical axis intraoperatively. Crossed K-wires are used for fixation. **D:** A clinical photo taken 2 years later shows maintenance of correction on the right. Spontaneous correction of physiologic bowing has occurred on the left.

Cook et al., using finite-element stress analysis, calculated that the compressive force resultant from weight-bearing on a bowed leg was sufficient to cause progressive growth disturbance (64). In some extremities, by chance, physiologic bowing remodels (35,39), and in others the varus focally worsens at the proxima tibia, and Blount disease develops. The resulting osteochondrosis is a consequence of increased pressure on the medial proximal tibial physis and adjacent epiphysis and metaphysis (35,42,44,62,65). A prediction for developing an osteochondrosis has been postulated (34,35 and 36,44,66). There is a variably occurring familial history of infantile tibia vara (34,37,42,67).

Pathoanatomy

In 1952, Langenskiöld identified six distinct radiographic stages of infantile Blount disease that can be seen during skeletal maturation (54) (Fig. 27-6). The ages at which each stage occurs varies, as does the observed prognostic significance (39,42,43,54,56). In stages I–II, irregular and reversible early metaphyseal ossification changes are often indistinguishable from physiologic bowing. Stage IV lesions can be associated with early, though often difficult-to-detect, bar formation across the deformed vertical physis (39,43). Profound disruption of normal physeal cartilage and adjacent bony growth is noted in stage V (more than age 8 years) with resultant severe joint depression deformity in stage VI (36). Langenskiöld and Riska (36) felt that the evolution from stages II–IV does not necessarily predict outcome or response to treatment (56). However, recent reports (37,39,42) note that in stage IV an osseous bar is often detectable. The severity of the secondary tibial varus deformity varies directly with the extent of the bony changes involving the proximal medial tibia. In some cases, a compensating secondary valgus deformity of the distal femur develops (35,68).

Treatment

Nonsurgical Treatment. Brace treatment should be considered in all patients less than 2½ years of age with early Blount disease changes (Langenskiöld stages I–II), and in other patients with persistent bowing and at-risk signs for Blount disease. A M-D angle of >16 degrees is a radiographic sign at risk (39,43,45). A relative radiographic sign at risk is a M-D angle of 10 to 16 degrees and a clinically noted persistent or progressive varus deformity. Obesity and ligamentous instability (evidenced by the presence of a lateral thrust [43]) potentiate the severity of varus deformity from any cause, and are added risk factors (4,9,45). The authors have previously noted successful definitive brace treatment of six patients with infantile Blount disease. Recent reports (37,38 and 39) demonstrate that brace treatment

can be definitive in correcting both the varus deformity and the pathologic proximal medial tibial growth disturbance. Brace treatment should be initiated early. A modified knee-ankle-foot orthrosis (KAFO) that prevents knee flexion is worn 23 of 24 h (39,57,58 and 59,69). The locked KAFO unloads the pathologic medial compression forces, allowing resumption of the growth and correction of the genu varum.

The bowleg deformity typically improves over the ensuing months. The pathologic radiographic changes at the proximal medial tibial metaphysis, physis, and epiphysis are much slower to remodel. The authors maintain the brace treatment until the bony changes in the proximal medial tibia resolves; typically, this takes 1½ to 2 years of brace treatment (57,58 and 59). To be predictably successful, definitive correction must be achieved before 4 years of age (37,38 and 39,43). In combining the results of the three recent reports of brace treatment for infantile Blount disease, a total of 79 extremities were treated. The best results were obtained with unilateral deformity, with brace treatment being reported as successful in 22 of 23 patients. Contrastingly, brace treatment was relatively unsuccessful in treating bilateral deformities, with only 18 of 28 patients noted to be successfully treated with bracing (57,58). Understandably, brace-wearing compliance was much more difficult to achieve for the child with bilateral deformity. Bracing should not be initiated after 3 years of age, nor should brace treatment be continued if Langenskiöld stage III changes develop (57,58 and 59).

Surgical Treatment. The goal of surgical treatment of early infantile Blount disease (Langenskiöld stage < IV) is to correct the abnormal limb alignment that indirectly restores more normal proximal-medial growth. Early corrective surgery (£4 years of age) is critical in predictably achieving restoration of normal growth (39,42,43,56,61). In older children with more advanced pathologic changes (Langenskiöld stage >IV), the goal is to directly correct both abnormal lower-limb alignment and pathologic bony changes, either at the proximal medial tibial physis or the articular surface of the proximal tibial. Comprehensive correction of all aspects of the often complex deformity is essential in achieving a satisfactory outcome.

Moderate Varus. A corrective proximal tibial osteotomy is indicated if, following brace treatment, the varus deformity and abnormal proximal medial tibial growth have not resolved (39,43) by age 4 years (Fig. 27-9A and Fig. 27-9B). Children 2 to 3 years old, who are either noncompliant or anticipatedly not good brace-treatment candidates (39,57) (relatively large thigh confluence and/or bilateral involvement, or ³3 years) at initial presentation, should be treated with a vagus correcting osteotomy. Performing the osteotomy early (at least prior to 4 years of age, < Langenskiöld III) is critical in optimizing restoration of eventually near-normal growth and morphology of the proximal medial tibia (39,42,43,56,61,70). Delay beyond this age potentiates inevitable progression of pathologic changes centered around the medial tibial physis. The proximal tibia osteotomy is performed with attention to both the known inherent risks (39,71,72) and the need for obtaining adequate correction of the deformity (39,43). The fibula is osteotomized with great care, so as to avoid injuring the deep motor branches of the peroneal nerve (27). The tibial osteotomy can be accomplished in a variety of ways (39,43,56,73,74 and 75) **[➥6.2–6.5]**. A straight transverse osteotomy optimally allows for necessary adjustment in correction of frontal, sagittal, and rotational deformity. The fragments are stabilized with smooth Kirschner wires. A slight over correction into valgus, and/or translating the distal fragment laterally, is desirable (39,42,43,76). This allows both for frontal plane alignment correction and places the mechanical axis of the leg laterally in the knee, optimally unloading the medial proximal tibia (39). In unilateral deformities, clinical comparison to the normal extremity is helpful in determining whether adequate correction has been obtained. An intraoperative anteroposterior x-ray of the entire lower extremity can be taken to assess the correction obtained.

Alternatively, the authors trace the mechanical axis of the leg from the hip to the ankle with the metallic Bovie cord and the C-arm (Fig. 27-9C). This simple technique provides for a reproducible method to verify that the mechanical axis has truly been transferred lateral to the center of the knee joint (77). Neurovascular complications are associated with a proximal tibia osteotomy (42,71,78,79,80 and 81). Subperiosteal exposure minimizes direct nerve and/or vessel trauma. Prophylactic limited fasciotomy (43) and utilizing drains help to prevent a build-up of compartment pressure. If a compartment syndrome is suspected postoperatively, immediate treatment with fasciotomies should be performed. In fact, in recent clinical experience, the authors have been more likely to observe an acute traction or impingement injury to the peroneal nerve (27). Again, prompt surgical release of the peroneal nerve compression has typically resulted in a satisfactory outcome.

Postoperatively, the extremity is immobilized in a long-leg, bent-knee cast or, alternatively, a spica cast, for the child with relatively short, fat extremities. It is essential to radiographically document that valgus alignment has been obtained and maintained. Alternatively, Price et al. have effectively utilized monolateral external fixation to stabilize the osteotomy(ies) (77). On occasion, short-term postoperative long-leg bracing (KAFOs) is utilized if the preoperative deformity was severe and associated with ligamentous laxity. Following corrective osteotomy, the bony medial pathologic changes must be carefully monitored because further progression in their development may or may not be associated with a recurrent of deformity (36,39,43) (Fig. 27-9D).

Worsening Varus Deformity

Recurrence of varus deformity and/or persistent pathologic tibia vara radiographic changes can occur despite restorative osteotomies done prior to 4 or 5 years of age. The recent clinical experience in North America (39,42,43,61) cites a recurrence rate of varus deformity much higher than observed by Langenskiöld, whose clinical experience with Blount disease has been in a very homogeneous Finnish population. In North America, the population is more heterogeneous, many children are obese, and a high percentage are black (35). Blount disease may be a more rapidly progressing disease in North America than it is in Finland (39,43,56). The authors have observed advanced changes in Langenskiöld stages (IV–V) in patients 4 to 5 years of age, both obese and nonobese, and of variable race. Risk factors that have been identified for recurrence include Langenskiöld stages III–IV, marked obesity (>95 percentile), ligamentous laxity, and black females (39,42,43,61). Alternatively, patients may initially present with more advanced pathology (³Langenskiöld stage IV) (Fig. 27-10A). If patients present initially or with recurrent deformity, MRI, CT, or conventional tomography should be utilized to search for the presence or absence of bony tether traversing the distorted proximal medial tibial physis. Identification of a bar through the serpentine, vertically sloped medial tibial physis can be difficult. Early bridging typically occurs at the most inferior aspect of the vertical limb of the distorted medial physis (Fig. 27-10B).

FIGURE 27.10. A: These anteroposterior radiographs show focal changes of unilateral stage IV Blount disease. The medial tibial physis is indistinct. These changes are suggestive of physeal bar formation. **B:** A CT scan shows the deformity in the medial physis. The growth plate has a vertical, rather than horizontal, orientation. A bridge of bone is clearly evident here. Varus will rapidly recur following osteotomy if the physeal bar is not recognized or treated. **C:** These postoperative films show correction of the varus and resection of the bar. The defect created by excision is filled with radiolucent methylmethacrylate (Cranioplast). **D:** Subsequent films show recurrent bar formation, with gradual loss of correction over 2 years. **E:** A second excision of the physeal bar, along with lateral physeal stapling, has resulted in improved alignment. **F:** Following removal of the staples, varus has gradually recurred. The abnormal medial physis tends to close prematurely.

On occasion, the varus recurs without an obvious bony bar (Langenskiöld III or early IV) (39). This occurs rather subtly, as a result of a relatively decreased growth rate of the proximal medial tibial physis. This can occur early or late, until the time of maturity. In this setting, the varus deformity can be controlled with temporary staple epiphysiodesis (39,82,83). The staples are removed after a slight over correction is obtained. Again, the growth of the involved tibia must be closely monitored for a tendency for recurrence and/or early physeal closure.

If recurrent progressive varus occurs with an identifiable osseous bar, appropriate restorative surgery is indicated. Progression of initial bar formation eventually results in complete arrest of the entire medial physis (Langenskiöld stage VI). Physeal bar resection **[➥4.22]** in conjunction with a second varus correcting osteotomy (39,43,56,61,84,85), will most likely be effective if the patient is relatively young (<10 years), the bar is relatively small, and the patient is not excessively overweight (39,43,86). A similar approach might be indicated for the unusual patient who presents for primary treatment with Langenskiöld late stage IV or stage V radiographic changes (Fig. 27-10C). The proximal tibia is approached through an anteromedial longitudinal incision, and the physeal bar is resected first. There may or may not be a discrete bar; often, there are several small punctate foci of bone that appear to coalesce and function as a tether. The medial edge of the normal physis is often difficult to locate. Excision of the bony bridges is done cautiously, so that as much normal physeal tissue as possible is preserved. However, resection must be

complete, such that an intact physeal line, coursing 180 degrees from the posteromedial to the anteromedial cortical edge of the tibia, is defined. The C-arm can be helpful in monitoring the procedure. Cranioplast is used to fill the void, inhibiting growth of another osseous tether.

The varus-correcting osteotomies of the tibia and fibula are then performed (Fig. 27-10C). Alternatively, in combination with the medial epiphysiolysis, a temporary lateral staple epiphysiodesis **[➥6.14]** may be very effective in correcting the varus deformity (Fig. 27-10E). This is most applicable if the varus deformity is not too severe, the patient is not obese, and there is no lateral knee-joint thrust. The majority of patients experience resumption of medial physeal growth (84,87). The remaining potential growth of the proximal medial physis is invariably limited. Long-term follow-up is essential to monitor the longitudinal growth and development of the proximal media tibia. The physeal bony tether may reform, with resulting recurrence of varus deformity. A second bar resection and varus corrective osteotomy is indicated for smaller recurrent bars in younger patients (Fig. 27-10D). If a lateral temporary hemiepiphysiodesis has been done, timing of staple removal is critical to prevent secondary deformity (Fig. 27-10E and Fig. 27-10F). Alternatively, and more appropriately for relatively larger osseous bars, obese patients, and/or older patients, a permanent lateral epiphysiodesis of the tibia and fibula may be indicated, with a varus corrective osteotomy (39,43,56). With this approach, it may later be necessary to surgically address problematic residual proximal medial joint depression. The potential for leg-length inequality exists with any of the above approaches. If anticipated, it often can be corrected early with an epiphysiodesis, or conceivably later with leg lengthening.

Severe Varus Deformity

In some patients with untreated or recurrent infantile Blount disease, the proximal medial tibia bony architecture can become very deformed. These patients have irreversible Langenskiöld advanced stage V and VI radiographic pathologic changes (Fig. 27-11A). Typically, they are older (>10 years of age) yet these changes have been seen as early as 6 years of age. The proximal tibial varus deformity (with limb-length discrepancy in unilateral cases) is characterized by severe depression of the medial tibial plateau and variable ligamentous laxity. A secondary distal femoral compensatory valgus deformity may develop (68). In severe cases, the tibia will be subluxed medially on the femur. Left untreated, degenerative arthritis is likely to occur early in life (70,88).

FIGURE 27.11. A: Blount disease that progresses to physeal bar formation results in severe depression of the medial metaphysis. Valgus may develop in the distal femur, because of overgrowth of the medial femoral condyle. Restoration of medial physeal growth is not possible. **B:** Optimum treatment requires a comprehensive approach that addresses all components of the deformity. This includes elevation of the medial tibia plateau and lateral physeal arrest. Image intensification is useful to control the direction of the medial elevation osteotomy. The cut begins at the apex of deformity in the medial cortex, and is completed between the tibial spines. **C:** A cortical strut is used to support the elevated plateau. **D:** Osteotomy of the tibia and/or femur is performed to correct residual tibial varus or femoral valgus. **E:** Normal anatomic and mechanical alignment can be achieved with this approach. Residual limb-length inequality can be managed by contralateral epiphysiodesis, if needed.

For a lasting satisfactory outcome, the surgical goal is to restore all aspects of this extensive deformity. The physis will be completely closed medially. In this setting, epiphysiolysis will not predictably restore proximal tibial growth (56).

Alternatively, the authors' preferred approach in attempting to restore this extensive deformity is a combination of tibial plateau elevation and realignment osteotomies of the proximal tibia, and occasionally the distal femur (36,56,76,89,90 and 91). The proximal medial tibia should not be approached subperiosteally. Rather, soft tissue attachments to the proximal medial tibia are preserved so as to minimize medial tibial circulatory changes, following the subsequent plateau-elevating osteotomy. A medial peripatellar arthrotomy is often performed to visualize the articular surface of the tibia. The posterior neurovascular structures are at risk, and are protected by placing either a curved subperiosteal retractor or the surgeon's finger between the structures and the potentially penetrating drill bit and/or osteotomes.

Intraoperative radiography or fluoroscopy is used to assure that the plane of the proximal osteotomy is directed superolaterally, with the apex of the osteotomy bisecting the tibia intercondylar eminence (Fig. 27-11B). The depressed tibial condyle must be sufficiently elevated and fixated without disturbance of the articular surface of the tibial condyle (Fig. 27-11C). The correction obtained following plateau elevation typically restores the tibial condylar angle to a near-normal value (89). A concomitant epiphysiodesis of the lateral proximal tibia and proximal fibula is always done.

Tibial plateau elevation alone will produce a marked correction of much of the preoperative varus deformity. However, concomitantly or staged, a proximal tibial varus-correcting osteotomy, and often, a distal femoral valgus osteotomy, are essential for restoration of normal axial alignment. The distal femoral osteotomy may be necessary to correct valgus deformity, which occurs secondary to relative overgrowth of the medial femoral condyle. The surgical goal of this comprehensive approach is to achieve correction of all components of the deformity, i.e., medial tibial plateau depression, asymmetric proximal tibial growth, varus of the tibia, and valgus of the distal femur (Fig. 27-11D). As noted above, precise intraoperative assessment of correction obtained is critical. The mechanical axis of the limb should bisect the center of the knee joint, and should be relatively perpendicular to the anatomically restored joint surface (Fig. 27-11E). After correction of the angulatory deformity, significant limb-length equality may remain. This may be managed by epiphysiodesis of the contralateral limb, or, in more severe discrepancies, a combination of lengthening and shortening may be required to equalize limb length. Davidson (76) has similarly utilized the circular external fixator to stabilize the elevated plateau fragment, and to concomitantly perform a gradual correcting osteotomy of the proximal tibia. By utilizing the external fixator there is also the option for lengthening of the proximal tibia.

Complications

Extensive soft tissue and bony dissection is necessary to concomitantly elevate the medial tibial plateau and perform a varus-correcting proximal tibial osteotomy. The medial proximal tibial becomes relatively more protuberant and longer, following a concomitant plateau-elevating and varus-correcting osteotomy. Wound closure may be relatively compromised, and possibly delayed. Three of the authors' 20 patients experienced wound healing complications. In two patients, eventual wound healing occurred with local care. One required operative repair, with subsequently satisfactory secondary wound healing. The extensive soft tissue and bony dissection necessary to perform a tibial plateau elevation potentiates the occurrence of avascular necrosis of the medial tibial condyle. This has occurred in 1 of 20 tibial plateau elevations the authors have performed. Satisfactory revascularization and reossification occurred following a 1-year period of non-weight-bearing for this morbidly obese 8-year-old child.

Adolescent Blount Disease

Definition

Blount also described a second group of patients with the onset of varus deformity in later childhood or early adolescence, which he described as adolescent tibia vara (53) (Fig. 27-12).

FIGURE 27.12. A: Adolescent Blount disease frequently occurs in very large teens. The deformity is often bilateral. **B:** Long cassette films are used to assess mechanical alignment, as well as the anatomic axes of the femur and tibia. Distal femoral and distal tibial valgus may be present, in addition to the obvious proximal tibial varus deformity. **C:** Restoration of normal alignment may include multilevel osteotomies. Preoperative templates are useful for planning operative strategies. **D:** In this example, the plan included immediate correction of distal femoral varus, using a blade plate, with gradual correction of proximal tibial varus and distal tibial valgus, using a circular small wire frame. Multiplane correction is facilitated with this technique. **E:** Radiographs confirm the restoration of alignment. Adjustments can also be made to correct the procurvatum that may be present. **F:** This film shows limb alignment following removal of the circular frame. Correction is generally well maintained. **G:** Clinical photo after bilateral treatment shows satisfactory clinical correction, compared to the preoperative photo. (Courtesy of J. Eric Gordon, M.D., St. Louis, MO.)

These children typically present for evaluation of a bowed-leg deformity later in childhood. They may or may not have a history of persistent physiologic bowing persisting through early childhood (92,93,94 and 95). However, there should be no confusion in differentiating patients with adolescent Blount disease from patients with persistent infantile tibia vara, which by later childhood will typically have advanced pathologic changes involving the proximal medial tibia.

Etiology

Adolescent Blount disease usually, but not always, occurs in obese patients with characteristically wide thighs (62,63,92,93 and 94,96). If biopsied, growth plate histologic aberrations are present throughout the entire physis. Medial, more than lateral, physeal growth is adversely affected (94). The histologic changes are very similar to histologic changes noted in infantile Blount and slipped capital femoral epiphysis (SCFE) (94,95). The resulting radiographic changes in adolescent Blount are less extensive, because of the well-formed secondary ossification center (94,95). Relative obesity potentiates the occurrence of adolescent Blount (92,93,96,97). Adolescent tibia vara and SCFE do occur in association with each other (94,98,99).

Davids et al. (92) examined the dynamic gait deviations that compensate for the increased thigh girth associated with obesity. During ambulation, individuals presumably attempt to keep foot placement close to the midline of foot progression in order to minimize weight transfer, thereby minimizing energy expenditure during ambulation. The obese individual with large thighs has a very difficult time adducting the hip adequately to place the foot in the midline progression. Davids et al. (92) speculated that this “fat thigh syndrome” produces a varus moment on the knee that leads to increased pressure on the medial proximal tibial physis (and presumably the medial distal femoral physis), and inhibits growth in accordance with the Hueter-Volkmann law (62). Davids and colleagues' work supports the observation that static varus of the knee is not a prerequisite in the pathomechanics of adolescent tibia vara. Seemingly, the incidence of adolescent Blount has markedly increased in the past 15 years, paralleling the increased preadolescency of adolescent obesity (93,100).

Pathoanatomy

The posteromedial growth inhibition of the proximal tibia initially produces varus, then progressive procurvatum of the proximal tibia (39,68,94). Although the name of the disorder would suggest that varus of the proximal tibia is the only deformity present, a similar associated varus deformity of the distal medial femur also occurs (68,94,100). This is in contradistinction to infantile tibia vara, in which the most common finding is a compensatory distal femoral valgus deformity. The intoeing in adolescent Blount disease is relatively less severe than it is in infantile Blount. The combined varus, procurvatum, and internal rotation results in a complex three-dimensional deformity of the proximal tibial. As the proximal tibial and distal femoral varus deformities increase, there is a significant strain placed on the lateral collateral ligament of the knee, which leads to laxity and varus deformity within the knee joint itself. Finally, in some very severe cases, compensatory distal tibial valgus can occur allowing the patient to place the foot flat on the floor. The natural progression of advanced infantile Blount disease is the formation of a medial proximal tibial physeal bar. Conversely, although overt bar formation in adolescent Blount disease does not occur, early closure of all lower extremity physis is frequently noted, perhaps as a consequence of the associated obesity.

Clinical Features

The typical patient with adolescent tibia vara is an obese, black male who typically presents for complaints of bowing and knee pain and/or instability (93,94,96,101,102). The patient should be observed during gait, walking both toward and away from the examiner, for overall gait mechanics, and specifically the presence of a limp or lateral thrust to one or both knees. Though unilateral complaints are more common (96,101), attention should be paid to the contralateral limb, because the patient's obesity can mask mild bowing on the contralateral limb (92). The knee stability is assessed; lateral collateral ligament laxity can occur. Proximal tibia procurvatum deformity variably occurs, effecting a relative knee-flexion contracture. Patients complain of medial knee pain secondary to medial knee-joint stress. They also experience anterior knee pain, no doubt secondary to holding the knee in a flexed position during gait. The magnitude of internal tibial torsion should be assessed with the patient prone on the examining table, looking at both the thigh–foot angle and the bimalleolar axis (Fig. 27-1). The hips should also be examined for evidence of SCFE. Morbidly obese patients presenting with adolescent Blount may have varying amounts of respiratory distress. The walk from the waiting room to the examination area can be quite taxing to these patients.

Radiologic Features

A standing long-cassette radiograph of both lower extremities is essential for evaluating the patient with adolescent tibia vara (Fig. 27-12B). Although some younger or smaller patients can be evaluated on a 36-in. cassette, most patients require a 51-in. cassette. Simultaneous satisfactory radiographic visualization of the hips through an abundance of soft tissue, as well as the ankles through a relative paucity of soft tissue, can be difficult. Care should be taken when positioning the patient to ensure that the knees are straight ahead, with the patellae centered. This is particularly difficult in large patients in whom the palpation of bony landmarks is uncertain. Radiology technicians who are not experienced in obtaining these radiographs frequently can compensate for the inability to visualize the patella by turning the feet straight ahead. However, internal tibial torsion produces external rotation of the knees and an inadequate radiograph for accurate assessment of bony deformity. Occasionally, because of the width of the patient or the patient's inability to sufficiently internally rotate the hip, it may be necessary to obtain separate standing radiographs of each lower extremity. A true lateral supine radiograph of the proximal tibia is obtained to evaluate the magnitude of the procurvatum deformity. The radiograph should be centered on the knee and the film positioned so that a significant portion of the tibial diaphysis can be visualized. Finally, with the feet positioned straight ahead, a standing AP radiograph of both ankles should be obtained to accurately assess distal tibial valgus.

The radiographs should be assessed according to the method described by Paley and Tetsworth (103). Initially, the mechanical axis deviation should be measured, using a line drawn from the center of the femoral head to the center of the ankle. The surgeon should also look for a limb-length discrepancy at this point. Both the lateral distal femoral angle and the medial proximal tibial angle should be measured, to evaluate the frontal plane deformity of both the distal femur and the proximal tibia. Beware of assuming that the distal femur is normal because the knee joint appears to be parallel to the floor. The genu varum produces relative abduction at the hip, and can mask a significant femoral deformity. Finally, the center of rotation of angulation (CORA—the intersection point of the proximal and distal mechanical or anatomic axes) (Fig. 27-13A) for both the femur and the tibia should be located, and the magnitude of the deformity measured (103,104). This is typically at a level close to the physis in both the femur and the tibia, but may lie anywhere between the joint and the metaphysis, and in some cases, may even be located beyond the joint surface. The knee must be examined in the weight-bearing film to assess the presence of significant lateral collateral laxity and an increased joint line congruency angle (the angle formed by an intersect of two lines, one drawn parallel to the distal articular surface of the femur and one parallel to the proximal articular surface of the tibia). Likewise, the lateral knee should be evaluated to assess the size and location of the procurvatum deformity (Fig. 27-13B). A standing radiograph

of the ankles is examined for the presence and location of any distal valgus deformity.

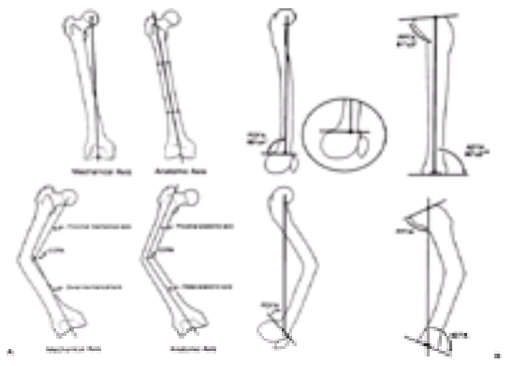

FIGURE 27.13. A: The anatomic and mechanical axes of the femur are different. The anatomic axis of the femur is its middiaphyseal line. The mechanical axis of the femur is the line from the center of the knee joint to the center of the ankle joint. When the femur is angulated, the mechanical and anatomic axes are also angulated. Just as there is a segment of femur proximal and distal to the break, there is a proximal and distal segment of the mechanical and anatomic axes. Where the two interact is the center of rotation of angulation (*CORA*). The mechanical and anatomic CORAs lie on the same bleactor line. **B:** Sagittal plane malalignment test. Femur: line from the center of the femoral head to the junction of the anterior and middle third of the distal femoral joint line. The posterior distal femoral angle (*PDFA*) should be 83±4 degrees. Tibia: line from the midpoint of the distal tibial joint line to the junction of the anterior and middle third of the proximal tibial joint line. The posterior proximal tibial angle (*PPTA*) should be 81±3 degrees. The anterior distal tibial angle (*ADTA*) should be 80±2 degrees. (From ref. 104, with permission.)

Treatment

Goals

The problems that must be addressed are a varus deformity of the proximal tibia and distal femur, and often a secondary deformity of the distal tibia. The goal of surgery is to restore normal anatomic alignment of the knee and ankle joint, and also a normal mechanical axis of the leg (77,80,96,100,101,103). For a unilateral deformity, leg-length inequality is also to be addressed. Nonoperative approaches are ineffective in adolescent tibia vara. When the diagnosis of adolescent tibia vara is made, surgical treatment is indicated. Osteotomy is the mainstay of treatment for adolescent Blount disease. However, depending on the patient's age, on occasion definitive treatment can be attained by staple hemiepiphysiodesis, or more likely by a combination of hemiepiphysiodesis and osteotomy.

Preoperative Evaluation

Because these patients are often obese and, not infrequently, morbidly obese, prior to any consideration of operative treatment a thorough preoperative evaluation of the cardiopulmonary system should be done. The extreme size of these patients can lead to nocturnal hypoxia, with significant decreases in sleeping O_2 levels and accompanying hypercardia (105). If these changes are prolonged, significant pulmonary hypertension can result, leading to right heart hypertrophy (105), if symptoms, such as marked snoring or irregular breathing patterns at night, are present. Sleep studies with pulmonary and cardiac evaluation may be indicated prior to a general anesthetic (105). Prior to proceeding with operative intervention, an appropriate, detailed preoperative plan is essential for obtaining a mechanically well-aligned limb (Fig. 27-12C). The magnitude and location of the various bony deformities, the presence of soft tissue laxity at the lateral collateral ligament, and the presence of joint contractures and leg-length discrepancy should all be assessed and incorporated into a global plan for addressing the deformity.

Hemiepiphysiodesis

Hemiepiphysiodesis, by a variety of techniques **[➥6.12–6.14]** is indicated if the growth plates are still open (82,101,106) and the varus deformity is relatively not too severe. The authors prefer staple hemiepiphysiodesis. Two to three reinforced “Blount staples” (Zimmer) may be placed extraperiosteally at the lateral distal femoral physis **[➥4.21]**, the lateral proximal tibial physis **[➥6.14]**, or the medial distal tibial physis, as needed (39,82). Once hemiepiphyseal stapling is performed, it is critical to follow the patient closely with clinical and radiographic examinations to monitor correction obtained, and possible staple displacement and/or breakage. If complete deformity correction is obtained, staple removal is necessary to prevent over correction.

Relative rebound (82) varus growth is unpredictable in this clinical setting. Accordingly, concomitant with staple removal, a permanent epiphysiodesis of the growth plate(s) previously stapled is preferred. The authors have successfully used stapling in obtaining either complete or partial correction or arrest progression of proximal tibial or distal femoral deformities in some of the patients with, typically, at least 15 to 18 months of growth remaining. Often, hemiepiphysiodesis obviates the subsequent need for a femoral, and on occasion, a tibial varus-correcting osteotomy. The exceptional patient, who is not a candidate for staple hemiepiphysiodesis, typically presents with a history of progressive varus deformity and knee-joint pain. A dynamic lateral thrust is often noted during walking. This severe, dynamically unstable deformity will predictably not be significantly improved by the slow correction obtained with staple hemiepiphysiodesis.

Osteotomy

The majority of patients with moderate to severe adolescent Blount disease will require a varus-correcting osteotomy of the proximal tibia, and perhaps also the distal femur, to obtain definitive correction of the varus deformity. To definitively determine the need for osteotomy correction of the varus deformity, the mechanical axes of the lower extremity, and also individually for the femur and the tibia, are determined (107) (Fig. 27-13A and Fig. 27-14A). In skeletally near-mature or mature patients, osteotomy(ies) is/are indicated if the mechanical axis of the lower extremity is deviated medial to the center third of the knee joint. The deformity in both the medial proximal tibial angle (MPTA) and lateral distal femoral angle (LDFA) is determined. In addition, the sagittal plane alignment is assessed (Fig. 27-13B and Fig. 27-14B), and procurvatum deformity noted. All patients will require a proximal tibial varus-correcting osteotomy, ideally restoring a normal anatomic alignment of the proximal tibia. The tibial osteotomy should be performed distal to the tibial tubercle. Regardless of the method chosen, the proximal tibial deformity should be completely corrected by the redirective osteotomy, including internal rotation (if present), procurvatum, and varus. Similarly, anatomic restoration of the distal femur with a concomitant femoral varus-correcting osteotomy is indicated if the DFLA measures >5 degrees varus (normal DFLA is 87 degrees). The distal femoral osteotomy is performed through a lateral approach. The preoperative deformity analysis should also include more assessment of the distal tibia. If the distal tibia growth plate is open, the authors correct distal valgus of ³5 degrees with a staple hemiepiphysiodesis. If closed, the authors will perform a valgus-correcting osteotomy for deformity ³8 degrees. The distal valgus-correcting osteotomy is performed through a medial approach.

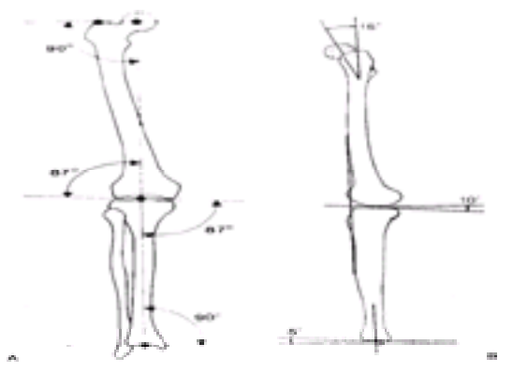

FIGURE 27.14. A: Frontal plane mechanical axis of the lower extremity consists of two components: (i) colinear centers (of the femoral head, knee joint, and ankle joint), and (ii) an almost perpendicular relationship of the hip, knee, and ankle joint orientation lines to the mechanical axis. **B:** Normal sagittal plane mechanical axis and joint orientation lines.

Limited Internal Fixation

Osteotomy with limited internal fixation, the mainstay of treatment of infantile Blount disease, has limited application in adolescent Blount disease. A supplemental long-leg cast often adds minimal additional protection for these extraordinarily large patients. The difficulties associated with non-weight bearing on the affected extremity make ambulation difficult in these patients. Outcome of treatment with this approach has far too often been unsatisfactory (96).

Inherently Stable Internal Fixator

Osteotomy, with acute correction and relatively stable internal fixation, can be effectively utilized in patients with mild to moderate varus and procurvatum deformity (39,108,109). Because the true location of the deformity is very close to the level of the physis, a transverse osteotomy of the tibia at the metaphysis distal to the tubercle must be translated laterally, sometimes as much as the entire diameter of the tibia, in order to prevent creating a translational deformity. To circumvent creating this deformity, Millis and Jakob and Murphy (108,110) has effectively utilized an oblique, laterally based closing-wedge osteotomy that hinges at the intact cortex, just distal to the proximal tibial physis **[➥6.4]**. Fixation is achieved using a laterally placed compression plate, which serves as a tension band and permits weight bearing without external immobilization. Because the hinge point is nearly at the level of the physis, the correction is achieved at the level of the deformity, and a translational deformity is not created. The distal femoral deformity may be addressed by supracondylar osteotomy and stable fixation of the distal femur, using a blade plate to maintain alignment. This may be performed through a medial or lateral approach, with an opening- or closing-wedge osteotomy technique. The authors prefer to use a lateral approach to perform an opening-wedge osteotomy of the distal femur, **[➥4.17]** fixing the fragments with an adult 95-degree condylar blade plate. The femoral osteotomy is done concomitant to the tibial osteotomy.

Monolateral External Fixation

External fixation of the tibia can be used for correction in the most severe deformities. The dynamic axial monolateral fixator has the advantages of ease of performing an acute correction, adjustability after the initial surgical correction has been achieved, and relative patient acceptance (77). Price et al. obtained satisfactory stability of the osteotomy fragments, even on heavier patients. In applying a monolateral fixator of any type, pin placement parallel to the adjacent knee and/or ankle joint enhances obtaining a satisfactory acute correction of deformity (77). Similarly, Gaudinez and Adar (111) and Stanitski et al. (112) have effectively incorporated the Garsche clamp, when utilizing a monolateral fixation in the treatment of adolescent Blount. The Garsche external fixator optimizes fixation, and allows for postoperative frontal plain adjustment and lengthening. It is, however, not conducive to postoperative adjustments in the sagittal plane, or in rotation (112).

Circular External Fixation

Circular external fixation, with a gradual correction of the proximal tibia, allows for the maximal adjustability of the alignment in all planes, and is most applicable in the most severe deformities and relatively more obese patients. This is the authors' preferred approach (80,113,114). Advantages include stable fixation with improved patient mobility; the ability to evaluate alignment in a functional, standing position; and the ability to accurately correct all of the tibial deformities, including proximal tibial varus and procurvatum, internal tibial torsion, and distal tibial valgus (112,113,115).

Ideally, all of the deformities are addressed in a single surgical procedure. First, if indicated, distal femoral varus is corrected acutely by a supracondylar distal femoral opening-wedge osteotomy, performed after a lateral approach, and fixed with a 95-degree condylar blade plate. The fibula osteotomy is then performed through a posterolateral incision made over the midshaft area of the fibula, at least 10 cm distal to the proximal fibula. Great care should be taken in obtaining subperiosteal exposure of the fibula, so that no injury occurs to the branches of the deep peroneal nerve, to the extensor hallucis longus, or the peroneal artery and vein, which lie just medial to the fibula. A section of the fibula is removed in performing the fibular osteotomy. The preconstructed circular fixator is suspended from the leg, and fixed with an appropriate combination of transfixing wires and half-pins. Ring strategy and transfixing wire placement vary with the presence or absence of growth plates, need for fibular transfer for ligamentaxsis, and need for distal tibial valgus-correcting osteotomy (112,113). The proximal tibial osteotomy is performed with a drill and osteotomes. If indicated, a distal tibial osteotomy is created in a identical fashion.

Gradual correction is begun on postoperative day 2 or 3 and serial radiographs are obtained to monitor the correction and bone formation. The patient is encouraged to be fully weight bearing as early as possible, and vigorous physical therapy is instituted to maintain mobility and joint range of motion (Fig. 27-12D). Circular frame adjustments in all planes are made, as necessary, to correct all aspects of the deformity. The fixator is left in place and progressively dynamized, until complete consolidation and cortication of the osteotomy site is completed. Bilateral deformities are corrected one at a time, the second extremity correction usually staged within 6 months of obtaining correction of the opposite extremity. Generally, very satisfactory results have been achieved in this most difficult group of patients (112,115) (Fig. 27-12F and Fig. 27-12G). The results are a marked improvement in outcome over traditional methods (96). Despite the procedure being done on often extremely large extremities, there have been notably very few surgical complications (112,113). All osteotomies, including those that also required lengthening, have healed without delay. The knee and ankle joints have been restored to relatively normal anatomic relationships. A near-normal mechanical axis of the leg has been reestablished. Knee pain has resolved. Patients have been satisfied with the more normal lower-extremity alignment.

KNOCK KNEES (GENU VALGUM)

Definition

Parental concerns regarding knock-knees are far less common than those regarding bowed legs (5,116,117). Genu valgum generally becomes a concern between 3 and 5 years of age, when the normal femoral–tibial angle is at its maximum valgus angle (5,116,117) (Fig. 27-15). Parents often notice the flat appearance of the foot before the valgus knee position is noted. There may be occasional complaints of medial foot or medial knee pain.

FIGURE 27.15. Physiologic genu valgus peaks between 3 and 4 years of age. It may be associated with asymptomatic flat feet. It is typically symmetric, and shows gradual resolution by age 8 years.

Typically, valgus knee position becomes apparent after 2 years of age, reaching a maximum femoral–tibial angle of 8 to 10 degrees at approximately 3 to 4 years of age, a time when it is most noticeable (2,5,38). As demonstrated by Salenius and Vankka (Fig. 27-4), valgus gradually decreases to a stable “adult” level of 5 to 7 degrees of femoral–tibial valgus by age 6 to 7 years. There is, however, wide variation among normal children. Normals are those children who fall within two standard deviations of the mean. This includes measurements of ±8 to 10 degrees, which means that normal femoral–tibial angles may range from 2 degrees varus to 20 degrees valgus at 3 to 4 years of age, and 0 to 12 degrees valgus after age 7 years (38,116,117).

Physiologic knock-knees are typically symmetric (5,116). The severity of the deformity can easily be assessed and documented by standing photographs. Radiographic evaluation is indicated in those children with clinically excessive femoral–tibial angles, those who present outside of typical age range for physiologic

valgus, those with asymmetric deformity, or those who fall below the tenth percentile of height.

Differential Diagnosis

Most children who present with knock-knees will have physiologic genu valgum. The differential diagnosis includes metabolic bone disease, such as rickets, posttraumatic valgus, or skeletal dysplasia (118,119,120 and 121). Osteomalacia, which has its onset when physiologic valgus is present, is more likely to progress as a knock-knee deformity. Valgus may result from overgrowth of the proximal medial tibia, following a proximal tibia fracture (Cozen fracture), or from distal lateral femoral physeal injury (121,122 and 123). Skeletal dysplasias most commonly associated with genu valgum are chondroectodermal dysplasia (Ellis-van Creveld), mucopolysaccharidosis type IV, and spondyloepiphyseal dysplasia tarda (120).

Natural History

Genu valgum in normal children typically decreases to a stable, slightly valgus position by age 7 years (2,5,38, 116,117). Minimal, if any, change in femoral–tibial angle should occur through adolescent growth. Rarely, valgus continues to increase, and may be associated with an out-toed gait. Lateral patellar subluxation may develop with increasing valgus deformity. The deformity apparent on clinical exam is often more striking than the radiographic appearance. Walking may become awkward because of the knees rubbing or hitting together as the child tries to narrow the base of support.

Assessment

Anteroposterior standing long-cassette radiographs of both lower extremities, which include the hips, knees, and ankles, are used to quantify mechanical axis deviation from normal. The lower extremities should be placed such that the kneecaps are facing directly forward. This must be done without regard to foot position. This technique produces the truest AP of the knees, and minimizes errors when serial examinations are compared. A normal mechanical axis, drawn from the center of the hip through the center of the ankle (Fig. 27-14A), should pass through the center of the knee, roughly in the zone determined by the tibial spines (124).

Lateral deviation of the mechanical axis, beyond the mid-portion of the lateral tibial plateau, can result in relative overload of the lateral compartment (124). The severity of deformity, which will produce premature degenerative changes in the lateral compartment of the knee, is not known. Genu valgum, severe enough to produce mechanical axis deviation beyond the lateral margin of the tibia, is pathologic, and should be corrected. In addition to improving the appearance of lower-limb alignment, normal mechanical axis can be restored (122,125).

Treatment

Conservative treatment of genu valgum includes education of the parents regarding the natural history of physiologic knock-knees (117). If medial foot, knee, or leg pain is a significant concern, foot orthotics may provide some relief of symptoms, but do not alter lower-limb alignment (116,117). Lower-extremity bracing is not indicated for the treatment of physiologic genu valgum (117). Bracing with a single upright, valgus-correcting KAFO might be considered in a child less than 4 years of age, who is also being treated for metabolic disease, such as rickets.

Surgical treatment can usually be deferred until 10 to 11 years of age. Correction of valgus in the skeletally immature child, with 1 to 2 years of growth remaining, can be accomplished with hemiepiphysiodesis, preferably by hemiepiphyseal stapling (82,83,106,125,126,127,128 and 129) (Fig. 27-16). Hemiepiphyseal stapling in younger children often results in rapid correction (within 4–6 months), but uncertain resumption of a normal growth pattern once the staples are removed (82,83,125). Once valgus resolves the staples may need to be removed to avoid over-correction to varus. Injury to the underlying physis can cause partial growth arrest. Premature physeal closure is less problematic near the end of growth than with several years' growth remaining.

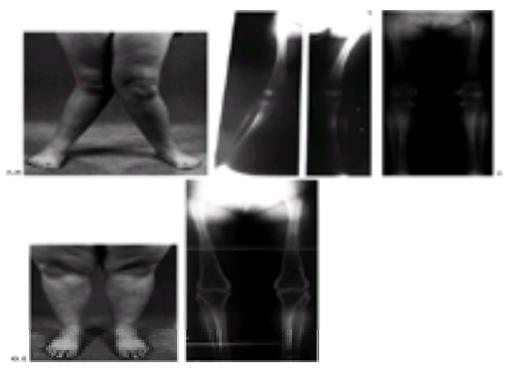

FIGURE 27.16. A: Lower-limb valgus that persists past age 8 years is not physiologic. It may cause an awkward gait, in addition to concerns about appearance. **B:** These long-cassette films of a 12-year-old girl confirm the presence of valgus in both the femur and tibia. She is not skeletally mature, making hemiepiphyseal stapling a treatment option. **C:** Stapling of the medial physis of both distal femurs and tibiae, in a growing adolescent, results in rapid correction. Within a year, correction of the mechanical axis is achieved in this patient. **D:** There is clinical improvement in alignment. **E:** Films at maturity show maintenance of correction.

Whether medial physeal stapling is performed in the distal femur, proximal tibia, or both, will depend on the site of deformity, and growth remaining (106,122,129). Most often, valgus deformity arises primarily from the femur. However, it is not correct to assume that this is always the case with valgus deformity. The anatomic alignment of the femur and tibia should each be evaluated. Although deformity may be present only in one bone, combined stapling of the femur and tibia may be considered, if bone age estimates that there are less than 18 months growth remaining, to afford maximum correction (122,125).

The technique of stapling, although simple, requires attention to a few important details. Placement technique, type and size of staple, and follow-up are three key areas (82,83,122,126,127). The staples are generally placed extraperiosteally. They should span the physis, but should not be excessively large. These staples should be placed so that the prongs of the staple are parallel to the physis. This may require a slightly oblique orientation to the cortex. Use of C-arm image intensification facilitates placement, and avoids errors. Two staples per location are generally sufficient. Three may be used if the bone is unusually large. The staples, made of cobalt-chrome alloy, should have reinforced corners (125,126). Patients must have reliable follow-up. Over-correction to a varus position can occur, and is not desirable. Long-cassette radiographs of the lower extremities should be obtained at 3-month intervals. Some correction of the valgus should be apparent 3 to 6 months after stapling. Once a normal mechanical axis is restored, the staples should be removed (if there is significant growth remaining), or the epiphysiodesis should be completed (83,125). Rebound growth in the previously stapled physis may occur (82,125,126 and 127). It is more likely to occur when stapling is performed in younger children, those under 10 years of age, or in children who show rapid (within 6 months) correction of the valgus deformity. Resumption of growth following staple removal may not occur if the staples have been in place for more than 24 months, or if they are placed subperiosteally (126,127). Children should be followed to skeletal maturity to document satisfactory correction and maintenance of normal alignment.

Alternatively, osteotomy can be used to correct deformity (48,49 and 50). The site of deformity correction is dependent on the anatomic deviations present in the tibia and/or femur (107,132,133 and 134). The femur is more often the primary site of valgus deformity. Immediate correction of femoral valgus, using internal fixation with a blade plate, is preferred for most adolescents. A lateral approach to the distal femur allows exploration and release of the peroneal nerve, which may be considered in severe deformities. Alternatively, an anterior midline incision can be used for medial and lateral exposure of the distal femur (134). Compression can be applied along the medial cortex by placing the blade plate along the medial cortex (132,133 and 134).

External fixation with immediate correction can also be used (130). Gradual correction, using external fixation, may also be considered (31,107,131). This technique is recommended when lengthening is also necessary, or when there is increased risk of peroneal neurapraxia, as in children with severe deformity. Circular frame fixation may facilitate angulatory correction combined with lengthening (31,108,130). A unilateral frame may be considered when external fixation is used with immediate correction.

Similar techniques can be used for correction of tibial valgus deformity in adolescents. Valgus correction in younger children can be accomplished by a simple

closing-wedge technique, using two or three crossed stainless steel wires (130). Alignment can also be restored with removal of a medial wedge and controlled fracture of the lateral cortex. A compression plate is placed along the medial cortex, following removal of the wedge. Compression is slowly applied through an outrigger, gradually closing the osteotomy.

Complications

Errors in technique can lead to failure with hemiepiphyseal stapling. Poor fixation, inadequate design, or number of staples will compromise results (82,83,126). Timing of placement, follow-up, and removal are sources of error (106,125). Stapling performed too late will not adequately correct deformity. Overcorrection can occur because of unrecognized premature physeal closure. Lack of appropriate, timely evaluation poststapling can result in overcorrection. This is a significant complication. Varus alignment results in greater mechanical loads across the medial compartment of the knee than the same degree of valgus would produce over the lateral compartment (39). Increased medial compartment load can accelerate degenerative changes. If reliable long-term follow-up cannot be assured, osteotomy may be preferred over hemiepiphysiodesis.

Complications related to osteotomy include failures of union and/or fixation, infection, blood loss, knee stiffness, and scar formation. None of these are unique to distal femoral or tibial osteotomy for valgus correction.

Peroneal nerve injury is a serious concern in the process of valgus correction. The nerve is tethered above and below the knee, as it passes around the distal femur and proximal fibula (27). Release of these tethers can reduce the risk of permanent injury. Closing-wedge technique for immediate correction is less likely to stretch the peroneal nerve than opening wedge. Gradual correction of severe deformities may allow the nerve to accommodate to these changes more safely than acute correction. Injury to the nerve must be avoided during pin placement, however.

BOWING OF THE TIBIA

Anterolateral Bowing

Definition

Bowing of the tibia that presents at birth typically occurs anteriorly, anterolaterally, or posteromedially. Anterior tibial bowing, occurring in association with a deficient or absent fibula, is diagnostic of fibula hemimelia. Posteromedial bowing occurs in association with calcaneal valgus foot deformity, and has a relatively excellent prognosis. In contrast, anterolateral bowing, which usually presents soon after birth, is typically a progressive deformity with resultant pseudarthrosis. Anterolateral bowing, associated with congenital pseudarthrosis of the tibia, is rare (1:140,000), yet it is the most common type of pseudarthrosis (135,136). Neurofibromatosis occurs in approximately 50% of patients with anterolateral bowing, with or without pseudoathrosis of the tibia (135,138,139). This bowing may be the first clinical manifestation of neurofibromatosis (137,138).

Natural History

Spontaneous resolution is uncommon (140). Rather, the anterolateral bowed tibia appears variably dysplastic with failure of tubulation, cystic prefracture, and/or frank pseudarthrosis, with narrowing of the fragments (135,137). Fracture, with resultant pseudarthrosis, typically occurs in the first 4 to 5 years of life (Fig. 27-17). Once established, the natural history of congenital pseudarthrosis of the tibia is that of persistent instability and progressive deformity. Numerous classification systems have been proposed in attempting to prognosticate the natural history and outcome of treatment. In reality, in the past there has been very little correlation with initial radiograph classification and eventual outcome of treatment (137,141,142,143 and 144).

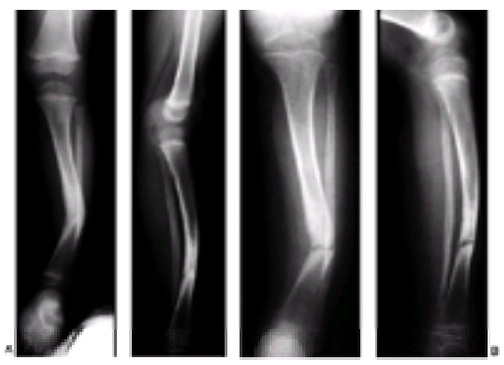

FIGURE 27.17. A: Anterolateral bowing of the tibia may be apparent at birth, or may progress with weight-bearing. Bowing usually occurs between the middle and distal thirds of the tibia. The adjacent bone may appear sclerotic, with increased density, or it may be atrophic and spindle-shaped. Once the deformity is recognized, the leg should be protected with a total-contact orthosis. Although fracture is not likely to be avoided, it may be delayed until the child is bigger. **B:** Fracture occurs at the apex of the bow, usually without prodromal symptoms, and with minimal or no trauma. Once fracture occurs, surgical management begins.

The most widely used classification system is Boyd's (135), who described six distinct radiographic types of anterolateral bowing deformity, noting the variable natural history and/or prognosis of each type (Table 27-1). Consolidation was most difficult to obtain in the dysplastic type II (Fig. 27-18). When anterolateral bowing occurs in association with neurofibromatosis, both progression of deformity and treatment failure are more likely to occur (137,138).

Boyd System	Anderson System
I Fracture present at birth	
II Hourglass constriction of tibia often associated with neurofibromatosis	Dysplastic type
III Bone cysts	Cystic type
IV Sclerotic segment of tibia without constriction, stress frature results	Sclerotic type
V Dysplastic fibula	Fibular type
VI Intraosseous neurofibroma	Clubfoot or congenital band type

TABLE 27.1. CLASSIFICATION OF TREATMENT OF CONGENITAL PSEUDARTHROSIS OF THE TIBIA

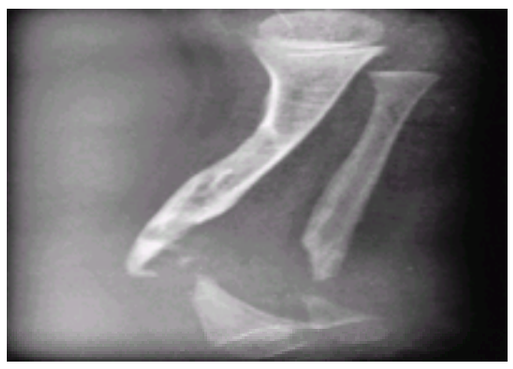

FIGURE 27.18. Early (Boyd type II) congenital pseudarthrosis of the tibia and fibula in a patient with neurofibromatosis.

Nonoperative Treatment

Once the diagnosis of anterolateral bowing is made, full-time brace treatment is indicated. An AFO is appropriate protection prior to walking, and a KAFO is fit as the infant begins walking. Orthotic support is continued indefinitely during the growing years with or without surgical reconstruction of a pseudarthrosis. Although very uncommon, anterolateral bowing occasionally does not progress (140). These unusual patients present with an anteriorly bowed tibia, with or without a previous fracture (Boyd type IV), which actually consolidates with immobilization (140). Supplemental onlay bone grafting may be beneficial (145). Patients seemingly carry less chance of further progression and fracture following this procedure.

Operative Treatment

Despite a gradual improvement in overall outcome of treatment in the past 100 years, congenital pseudarthrosis of the tibia has been, and still is, one of the most challenging problems in pediatric orthopaedics. Even with a consolidation, the tenuous status of the atrophic bone often markedly limits functional potential (146,147 and 148). A major improvement in outcome can be traced to Boyd and Fox's (149) use of dual onlay grafts, Moore's (150) use of staged bone graft and external fixation, McFarland's (151) bypass graft, and Sofield and Millar's (152) innovative use of intramedullary rod stabilization. Less-invasive technical innovations were developed by both Brighton and Bassett and their colleagues utilizing, respectively, implanted cathode leads and pulsed electromagnetic fields alone or in combination with surgical stabilization (153,154). Currently, there are three different surgical approaches that are being successfully used in the surgical treatment of pseudarthrosis of the tibia (Table 27-2) (Fig. 27-19). After obtaining consolidation with any of these techniques long-term follow-up is critical to properly address predictably occurring associated deformities. Vascularized composite donor tissue transfers have been utilized for the past 100 years in the surgical treatment of congenital pseudarthrosis of the tibia (155,156 and 157). In the last 25 years, refinements in microsurgical techniques have been developed that allow for a predictable successful transplantation of vascularized bone from a variety of donor sites to bony defects elsewhere in the body (158). Early reports (158,159) clearly demonstrated that a free vascularized fibular graft could successfully be used to biologically bridge a congenital pseudarthrosis of the tibia. The current technique of implanting a free vascularized fibular graft for a congenital pseudarthrosis of the tibia includes the following essential steps, as outlined by Tolo (160,161). Preoperative arteriography of both legs is obtained. A two-team approach is helpful in simultaneously harvesting the contralateral fibula and internally stabilizing the involved remaining distal fibula of the donor extremity to the tibia with a screw and autologous bone graft. The pseudarthrosis is resected extraperiosteally back to “good” bone. Next, the harvested fibula is dowel-fit into the host tibia, and fixed with a plate or an external fixator. Vessels are anastomized, and a skin paddle is used to monitor blood flow. A spica cast is used for 2 to 3 months, and a clamshell brace for several years.

Method	Rate of Union	Advantages	Disadvantages
Electrical stimulation	51–81%	Noninvasive; may be combined with other techniques	Limited ability to correct deformity; long time in cast
Intramedullary rod with bone graft (Williams, Coleman)	90–100%	Corrects deformity, provides long-term internal splint	May cause ankle stiffness; does not correct severe, established shortening
Free vascularized bone graft	90–95% eventual	Provides excellent bone stock, may add slight length	Requires specialized skill, relatively long operation, distal angulation hard to correct
External fixator (circular or monolateral frame)	90–100%	Corrects nonunion length, angulation	High risk of refracture; bowing; long-term follow-up not available

TABLE 27.2. OPTIONS FOR TREATMENT OF CONGENITAL PSEUDARTHROSIS OF THE TIBIA

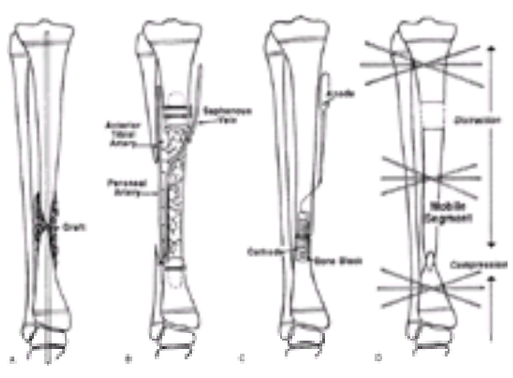

FIGURE 27.19. Operative options for pseudarthrosis of the tibia: **A:** Coleman osteosynthesis. **B:** Vascularized fibular graft from the opposite leg. **C:** Electrical stimulation. **D:** Ilizarov technique of lengthening above and compression of the pseudarthrosis to achieve union.

Using a similar protocol, Weiland et al. (162) reported 18 of 19 pseudarthroses to have ultimately healed at an average follow-up of 6.3 years. In a review of recent publications (163,164,165,166 and 167) reporting on treatment of congenital pseudarthrosis of tibia by a vascularized fibular graft, 65 cases were available for review, with sufficient follow-up to assess early outcome. Fifty-six cases eventually healed. Often, a secondary bone graft (162) was necessary to achieve the same. Subsequent to obtaining consolidation, several problems may have to be addressed. Following consolidation refracture, and resulting recurrence of a nonunion at one end of the graft site (162,163) or in the graft itself (166), variably occurred. Subsequent additional surgical treatment was often necessary with variable success in achieving a functional consolidation.

A second long-term problem is the occurrence of malalignment, either anterior bowing or valgus deformity (162). The angulatory deformity does not remodel, and often is progressive (162,165). Fourteen of Weiland et al.'s patients were noted to have residual angular deformity.

Donor site morbidity (progressive valgus with proximal migration of the distal fibula) can potentially occur following harvesting the fibula (166). The occurrence of this most-concerning deformity is not consistently addressed (162,163,164,165,166,167 and 168). Prophylactic stabilization of the donor site distal fibula tibia syndesmosis was done by Weiland et al. (162) and Kanaya et al. (165), and was not done by Dormans et al. (163) or Simonis et al. (167). In follow-up, the above authors noted minimal donor site morbidity, such as progressive valgus deformity. Tolo's (160) current indications for the use of a vascularized graft in the treatment of

pseudarthrosis of the tibia is specifically for those lesions with marked bony atrophy and/or measurable gap at the pseudarthrosis site (Fig. 27-20). For less-severe deformities, he prefers intramedullary (IM) rod stabilization of the tibia, without transfixing the ankle joint.

FIGURE 27.20. A: This film shows another fracture resulting from anterolateral bowing. Note the quality of the bone at the pseudarthrosis site. **B:** A contralateral vascularized fibular graft has been used to bridge the pseudarthrosis. Healing proximally and distally has occurred. (Courtesy of Vern Tolo, MD., Los Angeles, CA.)

Charnley (169) is credited with the first reported innovative use of an IM rod that both stabilized the pseudarthrosis site and transfixed the ankle joint. In a similar technique, Umber et al. (170) popularized in North America the two-part Peter Williams (171) IM solid rod. This IM rod technique, **[➥6.11]** in conjunction with pseudarthrosis excision and iliac crest bone grafting, has been further refined in dealing with all aspects of the deformity (156). It is the authors' approach of choice in treating congenital pseudarthrosis of the tibia (Fig. 27-21).

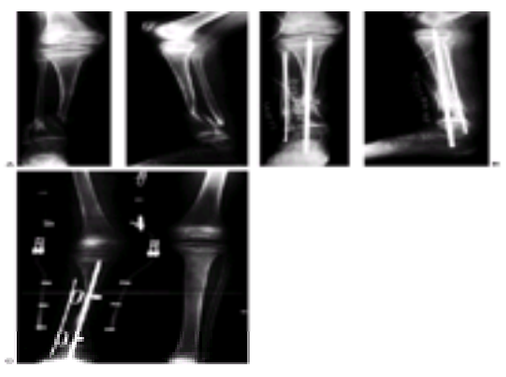

FIGURE 27.21. A: This is another example of a tibial pseudarthrosis. Treatment includes stabilization of the fracture, establishment of a source of healthy bone, and maintenance of alignment. **B:** Among the options for treatment is intramedullary stabilization and autologous bone graft. The pathologic bone was resected, and a Williams rod was used in the tibia with a Steinmann pin in the fibula. Iliac crest graft was packed around the pseudarthrosis. **C:** A spica cast is applied postoperatively, and a total contact orthosis used once union is established. Ankle motion is prohibited, as long as the rod remains across the subtalar and ankle joints. A knee-ankle-foot orthosis (KAFO) is used in smaller children. A PTB orthosis can be used in most children over 7 years of age.

A posterior iliac bone graft is always obtained, consisting of adequate corticocancellous strips and bits. The pseudarthrosis is excised, and the bone fragments stabilized with a Williams rod (171). The entire rod assembly is inserted at the pseudarthrosis site into the medullary canal of the distal fragment, and advanced antegrade across the distal tibia, the ankle joint, the calcaneus, and out through the heel pad. During the passage of the rod across the ankle joint, it is imperative that the foot be positioned to maximally correct the typical calcaneus and valgus deformity of the ankle and foot. The desired foot position is neutral dorsiflexion/plantar flexion, verified clinically and with the C-arm. The tibial fragments are anatomically reduced at the pseudarthrosis site, and the rod is driven retrograde into the proximal fragment. Occasionally, because of extensive deformity, an additional osteotomy in the proximal fragment is necessary to assure both intramedullary passage of the rod and a near-anatomic bony alignment. On occasion, it may be possible to stabilize the fibular fragments with an intramedullary rod. This is typically done with an appropriately sized Kirschner wire, which is placed into the distal fragment through an open incision. The rod is directed antegrade, out through the distal tip of the fibula, then retrograde into the proximal fragment. Fixating the fibula adds additional stability to the construct.

For planning purposes, the portion of the Williams (171) rod to be left in place should proximally be abutting the tibial physis, and distally extending to the hindfoot. With longitudinal growth of the distal tibia, the distal end of the rod “migrates” proximally. Therefore, the anticipated remaining growth determines the appropriate placement of the distal end of the rod at the time of surgery. The previously harvested iliac bone graft strips are then placed around the pseudarthrosis site. The composite is further secured with circumferentially placed absorbable heavy suture material, establishing a stabilizing, barrel-stave construct.

By protocol, for children 6 years and younger, a 1½ spica cast is applied to assure minimal rotatory stress at the pseudarthrosis site. The spica cast is replaced with a long-leg cast at 6 to 8 weeks, and cast immobilization is discontinued at approximately 4 months. Older children are treated with long-leg casts for the entire 4 months.

Once cast protection is discontinued, the involved extremity is protected with a custom-fabricated KAFO with a locked ankle joint and free knee joint. The presence of the rod across the ankle joint and in the hindfoot has a considerable advantage in providing optimal immobilization and protection of the consolidating pseudarthrosis. Refracture may occur, and spontaneous healing with plaster immobilization may occur. However, such is not always assured, and regrafting and/or rerodding may be required. With longitudinal growth of the tibia, the distal end of the rod migrates more proximally, and eventually will be positioned in the distal tibia (Fig. 27-22). As the tip of the rod crosses the ankle joint, the potential for disruption of articular cartilage exists. To minimize such, the rod can be surgically pushed across the ankle joint as the tip approaches the articular surface of the talus. This adjustment is easily accomplished with a slightly larger diameter, concave-tipped IM pusher rod inserted through the calcaneus, as monitored with a C-arm.

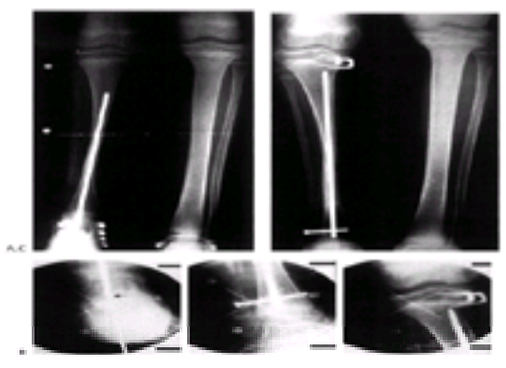

FIGURE 27.22. A: As the child grows, the rod remains in the tibia. Growth in the tibia, proximally and distally, makes the rod appear to migrate. As the distal tibia grows off the rod, the child may complain of pain, with stress of the ankle. **B:** The rod can be advanced into the tibia under image intensification guidance. A smaller rod, or Steinmann pin, can be positioned in line with the Williams rod, and used to push the rod across the ankle into the tibia. A syndesmosis screw was placed at the same time, to aid in valgus stabilization at the ankle, due to the fibular pseudarthrosis. Proximal medial stapling of the tibia was also performed to correct the mild valgus deformity. **C:** Tibial growth has continued. The pseudarthrosis remains healed with satisfactory alignment of the tibia. Limb-length inequality can be managed

with contralateral epiphysiodesis. Lengthening of the affected leg may be complicated by delayed bone formation and healing.

On occasion, despite consolidation of the pseudarthrosis and growth of the tibia, the rod does not migrate. If such occurs, the rod should be replaced. This has always been done with the intraoperative perceived need for additional bone grafting. In the case of failure of rod migration, the replacement rod should probably be proximally secured with methylmethacrylate (172).

Valgus deformity of the involved tibia of the ankle is a potential deformity that can compromise the functional result. The authors feel that the valgus deformity is more of a natural outcome of the initial deformity (deficient fibula and lateral support), and less of an iatrogenic complication of traversing the physis with the rod. Long-term bracing is mandatory during the growth years to minimize progressive valgus. This is particularly true once the rod no longer traverses the growth plate. Valgus has been satisfactorily treated by either proximal or distal medial tibial physeal stapling and/or insertion of a fibula/tibia transverse stabilizing screw. Following medial physeal stapling, the valgus deformity predictably improves over approximately a 1- to 2-year period. If complete correction occurs, the staples are then removed. At the time of staple placement or removal, a fibula/tibia transverse syndesmosis stabilizing screw may be placed. This is indicated for persistent valgus and/or a relative proximal position of, typically, an ununited distal fibular fragment. With this approach symmetric growth of the distal tibia has generally continued, and the valgus deformity has not recurred.

Leg-length inequality is often significant secondary to pseudarthrosis of the tibia. Fourteen of the authors' 20 patients had a noted leg-length discrepancy (LLD), which was greater than 2 cm in 10 patients. Six of these patients were treated with epiphysiodesis, for an average predicted LLD at maturity of 4 cm. Two patients underwent a proximal tibial leg-lengthening. One patient underwent an amputation at age 15 years, with a 9-cm leg-length inequality and other musculoskeletal abnormalities.

A relatively satisfactory functional outcome has been achieved in 16 of the 20 patients followed to an average age of 14±8 years with an average length of follow-up of 9±9 years. The remaining five patients have gone to amputation at various stages of treatment. The quality of ankle function and gait have varied considerably. The best results have been noted in those patients in whom the tibia is anatomically aligned and the foot is not in dorsiflexion. A recent gait analysis assessment of the outcome of treatments of CPT (173) cited relatively poor push-off following IM rod treatment. Although this potential exists for all techniques of treatment, it is more potentially problematic following long-term IM splinting of the ankle joint. To date, gait analysis of the authors' most recently treated patients has shown a more favorable outcome regarding demonstrable push-off activity. The authors now are utilizing a more active strengthening program about the ankle, once the rod has migrated or is surgically advanced proximal to the ankle.

Ilizarov pioneered the innovative use of a circular external fixator, utilizing combinations of compression, distraction, resection, and bone transfer via means of a circular external fixator. Subsequently, numerous authors have made further refinements in the technique (174,175,176,177,178 and 179). Notably the initial reports of Paley et al. (177), citing the early combined multicenter experience with this technique, cited a very impressive initial union rate in 16 CPTs (94% after one treatment and 100% with two treatments). The mean age at treatment was 8 years. Five refractures occurred, and were successfully treated with a variety of additional procedures. In a more recent multiauthor study, Boero et al. (179) reported 7 of 21 failures in treating CPT with Ilizarov's technique. In their study, all 21 patients had neurofibromatosis. The best results were obtained with sclerotic and/or normotrophic bone (6 of 6 consolidated early at an average of 10 to 12 months), and did not refracture, whereas only 5 of 11 hourglass CPTs eventually healed. In the same series, consolidation was obtained in 86% of those patients operated on who were older than 5 years of age, and on only 14% of those younger than age 5 years.

Dahl's report on work in progress is indicative of the state of the art in treatment of CPT with external fixation (180,181). He reported on 21 patients, treated by a single surgeon, followed to maturity. To date, Dahl (180) has reported a satisfactory outcome of treatment (consolidation sustained, independent ambulation, with a score of at least 87, according to the Musculoskeletal Tumor Society rating scale), in 20 of 21 patients. One patient had an amputation. The average age was 11 years (range 8 months to 29 years), and 18 of 21 patients had been treated with multiple prior surgeries. Dahl noted refractures in 33% of the first 12 patients he treated. Refinements in his techniques have led to fewer fractures. His protocol in achieving prompt and lasting union includes resection of the pseudarthrosis and pathologic periosteum, creating a stable intrinsic fit of the bone end, bone grafting the site of pseudarthrosis to maximize the cross-sectional area, ideal axial alignment eliminating bending forces, judicious length, and deformity correction through the proximal tibia. To deal with the inherent problem of refracture, he has chosen to prophylactically place an IM pin 8 weeks postfixator removal (181) (Fig. 27-23).

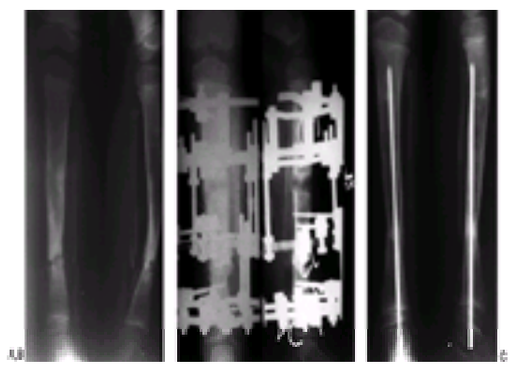

FIGURE 27.23. A: These anteroposterior and lateral films are of a 6-year-old with neurofibromatosis, whose tibial pseudarthrosis recurred following multiple bone graft procedures and intramedullary pinning. **B:** The pseudarthrosis was resected. The circular frame was used to apply compression across the distal site, and to lengthen proximally. **C:** Subsequent to this, an intramedullary rod was placed across both osteotomy sites in the tibia and the ankle. A solid AFO has also been used. Alignment and bone union have been maintained, as shown in these films 2 years later. (Courtesy of Mark Dahl, M.D., Minneapolis, MN.)

Congenital pseudarthrosis of the tibia has and will continue to be a very challenging problem. A stable consolidation is essential for a long-term satisfactory functional outcome. Each case is unique, and, as such, the treatment plan must often be modified. The newer techniques (vascularized bone graft, IM stabilization, external fixator) have been refined and successfully used by a few. All of these authors have had considerable experience in learning how to apply and adapt their particular surgical technique to the variables of each individual case. The overall good early results, with these newer and/or refined surgical techniques, are encouraging. However, as Boyd and Sage (182) suggested years ago, the true success of treatment of CPT in the growing child can only be known by following these patients until maturity.

Amputation

Amputation can be a viable and prudent alternative. Amputation should be considered following failure to obtain consolidation with the above-described surgical techniques and/or an unsatisfactory outcome, despite having obtained consolidation. Crawford and Jacobsen et al. prefers preserving the hind foot with a Boyd-Syme procedure (137,183), which preserves the distal leg and hindfoot length, potentiating optimal prosthetic fitting. Having done such, the authors subsequently have observed problematic stump instability. Eventually, more proximal stump revision was necessary to improve the prosthetic fit.

Congenital Pseudarthrosis of the Fibula

Definition

Congenital pseudarthrosis of the fibula almost always occurs in association with congenital pseudarthrosis of the tibia. It rarely occurs as an isolated entity, with only 21 cases reported to date in the literature (184,185,186,187,188,189 and 190). Congenital pseudarthrosis of the fibula presents later in life than congenital tibial pseudarthrosis. It occurs typically with a gait abnormality and/or a valgus deformity of the leg with a prominent fibula (184,185,188,189). The condition is frequently linked to neurofibromatosis. The tibia is involved by a prepseudarthrotic process with variable deformity (184).

Pathology

As with congenital pseudarthrosis of the tibia, congenital pseudarthrosis of the fibula may occur after a fracture through pathologic bone, or through an area of mesodermal maldevelopment (185). Dooley et al. (185) outlined a gradation in the severity of the condition: (i) fibular bowing without pseudoarthrosis, (ii) fibular pseudoarthrosis without ankle deformity, (iii) fibular pseudoarthrosis with ankle deformity, and (iv) fibular pseudoarthrosis with late development of tibial pseudoarthrosis.

Treatment

Bowing of a congenitally abnormal fibula needs no treatment, if no ankle deformity or tibial pseudoarthrosis exists (184,185). Isolated pseudarthrosis of the fibula in a growing child may (186) or may not (185) potentiate ankle valgus deformity. Dooley et al. (185) suggest observation if no ankle deformity is noted. Hsu et al. (186) suggest the potential for ankle valgus is too significant without an intact fibula, and suggest interpositional bony reconstitution of the fibula. If pseudarthrosis of the fibula is associated with an ankle valgus deformity it should be treated. Langenskiöld (187) has successfully synostosed the fibula to the tibia, correcting progressive deformity in the growing child (184,185).

If there is associated significant distal tibial valgus deformity it should be surgically addressed. In less-severe deformities, and in skeletally immature patients, this can be accomplished with medial distal or tibial staple hemiepiphysiodesis. In severe deformities and/or skeletally mature patients, this is best done with a supramalleolar valgus-correcting osteotomy.

Posterior Medial Bowing of the Tibia

Definition

Posteromedial bowing of the tibia is a congenital anomaly, associated with calcaneovalgus foot deformity (191). Unlike its counterpart, anterolateral bowing, posteromedial bowing is not associated with pathologic fracture or pseudarthrosis of the tibia, and has generally been considered a relatively benign condition. Although the severity of the bow does diminish, significant leg-length discrepancy develops (191). It is this sequela that presents the greatest need for orthopaedic management.

Etiology

The pathogenesis of posteromedial bowing is unclear. Mechanical forces (the dorsiflexed foot against the tibia) and embryologic vagaries of tibial development (circulatory or limb bud anomaly) have been suggested as causes, but remain unproven. The rapid decrease of bow in the tibia in the first 6 to 12 months supports mechanical factors as a cause of bowing (191,192). It cannot, however, account for the growth inhibition.

Assessment

What is most evident at birth is the extreme dorsiflexed position of the foot against the tibia (Fig. 27-24). Plantar flexion of the foot may be limited. Bowing of the tibia may be overlooked by parents, and upon initial newborn examination. The bow is most easily felt by palpation of the anterior tibia. A normal infant has an anterior bow, which is distinct from the posterior defect palpated in infants with posteromedial bow. A skin dimple is usually present over the posterior apex of the bow. Shortening of the affected tibia may not be readily apparent clinically in newborns, but is expected to increase in these children. Evaluation should include AP and lateral radiographs of both tibias. The severity of the posterior and medial deformity can be measured and a percent inhibition of tibial growth can be calculated. The lateral tibial films provide more accurate tibial length measurements in infants. Orthoroentgenograms or similar radiographic techniques can be used for serial assessments of limb-length inequality. The posterior angulation rarely persists, often producing a mild S-shaped tibia. The medial angulation is less likely to resolve completely, and residual valgus in the tibia may be clinically significant (Fig. 27-25). Growth inhibition is fairly constant, as the absolute leg-length difference increases with growth.

FIGURE 27.24. A: Infants with posteromedial bowing usually present because the foot is in an abnormal, severely dorsiflexed, position. The bow can be palpated along the subcutaneous border of the tibia. A skin dimple is usually present over the apex of the bow. Shortening of the leg may not be as obvious as the bowing deformity. **B:** This infant's lateral radiograph shows how the foot seems to nestle against the curve of the tibia. The bone appears normal, or may show signs of remodeling with thickening of the anterior cortex, and smoothing posteriorly.

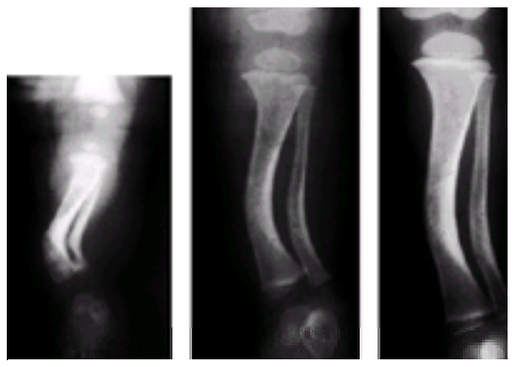

FIGURE 27.25. Both the posterior and medial components show spontaneous resolution. Improvement is often very dramatic within the first year. This series of AP films show the typical course of resolution from 1 month to 6 months and 12 months of age. Medial bowing may not fully resolve, resulting in residual valgus. Posteromedial bowing is not associated with risk of pathologic fracture.

Differential Diagnosis

There is little to consider in the differential diagnosis of posteromedial bowing. Its direction is clearly different from the more serious pathology of anterolateral bowing. Posteromedial bowing may be overlooked in the presence of severe calcaneovalgus foot deformity. Occasionally, adolescents will present with limb inequality and mild valgus, the result of previously unrecognized posteromedial bowing. Metabolic bone disease, such as osteogenesis imperfecta, rarely results in this type of

bowing deformity.

Treatment

Initial treatment of infants is primarily passive stretching of the foot. Serial cast application may be used for severe deformities. The bowing generally corrects rapidly in the first year (191,192). Rarely, extreme dorsiflexion and valgus persist, such that plantigrade weight-bearing cannot be accomplished. Use of a solid AFO or SMO may be facilitate weight-bearing for walking (193,194). As tibial length inequality increases, a shoe lift may be needed to balance the pelvis. Gradual contracture of the plantar flexors is not uncommon. Passive stretching is usually adequate treatment in young children.

Recently, 35 patients with posteromedial bowing of the tibia were reviewed at the Shriners Hospitals for Children in St. Louis. All had some degree of limb-length inequality. The minimum discrepancy was 1.4 cm at 1 month of age, and the projected difference at maturity ranged from 3 to 8 cm. Pes planovalgus, which was seen in some children, resulted in decreased foot height as well. This degree of inequality is best managed by surgical equalization, either by shortening the long tibia or lengthening the short tibia.

Appropriately timed epiphysiodesis has been most widely used for differences up to 4 to 5 cm. Shortening is almost always confined to the tibia. Epiphysiodesis of the proximal tibia is usually sufficient. There are several techniques that can be employed **[➥6.12, 6.13]** (see Chapter 28). A staged hemiepiphysiodesis may be used to correct residual angulation prior to completion of the epiphysiodesis. Lengthening techniques **[➥6.9, 6.10]** are recommended for those children with projected discrepancies greater than 3 to 4 cm, and for those with residual valgus angulation (Fig. 27-26). Lengthening alone in this latter group can add to existing valgus, particularly when unilateral frames are used. Circular frame fixation allows better control of valgus (31,108). Bi-level osteotomies in the tibia (lengthening proximally, deformity correction distally) provide optimum management of length and angulation. The foot may assume a varus position to compensate for residual tibial valgus, and require modification of the frame, if it is rigid. Stability of the knee and ankle is normal with posteromedial bow, making these relatively less complicated corrections than other congenitally short tibiae.

FIGURE 27.26. A: This 17-year-old male has a history of posteromedial bowing of the left tibia. At age 14 years, he had lengthening of his tibia, for a 4.8-cm discrepancy. **B:** The residual valgus was not corrected. Lengthening exaggerated the valgus appearance. There was also residual shortening, in part, from decreased foot height secondary to the valgus position. **C:** Subsequently, a bilevel tibial osteotomy was performed. Residual valgus was corrected through the distal tibia, and limb-length equalization accomplished with proximal lengthening. **D:** Valgus has been corrected, as well as balancing the pelvis.

CONGENITAL DISLOCATION OF THE KNEE

Definition

Congenital dislocation of the knee (CDK) is a relatively rare deformity that varies from simple hyperextension to anterior dislocation of the tibia on the femur. The variable spectrum of deformity in the clinical presentation of CDK has been classified as recurvatum, subluxation, and dislocation (195,196). The incidence of CDK is estimated at 1 per 100,000 live births, nearly one-tenth the incidence of developmental hip dysplasia (197,198 and 199). Although there are some reports of occurrence within families, most cases are sporadic occurrences (200,201 and 202). The deformity may be unilateral or bilateral.

Etiology

Several etiologic factors have been proposed for CDK. The abovementioned familial occurrence suggests a possible genetic basis. There is also a strong relationship of CDK with both hip dysplasia and congenital foot deformities (195,197,203). Both congenital deformities (clubfoot and vertical talus) have polygenic modes of inheritance, again suggesting a genetic link with CDK (195,197,204).

Milder forms of CDK occur in association with breech position *in utero*. In one study, 41% of otherwise normal newborns with CDK were breech position. These are generally believed to be positional, not pathologic deformities (197). Severe CDK often occurs in the presence of muscle imbalance and/or ligamentous laxity, as occurs in myelodysplasia, arthrogryposis, Larsen syndrome and maternal oligohydramnios (195,197,203,205).

Imbalance about the knee created by a relatively strong or contracted quadriceps muscle, along with deficient hamstrings, can lead to anterior dislocation of the knee. These infants typically have severe hyperextension *in utero,* and presumably decreased fetal mobility. The chronic knee hyperextension allows anterior subluxation of the hamstrings, making them “perverted” knee extensors (206). The quadriceps muscle is short and contracted. Uhthoff and Ogata were able to study a 19.5-week-old fetus with such a deformity (207). They found early fibrosis of the quadriceps, absence of the suprapatellar pouch, and incomplete patellofemoral cavitation. The authors suggest that these abnormalities, intrinsic to the extensor mechanism, were the primary cause of knee subluxation, rather than being secondary to some other extrinsic cause. The pathologic findings in this fetus are the same as those found in patients treated surgically.

Clinical Presentation

The hyperextended knee(s) deformity is obvious, but of variable severity. There is inability to actively or passively flex the knee (Fig. 27-27). The quadriceps tendon is often severely contracted. A dimple or deep crease may be present over the anterior aspect of the knee. The patella is difficult to palpate, and often laterally displaced. In the more severe forms, hip dysplasia and congenital foot deformities are present. Milder forms, such as hyperextension or recurvatum, are usually isolated abnormalities. Radiographs (Fig. 27-28) help to differentiate anterior dislocation of the tibia from the less complex hyperextension deformity. CDK, occurring in association with a neuromuscular or genetic syndrome, is typically very severe and the most difficult to manage (195,208,209).

FIGURE 27.27. This infant has bilateral anterior knee subluxation and club foot deformities. These deformities are often associated with intrauterine breech position.

Deep skin creases are often found across the front of the knee. The skin may be dimpled posteriorly. See Fig. 27-29 for follow-up of this patient.

FIGURE 27.29. Follow-up photos of patient seen in Figure 27-27. **A:** The upper photo shows knee extension following open reduction of these bilateral knee deformities. Hyperextension is no longer evident. **B:** Knee flexion greater than 90 degrees has been accomplished. Range of motion exercises and intermittent use of orthotics may be needed to maintain this correction.

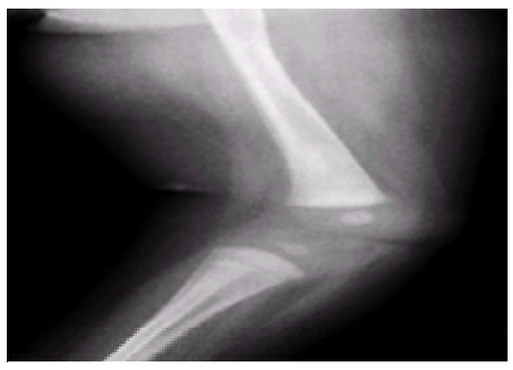

FIGURE 27.28. A lateral radiograph differentiates between simple hyperextension, subluxation, and anterior dislocation. The anterior aspect of the knee is to the left. Note the deep skin crease anteriorly. The ossification center of the proximal tibial epiphysis is anterior to that of the distal femur. Serial lateral radiographs should be used to document anatomic reduction of the knee. Failure to achieve anatomic reduction by closed manipulation, or inability to flex the knee more than 60 degrees, are indications for surgical treatment.

Nonoperative Treatment

Treatment begins with gentle stretching. The use initially of serial casts changed weekly, and subsequently, removable splints changed every 2 to 3 weeks, is often helpful, particularly in the milder forms. These knees often show rapid improvement in flexion. A Pavlik harness is useful for maintaining knee flexion (210,211 and 212). Once flexion beyond 90 degrees is obtained it is unlikely that additional treatment will be needed. It is important to document the restoration of a normal relationship of the femur to the tibia. A lateral plane radiograph of the knee is usually sufficient. Ultrasound can also be used. Knees with more severe subluxation or dislocation may not respond to passive stretching or splinting. Traction has been suggested as a means to achieve gradual reduction (195,209,213). During attempted closed treatment, it is particularly important to radiologically document the restoration of a normal relationship of the tibia on the femur. A lateral plane radiograph of the knee joint is usually sufficient. Ultrasound can also be used. It is possible to create an iatrogenic separation through the distal femoral physis, or plastically deform the proximal tibia. Rather, flexion obtained must occur at the knee joint as the tibia translates on the femur.

Surgical Treatment

Those infants who do not respond to nonoperative treatment (failure to achieve knee flexion beyond ³60 degrees) should be considered for surgical treatment **[➥5.3]** (199). Early surgery (<4 to 6 months of age) is desirable. However, extensive and often bilateral releases are required. Often, surgery must be delayed if the child's general health status is compromised by coexisting medical conditions. Alternatively, Roy and Crawford (203) have used a percutaneous release of the quadriceps mechanism, in conjunction with serial casting. This has been performed as early as 1 to 2 months of age.

The extent of the incision and dissection necessary should not be underestimated. The typical incision extends from the proximal thigh, in a serpentine fashion distally, and slightly past the tibial tubercle distally. A serpentine incision, rather than straight, may facilitate wound closure and healing. Subcutaneous flaps are raised to expose the contracted quadriceps mechanism. Fibrosis and scarring of the muscle is usually extensive. It may be adherent to the periosteum of the femur. The patella is usually very small and laterally displaced. The extensor mechanism is usually malrotated, and pulls the tibia into valgus. The quadriceps mechanism must be considerably lengthened, yet remain attached both proximally and distally. This requires extensive dissection through fibrotic tissue. A V-Y advancement, done more proximal to the patella, satisfactorily lengthens moderate contractures (195).

For the relatively more severe quadriceps contractures, the authors have found that greater lengthening can readily be obtained by a Z-plasty of the entire distal portion of the quadriceps mechanism (195). The anterior knee joint is transversely released to the collateral ligaments, which often must be reflected forward and/or partially released. Typically, the knee can be flexed to 90 degrees. Occasionally, the medial hamstrings, iliotibial band, and the lateral intermuscular spectrum must be released to correct valgus and external rotational deformity (199). The cruciates are typically present, but may be attenuated (195,204,206). The authors have not found it necessary to release the cruciates. The tenuous quadriceps mechanism is repaired with the knee in ³30 degrees of flexion (195,199,206). Postoperatively, the knee is immobilized in a spica cast, in enough flexion (30 to 45 degrees) to prevent recurrent tibial subluxation (197,199). Immobilization in too much flexion both jeopardizes the quadriceps mechanism repair and potentiates necrosis of the rather tense skin and subcutaneous soft tissue (195). It is essential to continue with long-term range of motion and orthotic splinting to maintain maximal flexion and yet minimize loss of extension. Flexion contracture can be more debilitating than lack of full flexion.

Treatment of an ipsilateral hip dislocation is best performed after correction of the knee dislocation. Following release of the contracted quadriceps mechanism, the knee can be flexed, which facilitates treatment of the hip (195,197,199). Mild hip dysplasia, which can be managed by simple closed reduction or limited open reduction with a medial approach **[➥3.3, 3.4]**, can be treated in conjunction with the spica cast utilized to immobilize a surgically reduced CDK. For more severe hip dysplasia open reduction should be done later as a staged procedure. If a coexisting foot deformity requires operative treatment, this can be done in conjunction with the knee reconstruction. Knee flexion facilitates cast application necessary for the treatment of associated foot deformities.

The long-term outcome of treatment is variably good. Those who require only stretching, and minimal intervention as infants, anticipatably have the best results. They do not report problems later on. Function is very good and radiographs appear nearly normal (198,208,211,212). Those children who require an open reduction, but do not have any other musculoskeletal problems, generally do well (Fig. 27-29A and Fig. 27-29B). These patients have knee range of motion from near-full to full extension, and flexion, which averages 80 to 120 degrees. This allows very functional independent ambulation. All have some degree of ligamentous laxity of the involved knee. Radiographic abnormalities are found in some, but not all knees. This usually consists of flattening of the femoral and tibial articular contours (195,197).

Those with bilateral deformity do not do as well as those with unilateral deformity. These also tend to be children with neuromuscular disorders. Early repair generally

has a more satisfactory functional result than late repair (195,197,203). Recurrent hyperextension deformity is not likely. However, loss of flexion, particularly that gained at surgery, can be a late complication. The development of a flexion contracture can compromise long-term function. This may result from poor quadriceps muscle function or postoperative fibrosis. Release of contracted soft tissues and/or osteotomy may be necessary to place the limb in a functional position.

IDIOPATHIC TOE-WALKING

Definition

Children may present at any age with a history of toe-walking. The habit of doing so is not that uncommon or abnormal in 2- or 3-year-old children. Typically, the habitual toe-walkers, with coaxing, can alternatively walk plantar grade. By the age of 3 years, children should walk with a heel strike (6,214,215). Persistent toe-walking beyond this age is abnormal in the child who is otherwise neurologically normal, and typically is associated with a shortened heel cord of variable severity (216,217 and 218).

Etiology

Although originally described as having congenitally short heel cords (217), most children in retrospect did not have a history of recognized heel cord shortening noted at or soon after birth (218). In some idiopathic toe-walkers, there is little evidence of static triceps surae contracture (217). In practice, though, those idiopathic toe-walkers with the greatest degree of heel cord contracture will most likely have a persistence of toe-walking and a need for treatment (218).

Natural History

In actuality, very little is known about the natural history of idiopathic toe-walking (ITW). Stricker and Angulo (218) retrospectively reviewed 80 patients who were evaluated and treated for ITW. Forty-eight of the 80 patients, generally those with the mildest deformity, were observed without treatment for an average of 3 years to 6 years. The degree of minor heel cord contracture remained essentially unchanged for these patients. Only 25% of parents noted a spontaneous improvement; that is, appreciably less toe-walking occurred. Seemingly, for the children with relatively less severe heel cord contracture (dorsiflexion >5 degrees), persistent toe-walking is not a functional problem resulting in any foot deformities or pain. Toe-walking, for many patients, either diminishes or ceases with time. This perhaps occurs as the body mass becomes too large to be supported by the triceps surae and/or by the secondary development of external tibial torsion (217).

Clinical Features

Patients typically present to the orthopedist for evaluation of ITW at 3 to 4 years of age (218). Males predominate, and the family history (siblings and also generation to generation) is often positive for similar ITW, persisting into adulthood (216,218,219). The suggested inheritance pattern is autosomal dominant with variable penetrance (220,221). Although Stricker and Angulo noted a frequent history of both prematurity and developmental delay, walking age was not delayed (218). On examination, ITW occurs bilaterally, and is best seen when walking barefoot (Fig. 27-30). When the children stand still their feet are flat on the ground. Toeing-out and splaying of the forefoot variably occur. Idiopathic toe-walkers, in contrast to children with spastic dysplasia, do not have any noted tendency to walk with a back-knee thrust.

FIGURE 27.30. A: Children with idiopathic toe-walking assume an externally rotated posture, to facilitate a foot-flat position. They typically do not hyperextend the knee. **B:** While up on their toes, the heel moves to a varus position. Chronic toe-walking can cause the forefoot to splay, because of the overload of the intermetatarsal ligaments. Forefoot splay and tibial external rotation typically do not resolve after heel-cord–lengthening.

On bench exam, the range of passive ankle flexion will be normal, and dorsiflexion will be limited, secondary to a variable degree of true shortening of the heel cord (216). The posterior calf muscles are typically very well developed; in fact, they may appear to be enlarged. However, the muscle texture will feel normal on exam, and there will be no evidence of any weakness, proximal or distally in both the upper or lower extremities. Importantly, no spasticity is present. The diagnosis of ITW is a diagnosis of exclusion, and typically can be made from the child's history and physical examination (216,219,222,223).

Other Diagnostic Studies

The differential diagnosis of early-onset toe-walking includes spastic dysplasia and other neurologic etiologies (218,219). Idiopathic toe-walking that develops after the onset of a mature gait pattern must be differentiated from primary muscle disease, tethered cord syndrome, and CNS neoplastic abnormalities (218,219). On occasion, neurologic consultation may be indicated, to assist in the often subtle differentiation of ITW from toe-walking as a manifestation of typically static encephalopathy or remotely secondary to primary muscle disease (dystrophy, myotonia) (218). Diagnostic tests that may be helpful in this setting are MRI of the CNS and/or gait analysis, including dynamic EMG. Usually, the diagnosis of ITW is made without computerized gait analysis. However, gait analysis may be helpful if it is essential to differentiate between ITW and spastic diplegia (217,222,224). Children with mild cerebral palsy who walk on their toes may have out-of-phase gastrocnemius soleus muscle activity, whereas the same EMG data for children with ITW will be in phase (224). Kinematic differences include lack of heel strike in both groups, but with greater sustained knee flexion at terminal swing in patients with mild cerebral palsy (217,222,223). Subtle kinematic differentiating patterns exist. Maximal knee extension occurs at ground contact for idiopathic toe-walkers, and at mid- to late-stance for diplegics (222). Maximal swing ankle dorsiflexion occurs early in ITW, followed by plantar flexion; ankle dorsiflexion occurs throughout swing in diplegics (222).

Treatment Recommendations

Nonsurgical Treatment

The treatment of ITW begins with instructions given to the parents regarding the importance of a long-term commitment to assisting the child with heel-cord–stretching exercises. This is particularly true in early childhood, when stretching exercises are more likely to make a difference. A 3- to 4-month course of twice-daily dorsiflexion manipulations, with the hindfoot inverted, may be effective in obtaining increased dorsiflexion. Less toe-walking may be noted. This clinical improvement will be sustained with continued daily heel-cord–stretching exercises and active dorsiflexion-strengthening exercises. There is more often than not a failure to comply with this regimen.

If toe-walking persists, serial stretching casts should be considered. A series of two or three sets of short-leg casts will often physiologically elongate the heel cord, resulting in greater passive dorsiflexion. Typically, a marked decrease in the tendency to toe-walk is noted. After casting, articulated AFOs with plantar flexion stops are fitted, and the heel-cord–stretching and dorsiflexion-strengthening regimen is resumed. If dorsiflexion can be maintained the children are, over the ensuing months, gradually weaned from daytime and eventually nighttime use of AFOs. This approach will achieve initial correction, particularly in the majority of the younger patients, and even in some of the older patients. However, persistence of relapses are very common, often requiring repeating the casting and orthotic treatment

regimen. Although serial casting and subsequent orthotic usage is widely recommended, very little is known of its long-term effectiveness (223).

Surgical Treatment

If the use of serial stretching casts does not realize a satisfactory clinical improvement in the tendency to toe-walk, then heel-cord–lengthening procedures will be necessary to effect a change in gait (216,218). The timing of definitively restoring a more normal gait is of importance. The authors feel that by 6 to 8 years of age, children should have treatment sufficient to realize a more normal heel–toe, rather than toe–heel gait. Persistent toe-walking can potentiate both forefoot splay and an associated permanent, disproportional hindfoot–forefoot size relationship and external tibial torsion. The associated external tibial torsion deformity becomes more obvious once the heel cord has been lengthened. It may be severe enough to warrant corrective osteotomy. In addition, treatment of neglected ITW in early adolescence necessitates a heel-cord–lengthening at a relatively late age.

The heel-cord–lengthening can be done by a variety of techniques **[➥7.16, 7.17]**. The authors prefer performing a fractional lengthening at the junction of the middle and distal thirds of the triceps surae complex. Lengthening is performed sufficient to obtain 10 degrees of dorsiflexion with the knee extended. Short-leg walking casts are used for 5 to 6 weeks, then the child is fitted with AFOs, which are used 22 of 24 h for 4 to 6 weeks, then gradually weaned. Heel-cord–stretching and strengthening and dorsiflexion-strengthening exercises are performed twice daily.

Generally, parents are very satisfied with the improved gait following heel-cord–lengthening; however, they need to be well informed as to the anticipated post-operative course. The child's post-op gait (relatively weak plantar flexor power) will be considerably different from the pre-op gait (relatively strong plantar flexion power). The predominantly equinus gait is replaced with a gait with relatively weak push-off. Quick cadence is replaced by a gait with a slower cadence. It takes time for the push-off power to recover to near-normal parameters (216). Surgical correction predictably has a satisfactory outcome. Hall et al., at an average length of follow-up of 3 years post-heel-cord–lengthening, reported a satisfactory outcome for all 20 patients (216). In a review of all treatment methods, Stricker and Angulo (218) noted that only surgical lengthening of the heel cord permanently improved ankle dorsiflexion. Although 33 of 56 patients still exhibited some degree of toe-walking, most parents were satisfied with the outcome of heel-cord–lengthening (218).

CHAPTER 28

LEG LENGTH DISCREPANCY

COLIN F. MOSELEY

C. F. Moseley: Department of Orthopaedics, University of California—Los Angeles 90020; Chief of Staff, Shriners Hospital for Children, Los Angeles, California 90020

Cases of leg length discrepancy frequently present challenges to the orthopaedic surgeon. The orthopaedic surgeon must understand the mechanisms and concepts of growth, including the relations among age, maturity, and leg length. Because the patient usually presents during the growing years, the orthopaedic surgeon must understand the need to correct the discrepancy as it will exist at maturity and not the discrepancy that is present in the growing child. The surgeon must be conversant with the methods used to analyze growth and predict future growth and the effects of surgery. The techniques of leg lengthening evolve rapidly, and the orthopaedic surgeon must consider these new techniques in choosing the most appropriate treatment. As surgeons become more confident in their ability to lengthen legs, discrepancies of greater magnitude for correction are accepted; surgeons must be confident that the improvements in their abilities outweigh the increased risks. The final challenge facing the orthopaedic surgeon is to maintain perspective on the whole patient, and resist the temptation to direct attention solely toward the lengths of the legs, neglecting the other factors that are important in the patient's overall function and appearance.

The treatment of leg length discrepancy must be preceded by careful and sometimes difficult education of the patient and parents. In the case of epiphysiodesis, parents frequently find it difficult to understand why a problem in one leg requires an operation on the other normal leg, and they are not pleased at the thought that their child will be shorter. In the case of leg lengthening, the parents and the patients must understand that a fairly high morbidity is associated with this procedure, even if things go well, because the child must wear an external device for many months, and be restricted in recreation and athletics. They also must understand that the risk of complications is high, and that these complications can compromise the final result. The orthopaedic surgeon knows that surgery is necessary to correct leg length discrepancy, but parents often are anxious to find some nonsurgical method of stimulating the growth of the short leg. If all other factors were equal, it would be better to correct the leg length discrepancy by lengthening the abnormally short leg than to compensate for the discrepancy by shortening the normal long leg.

EFFECTS

The mechanical and functional effects of leg length discrepancy are immediately apparent. The long-term effects, however, are less understood. Despite a consensus in the orthopaedic and lay communities that leg length discrepancy does have deleterious effects on the spine and the hips, good documentation to support that consensus is lacking.

Mechanisms of Compensation

The child with leg length discrepancy usually compensates better than the adult, probably because of a greater strength-to-weight ratio. The child may compensate for minor degrees of leg length discrepancy by walking on the toes of the short leg with the heel never touching the ground. This can result in a smooth, symmetric gait that shows no abnormality, except for the lack of heel strike on the short side.

The adult, on the other hand, seldom compensates in that fashion, but tends to walk with a heel-to-toe gait, even on the short side, and to vault over the long leg. This action produces excessive up and down motion of the pelvis and trunk (Fig. 28-1). Although, theoretically, it is possible to compensate for the leg length discrepancy by flexing the knee on the long side, this almost never is done by either adults or children, probably because too much physical effort is required to do so.

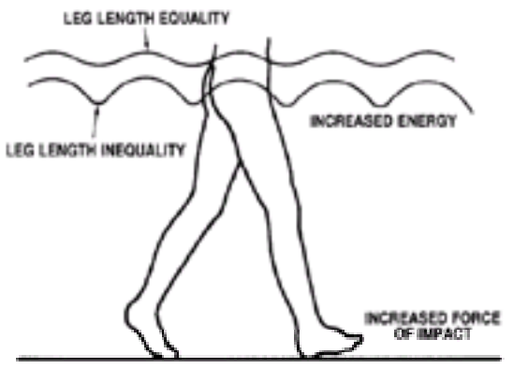

FIGURE 28-1. Motion of pelvis during gait. The amplitude of vertical pelvic motion is increased by leg length discrepancy. The patient vaults over the long leg and descends to plant the heel of the short leg.

Gait

Despite evidence to suggest that discrepancies of less than 2.5 cm are not significant (1), postural sway has been shown to increase as the result of simulated discrepancies of as little as 1 cm (2). Liu et al. proposed the symmetry index (SI) as a measure of the quality of gait, and found that correction of discrepancy by a heel lift significantly improves the SI (3).

It appears that patients are able to compensate extremely well for their discrepancies. The moments about lower limb joints with simulated and real leg length discrepancies have been found to be essentially unchanged with small discrepancies (4). Song found that discrepancies greater than 5.5% of the long extremity increased the mechanical work performed by the long limb, and increased the vertical displacement of the center of body mass. Children with lesser discrepancies were able to normalize the work performed by the two extremities.

Hip

Degenerative arthritis of the hip, which is termed “idiopathic” in the elderly patient, may actually be the result of some previously unrecognized minor problem, such as mild dysplasia, slipping of the capital femoral epiphysis, or possibly leg length discrepancy. In two-legged stance with the legs straight, the patient with leg length discrepancy has a pelvic obliquity, with respect to the floor, that relatively uncovers the hip of the long leg and increases coverage of the hip of the short leg (Fig. 28-2).

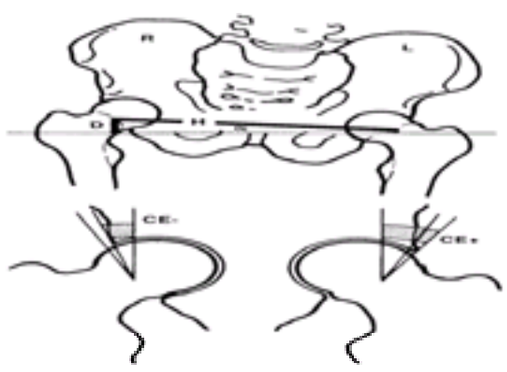

FIGURE 28-2. Decrease in center–edge (CE) angle with pelvic obliquity. The CE angle is decreased on the side of the long leg. Coverage is decreased, and the resulting decrease in the load-bearing area causes an increase in pressure. Such a hip may be susceptible to late degenerative arthritis (*L*, left; *R*, right). (From ref. 5, with permission.)

As the leg length discrepancy increases, so does the uncovering on the high side with a decrease in the center-edge angle. This relation is illustrated in Figure 28-3.

It is reasonable to suspect that the patient with a leg length discrepancy throughout his or her life may be subject to an increased risk of developing degenerative arthritis in the hip of the long leg (6); however, there is no documentation to prove this hypothesis. The effect of the leg length discrepancy in decreasing coverage is present only during two-legged stance, and perhaps during gait if dipping of the pelvis is used as a compensatory mechanism. When one is in one-legged stance, sitting, or lying down, as is the case most of the time, the effect disappears.

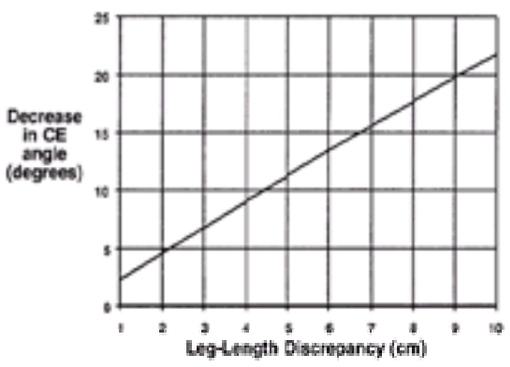

FIGURE 28-3. Relation between leg length discrepancy and center–edge (CE) angle. The CE angle and coverage decrease with increasing leg length discrepancy. For every centimeter of leg length discrepancy, there is a decrease of approximately 2.6 degrees in the CE angle. (From ref. 5, with permission.)

Knee

Although the nature of the relation has not been elucidated, there are reports that leg length discrepancy increases the incidence of knee pain in athletes (7).

Spine

The effects of leg length discrepancy on the spine also are not clearly established. The parents of young children with leg length discrepancy worry about their children developing degenerative arthritis of the spine, low back pain, and scoliosis. Contradictory evidence exists concerning the possibility that leg length discrepancy causes low back pain in the long term (8,9 and 10). Low back pain is unusual in the younger child and more common in the adolescent, but there is no evidence that low back pain and leg length discrepancy are related in this age group. Froh and colleagues looked for an effect of leg length discrepancy on the orientation of the facet joints in adults, and found none, whereas Giles and Taylor did find changes in the facet joints of cadavers with leg length discrepancy (11). It is not clear that the incidence of back pain is higher in patients with leg length discrepancy than it is in the general population. Radiographs of the spine should be examined carefully to rule out anomalous development of the vertebrae.

Several studies have been performed to determine whether leg length discrepancy leads to scoliosis. Gibson and coworkers assessed 15 patients with leg length discrepancy following femoral fractures, and found that after 10 years none had structural scoliosis (12), but minor structural changes have been reported in such patients (13). Studies have demonstrated an increased incidence of structural scoliosis in patients with leg length discrepancy, when compared with the general population (14), but it has not been established that the leg length discrepancy has caused the scoliosis. If leg length discrepancy were the cause, the scoliosis would be expected to be in the direction that would compensate for the leg length discrepancy, but in up to one-third of the cases in these studies, the scoliosis was in the opposite direction (Fig. 28-4). Because the leg length discrepancy affects the spine only during two-legged stance, and to some extent while walking, some skepticism toward the cause-and-effect hypothesis seems justified. It has been suggested, however, that scoliosis develops more as the result of the dynamic forces of walking,

and not of the static forces of standing (15).

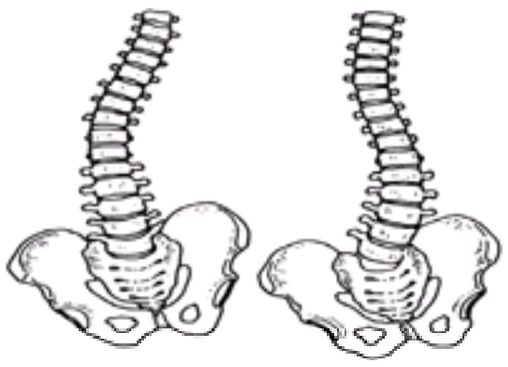

FIGURE 28-4. Oblique pelvis with scoliosis in compensatory and noncompensatory directions. If leg length discrepancy causes scoliosis, the direction of the spinal curvature is expected to be in the direction that is compensatory for the scoliosis. When scoliosis occurs in the other direction, it must be concluded that the leg length discrepancy is not responsible.

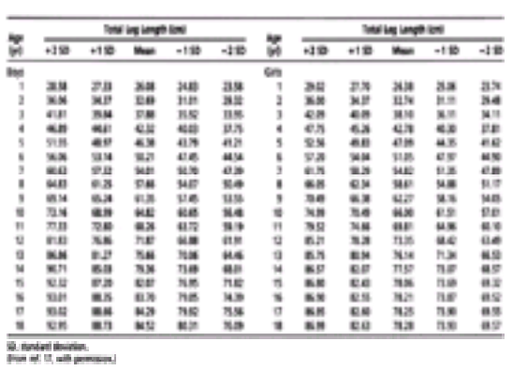
If leg length discrepancy has long-term effects on the spine or hips, it is reasonable to suspect that the severity of the problem is related to the severity of the discrepancy, the degree to which it remains uncompensated or uncorrected, and the age of the patient at onset.

GROWTH

An understanding of growth is an essential prerequisite to the treatment of patients with leg length discrepancy. The mechanisms of growth are discussed in Chapter 2. In the study of leg length discrepancy, one is concerned with rates and patterns of growth. Growth of the leg is the result of both growth at the four physeal plates at the proximal and distal ends of the tibia and femur, and an increase in size of the four adjacent epiphyses. The growth of the epiphyses contributes only 5% to the total growth of the legs, and this usually is ignored in treating patients with leg length discrepancy.

The only good studies relating growth of the legs to age were performed by Anderson and colleagues. Their first study involved populations of girls and boys at various ages from 5 years of age to physeal closure (16). Their second study was longitudinal, in that a single group of children was followed until maturity. They published their data in two forms. The first form related the lengths of the femur and the tibia of boys and girls to their ages, from 1 to 18 years (17). These data can be combined to show the total leg lengths rather than the lengths of the individual bones. The total leg length data are shown here in tabular (Table 28-1) and graphic forms (Fig. 28-5 and Fig. 28-6). The graph showing leg lengths related to age is a useful tool in the analysis of leg length data. They later published their data in the form of a graph showing the growth remaining at the distal femoral and proximal tibial physes of boys and girls related to skeletal age (18) (Fig. 28-7). Most of the growth of the lower extremity occurs in the physes near the knee, as opposed to the upper extremity, where most growth is contributed by the physes farthest from the elbow. The four growth plates of the lower limb contribute consistent proportions of growth to their individual bones and to the entire extremity (19) (Fig. 28-8). These percentages are worth remembering, because they can be useful in clinical situations. For example, a child with avascular necrosis of the femoral head in infancy cannot lose more than 15% of future growth of the affected leg, and a child whose distal femoral growth plate was destroyed as a result of infection will lose at most 38% of the future growth of the leg. Also noteworthy is that the femur is longer than the tibia, comprising 54% of the total length of the leg.



Age (yr)	Total Leg Length (cm)					Age (yr)	Total Leg Length (cm)				
	+2 SD	+1 SD	Mean	−1 SD	−2 SD		+2 SD	+1 SD	Mean	−1 SD	−2 SD
			Boys						Girls

TABLE 28-1. LENGTH AS A FUNCTION OF SKELETAL AGE

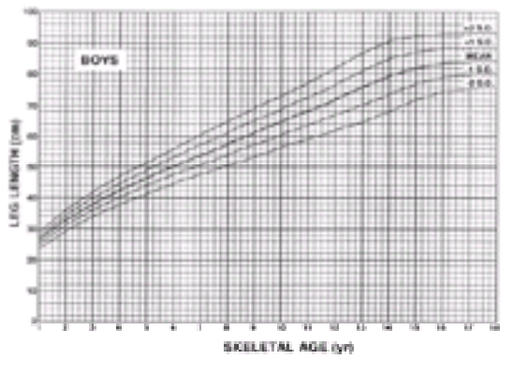

FIGURE 28-5. Total leg length versus skeletal age for boys allows a specific boy to be related to the population by plotting his leg length as a function of his skeletal age. It is useful in the analysis of leg length data because it allows a projection into the future based on the present situation. (From ref. 16, with permission.)

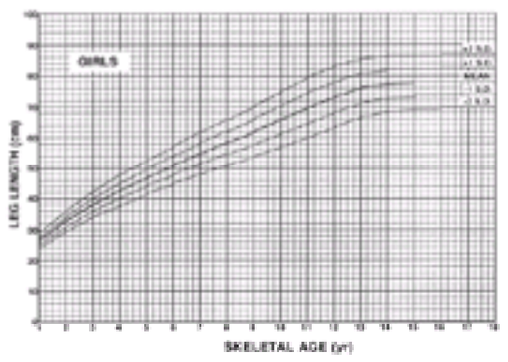

FIGURE 28-6. Total leg length versus skeletal age for girls serves the same purpose for girls as Figure 28-5 serves for boys. (From ref. 16, with permission.)

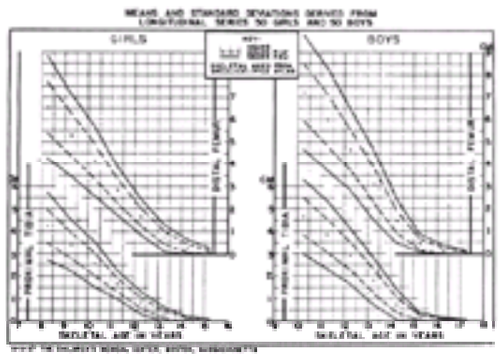

FIGURE 28-7. Green and Anderson growth-remaining graph. This graph shows the amount of growth potential remaining in the growth plates of the distal femur and proximal tibia of boys and girls as functions of skeletal age. It is useful in determining the amount of shortening that will result from epiphysiodesis. (From ref. 17, with permission.)

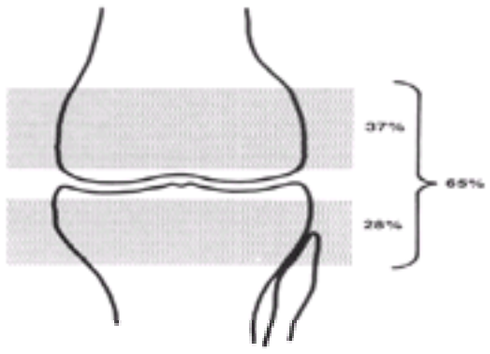

FIGURE 28-8. The growth plates of the lower limb contribute definite and constant proportions to the growth of the long bones of the leg and the total growth of the limb. These contributions determine the slopes of the reference lines of the straightline graph method, and are thus automatically taken into account by it.

The study of growth as it pertains to leg length discrepancy involves relationships among three factors: leg length, maturity, and chronologic age (Fig. 28-9). Although these relationships are familiar, some aspects deserve elaboration.

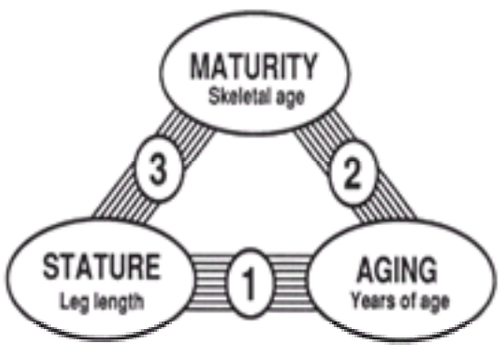

FIGURE 28-9. Leg length, maturity, and age all change with time, and the way they do so is not identical in every child. The three relations among them can be examined individually, and it is important to do so to understand parents' perceptions and to predict future growth. Relation 2 is maturation, whereas relations 1 and 3 are both growth, but from different perspectives.

It is evident to all physicians who deal with children that maturation and aging are only loosely related. Some children mature rapidly, and go through their growth spurts early. These children appear tall during the growing years, not because they are of a taller growth percentile, but because they are of advanced maturity. Many of these children, who are tall for their chronologic ages during early adolescence, cease growth early, and are shorter than the mean at maturity. Pediatricians, in their studies of stature, and orthopaedic surgeons, in their studies of leg lengths, need a measure of maturity, rather than a measure of age. Although leg lengths and chronologic age can be measured accurately and easily, maturity cannot. The best measure of maturity appears to be the development of the bones of the skeleton as seen on radiographs. By comparing the radiographs of a patient with standard radiographs in an atlas (20), it is possible to derive a number known as the “skeletal age.” It is used as a measure of maturity, but the skeletal age is actually the most likely age of a person with the given x-ray. It correlates well with menarche and other signs of maturation, such as the appearance of secondary sexual characteristics, and also correlates more closely with the growth of the legs than does chronologic age. Because skeletal age is, in a sense, an average of the general population, it should be apparent that, for a random group of children, the mean skeletal age should be equal to the mean chronologic age.

The three relations seen (Fig. 28-9) among chronologic age, skeletal age, and leg length can be examined individually, and it is instructive to do so. First, consider the relation between growth and chronologic age. This relation is obvious to parents. The parent who is concerned about his or her child being too short or too tall is always comparing the child to classmates and other children of the same age. In this relation, there is steady growth throughout life, with a growth spurt in early adolescence and cessation of growth at the age of 16 to 17 years in boys and 14 to 15 years in girls (21) (Fig. 28-10). Although this relation is the most obvious, it is virtually meaningless without a consideration of maturity, and its variability from child to child presents problems to the treating doctor. A more consistent relation must be used.

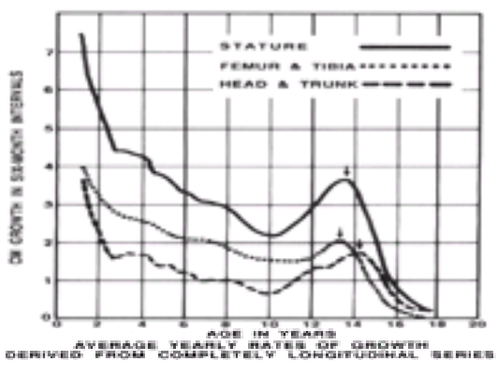

FIGURE 28-10. Green-Anderson growth curve. The examination of growth rate as a function of chronologic age shows a major growth spurt in adolescence. It is of

interest to note that no such spurt appears in the growth curve of Figure 28-6 and Figure 28-7. (From ref. 105, with permission.)

Although the relation between chronologic age and skeletal age is extremely variable within the population, children tend to pass the various landmarks of maturity in the same orderly and consistent fashion. The child who develops secondary sexual characteristics early also goes through the growth spurt early, reaches menarche early, and has advanced skeletal age. The implication is that children who mature more quickly or more slowly than average do so throughout their growing years, but this is not necessarily so. Some children appear as if they are going through a maturation spurt, during which they mature faster than they age. This maturity spurt tends to coincide with the growth spurt, and the orthopaedic surgeon who is waiting for just the right time to do an epiphysiodesis can be caught unaware. It is as if these children deal with their rapid growth rate by turning the pages of the skeletal age atlas at a faster rate than normal.

The third relation, that between maturity and growth, correlates more closely than the relation between chronologic age and skeletal age, and is of most interest to the orthopaedic surgeon. This is the relation shown in the data of Green and Anderson (Fig. 28-5 and Fig. 28-6), and it has interesting properties. The first property is that growth is never faster, in either absolute or relative terms, than it is in the newborn. The growth rate continually slows down until it stops completely at maturity. There is no inflection point in the curve, meaning that no growth spurt occurs, as happens when growth is correlated with chronologic age. The absence of the growth spurt has two possible explanations. The first is that these curves are derived from averages of a number of patients, and averaging data tends to dampen individual fluctuations that occur at different times. The second, more interesting, explanation is that the growth spurt may really be a maturation spurt with growth maintaining its customary relation to skeletal age.

The Green and Anderson study provides good documentation of the relation between skeletal age and leg length for the population studied, but there is no guarantee that these data hold for children of other races or of other genetic stocks from within the same race. Indeed, there is one report that shows that Dutch children are taller than those described by Green and Anderson (22). It is not clear, however, that these children actually follow a pattern of growth different from that described by Green and Anderson. They may just behave like children taller than Green and Anderson's mean. These authors modified the straight-line graph to be consistent with their data, but it is not yet clear that it is of benefit, since it has only been tested on the same population from which it was derived. Because the literature contains no reports of consistent errors having been made in the prediction of growth in non-white children, it seems reasonable and practical to assume that the Green and Anderson pattern of growth is followed by children of all races, and that it can be used reliably in predicting future growth.

ETIOLOGY

Leg length discrepancy can be classified purely by etiology, but the concepts involved in understanding and treating patients suggest a more logical approach. Leg length discrepancy can result from two types of processes: those that change the length of the leg directly, and those that alter its growth. A fracture that heals with overriding is an obvious example of an effect on length with no effect on growth, and injury to the growth plate from osteomyelitis is an example of an alteration in growth rate with no immediate effect on length. These two effects determine whether a discrepancy is static or dynamic, and greatly influence the choice of treatment. The causes of leg length discrepancy can be classified according to their effect on length and growth, but the classification system breaks down because certain causes can affect different patients differently, and some affect both length and growth. A fracture, for example, can cause shortening in one patient and overgrowth in another, and a congenitally short femur can be thought of as being both short and retarded in its growth. Such a classification is shown in Table 28-2.

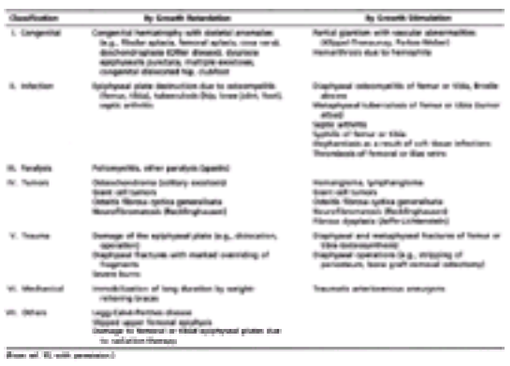

TABLE 28-2. CLASSIFICATION OF CAUSES OF LEG LENGTH DISCREPANCY

Some patients with asymmetry above or below the legs present as having leg length discrepancy and are treated as such, even though their legs may be of equal length. One example is the patient with the neglected, high-riding congenital dislocation of the hip (Fig. 28-11).

FIGURE 28-11. High-riding dislocation of hip. This patient has a functional leg length discrepancy that is greater than the actual discrepancy in the lengths of the legs, because of the adduction of the short leg.

Interference with Length

By definition, the only processes that can acutely affect the length of the leg are fractures and dislocations. Whether or not a congenitally short bone has had a direct interference with its length is a moot point, because it occurred before birth, and it is the inhibition of growth that is the important factor. The terminal deletions and proximal focal femoral deficiency and its variants can be thought of as growth inhibition superimposed on a short limb.

Fractures can result in short bones either by overriding or by angular deformity. In the latter case, the shortening often disappears when the angulation is corrected (23). Sugi and Cole have shown that shortening of up to 10% of the femoral length can be accepted in the treatment of femoral fractures by early spica without causing significant discrepancy (24). Overgrowth frequently accompanies healing of fractures, and can spontaneously correct the shortening (25). Excessive length can result when excessive force is applied in traction.

Dislocations have a direct effect on length only if they are unreduced.

Inhibition of Growth

The growth of the physis can be slowed by three mechanisms. First, congenital short bones grow more slowly than normal bones, as the result of abnormal programming of the genetic mechanism that determines growth rate. Second, the growth plate can be injured in such a way that part or all of it is no longer able to grow, and eventually gets converted to solid bone in the form of a physeal bridge or a prematurely closed plate. Any part of the plate that has retained its ability to grow cannot do so effectively, because of tethering by the fused part. Third, a change in the environment of the plate can influence its growth rate. Unusual vascular malformations can stimulate or inhibit growth (26,27). Children with paralysis usually have shortening of the more severely affected leg, presumably because the growth rate of the plate responds to the decreased compressive forces across it. The concept that pressure might change the direction of the growth of the plate is commonly known as the “Heuter-Volkmann law” (28,29), but the concept was first proposed by Delpech (30,31). He treated an angular deformity of the ankle with casting, to cause the distal tibial plate to change its direction of growth.

Congenital Shortening

When a patient is born with legs of unequal length that are otherwise normal, it is often impossible to know which leg is the abnormal one. Because the more severe cases clearly involve shortening, it is appropriate to think of these cases as hemiatrophy, rather than hemihypertrophy. Beals has stated that the two are separate and distinct clinical syndromes, partly because of associated anomalies (32). The dysplasia usually involves the entire limb, with some shortening of all components, and usually is accompanied by a diminution in girth. Each leg appears to be genetically programmed to be a different size (33).

Congenitally short bones frequently show qualitative as well as quantitative changes (34) (Fig. 28-12). The congenitally short femur also can show coxa vara, bowing, hypoplasia of the lateral condyle (Fig. 28-13), and external torsion (35). It can be associated with anterior cruciate insufficiency (36,37 and 38), a short or missing fibula (39,40), and absence of the lateral rays of the foot. Indeed, the congenital short femur is thought by some to be a variant of proximal focal femoral deficiency (41).

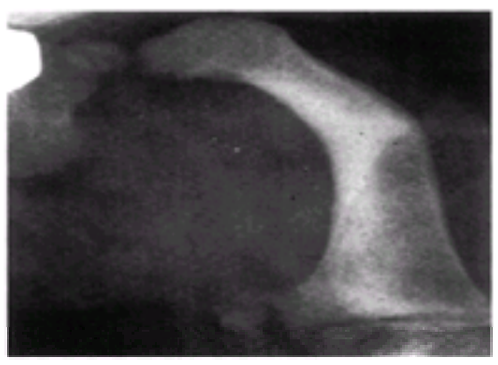

FIGURE 28-12. In proximal focal femoral deficiency, the leg length discrepancy is accompanied by qualitative changes, including coxa vara and bowing.

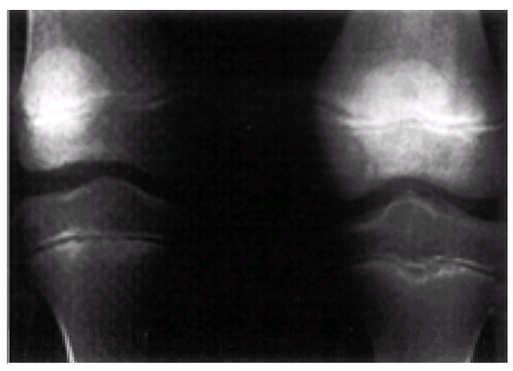

FIGURE 28-13. Hypoplasia of femoral condyle is frequently found in association with congenital shortening of the femur.

Congenitally bowed tibias are frequently accompanied by leg length discrepancy and hypoplastic feet (42,43 and 44). Askins and Ger (45) found that 24% of patients with congenital constriction bands have leg length discrepancy; and Garbarino and colleagues (46) reported short tibias in association with congenital diastasis of the inferior tibiofibular joint.

Trauma

Trauma that injures the physeal plate may slow its rate of growth either by direct injury to the cells responsible for growth or by formation of a bony bridge that tethers the epiphysis to the metaphysis. Salter and Harris provided a classification of fractures of the physeal plate that is useful in anticipating the effect of fractures on future growth (47). This classification is shown diagrammatically in Figure 28-14. Fractures can wander through all zones of the plate, but tend to pass through the zone of cell hypertrophy where the material is weakest and the amount of material is least. The material in that zone is cartilage that is weaker than bone, and because the cells there are large, the ratio of matrix volume to cell volume is low (Fig. 28-15). It is important to note that this part of the plate is the site of conversion of cartilage to bone, but is not primarily responsible for growth that occurs by virtue of cell multiplication and matrix production in the zones nearer the epiphysis.

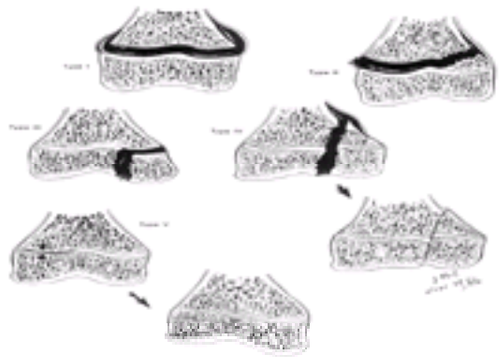

FIGURE 28-14. Salter-Harris classification of epiphyseal fractures. Fractures of types I and II do not cross the part of the growth plate responsible for growth, whereas those of types III and IV do. In the type IV fracture, approximation of epiphyseal bone to metaphyseal bone can result in formation of a bony bridge. (From ref. 46, with permission.)

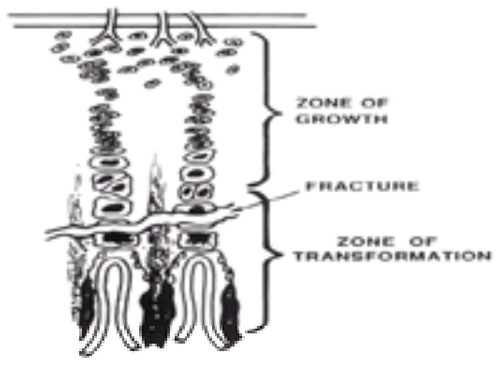

FIGURE 28-15. Location of fractures in the growth plate. Fractures tend to occur through the part of the growth plate where the matrix is least, although individual fractures may wander from zone to zone.

Because the type I and type II fractures do not pass through the growth zone, they are less likely than other fractures to interfere with growth. Both types, however, may be associated with a crush injury that injures the cells by compression. This mechanism may account for the higher-than-expected incidence of growth disturbance in type II fractures of the weight-bearing bones, such as the distal femur, where growth arrest is found in more than one-third of patients (48). Type III and IV fractures do, however, cross the growth zone, and therefore are more likely to result in growth arrest. The type IV fracture, in particular, can result in a bony bridge, when the fracture fragment displaces in the diaphyseal direction (Fig. 28-14). This is one reason why these fractures must be anatomically reduced. Type V fractures can occur in isolation, or can accompany any of the other types. They are insidious because they are not initially recognizable on radiographs, and they always demonstrate their presence by a disturbance of growth—either shortening or a combination of shortening and angulation—usually in the first year after the fracture. Although the fracture classifications provide guidelines about the likelihood of growth arrest, the orthopaedic surgeon must be wary of giving a definite prognosis for a given epiphyseal fracture, until enough time has elapsed to rule out a type V injury.

The bony bridge that causes a growth disturbance following physeal fractures usually is discrete and well defined, and lends itself to excision if small and peripheral. Bridge resections usually are limited to those that involve less than 50% of the plate, in patients who have at least 2 years of growth remaining. Even more extensive resections can be considered in very young children because, if successful, difficult treatment of severe leg length discrepancy might be avoided. Resection of a bony bridge always should be considered if there is significant growth remaining, even if leg length discrepancy is already present. The angular deformity, which also may be present because of the bridge, can influence treatment of the discrepancy, because both deformities can be corrected at once.

Infection

Osteomyelitis adjacent to the plate can result in destruction of physeal cells and disturbance of growth if not treated early (49). The infection is usually hematogenous osteomyelitis of the metaphysis, but can be epiphyseal in infants, and follow or precede septic arthritis of the joint. The bony bridge that results from infection is more difficult to treat than that following trauma, because it is not so amenable to resection. The bridge tends to be larger, more central, and less discrete than that following trauma, and can even consist of multiple small bridges. It is difficult to define by radiograph, is usually more extensive than it appears, and is more difficult to define during resection. There is the danger that minor components of the bridge can be left behind, because the usual end point of resection, a continuous line of physis around the resection tunnel, can be achieved despite incomplete resection of all components of the bridge.

Infection tends to produce more serious leg length discrepancy problems than trauma, because it occurs so commonly in younger children with so much growth ahead of them. As with trauma, angular deformity and leg length discrepancy can coexist.

Paralysis

Inhibition of growth commonly accompanies weakness or paralysis of the leg, but the mechanism is not clear. It may be true that blood flow to the limb is reduced because of the reduced muscle mass, but this does not necessarily mean that flow to the plate also is reduced. Venous return results partly from muscle activity, and therefore, blood flow to the limb and perhaps to the plate could be reduced as a result of reduced muscle activity and decreased pumping effect. Alternately, abnormal vasomotor control, which is part of the basic neurologic abnormality, could affect blood flow.

The effect of paralysis and reduced muscle activity can have a more direct effect on the growth rate. The Heuter-Volkmann law suggests that the growth rate of the physis responds to the compression forces across it, and frequently is invoked to explain how a spontaneous reorientation of the physis occurs in contributing to the remodeling of angular deformities in the immature child. This mechanism also can explain the decrease in the overall growth rate that occurs in children with muscle weakness.

The parents of children with cerebral palsy frequently are concerned about leg length discrepancy, and minor degrees of discrepancy can be seen in this condition. More often, however, the discrepancy is more apparent than real, and results from pelvic obliquity due to hip contractures or asymmetric posturing due to asymmetric spasticity. It is likely that serious discrepancies do not occur more often, because even dysfunctional spasticity can be effective, through the Heuter-Volkmann law, in stimulating the physis to grow.

Tumors

Leg length discrepancy can be related to tumors in several ways. The first involves destruction of the plate by direct tumor invasion behaving, in this instance, much like infection.

The second way involves damage to the plate by irradiation used to treat the tumor (50). Irradiation has a particularly harmful effect, because the osteocytes of neighboring bone also are killed, and the bone can take many years to become revascularized and repopulated with healthy osteocytes. The absence of healthy osteoblasts and precursors can complicate the treatment of the ensuing leg length discrepancy, by precluding lengthening procedures through the affected bone. Radiation damage to regional soft tissues also complicates lengthening procedures (51,52).

The third way that leg length discrepancy can be associated with tumors involves those that originate from the cartilage cells of the physis, thereby stealing growth potential from the plate. Examples of this are enchondromatosis and Ollier disease, which can produce growth inhibition of the affected bones (53), and osteochondromatosis, which frequently results in shortening of the ulna with a Madelung deformity. Although unicameral cysts usually do not result in significant leg length discrepancy, some disturbance of growth can result from aggressive attempts to remove the cyst wall, when the cyst is active and immediately adjacent to the plate. Unicameral cysts and fibrous dysplasia cause leg length discrepancy as the result of both growth inhibition and repeated fractures with minimal displacement that produce progressive varus.

Avascular Necrosis

Because the circulation of the physis is derived from the epiphyseal circulation, avascular necrosis of the epiphysis frequently involves the growth plate as well, and these patients can develop leg length discrepancy. This effect may be seen in Legg-Perthes disease, and following treatment of developmental dislocation of the hip. Peterson has reported a case in which a discrepancy resulted from a temporary but significant episode of vascular insufficiency during surgery in an infant (54). This effect, in the case of congenital dislocation of the hip, is maximized by the early age of onset and the years of future growth affected, but is moderated by the fact that the growth plate of the proximal femur contributes only about 15% of the growth of the limb. The likelihood of significant discrepancy has been correlated with the pattern of ischemic damage to the head, and increases with increasing involvement (55). That patients with Legg-Perthes disease do not usually develop significant deformity indicates that the vascular damage to the epiphysis does not always significantly affect the physis (56). Leg length discrepancy also has been reported as a complication of catheterization of the umbilical or femoral artery (57), presumably due to impairment of the arterial supply to the physis.

Stimulation of Growth

Certain conditions are known to stimulate growth, but although the mechanism is popularly thought to be increased circulation, only circumstantial evidence supports this theory. Attempts to stimulate growth in the treatment of leg length discrepancy have been made by numerous means, including sympathectomy to increase blood flow, insertion of foreign materials next to the physis, stripping and elevation of the periosteum (58,59 and 60), surgical establishment of an arteriovenous fistula (61), short wave diathermy (62), and electrical stimulation (63). None of these methods has consistently produced sufficient growth stimulation to be clinically useful (64,65), but the fact that the arteriovenous fistula does produce stimulation at all supports the hypothesis that increased circulation can be a final common pathway for the conditions that stimulate growth.

Tumor

Vascular malformations, particularly when they involve large portions of the limb, produce growth stimulation that often involves all growth plates of the limb, and not just the ones in proximity or those of the involved bone. This stimulation is seen with hemangiomatosis and the Klippel-Trenaunay-Weber syndrome (66). Stimulation is also seen with certain nonvascular tumors, such as neurofibromatosis, fibrous dysplasia, and Wilms tumor, although an increase in circulation can be the final common pathway in these cases.

Inflammation

Overgrowth of the involved bone is a common feature of chronic osteomyelitis, presumably because of the increased blood flow to the limb as part of the inflammation. Infection therefore can both inhibit and stimulate growth. Overgrowth of the affected limb can be seen in pauciarticular juvenile rheumatoid arthritis (67), particularly in those cases with onset before the age of 3 years (68), and also has been reported in a hemophiliac with chronic knee synovitis (69).

Fracture

Overgrowth usually is seen following fractures of long bones in children, and also is believed to result from the increased blood flow to the limb that is part of the healing process (70). One particularly pernicious example of this effect is the overgrowth of the tibia and valgus deformity that can follow minimally displaced proximal metaphyseal fractures (71). The mechanism involves overgrowth of the medial side of the tibial growth plate (72), possibly as the result of tethering by the fibula or by release of the torn medial periosteum (73,74,75 and 76).

Overgrowth most commonly occurs following femoral fractures in young children (77,78). Some studies have reported that the stimulatory effect can last for years, but it is believed to occur principally during the healing and remodeling periods in the first 2 years after the fracture (79). The stimulation has been reported variously to be greatest in fractures in the proximal third of the femur, the middle third of the femur (80), and in those fractures with greater degrees of overriding (81) and can be accompanied by overgrowth of the fractured tibia on the same side. Conversely, Meals (82) found that the patient's age and the type and location of the fracture did not influence the extent of overgrowth, although, inexplicably, handedness did.

PATIENT ASSESSMENT

There is a tendency when dealing with patients with leg length discrepancy to concentrate attention on the lengths of the legs and the discrepancy, and to ignore other factors that have some importance with respect to the patient's function and the ultimate outcome of treatment. When choosing treatment goals, as discussed later in this chapter, the importance of a complete and thorough assessment of the patient is emphasized.

History of Discrepancy

A complete history of the patient, the discrepancy, and its previous treatment should be obtained. The cause is important, because knowledge of whether length, growth, or both is affected, is essential to understanding the growth pattern. Also important is knowledge of the affected physeal plates, because this permits an estimation of the future increase in the discrepancy. Parents expect this kind of information on the first visit, and it is important, in establishing a good parent–patient–surgeon relationship, to be as knowledgeable as possible about the condition and its future. The history of surgery, including surgery to correct angular deformity, is needed, because the numeric data concerning leg lengths may be misinterpreted if the examiner is unaware of previous surgery that might have affected the leg lengths.

The history, which delineates the cause, associated deformity, and neuromuscular deficits, is referred to during selection of the treatment goal. That a patient's discrepancy is of congenital origin suggests increased risk, and certain precautionary steps to avoid complications must be taken in conjunction with lengthening. Instability of an adjacent joint can preclude lengthening. Weakness of the leg suggests that the weak leg be left a little short to facilitate floor clearance during swing phase.

Clinical Assessment

The accuracy and ease of obtaining radiologic measurements of the patient should not blind the physician to the necessity of conducting a careful and complete physical examination. There are two reasons for this. First, the radiographic measurements may be wrong because of artifacts caused by angular deformity, positioning, or patient movement. Second, there are important factors not measured by routine radiographs that can be crucial to the outcome of treatment. This latter point is mentioned repeatedly in the section on goal selection. After assessment of the patient is complete, the clinical assessment must be consistent with the radiologic assessment; if it is not, an explanation must be sought. Additional radiographs or reexamination may be necessary to discover the reason for the inconsistency. In the final analysis, it is the functional leg length discrepancy that must be treated, and that cannot be determined by radiographs.

Leg Length

A tape measure is used to measure the real length of each leg from the anterosuperior iliac spine to the tip of the medial malleolus. The apparent length is measured from the umbilicus to the tip of the medial malleolus. The discrepancy determined from these two measurements may be different, because the apparent length is affected by pelvic obliquity and hip position. The leg on the side of the adducted hip appears shorter, but the real length is minimally affected (Fig. 28-16). The patient should be undressed completely for this measurement, to avoid tenting of the tape over the clothes. In any case, the tape often tents over or around the knee, impairing the accuracy of the measurement. Because different landmarks are used, the lengths of the legs measured in this way are not the same as those measured by radiograph, but the discrepancies should correspond closely.

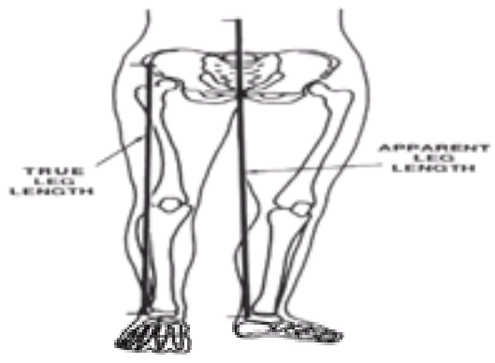

FIGURE 28-16. The measurement of real length is relatively immune from error because of pelvic obliquity. Measurement of apparent length is susceptible to error.

The medial aspect of the joint line of the knee can be used as a landmark for measuring the segment lengths of the tibia and femur. Although this method is less accurate than the radiologic measurement, it is useful for comparison purposes to avoid errors. If the relative heights of the knees will be a strategy factor, then the lengths of the individual bones can be determined as well.

It is useful to place blocks under the foot on the short side, to lengthen the short leg effectively (Fig. 28-17). The block height required to produce a level pelvis should correspond to the measured discrepancy. Blocks also can be used to estimate the amount of correction that feels best to the patient, and provides him or her with the best correction. This amount may be different from the radiographic measurement, and may indicate that the goal of treatment should be something other than exact correction of leg length. This assessment is most useful in the mature patient whose discrepancy will change further with growth. Even though it only measures the present length and does not indicate the desired amount of correction, it can be helpful with immature patients to indicate that exact correction is not the best goal. Carrying this idea further, the patient can be provided with a temporary shoe lift, and assessed after a period of ambulation. These techniques are especially useful for patients with complex deformities, because they take into account the combined effects of asymmetric feet, angular deformities, contractures, pelvic obliquity, and spinal balance.

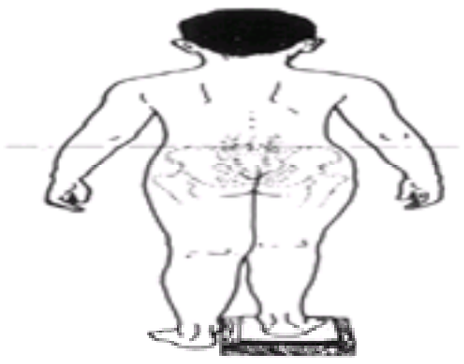

FIGURE 28-17. Placing blocks beneath the heel of the short leg allows assessment of the combined effect of all factors that produce functional leg length discrepancy.

Other Factors

Several factors besides leg length must be assessed, because they affect the measurement of leg length or influence the final outcome of the patient's treatment.

The examiner must remain aware that knee and hip flexion contractures tend to shorten the leg; an equinus contracture of the ankle tends to lengthen it; and apparent length also is affected by pelvic obliquity. The term “pelvic obliquity” has a broader meaning here than when used by spinal surgeons, who use it to refer to the relation of the position of the pelvis to that of the spine (83). In the context of leg length discrepancy, it refers to the relation of the position of the pelvis to that of the legs, and is affected both by adduction and abduction contractures of the hips and by spinal deformity. An adduction contracture of the hip causes the leg on that side to appear short, and to be functionally short, whereas an abduction contracture has the opposite effects (84). This situation is common in patients with cerebral palsy and those with the residuals of poliomyelitis. A difference between the measured real and apparent discrepancies indicates that pelvic obliquity is present.

Hip contractures are particularly important, since adduction contractures produce a functionally short leg, and abduction contractures produce a functionally long leg (85). These effects occur even in the absence of an actual discrepancy, as measured by scanogram. Conversely, in a patient with true shortening, a limitation of ipsilateral hip abduction or contralateral hip abduction will prevent him or her from compensating easily, and exaggerate the effect of the discrepancy.

Angular deformity must be assessed because it affects the measurements of leg length and influences the final outcome if it is to be corrected later. Joint stability must be assessed because it pertains particularly to the risks of lengthening. Femoral lengthening is contraindicated in the presence of hip instability. Congenitally short femurs always are associated with laxity of the anterior cruciate ligament (86) and hypoplasia of the lateral femoral condyle (Fig. 28-13), which predisposes to posterolateral subluxation of the tibial plateau. Lengthening of the tibia can be contraindicated in the presence of an unstable ankle or useless foot, which might be better handled by amputation and prosthetic fitting.

Spinal deformity and balance should be assessed. If there is stiff suprapelvic obliquity, such that the axis of the trunk cannot be brought perpendicular to the transverse axis of the pelvis, an equalization of leg lengths will result in imbalance of the trunk, and some modification of that goal will be necessary. Adduction and abduction contractures of the hips produce infrapelvic obliquity with apparent and functional leg length discrepancy (87).

Weakness and the need for bracing must be assessed, because leg length discrepancy in patients with paralysis or weakness is usually best handled by undercorrection, leaving the weak leg short to facilitate swing-through, particularly if the leg is braced with the knee locked in extension. Patients who require bracing of the short leg to walk can have their leg length discrepancy corrected in the brace and may not require surgical correction at all.

Finally, the concerns, compliance, and emotional state of the parents and patient must be taken into account. This aspect is particularly important when lengthening is being considered, because this is a long and difficult process requiring understanding and cooperation by all. In spite of excellent education and preparation, parents and patients always underestimate the challenge of dealing with duration of lengthening and for later restriction of activities. If there is a lack of understanding or a suggestion of poor compliance, then another approach may be more appropriate. The surgeon constantly must be aware that patients frequently express concerns about function when they are concerned actually about cosmetic effect, which may be less important when compared with the risks of surgery.

Radiologic Assessment

Leg Lengths

Several methods exist for the radiologic measurement of leg length. These methods are more accurate than clinical methods, but each has its advantages and disadvantages. The nonexistent ideal method allows the hip and ankle to be viewed, minimizes radiation, uses only one exposure, uses a film of convenient size, demonstrates angular deformity, has no magnification, gives true readings from a scale on the film, and is inexpensive.

The bony landmarks used are the top of the femoral head, the medial femoral condyle, and the ankle. The ankle mortise is slightly saddle-shaped, and the midpoint of the saddle can be easily identified. Although these techniques allow the measurement of the femur and tibia individually, these values are not required in analyzing and predicting growth, and the length of the entire leg suffices.

The surgeon cannot rely on measurements recorded in the patient's record, but must review all films before performing surgery to check their accuracy and reliability. There is the possibility that films taken over the years have been read by different people using different techniques and landmarks. It is also possible that the scales have been misread or that arithmetic errors have been made in determining lengths and discrepancies.

There are four radiologic techniques that measure leg lengths directly, and others that provide useful information. The terminology is confusing, because names used for these techniques are inconsistent in the literature and in use. The term “scanogram,” for example, was derived from the technique of split scanography, in which the x-ray beam was tightly collimated to a thin transverse slit that exposed the film, as the x-ray tube was moved from one end of the leg to the other. The principles are more important than the terminology.

The teleoradiograph (Fig. 28-18) is a single exposure of both legs on a long, 35 × 90 cm (14 × 36 in.) film. It is taken from a 2-m (6-ft) distance, usually with the patient standing and a radiopaque ruler placed on the cassette. It has the advantages of showing angular deformities and using a single exposure, but produces a film that is inconvenient to handle and measurements that are subject to magnification, because of parallax of the x-ray beam. There is no significant difference between

measurements of the leg taken supine and those taken standing (88).

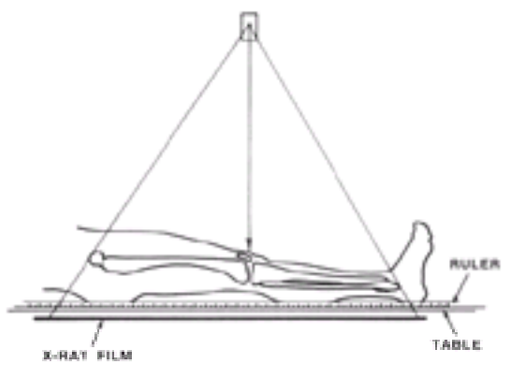

FIGURE 28-18. The diagram of teleoroentgenogram technique reveals angular deformity, but is subject to errors of magnification. It is probably the best technique for children who cannot reliably comply with instructions to remain still for multiple exposures.

The orthoradiograph (Fig. 28-19) avoids the magnification factor by taking separate exposures of the hip, knee, and ankle, so that the central x-ray beam passes through the joints, giving true readings from the scale (89). The film is still cumbersome, however, and the need for multiple exposures introduces the risk of error, because of patient movement.

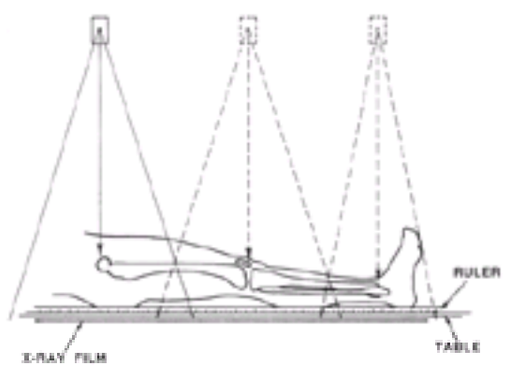

FIGURE 28-19. The orthoroentgenogram technique exposes each joint individually, thereby ensuring that the x-ray beam through each joint is perpendicular to the x-ray film, thereby avoiding errors of magnification.

The scanogram (Fig. 28-20 and Fig. 28-21) avoids magnification in the same way, but reduces the size of the resulting film by moving the film cassette beneath the patient between exposures (90). This technique is preferred in children over the age of 5 or 6 years who can be compliant with instructions not to move, because it gives true measurements without magnification, but younger children are better assessed using the teleoradiograph.

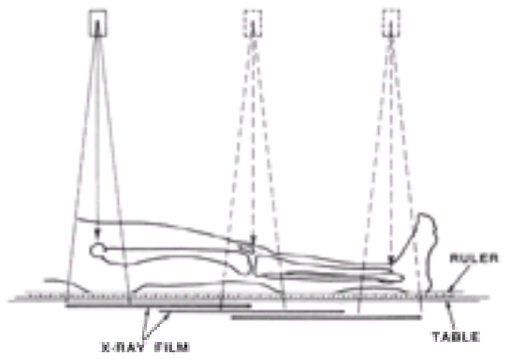

FIGURE 28-20. The scanogram technique avoids magnification error in the same manner as does the orthoroentgenogram, and is the preferred technique for children who can remain still for three exposures.

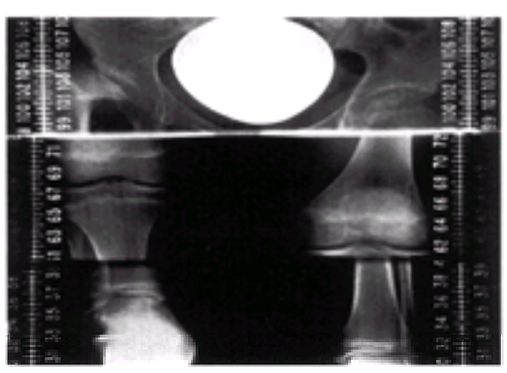

FIGURE 28-21. Scanogram technique allows the images of the three joints to be captured on a film of convenient size by moving the film beneath the patient between exposures.

Positioning for the scanogram must be modified for patients with contractures of the hip or knee. Patients with hip flexion contractures can have accurate measurements made in the reclining position. In those with only knee contractures, the femur can be measured in either the lateral or prone position, and the tibia in the lateral position. Assessment of both bones can be performed on one x-ray film in the lateral position, if two rulers are used, one parallel to each bone. If a hip contracture is also present, the femur must be assessed in the lateral position. The scanogram of both femur and tibia can be done in the lateral position.

Digital radiography is promising in the measurement of leg length (91,92). Computed tomography can be used to measure the distances between points on the film, and errors from angular deformity are reduced (93). If the examination is done specifically for this purpose, multiple sections are unnecessary, the radiation exposure is less, especially with microdose techniques (94), and the cost is comparable to more traditional techniques (94,95 and 96).

Whatever technique is used, it is important to be consistent and, when analyzing data to determine the timing of surgery, not to mix true and magnified measurements.

Because errors are possible with all of these techniques, the resulting measurements should be compared with, and should correspond with, the clinical measurements.

An anteroposterior standing film of the pelvis and hips, taken with the legs straight (on blocks if necessary), is occasionally useful in assessing the combined effect of leg length discrepancy, angular deformity, and asymmetry of the foot and pelvis, because it more closely approximates the functional discrepancy. The leg length discrepancy is calculated from the heights of the femoral heads from the floor taking into account the height of the blocks. This assessment can supplement the clinical examination done with blocks.

It is important for the surgeon to integrate all the information from the various methods of measuring leg length in preparing a treatment strategy.

Skeletal Age

All methods of estimating skeletal age involve comparing radiographs of the patient with standards in an atlas. Methods have been described for using the bones of the pelvis and hip, the knee, and the hand and wrist (98,99). The estimation of skeletal age is only moderately accurate, and is the weak link in the techniques of analysis and prediction of growth.

The Greulich and Pyle method is used universally in this context. Their atlas (20) consists of reproductions of radiographs of the left hand and wrist of boys and girls that were considered typical for the stated skeletal age. To estimate the skeletal age of the patient, a radiograph of the left hand and wrist is taken according to the technique described in the atlas, and this film is then compared with the standard radiographs of the appropriate gender, according to qualitative (e.g., the visibility of the hook of the hamate) and quantitative (e.g., the degree of conformity of an epiphysis to its metaphysis) criteria. The standard that most closely matches the patient's radiograph is taken as the skeletal age.

This technique has certain deficiencies. The first is that, in some parts of the atlas, the standards represent skeletal ages that are far apart, with a gap as great as 14 months. There is, therefore, a large standard error built into the technique. With practice, it is possible to interpolate between standards, but this practice is difficult, and studies have shown significant interobserver and intraobserver errors (100). A second problem is that some children do not follow the same orderly succession of maturity indicators shown in the atlas, and an arbitrary choice must be made in assigning a skeletal age. Third, some children with leg length discrepancy of congenital origin also have congenital anomalies of the hand and wrist, making it impossible to reliably compare their radiographs with the standards. Finally, one of the features of almost all skeletal age atlases is that the mean skeletal age of a sample of similarly aged children is equal to their chronologic age, so that the skeletal age is, in fact, the best possible predictor of chronologic age. That is, of a random sampling of boys or girls of the stated chronologic age, half would be more developed and half would be less developed than the standard radiograph. Greulich and Pyle, however, in selecting standards for their atlas, did not follow this principle exactly, and in some cases, selected radiographs that they believed were more representative. It is important to note that Green and Anderson used the Greulich-Pyle standards in their leg length studies.

The Tanner-Whitehouse method (101) is similar in that it uses radiograph of the hand and wrist, but was developed using modern computerized mathematical procedures. It adds a level of refinement and accuracy to the Greulich-Pyle technique, by defining and showing examples of successive stages of development of 20 specific bony landmarks in the hand and wrist (Fig. 28-22). The same standards are used for boys and girls. The patient's radiograph is compared with the standards, and a letter score is assigned to each of the 20 landmarks. The letter score is then converted to a numeric score by consulting a table for the appropriate gender. The sum of these 20 scores represents the level of skeletal maturity attained by the patient, and can be converted to years and months with a much smaller standard error than with the Greulich-Pyle technique. Of special interest in dealing with leg length discrepancy is that the bony landmarks can be divided into two groups. Tanner and Whitehouse provide tables for including either the 12 longbone standards of the hand or the eight cuboid bone standards of the wrist in the assessment. When these two approaches give different results, it is reasonable to assume that the long-bone standards give a skeletal age that is more pertinent to the growth of the long bones of the leg. The concept that the long bones are more important than the cuboid bones, in the context of leg length discrepancy, can be useful even with the Greulich-Pyle atlas in allowing the resolution of difficulty in selecting the appropriate standard for a given radiograph.

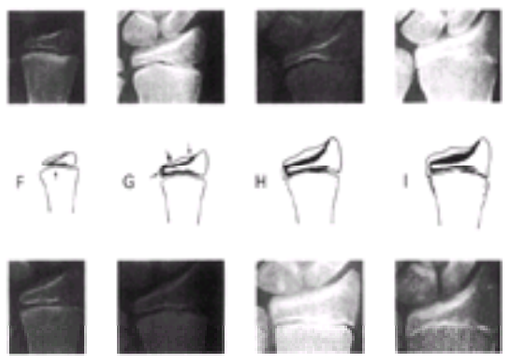

FIGURE 28-22. The Tanner-Whitehouse atlas provides standards like this for twenty different landmarks in the hand and wrist. This technique allows the determination of skeletal age to an accuracy of months, but is not consistent with the Greulich-Pyle atlas. (From ref. 100, with permission.)

There are two areas of difficulty with this method. The first is that it is more cumbersome and time-consuming than the Greulich-Pyle method, and the second is that it has not been correlated with leg length, and cannot be used by orthopaedic surgeons in the analysis of growth. Tanner-Whitehouse skeletal age cannot be used with the Green and Anderson data derived from the Greulich-Pyle method, because these two methods give different skeletal ages. This is surprising, and probably is related in part to the fact that different populations were used to develop the standards.

The relation between skeletal age and leg length, although reliable, is not as reliable as one would like it to be, and the relative inaccuracy of skeletal age estimation must be accepted. It is still possible to make acceptably accurate predictions.

DATA ANALYSIS

The adult with leg length discrepancy, who has no future growth and no possibility of a changing discrepancy, presents no need to analyze data. The growing child, on the other hand, whose legs may be growing at different rates, and whose discrepancy may be changing, presents another level of difficulty. The treatment goal must be chosen with respect to the discrepancy that would be present at maturity, and not the present discrepancy; therefore, before performing surgery, the orthopaedic surgeon must be able to predict the situation at maturity. The importance of proper data analysis cannot be overemphasized. Blair and associates (102) reviewed 67 epiphysiodeses, and found that correction to within 1 cm had been achieved in only 22 cases, and 35 failures occurred, because of incorrect use of the Green and Anderson data.

Three methods are useful in analyzing leg length data: the growth-remaining method, the arithmetic method, and the straight-line graph method. These methods differ significantly in their convenience, complexity, and accuracy, but the analysis moves through the same stages in all three. The first stage is the analysis of past growth, including the determination of the present discrepancy, and depending on the method, the growth percentile and the growth inhibition. The second stage involves the prediction of future growth, including the lengths of the legs and discrepancy at maturity. The third stage is the prediction of the effects of corrective surgery.

All three methods have their place in the armamentarium of the orthopaedic surgeon. All require good understanding of the principles of growth and their methodologies, to be used properly without error. The three methods are discussed here in general terms, and step-by-step instructions for their use are shown in Figure 28-23, Figure 28-24, and Figure 28-26. Included in those charts are examples of their use in a specific case. It should be noted that the arithmetic method and the growth-remaining method are designed solely to arrive at the correct timing of epiphysiodesis, whereas the straight-line graph method provides a general description of growth, and also provides for the prediction of future growth.

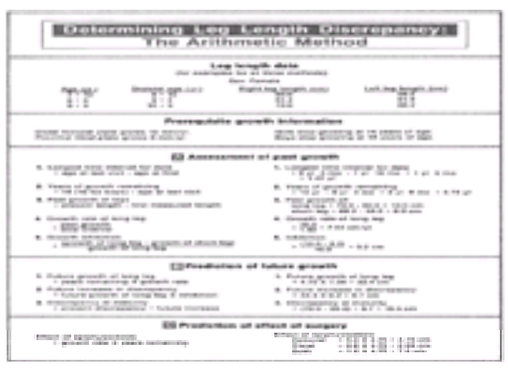

FIGURE 28-23. Step-by-step instructions for use of the arithmetic method. The method presented here is modified from that presented by Menelaus and Westh, in that the future increase in discrepancy is calculated from past growth instead of being assumed to be 0.125 inch per year of growth remaining. An example is shown in the panels in the right column.

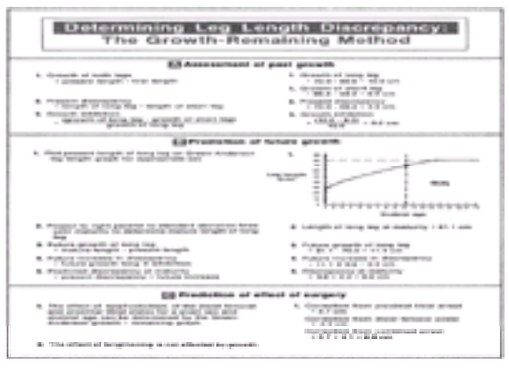

FIGURE 28-24. Step-by-step instructions for use of the growth-remaining method. An example is shown in the panels in the right column, using the same data as in the example in Figure 28-23.

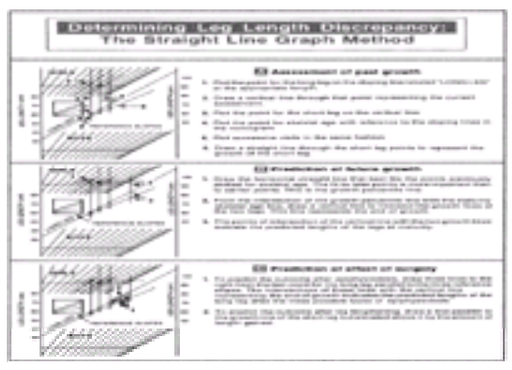

FIGURE 28-26. Step-by-step instructions for use of the straight-line graph method. The data used are the same as in the example in Figure 28-24.

The accuracy of all methods depends to a degree on the nature of available data. The calculation of growth inhibition, for example, is more accurate with data over longer intervals. It is the interval over which data is collected, and not the number of visits that is important, and data should be gathered for at least 1 or preferably 2 years. Minor errors in measurement over a short time can lead to major errors in estimating the growth inhibition, and consequently, major errors in predicting the discrepancy at maturity. A greater number of visits can be useful in recognizing values that are in error, because they do not fit the pattern established by other visits. For example, one erroneous radiographic reading can be noticed in a group of other, valid, points but can be missed if the patient makes only one or two visits. The straight-line graph is the only one of the three methods that uses all available skeletal ages, and in that method the accumulation of more skeletal age estimates diminishes the errors in single estimates.

Arithmetic Method

The arithmetic method was first described by White, and more recently evaluated by Menelaus and Westh (103,104). It is a method designed solely to manage discrepancy and determine the timing of epiphysiodesis, and not a general method to describe growth. Menelaus intended the method to be based on measurements of discrepancy by blocks, and not on measurements of leg length (105). Although the method uses calendar age and not skeletal age, Menelaus suggests that it only be used in children whose skeletal and chronologic ages are less than a year apart, rendering moot the question of calendar versus skeletal age (105).

It depends on the following statements, all of which are first approximations of the true growth pattern described by Green and Anderson.

Girls stop growing at the age of 14 years.
Boys stop growing at the age of 16 years.
The distal femoral plate grows 10 mm ($^3/_8$ in.) per year.
The proximal tibial plate grows 6 mm ($^1/_4$ in.) per year.
The discrepancy increases by 3 mm ($^1/_8$ in.) per year.

These approximations are reasonably good during the last years of growth, but are inaccurate in young children. The statement that the discrepancy increases by $^1/_8$ in. per year is obviously not true in all cases. It is, however, fairly accurate in those children who are in the last few years of growth, whose discrepancies began at birth, whose maturation is not significantly advanced or delayed relative to their chronologic ages, and whose discrepancies are within the clinical range for epiphysiodesis.

Its most significant advantage is its convenience, because no special tools are needed for its use. It is easiest to use with English measure rather than metric. Its disadvantages are that it uses chronologic age rather than skeletal age, and is therefore subject to error in children who grow and mature very early or very late. It uses an approximation of the growth curve rather than the growth curve itself, and is increasingly inaccurate in young children. If, however, its use is restricted to determining the timing of epiphysiodesis, and is applied only to the patients described earlier, then good results can be anticipated, as have been reported by Westh and Menelaus (104). Step-by-step instructions for the use of this method are shown in Figure 28-23.

Fries also has published straight-line approximations to the growth-remaining graph, in which the remaining growth in the epiphyses of boys and girls is determined by first-order equations using skeletal age, but this approach lacks the simplicity of the arithmetic method (64).

Growth-remaining Method

The growth-remaining method is based on the data and tables of growth that Green and Anderson published in their two studies (16,17). These studies are, to the author's knowledge, the only good studies published relating leg lengths to chronologic and skeletal age, and serve as the foundations of the more accurate methods of analyzing growth. Their graphs describing the lengths of the legs of boys and girls, related to age, can be used to determine the growth percentile of the child and the future growth of the long leg. Their graph showing the growth remaining in the distal femur and proximal tibia can be used to predict the effects of epiphysiodesis (106) (Fig. 28-7).

The advantages of this method are that it uses skeletal age, is based on an accurate description of the growth pattern, takes into account the child's growth percentile in predicting future growth, and has been demonstrated to be accurate over decades of use. The disadvantages are that it requires the availability of the two sets of graphs, does not take into account the growth percentile in predicting the effect of epiphysiodesis, and, because it uses only the most recent skeletal age estimation, it will be in error to the extent that the skeletal age estimate is in error. An inherent hazard of this method is that the growth-remaining graph is so familiar and easy to use that the unwary are tempted to correct the present discrepancy in a growing child, neglecting the steps that involve the prediction of future change. Step-by-step instructions for the use of this method are shown in Figure 28-24.

Straight-line Graph Method

The straight-line graph method initially was devised as a method of presenting the relative growth of the legs in a clear, graphic, fashion (Fig. 28-25). By incorporating the data of Green and Anderson (17), it evolved into a method of recording, analyzing, and predicting growth (107,108). The method is based on two principles: the growth of the legs can be represented graphically by straight lines, and a nomogram can be used to determine the growth percentile from the skeletal age and leg length.

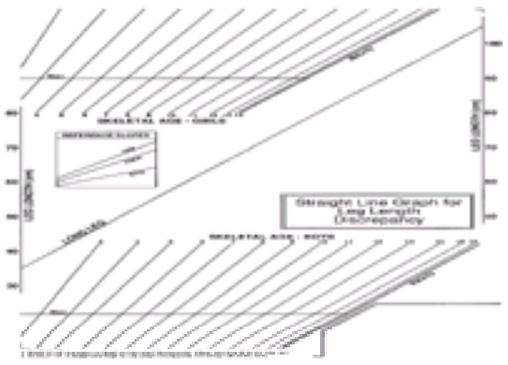

FIGURE 28-25. The straight-line graph comprises three parts: the leg length area with the pre-defined line for the growth of the long leg, the areas of sloping lines for the plotting of skeletal ages, and reference slopes to predict growth following epiphysiodesis.

The representation of leg growth by straight lines appears to contradict the Green and Anderson description of growth, in which the growth lines of the legs are clearly curved. It is accomplished by manipulating the scale of the abscissa (*x* axis), in strict accordance with the Green and Anderson data, so that the curve that disappears from the growth lines reappears as an irregularity of that scale. This curve actually appears on the straight-line graph as a variable distance between the skeletal age lines. The important fact is that the straight line is not an approximation of the Green and Anderson data, but represents the data just as accurately as did their original graphs. In the absence of active disease or treatment, the relative rates of growth of the two legs stay constant, with the result that the growth line of the short leg also follows a straight line on the graph. This means that the length of the leg is represented on the graph by the vertical position of its growth line, and its growth rate by the slope of the growth line. The discrepancy therefore is represented by the vertical distance between the two growth lines, and the inhibition by the difference in slope.

The nomogram for skeletal age allows the plotting of points in a way that relates the length of the patient's long leg to the population and, in a sense, depicts the growth percentile. The nomogram is constructed so that all points, for the child whose growth pattern follows exactly that described by Green and Anderson, lie on a horizontal straight line. In practice, this is rarely the case, partly because of the inaccuracy of estimation of skeletal age, but also in part because of the possibility that children of other races or other genetic stock have different patterns of growth. It is likely that the plotting of every skeletal age point on the nomogram, before drawing the horizontal line representing the growth percentile, “averages out” the inaccuracies of individual determinations of skeletal age. Similarly, the risk of error, due to single estimates of skeletal age, is likely to decrease with an increasing number of estimates.

The straight-line graph facilitates the prediction of the effect of surgery. Lengthening or shortening will be represented on the graph by a vertical shift of its growth line, either upward or downward by the appropriate amount, without any change in its rate of growth. Conversely, the effect of an epiphysiodesis will be to decrease the slope of the growth line of the long leg. This is a strict mathematical relation, and, because the contributions of the individual growth plates to the overall growth of the leg are known, the future slope of the growth line can be predicted accurately. Reference slopes on the graph depict the slopes to be followed after each of the three possible types of epiphysiodeses: distal femoral, proximal tibial, or both. For example, the slope of the growth line of the leg, following a proximal tibial epiphysiodesis, will be reduced to 73%, having lost the 27% normally contributed by that epiphysis. Because the unoperated long leg is defined on the graph as having a slope of 1.0, the slope following that surgery would be 0.73.

The advantages of this method are that it uses skeletal age and the actual growth pattern described by Green and Anderson, takes into account the growth percentile in predicting future growth and the effect of surgery, minimizes errors due to the inaccuracy of skeletal age estimation, facilitates the flagging of erroneous values, and avoids arithmetic errors (109). It is a general tool for analysis, illustration, and prediction in leg length discrepancy, and can be used in children with large discrepancies and inhibitions, extreme growth percentiles, and marked delay or advancement of maturation. Step-by-step instructions for the use of this method are shown in Figure 28-26.

Patterns of Inhibition

In all three of the preceding methods, the growth inhibition is determined on the basis of past growth, and is then used to predict future growth. Evidence supports the assumption that the growth inhibition will remain constant throughout the growing years (110). Indeed, in the author's study of patients who went on to have epiphysiodeses, the linear correlation coefficient between the lengths of the two legs was greater than 0.955 in every case (107,108). This is an extremely close fit, and suggests that growth inhibition does indeed remain constant. It should be noted, however, that no children in this group had active disease, or were under treatment that could affect growth.

Shapiro reported different patterns, and has also reported that the growth rate of the femur tends to increase, and that of the tibia tends to decrease, following a lengthening procedure (111). This effect is relatively short-lived, and is not of sufficient magnitude to affect clinical decisions. Koman and colleagues have demonstrated constant inhibition in unilateral and bilateral proximal focal femoral deficiency (112), and Hootnick and associates have shown constant inhibition in congenitally short tibias (113).

The important question for the orthopaedic surgeon concerns the possibility of errors in correction because of changing inhibition. Does changing inhibition cause clinically significant errors in clinical judgment? A partial answer can be derived from the author's study, mentioned earlier, in which the inhibition appeared not to change and the straight-line graph predicted the final outcome within 1 cm in all cases. This suggests that, whatever effect changing inhibition has, it is not sufficient to prevent reaching predictions of future growth that are sufficiently accurate for good clinical results.

Inadequate Data

There are certain situations in which patients present late, it is suspected that the time for epiphysiodesis is imminent, and there is insufficient time to accumulate sufficient data for accurate assessment and prediction. In some cases, it is still possible to make reliable assumptions about the growth pattern that allow accurate

prediction and confident treatment planning.

Consider the situation in which a child presents without any prior data, and the only information available is from that particular visit. The difficulty here is that it is impossible to calculate the growth inhibition, and to predict the discrepancy at maturity. If, however, the onset of the growth inhibition can be determined, it may be assumed that the legs were of equal length at that time. The length of the long (and therefore the short) leg at that time can be estimated by using either the Green and Anderson growth graph or the straight-line graph, and the growth inhibition can then be calculated in the usual way. Likewise, in the case of a congenital discrepancy, with inhibition beginning before birth, it can be assumed that the legs were of equal length when there was no length or, in other words, that the growth inhibition is equal to the percentage difference in the length of the legs. This assumption is consistent with the conclusion of Herron and associates (114).

At times, an opinion is sought on the basis of leg length films without skeletal age films, when the patient is not immediately available to obtain them. In this case, the child's chronologic age can be used in place of the skeletal age, and this approach is validated if the development of secondary sexual characteristics and menarche are consistent with the chronologic age. Little et al. have suggested, in fact, that chronologic age is as accurate as skeletal age in determining the timing of epiphysiodesis, but their study eliminated several patients on the basis of skeletal age, and dealt with a select population (115). In the author's view, a surgeon should not base the timing for epiphysiodesis on chronologic age, and should take this approach only as a rough guideline.

In certain patients with remote disease that is no longer active, no continuing growth inhibition or accentuation exists. Patients with leg length discrepancy due to stimulation from fracture healing or osteomyelitis, or with shortening due to fracture malunion that is more than 2 years old, can be confidently assumed to have a static discrepancy. The discrepancy at maturity therefore will be the same as at present, and attention can be directed at correcting the present discrepancy.

Patients with complete destruction of one physis caused by trauma or infection can present with an early minimal discrepancy but significant inhibition that, with growth, will certainly lead to a greater discrepancy requiring treatment. In some cases, these children can be treated with an epiphysiodesis of the corresponding plate of the other limb. This plan does not correct the discrepancy, but ensures equal inhibition in both legs, and an unchanging discrepancy throughout growth.

Sometimes no such assumptions are reasonable, and a decision reliable enough to undertake surgery cannot be made. In these cases, it is best to abandon the possibility of epiphysiodesis, and wait until maturity, when the discrepancy can be corrected without error by shortening or lengthening.

DETERMINATION OF TREATMENT GOALS

The choice of the goal of treatment and the choice of the treatment method are two different and independent steps in the treatment of patients with leg length discrepancy, and are discussed separately here. The selection of the treatment goal depends heavily on the careful and thorough assessment of the patient, both clinically and radiologically, and the reader is referred to the earlier sections on patient assessment.

Equal Leg Lengths

Many patients who have leg length discrepancy as an isolated problem, such as those with hemiatrophy, present no difficulty in the choice of treatment goal. Leg length equality at maturity is the appropriate goal.

Unequal Leg Lengths

Many patients do best with less than complete correction. Undercorrection of 1 or 2 cm is best for patients with paralysis of the short leg. The residual discrepancy facilitates clearing of the floor by the weak short leg during the swing phase of gait, and this is even more important in patients who wear braces and have the knee locked in extension, in order to ambulate. In patients who cannot walk without braces, the leg length discrepancy usually can be made up in the brace, and corrective surgery may not be indicated.

Level Pelvis

Patients with leg length discrepancy often have asymmetry that extends beyond the legs. Patients with congenital shortening, for example, may have a small foot or hemipelvis, and in these cases, perfectly equal leg lengths result in residual pelvic obliquity and tilting of the lumbosacral joint. A similar situation can arise in patients with leg length discrepancy from avascular necrosis of the femoral head, following treatment of congenital dislocation of the hip, who have also had an innominate osteotomy. These patients should be examined standing with blocks beneath the short leg to relate the desired correction to the leg length discrepancy. The treatment goal can be modified as required.

Vertical Lumbar Spine

Patients with fixed obliquity of the lumbosacral junction cannot achieve a level pelvis and a vertical lumbar spine at the same time. Usually, a vertical lumbar spine and good balance of the spine are more important than a level pelvis, and treatment of the leg length discrepancy should be consistent with the more important goal. It is interesting to consider the possibility that such a patient could benefit from lengthening of the already long leg, if the pelvic obliquity were greater than the leg length discrepancy.

Equalization by Prosthetic Fitting

Some discrepancies are too great to be considered for correction. The traditional guideline has been that femurs less than half of the length of the other side, and legs that are destined to be more than 15 cm short, are candidates for prosthetic fitting. This is often done in conjunction with other procedures, including knee fusion, Syme amputation, and Van Nes rotationplasty. Modern advances in lengthening have led to the hope that one is more proficient at correcting very large discrepancies, with acceptable morbidity (116, 117). It is the author's opinion that some discrepancies, up to 20 cm, are reasonable candidates for correction by a variety of combined simultaneous or staged shortening and lengthening procedures, but there is no reason for wholesale abandonment of the traditional guideline.

Correction of Coexisting Problems

The treatment plan must include those intermediate goals that are prerequisites to surgical treatment of the leg length discrepancy itself. These intermediate goals can include stabilization of unstable joints, release of contractures, correction of angular deformity, correction of spinal deformity, completion of partial growth arrests causing angular deformity, and excision of bony bridges, in an attempt to restore growth.

TREATMENT

General Principles

In general, it is wise to correct coexisting deformities before undertaking correction of the leg length discrepancy. There are two reasons for this. The deformity can adversely affect the outcome of the leg length discrepancy correction, or vice versa. The other reason is that the correction of some deformities affects the treatment goal. The correction of angular deformity of the limb usually increases the length of the leg, and the correction of spinal imbalance often changes pelvic obliquity and the desired amount of correction of leg length.

The choice of treatment method is more dependent on the magnitude of the predicted discrepancy at maturity than it is on its etiology. Fairly straightforward guidelines, expressed in terms of the magnitude of the predicted discrepancy, can be used to choose from among the major treatment categories:

0 to 2 cm:	No treatment
2 to 6 cm:	Shoe lift, epiphysiodesis, shortening
6 to 20 cm:	Lengthening, which may or may not be combined with other procedures
>20 cm:	Prosthetic fitting.

There is some flexibility in these guidelines, to account for factors such as environment, motivation, intelligence, compliance, emotional stability, patient and parent wishes, and associated pathology in the limbs.

There are good reasons for the values of these thresholds. It has been shown that discrepancies of less than 2 cm are of no functional or clinical consequence in adults, and do not require treatment (118). Indeed, Rush and Steiner found leg length discrepancy in 71% of new recruits into the United States Armed Forces (119). Because there is some advantage to being tall (120,121,122 and 123), lengthening procedures are often preferred by parents and patients, but lengthening is not generally done for discrepancies less than 6 cm, because there are other alternatives. The high morbidity and complication rate of lengthening should be avoided, in favor of epiphysiodesis or shortening, whenever possible. Because these alternatives are reasonable for corrections of up to 6 cm, they are the procedures of choice. Shortening procedures are usually not appropriate for correction of greater than 6 cm, because a disproportionate appearance results that is not pleasing to the patient. It should be noted that epiphysiodesis can be performed to correct a discrepancy of any magnitude, in cases in which the long leg is clearly the abnormal leg, because it corrects the abnormally long leg and does not result in abnormal proportions in these patients. It is reasonable to consider patient preference for lengthening over shortening only in the 5 to 6 cm range of correction, because there are overriding considerations outside that range.

The site of correction is chosen to leave the patient as symmetric as possible with knees as level as possible. This involves lengthening the shortest bone or shortening the bone corresponding to the shortest bone on the other side. This principle can be ignored in some cases of correction by epiphysiodesis, in which a single plate is arrested, to reduce the magnitude of surgery and risk of problems, although a combined femoral and tibial epiphysiodesis might produce the most symmetric result. It also can be ignored if more time for data gathering allows a more confident prediction of future growth and a more dependable treatment plan. Symmetry of knee height is a secondary consideration to equality of leg length. Knee height is not a factor in function or comfort, and is not very important in cosmesis.

Shoe Lift

A shoe lift is excellent treatment for discrepancies up to 6 cm. It is believed to be less desirable than surgical correction of the discrepancy, but is a satisfactory answer for those patients who do not wish, or are not appropriate for, surgery. The shoe lift is only effective when the patient is walking or is in two-legged stance, and is only prescribed for its benefit on gait.

No lift is required for discrepancies less than 2 cm. For larger discrepancies, the height of the lift should be less than the discrepancy. For reasons of cosmesis, up to 2 cm of the lift can be put inside the shoe, with the remainder, if necessary, on the outside. Lifts higher than 5 cm are poorly tolerated, because the muscles controlling the subtalar joint are not strong enough to resist inversion stress, and frequent ankle strains result. If a higher lift is required, an orthotic extension up the posterior calf can be added for stability. The optimum height of the lift can be determined by clinical trials in which the lift height is temporarily modified to suit the patient. Liu et al. found that the benefit provided by a heel lift, insofar as it affects the symmetry index, is unpredictable (3).

Prosthetic Fitting

Prosthetic fitting, often in association with amputation, is a treatment of last resort, but is useful for those patients with very large discrepancies and those with deformed and functionally useless feet (124,125). Discrepancies anticipated to become greater than 15 to 20 cm, and those involving a femoral length less than 50% of the other side, should be treated in this way (35). This approach has the significant advantage of involving one hospitalization and one definitive operation. Patients with fibular hemimelia and an unstable ankle do better with this approach than with multiple hospitalizations and surgical procedures in a futile attempt to conserve the foot; the latter situation usually results in late amputation, which is then more difficult to accept.

Children with below-knee amputations, such as those amputated for fibular hemimelia, do very well functionally. They have an almost normal walking gait and can participate in recreational and sporting activities. Children who are treated for proximal focal femoral deficiency require above-the-knee prostheses, and function well, although not as well as the former group. Some of the latter can function as below-the-knee prosthesis wearers following a Van Nes rotationplasty, in which the reversed ankle functions as a knee, providing active control and motor power to the prosthetic knee (126).

Although the decision to do an amputation is difficult for the parents of a young child, the children who do best are those who have their surgery and prosthetic fitting early in life. The optimum time for the Syme amputation is toward the end of the first year of life, and for the rotationplasty, at about 3 years of age. It is helpful for parents of children who are candidates for these procedures to see older children who have had the same procedure, and to talk with their parents.

Epiphysiodesis

Epiphysiodesis has very low morbidity and a very low complication rate, and is the treatment of choice for the surgical correction of leg length discrepancy (19,103,127,128). The operation is effective by slowing the growth rate of the long leg and allowing the short leg to catch up. In planning for this procedure, therefore, it is necessary to take into account the ability of the short leg to catch up, by using the growth inhibition to predict the discrepancy at maturity. For all surgical treatments of leg length discrepancy, it is the discrepancy at maturity that should be corrected, and not the present discrepancy in a growing child. Epiphysiodesis is a highly acceptable procedure, because it is straightforward, does not require postoperative immobilization, and disables the child minimally and for short duration. It is only suitable for those children who have sufficient leg length data to enable a confident prediction of the discrepancy at maturity, and who require correction of 2 to 6 cm (129).

Epiphysiodesis is an all-or-nothing procedure that completely and permanently arrests physeal growth. Thereafter, the leg grows at a slower rate, having lost the contribution to growth of the operated physis. The loss is 27% for the proximal tibia plate, 38% for the distal femoral plate, and 65% for combined epiphysiodesis of both plates. The surgeon thus induces a known degree of growth inhibition and has before him or her not a continuous spectrum of shortenings, but only three discrete choices. The exact amount of desired shortening can be achieved only by performing the surgery at exactly the correct time. Performing the operation too late results in undercorrection, and performing it too early results in overcorrection. This is in contrast to shortening and lengthening procedures that can be performed at any time.

The prediction of the effect of surgery can be made accurately within 1 cm in almost all cases (107). Because there is an advantage to being tall (120,121,122 and 123), it is better to err on the side of undercorrection than overcorrection. Because slight discrepancies are well tolerated, it is best to aim for 0.5 to 1.0 cm of undercorrection by doing the epiphysiodesis slightly later than the time for perfect correction. It should be done in the bone that is opposite the shortest on the other side, although this principle may have to be compromised if future growth is insufficient for such an epiphysiodesis to be effective.

The principle of the surgery is to produce a symmetric bony bridge that tethers the physis and prevents future growth. The traditional open techniques involve removing a block of bone from the medial and lateral aspects of the plate, extirpating the plate with a curette, and replacing the block of bone in such a fashion as to produce a bony bridge (130). Phemister described removal of a rectangular block, two-thirds on the metaphyseal side and one-third on the epiphyseal side of the plate, and its replacement in the reversed position (Fig. 28-27) **[➥4.19, 6.12]**. White and Stubbins used a special chisel to remove a square block that later was rotated 90 degrees before replacement (128), and Blount used a circular trephine to remove a cylindrical block that was rotated in the same way. Macnicol and Gupta have reported a percutaneous version of the Blount technique (131). All serve to bridge the physis medially and laterally with solid bone.

FIGURE 28-27. In epiphysiodesis by the Phemister technique, a rectangular bone block is replaced in reverse position, to produce a bar across the growth plate.

Blount produced physeal arrest by placing three staples across the physis both medially and laterally, producing a tethering effect resulting in arrest of growth (132,133 and 134) (Fig. 28-28). The rationale was that the arrest was temporary and growth would resume following later removal of the staples (135,136). This concept was attractive, because it alleviated the need to make accurate predictions of future growth. Certain patients, however, went on to fuse their physes while the staples were in place, did not resume growth on their removal, and went on to overcorrection of their discrepancies (137,138). Stapling, therefore, lost proponents, and was considered to be a permanent form of growth arrest. Staples caused problems by extruding, entering the adjacent joint, or causing overlying bursitis (139). Growth arrest was occasionally asymmetrical, and a second operation was sometimes necessary to remove the staples.

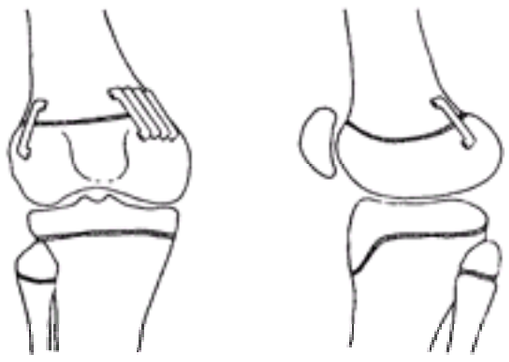

FIGURE 28-28. Epiphysiodesis by stapling. Growth arrest can be accomplished by careful placement of three extraperiosteal staples over the medial and lateral aspects of the plate.

There have been recent reports that it is possible to perform stapling in such a way that growth confidently resumes when the staples are removed (140). The important technical point is to remain extraperiosteal and not directly expose the growth plate.

Traditional epiphysiodesis requires incisions on both the medial and lateral aspects of the knee, for a total of four incisions if both tibial and femoral epiphysiodeses are performed. Canale and others have reported percutaneous techniques developed to avoid unsightly scarring (131,141,142). It is done with a drill or burr, through small medial and lateral incisions, under image intensifier control. This technique has gained wide acceptance, and is considered by most to be the technique of choice. Great care must be taken to line up the image intensifier beam perfectly to ensure that the tool is in the plate. The percutaneous technique results in a wider excision of the plate, and can be accompanied by excessive bleeding or hematoma formation.

Percutaneous epiphysiodesis **[➥4.20, 6.13]** is usually performed through two incisions, one medial and one lateral. Because the growth plates, particularly the distal femoral, are not perfectly flat, there is a significant technical challenge in making sure that the tip of the tool is in the plate, and that it stays there. Scott et al., for example, reported a rate of continued growth of the physis of 12% (143). In the distal femur, the intercondylar notch intrudes into the posterior aspect of the plate, and the surgeon must be careful not to inadvertently enter the notch by being sensitive to the feel of the tool touching cortical bone. Entering the notch can escape the notice of the operator, because it is not obvious on the anteroposterior view of the image intensifier.

Approximately 50% of the area of the plate should be removed in the pattern shown (Fig. 28-29). This is sufficient to ensure arrest of the physis, and maintains enough bone strength through residual plate and surrounding periosteum and perichondral ring to make postoperative immobilization unnecessary. Tibial epiphysiodesis should be accompanied by arrest of the proximal fibular physis, if the tibial shortening is greater than 2.5 cm (144).

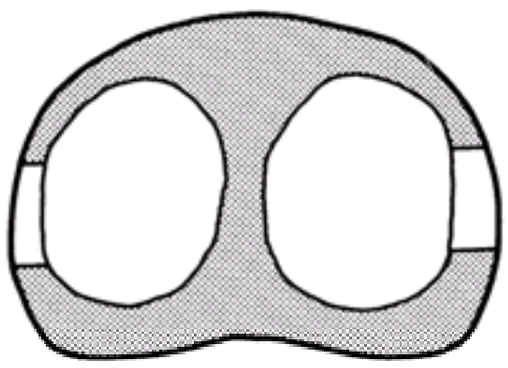

FIGURE 28-29. Area of plate to be removed in epiphysiodesis. Obliteration of medial and lateral circular segments of the plate, leaving the central part and the strong periphery, successfully stops growth, yet the bone retains sufficient strength to forego immobilization.

Epiphysiodesis has significant advantages over other approaches, because of its low morbidity and low complication rate, but there are minor disadvantages (115,146). It is a compensatory, and not a corrective operation, in that it makes the normal leg abnormal. Compared to lengthening, it results in a decrease in the patient's stature that may be undesirable.

Femoral Shortening

Shortening of the femur has the same indications as epiphysiodesis, but is offered to patients who do not meet the prerequisites for epiphysiodesis, either because they are too old or their conditions are such that confident prediction of the discrepancy at maturity cannot be made. It has the advantage over epiphysiodesis that it can be done in the mature patient when the discrepancy is known and unchanging, and the desired degree of correction can be obtained precisely.

Shortening of the tibia also has been performed, but is very rarely done, except in cases in which the femur does not lend itself to shortening. Although shortening of 7.5 cm in the femur and 5 cm in the tibia have been reported with no loss of function (147), it is believed that no more than 3 cm of shortening can safely be achieved in the tibia, and it is unusual to perform shortenings of more than 5 cm in the femur. The risk of neurovascular complications is higher in the tibia, because of the proximity and tethering of neurovascular structures, as is the risk of delayed and nonunion. Fasciotomy is advisable to reduce the risk of compartment syndrome. Internal fixation is more difficult in the tibia: closed techniques cannot be used, because the bone is subcutaneous, and the muscles of the leg are slower to recover strength than those of the thigh.

It is interesting to contemplate the reason for this last factor. The ability of a muscle to adjust to shortening of the underlying bone rests on its ability to remove sarcomeres from the ends of its fibers, until the average length of the remaining sarcomeres regains the normal, which is relatively constant throughout the body. The lengths of the hamstring and quadriceps muscles, crossing two joints, are approximately twice as long as the soleus, but more importantly, there is an even greater difference in the lengths of the fibers within those muscles. The soleus muscle, requiring high strength and short excursion, has a high number of short fibers oriented obliquely, whereas the hamstrings, requiring excursion more than strength, have a smaller number of longer fibers oriented longitudinally. The fiber lengths in any one muscle are relatively equal, and the fiber length in the hamstrings is much longer than the 4-cm length of fibers in the soleus muscle (148). It is not difficult to imagine

that a shortening of the tibia of more than 3 cm might completely overwhelm the ability of the fibers of the soleus muscle to accommodate.

The early techniques of shortening involved making step cuts or other complex cuts in the diaphysis of the bone, using interfragmentary screws or intramedullary rods for fixation (149). These techniques are of historical interest only because better techniques with more secure fixation are now available (150). The two principal techniques in use today are proximal shortening with blade plate fixation, and middiaphyseal shortening, open or closed, with intramedullary rod fixation. Both approaches provide secure fixation, and neither requires postoperative immobilization.

Proximal Shortening

Shortening through the proximal femur at the level of the lesser trochanter with blade plate fixation has the advantage of being proximal to most of the quadriceps origin, and therefore does not disadvantage the knee to the same extent as shortening in the midshaft. Patients recover strength and the ability to climb stairs more quickly. This approach leaves a large scar on the lateral thigh, and requires a second later operation of moderate magnitude, to remove the plate.

Closed Femoral Shortening

Winquist and colleagues have pioneered a technique that involves the use of a special set of instruments designed to allow the procedure to be performed entirely from within the medullary cavity **[➥4.10]** and without any direct approach to the shaft of the femur (151,152). The bone is cut by a special eccentric cam saw, which is passed down the shaft and cuts through the cortex from within. The size of the saw required is determined from the outside diameter of the bone, and the femoral shaft is first reamed to an internal diameter sufficiently large to accept it. The distal cut is made first, and a second cut then is made more proximally, at precisely the correct location to give the desired amount of correction. The cuts should be placed so that the cylindrical fragment is removed from the isthmus of the femur, where the internal diameter is least, because this provides the best fixation to the rod both proximally and distally. The cylindrical piece of bone can be cut into two sections, using a special hook-shaped reverse-cutting osteotome, and the pieces are pushed aside. The gap can then be closed over an intramedullary rod to provide rigid internal fixation. Locking at both ends maintains shortening and rotation. A second operation is later required to remove the rod.

The technical complications of this procedure usually result from less-than-rigid fixation of the fragments, usually due to inadequate reaming without locking. It is apparent, in using an unlocked nail, that if a 5-cm segment of bone is to be removed and 2.5 cm of fixation is desired both proximally and distally, then the bone has to be reamed until 10 cm of the shaft is reamed to the minimum diameter. This in itself can be a problem, because the cortex can become very thin at the level of the osteotomies, especially because the reaming is usually eccentric, and can lead to fracture of the shaft. Less than rigid fixation can lead to loss of rotational control and opening of the shortening gap, two problems that are difficult to control without locking. Less reaming is necessary for a locked nail, but in that case, the reduced internal diameter of the canal may not allow passage of a cam saw large enough to cut completely through the cortex, and a percutaneous osteotomy may be required to complete the cut. Nevertheless, the benefits of control of position with the locked nail far outweigh this disadvantage, and locking is desirable.

Acute respiratory distress syndrome has been reported during or following closed intramedullary shortening, and has been believed to be the result of fat embolization caused by reaming (153). Possible preventative measures include venting of the distal metaphysis and use of reamers with flutes sufficiently deep to allow the unimpeded egress of reamed material, but the effectiveness of these measures has not been demonstrated. It may be wise not to use this technique until this serious complication can be avoided with certainty.

Although this is an appealing technique, it requires familiarity with the instruments, is technically demanding, and has best results in experienced hands. The major disadvantages are the technical complications and risk of respiratory distress syndrome, as noted above, and the significant quadriceps weakness that results. Patients with greater shortening require 6 to 12 months to regain normal knee control and function (154). It leaves a small cosmetically acceptable scar, and the later procedure to remove the rod is of lesser magnitude than that required to remove a blade plate.

Growth Stimulation

A technique is desired to stimulate the growth of the short leg, so that children discovered early to have growth inhibition could have their growth stimulated to normal. Many techniques have been used in attempts to accomplish this, but none has been successful enough to be clinically useful. Based on the concept that the periosteum acts as a tether inhibiting growth, circumferential release of the periosteum has been assessed both clinically and experimentally, and found to stimulate growth (155,156). A variety of foreign materials have been implanted next to the growth plate (157), but the stimulation, if it occurred, was too little and too short-lived to be of use. Sympathectomy (158,159) and surgically constructed arteriovenous fistulae (160,161) temporarily stimulate growth, presumably by altering the circulation to the physis, as does stripping and lifting the periosteum by packing bone beneath it (58,59,162). However, these techniques have little or no clinical usefulness. Electrical stimulation inconsistently stimulates physeal growth, but even the maximum effect is insufficient to correct clinical discrepancies (63).

As desirable as this approach might appear, there is no method of growth stimulation available at this time that is useful in the treatment of leg length discrepancy.

Leg Lengthening

Lengthening an abnormally short leg would, at first glance, appear to be the preferable method of dealing with leg length discrepancy, because it is a corrective procedure. It involves operating on the abnormal leg to correct its abnormality, as opposed to epiphysiodesis and shortening, which make the normal leg abnormal and only compensate for the discrepancy.

Lengthening was first mentioned in the 18th century, in an account of injuries sustained in battle by Ignatius of Loyola. It was next reported by Codivilla at the beginning of the twentieth century (163). A number of advances have been made involving changes in surgical technique or the lengthening apparatus, or both, and each change has been greeted with hopes that it would solve the problems associated with lengthening (164).

Lengthening is a procedure of last resort, and is reserved for those situations in which other methods of correction are inappropriate. Lengthening is usually not appropriate for patients requiring correction of less than 6 cm, because procedures of lesser risk and morbidity can be used. A reasonable goal of lengthening for most patients is less than 10 cm for the femur and 7 cm for the tibia. Patients requiring large corrections may require simultaneous lengthenings of femur and tibia, repeated staged lengthenings of the same bone (165), or supplementary shortening procedures on the long side. There is a threshold, at about 15 to 20 cm, where the risks outweigh the benefits, and lengthening is abandoned in favor of amputation and prosthetic fitting.

Since Codivilla's report there have been many techniques described for lengthening the leg. These have included step cuts (166), periosteal sleeves (167), onlay cortical grafts (168), slotted plates (169), intramedullary rods (170), and other internal and external devices for gradual controlled lengthening (171,172,173 and 174). Transiliac lengthening has been performed (175), and may be indicated in cases of infrapelvic asymmetry and decompensated scoliosis cases requiring concurrent hip stabilization (176,177). Techniques of instantaneous lengthening of the femur (114,150,178,179) and tibia (180) have been reported, but have not gained widespread support, because the amount of length to be gained is limited. Simultaneous shortening of one femur, and lengthening of the other with the excised bone segment from the other side, has been recommended (181,182). The Anderson device, using large pins and an external fixator with threaded rods for lengthening, became widely used, but confined the patient to bed (Fig. 28-30). Some of the older methods persist in nonindustrialized nations, as, for example, double oblique osteotomy followed by elongation by balanced skeletal traction (183). Many of these methods became obsolete with the introduction of the Wagner device and, later, the Ilizarov and Orthofix devices.

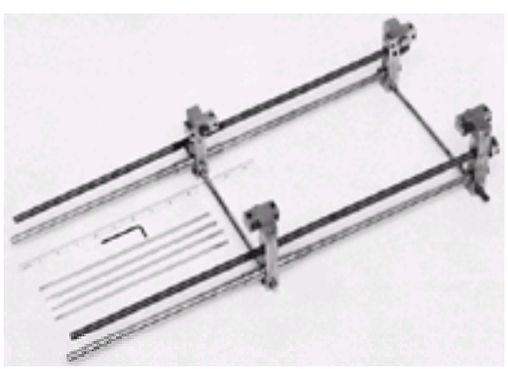

FIGURE 28-30. The Anderson lengthening device was commonly used, until it was superseded by the Wagner device, then by the Ilizarov and Orthofix devices. It accomplished stable fixation and gradual lengthening, but was not appropriate for application to the femur, and confined the patient to bed.

Historically, new lengthening technology has been adopted enthusiastically by the orthopaedic community, and has been used extensively with great optimism. However, the complication rate has remained high and the patient's course difficult, leading to the realization that the human leg has not made similar advances, and lengthening is still a difficult matter for both surgeon and patient.

The surgeon should prepare for an intensive period of education and attention for 2 weeks after the application of the lengthening device, either in or out of the hospital. This allows time for the initial delay, and for the patient and parents to understand and become comfortable with the lengthening mechanism, pin site care, and an exercise program to maintain mobility and attain ambulation with weight bearing. Patients undergoing lengthening as inpatients should be examined daily with respect to blood pressure, neurologic status, and range of motion. The reading from the scale of the lengthener should be recorded daily and checked to be sure that the lengthening is going according to plan. These assessments also should be made at weekly or biweekly visits after discharge. Radiographs are taken at intervals of 2 to 4 weeks to evaluate alignment and the quality of bone in the lengthening gap (i.e., the regenerate). Ultrasonography can be used instead of radiographs to measure the lengthening gap (184,185). The rate of distraction can be modified according to clinical progress or radiologic appearance.

Maintaining motion is extremely important during lengthening. Patients and parents should be instructed in a home exercise program, and range of motion monitored regularly. Stopping the lengthening should be considered, if limitation of motion develops that is resistant to a more intensive motion program. Wagner recommended that distraction should not be performed on any given day if the patient cannot achieve 60 degrees of flexion (186). The author's personal guidelines are to discontinue lengthening of the femur in the face of a knee flexion contracture greater than 10 degrees, or knee flexion less than 30 degrees. Lengthening can be started again, if those guidelines are later met, before consolidation of the regenerate prevents it. There is evidence in the literature that all patients regain flexion in the first year after lengthening (187), and it appears that maintaining extension is more important. Patients are allowed to ambulate full weight bearing, with aids if necessary. The pin sites are cleaned twice daily, and, if necessary, the stab wounds are elongated weekly under local anesthesia, to prevent tenting and ischemia of the skin, which could lead to pin tract infection. Cutting pins and small wires circumvent the need to release pin sites.

Distraction is discontinued, either when the goal has been achieved or an unresolvable complication (usually loss of motion) supervenes. The device is retained until radiographs show consolidation and suggest adequate strength of the regenerate bone. In the consolidation period, dynamization of the device is considered important, to subject the bone to cyclic longitudinal loading to stimulate bone formation. If the bone in the lengthening gap is slow to consolidate, the device can be shortened to put the bone under longitudinal compression, either leaving it somewhat shortened, or lengthening once again, when the regenerate responds. Valid objective guidelines for what constitutes adequate consolidation for removal of the lengthening device have not been established. Findings such as corticalization, with three cortices visible on two radiographs and the appearance of a medullary cavity, are considered to be signs of adequate strength, but the decision to remove the device is still empiric.

It is possible to protect the tibia externally with a cast or brace after device removal, allowing removal from the tibia earlier than the femur. In addition, the mechanical and anatomic axes of the tibia are collinear, and the bone is subject mainly to compressive forces. This is not the case for the femur, in which the regenerate bone, especially for proximal lengthenings, is eccentric and subject to bending loads. Patients should be restricted from violent body-contact sports for a long time, and perhaps until the bone is radiologically normal, because fractures through the lengthening gap have been reported years later.

Wagner Technique

Wagner developed a lengthening device that was first used in North America in 1973 (Fig. 28-31), and appeared to offer several advantages over older devices, such as the Anderson device (51,186,188,189 and 190) (Fig. 28-30). It is unilateral, and uses half-pins instead of through-and-through pins, thereby facilitating application to the femur. It is small and light, and was the first device to allow the patient to be ambulatory, whereas older devices required confinement to bed. The patient can do the lengthening simply by turning a knob at one end. It is adjustable in varus–valgus and anteroposterior angulation, but not rotation (Fig. 28-31), so that minor angulation that occurs during lengthening can be corrected without removing the pins.

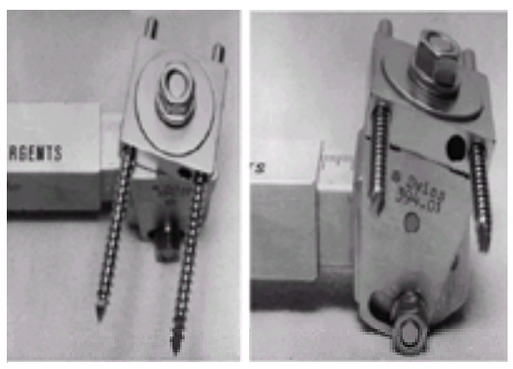

FIGURE 28-31. The Wagner device can be adjusted in two planes, but not in rotation. It allows correction of angulation that develops during lengthening, but does not allow simultaneous lengthening and gradual correction of angular deformity.

The Wagner technique involves at least three surgical procedures. The first involves performing an osteotomy, releasing soft tissues, if necessary, and applying the device. At the end of the lengthening phase, a second procedure involves bone-grafting the lengthening gap, plating the bone, and removal of the lengthener. Months or years later, when the bone has achieved sufficient strength, a third procedure is done to remove the plate. There is a prolonged period of restriction of activities to protect the bone and avoid late fracture.

Although the Wagner device retains its simplicity and utility, it has become clear that it is ill-advised to plate the bone in the face of contaminated pin tracts. For that reason, the technique mostly has been replaced by newer methods that involve neither plating nor grafting, and appear to reduce the complication rate. The device, however, remains simple and satisfactory, and can be used with the newer biologic principles.

Orthofix Technique

De Bastiani and colleagues have developed a lengthening device, the Orthofix device (Fig. 28-32), which is applied to the bone with two sets of conical screws (191,192). It has evolved into a lengthener in which pin blocks move along a rail placed beside the pins (Fig. 28-32). This allows the pin sets to start close together and provides long excursion **[➥4.15, 6.10]**. It allows the use of up to three screws in each set, which is an advantage, especially in the proximal femur. It is technically similar in operation to the Wagner device, but, although it offers more stable fixation to bone, it has a more cumbersome method of elongation, and is not easily adjustable once in place. Good results have been reported with this method with a complication rate similar to other techniques (193).

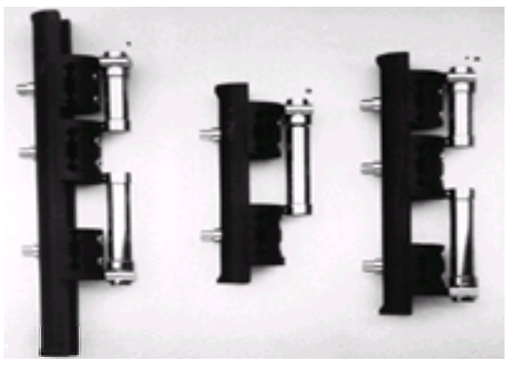

FIGURE 28-32. The Orthofix track lengthening device places the lengthening mechanism beside the pins instead of between them, thereby increasing the excursion and obviating device exchange during lengthening. Like the standard device, it is not adjustable once the pins are in place.

Distraction Epiphysiolysis

Distraction epiphysiolysis was pioneered by Ring, and more recently reassessed by Monticelli and Spinelli and others (194,195,196,197,198,199 and 200). It is achieved by applying a distraction force across the physis until it fractures. Lengthening can then be obtained by gradual distraction. This method has the disadvantages that the lysis is sudden, painful, and not well tolerated, and that the physis can be injured, thus compounding the leg length inequality (201,202). The complication rate is high (203) and, if it is to be used at all, it should be reserved for children very near the end of growth, to minimize the consequences of physeal damage.

Ilizarov Technique

Ring fixators have been developed (198,200,204,205,206 and 207) (Fig. 28-33 and Fig. 28-35) **[➥4.16, 6.9]**. They are more complex than the Wagner and Orthofix devices, but are also more versatile, in that they lend themselves to the correction of complex deformities. They can control more than two segments (209), can extend across joints, and can be used to translate segments of bone in the treatment of congenital pseudoarthrosis and acquired absences (204). Fixation is accomplished by tensioned through-and-through wires attached to complete or partial rings. Unwillingness to use through-and-through wires in the proximal femur has led to the development of half-pins, which are now gaining favor at all levels.

FIGURE 28-33. Ilizarov lengthening device. External fixation is accomplished by tensioned wires fixed to circumferential rings. (From ref. 208, with permission.)

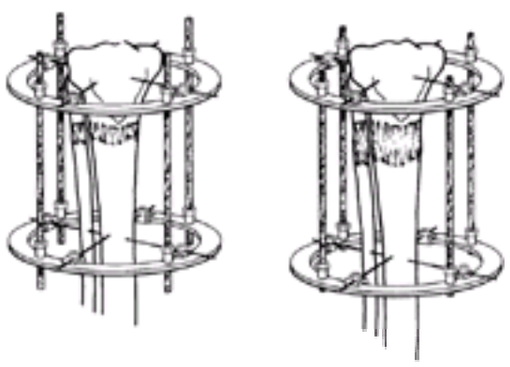

FIGURE 28-35. Metaphyseal lengthening. Elongation through the metaphysis promotes osteogenesis in the lengthening gap because metaphyseal bone is so active, and it promotes strength by the large cross-sectional area.

Lengthening over an Intramedullary Rod

In the traditional application of any of the external lengthening devices, the device is responsible for both maintaining alignment and achieving distraction. Numerous unsightly scars result, because of the multiple percutaneous pins or wires used to achieve sufficient stability, and the fact that they must be left in place for a prolonged period until the bone is strong. It is possible to use an intramedullary rod to maintain alignment during both the distraction and consolidation phases, and the external device only to achieve length (210). In this way, the number of percutaneous tracts can be reduced, the external device can be removed at the conclusion of lengthening, and the complication rate may be reduced (211). Lin et al. reported 2 of 15 cases that required bone grafting (212), so the effect of rodding on osteogenesis remains unclear.

Lengthening over the rod has the disadvantage, compared with other lengthening techniques, that alignment of the anatomic axis of the femur cannot be changed, and that the mechanical axis of the leg cannot be changed. Because the anatomic axes of the femur and tibia are not collinear, elongation in this manner increases valgus of the mechanical axis of the leg. Whether or not this is a problem depends on the initial configuration of the leg. The correction, if necessary, of preexisting angular deformity, or the valgus produced by the lengthening, must be performed at another time, when the rod is no longer in place.

There has been reasonable hesitation in using this approach, because of the fear of producing a serious intramedullary infection with the intramedullary foreign material in continuity with the exterior through the pin tracts. Although early experience suggests that with care the external device need not contact the rod, and that the risk of intramedullary infection is not as great as feared, widespread use of this technique awaits more definitive reports concerning this and other risks. Fully implantable devices would appear to be the solution, and have been used on a trial basis (213), but reports are preliminary.

The application of this technique is limited to those femurs that are straight enough to accept the rod, and, in the case of the femur, children who are old enough not to be at risk for avascular necrosis of the femoral head.

Wu et al. performed acute lengthenings over a locking rod, but achieved a mean lengthening of only 2.8 cm (214).

Biologic Factors

Several groups have been working in parallel over the past three decades to develop not only improved devices, but also improved concepts and methods of lengthening. In particular, Ilizarov and De Bastiani have contributed new concepts and a new understanding of the biology of lengthening that are more important contributions than the devices themselves (191,192,204,205 and 206). Because the biologic principles are not device-specific, they are considered in principle. Then, with that foundation, technologic issues are considered.

Minimal Disturbance of the Bone. Ilizarov recommended corticotomy, a technique in which the cortex is cut, but care is taken not to disturb the medullary contents (Fig. 28-34). He felt it important to preserve the intramedullary blood supply of the bone. It is difficult, however, even with careful technique, to avoid disturbing intramedullary contents, and it has been demonstrated that the intramedullary circulation reconstitutes very quickly, even if interrupted (215). The current consensus is that it is not necessary to perform a corticotomy, but care not to burn the bone with a saw, and care and preservation of the periosteum, are very important.

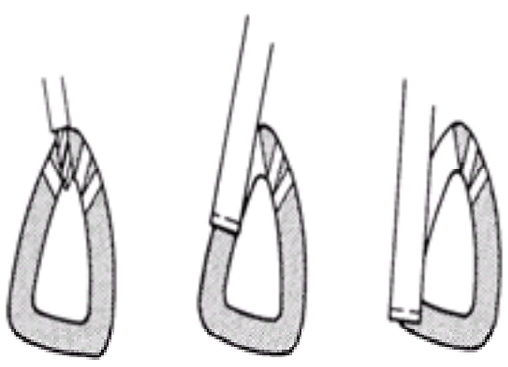

FIGURE 28-34. In the corticotomy technique, care is taken to preserve the contents of the medullary cavity of the bone, so that they may make their greatest contribution to osteogenesis during lengthening. Drill holes of controlled depth are made through the anterior cortex; the lateral cortices are cut with a narrow osteotome to avoid entering the medullary cavity; and the posterior cortex is cracked by bending.

In contrast to the principle of minimal bone disturbance, massive bone production in the lengthening gap, following peripheral decortication near the osteotomy, has been reported (216).

Location of Lengthening. Whenever appropriate, the lengthening is done in the metaphysis, where the bone is more active, and there are greater numbers of active osteoblasts to participate in the process of regeneration (217) (Fig. 28-35). A second benefit of this location is purely mechanical, and is based on the principle that the strength of a structure in bending varies with the fourth power of its diameter. Because the diameter of the metaphysis is so much greater than that of the diaphysis, the bone is stronger at any stage of healing. This allows earlier removal of the fixator, with decreased risk of fracture when subjected to bending loads.

Number of Lengthening Sites. Devices that lend themselves to fixation of more than two segments of the same bone make it possible to lengthen a single bone both proximally and distally at the same time. Although, theoretically, this doubles the rate of bone elongation, the soft tissues do not easily double their elongation rate, and articular cartilage has been shown experimentally in animals to suffer with rapid elongation (218).

Delay before Distraction. It appears beneficial to delay the onset of distraction after the bone-sectioning procedure, in order to allow the osteogenic process to become established. Osteogenesis can then keep up with the elongating gap. Delays of several days for young children, 1 week for adolescents, and 10 days for adults appear appropriate, without risking premature consolidation that would prevent distraction.

Rate of Distraction. Ilizarov and Deviatov (204) recommend a distraction rate of 1 mm/day, which is slower than the 1.5 mm/day used in the Wagner technique. The rationale is that the separation of the bone ends should proceed in advance of the ability of the regenerating bone in the gap to effect union, and that a rate that is too fast will inhibit bone formation. The rate may have to be slowed, if radiographs show inadequate regeneration and a widening lucency in the regenerating bone. Faster rates induce ischemia and significant slowing of osteogenesis, but some patients, who show excellent regeneration radiologically, can have their distraction rate increased. The rate of 1 mm/day also appears to be appropriate for the soft tissues to grow in length in tandem with the bone (219).

Rhythm of Distraction. Increasing the frequency of lengthenings, without changing the rate, promotes faster consolidation experimentally, and reduces the tension stress on the regenerating bone. Lengthening by 0.25 mm, four times per day, is better than lengthening by 1 mm, one time per day, and it appears that gradual continuous elongation, perhaps by a motorized device as suggested by Ilizarov, is ideal.

Quality of Regenerate Bone. Osteogenesis in the gap begins first in the medulla, and expands to fill the gap. Multipotential cells become osteoblasts and form bone without a cartilage foundation in a fashion reminiscent of membranous bone formation. Microscopic examination of the regenerating bone, elongated according to modern concepts, shows that it has a longitudinal orientation, probably because its formation is guided so intimately by the architecture of the osteotomy surface (220). The architecture of the regenerate resembles haversian bone, and is said to be stronger than woven bone, and to remodel and calcify faster.

Thin Wires. The ring fixators allow the use of thin (1–2 mm) wires instead of large screws. The wires cause less reaction of surrounding skin and bone, move through the skin more easily, and allow some axial dynamization of the bone fragments.

Amount of Lengthening. It is not known if there is an upper limit to lengthening. Reports on the new techniques suggest that greater lengthening may be possible than was formerly thought. Carroll et al. have shown that permanent changes occur in muscle and joint cartilage with tibial lengthening greater than 11% (221), and Bell has shown effects on the adjacent joints in animal experiments (218). These effects may be related more to the rate than the magnitude of lengthening, and the degree to which they occur in human patients is uncertain.

Activity Level. Patients can be encouraged to be active and fully weight-bearing from the start, and participate in vigorous calisthenics and physical therapy to maintain normal joint motion and muscle strength. Weight-bearing takes advantage of the flexibility of the devices to apply dynamic compression to the regenerating bone that is believed to stimulate bone formation.

Dynamization. Cyclic loading of the regenerate is thought to promote osteogenesis. The ring fixators have the advantage of allowing dynamic loading of the lengthening gap throughout the period of fixation, while simultaneously controlling length. Their construct of thin wires and circumferential rings provides rigidity against bending in the sagittal and coronal planes, but is not so rigid in the axial direction, allowing slight axial movement in response to applied loads. The Orthofix device can be dynamized by applying an elastic buttress, and when the regenerate bone appears strong enough to resist shortening, the buttress can be removed. The device then maintains alignment, but not length, thus allowing dynamization. The Wagner device cannot be dynamized, but can be put into compression mode when the regenerate bone is strong enough. All of the devices allow some dynamization by virtue of their elasticity, and can be made less rigid by the removal of wires or pins in a staged fashion.

Lengthening Index. This quantity is the number of months of external fixation required per centimeter of lengthening. It is generally between 1 and 1.5 months per centimeter, and tends to be greater for lesser lengthenings, because one component of this time, the interval from the arrest of elongation to the removal, tends to be constant. This number is a very rough guideline to predict the duration of fixation for patients about to undergo lengthening, but is of little clinical importance (222).

Factors Affecting the Choice of Lengthening Hardware

The biologic factors discussed above are, for the most part, device-independent. The choice of lengthening device is not, however, completely arbitrary. The devices have certain characteristics that affect their ease of use in specific situations. Because deformity correction often goes hand in hand with lengthening, this discussion

includes some aspects of device selection and use in the correction of angular deformity

Gradual versus Acute Correction. Not all deformities need to be corrected gradually. There is a long and successful history of acute correction of deformity by osteotomy, with internal or external fixation or no fixation at all. Although there may be advantages in the use of external fixation, in some cases, there appears to be no advantage to correcting these deformities gradually, as Ilizarov et al. have proposed (220,221).

The question then arises as to the possible advantages or disadvantages of gradual correction, if an external fixator is in place in any case to accomplish lengthening. There is good evidence to suggest that, if an external device is already in place for lengthening, either gradual or acute correction of coexisting deformity can achieve good results (223). Acute correction has the effect of simplifying the lengthening and widens the selection of devices, whereas gradual correction with the Ilizarov or other ring fixator allows the physician to monitor and modify the correction on an ongoing basis.

If the surgeon wishes to perform a gradual deformity correction, then the Ilizarov device or another ring fixator, or the Orthofix device with the Garches clamp, can be used. Using the Ilizarov apparatus to perform gradual angular correction, with or without lengthening, requires attention to the geometric principles of hinge placement, as described by Herzenberg (222). Careful hinge placement can control both translation and angular correction. Placing hinges so that the axis of rotation is outside the bone can accomplish lengthening and angular correction simultaneously.

Thin Wires versus Half-pins. The Wagner and Orthofix devices require thick half-pins, whereas the Ilizarov device can be used with either thin wires or half-pins. Thin wires appear to pass through the skin more easily, but leave twice as many unsightly scars in the skin, and tether the muscles in twice as many locations, thereby interfering with joint motion (217). Loosening of a wire does not result in a loss of position, as with a screw, because the bone is prevented from sliding on the wire by other oblique wires at the same level.

On the other hand, thin wires have a number of disadvantages. They do not lend themselves to fixation of the proximal femur, and most prefer half pins and partial rings at that level. There is a growing trend to the use of half pins at other levels as well. Wires must be tensioned to close to their elastic limit, and it does not take much additional force to stretch the wires plastically, which compromises the rigidity of the frame.

Conical Screws. The Orthofix device uses 6-mm pins that taper slightly toward the tip. If they loosen, they can be tightened by advancing them slightly. Conversely, if they are inserted too far, they cannot be retracted without loosening. Screws are also manufactured with cutting edges on one side of the shaft, which, when oriented in the proper direction, facilitate passage through the skin.

Excursion. The standard Orthofix lengthener is limited in its excursion. The short model, for example, has an excursion of only 5 cm, meaning that it will have to be replaced with a longer model, if further lengthening is to be attained. The Orthofix rail lengthener is available in several lengths, and can accommodate any desired excursion. The Wagner device has excursion of more than 15 cm, and can accomplish all but the longest lengthenings. The Ilizarov device has the advantage that its external components can be replaced without general anesthesia, and therefore virtually any amount of lengthening or angular correction can be accomplished.

Ease of Replacement of Pins and Wires. Because the Ilizarov device allows pins and wires to be placed at almost any level and angle, there is no problem in removing troublesome wires and inserting new ones. The monolateral fixators, on the other hand, are more limited in that the pin clamps have predesignated locations, and all pins in one cluster are in the same plane. Replacement of one pin may require replacement of all pins of that cluster.

Ability to Place Pin Clusters Close Together. The Ilizarov apparatus and the Wagner device allow the pin clusters in the proximal and distal segments to be placed as close together as desired. The original Orthofix lengthening device had the body between the pin clamps, so that the pin clusters had to be placed far enough apart to accommodate the length of the device. This is a disadvantage in a short bone, or if other factors govern pin placement. The Orthofix rail lengthener does allow the pin clamps to be placed close to each other.

Number of Pins in Each Segment. The Wagner device permits two pins in each clamp, the Orthofix allows three pins, and the Ilizarov device sets no limits on the number of pins or wires. There may be an advantage to using more than two pins to fix the proximal femur, especially if the lengthening is through the proximal part of the shaft, and the pins must be placed proximally. In that configuration, the loading is eccentric, and three pins provide better fixation with less risk of loosening.

Total Number of Pins and Wires. The Ilizarov apparatus usually requires at least three wires in each segment for a simple lengthening, a total of 12 scars in the skin. The monolateral fixators usually can be applied with only two screws in each segment, producing fewer than half the number of scars, and reducing the operative time for the application.

Ability to Fix More Than One Segment. The Wagner device only allows fixation of two segments, and is incapable of transporting intermediate segments of bone, in cases of bone loss or congenital pseudarthrosis. It is also incapable of traversing joints. The Orthofix rail lengthener can be assembled to fix more than two segments, and, with special clamps and hinges, can traverse joints. The Ilizarov device can easily be extended to provide fixation of as many segments as required, and can be extended across joints, with or without hinges.

Complex Deformities with Multiple Axes of Correction. Only the ring fixators can accomplish gradual correction of deformities in more than one plane. Not only can multiple segments be controlled and multiple hinges incorporated, but the system can be modified, as correction progresses to meet emerging demands.

Ability to Adjust Device while in Place. The Wagner device can be adjusted in two planes, but requires a general anesthetic to do so. With this device, there is a tendency for femoral lengthenings to go into varus, and tibial lengthenings to go into valgus. It is therefore recommended to begin lengthening with the femur in 10 to 15 degrees of valgus or the tibia in 10 to 15 degrees of varus. The Orthofix rail device is adjustable, under general anesthetic and with special pin clamps, only in the plane of the pins. The Ilizarov method is well suited for continual modification of its configuration by differential lengthening of the individual rods. In addition, its components can be changed and the hinges realigned repeatedly, if required. This can be done without a return to the operating room for anesthesia.

Ease of Adjusting the Lengthening Mechanism. This is of no concern while patients are hospitalized under the care of trained personnel, but it becomes an issue when they are discharged home. A simple mechanism results in less anxiety and fewer errors. The Wagner mechanism is the simplest, requiring only the turn of a single knob. The Orthofix devices require use of a special extender that is advanced with a wrench. The Ilizarov device requires elongation of up to three or four rods individually, perhaps by different amounts.

Conclusion

Simple lengthenings can be accomplished by a number of devices, none of which has a clear advantage over another, except that it might be argued that the simplest device capable of solving the problem is advantageous. Gradual correction of complex deformities may present demands that can only be met by a more versatile device, such as the Ilizarov device.

Complications of Lengthening

All studies of leg lengthening, regardless of technique, have reported high complication rates (160,222,225,226,227,228,229,230,231,232 and 233). Most studies report more complications than there are patients, and many patients do not reach their anticipated lengthening goals with uncompromised function. The complication rate, however, is related to the amount of lengthening, and if the goal is modest, the rate is reduced and the proportion of patients reaching their preoperative goals is increased (234). Ghoneem et al. found that all children who had undergone lengthening had a normal psychologic score, 92% had no limitations in daily activities, and 81% were satisfied with the over-all result (116).

Deformity due to soft tissue tension can occur during lengthening, and angular deformity of the tibia has been related to the degree of elongation (235). The Ilizarov technique has been proposed to supplant amputation and prosthetic fitting in fibular hemimelia, but uncontrollable deformity of the tibia and ankle joint has been encountered (236). Ultimate alignment may be improved by using arthrography to delineate the joint surfaces when applying the lengthening device (237).

Hypertension may be seen during lengthening, and may occur suddenly (238,239 and 240). The mechanism is not clear, but it resolves dependably, with shortening

of the lengthening gap, and may not recur when lengthening is resumed.

Pin tract inflammation is common and of little consequence, in its own right. True pin tract infection usually responds well to local care and systemic antibiotics. It may, however, be elevated to a serious complication by plating and grafting, as in the Wagner procedure, and that is the main reason this is no longer commonly done.

Mechanical failure can occur in several modes. Pins can break or loosen, and require replacement. Fractures through the lengthening gap or deformation of the bone in the lengthening gap may occur early or late. It may occur soon after removal of the device, indicating that it was removed too soon, or may occur late, while the bone is still remodeling, and has not yet regained its normal strength (240). In the author's series of Wagner lengthenings, there was one fracture 8 years after the lengthening, which suggests that the bone is extremely slow to remodel and regain full strength, and is probably weak, even after it looks normal radiologically. Long-term follow-up is important in assessing the results of leg lengthening, because complications can occur late.

Nakamura and colleagues have examined the diameter of the bone in the lengthening gap, and concluded that axial loading, while the device is in place, may not be enough to increase the diameter, but that the diameter increases dependably after removal of the device (242). This finding has profound implications for the strength of the bone, since strength in bending varies as the fourth power of the diameter. Indeed, there is a report substantiating this conclusion (243).

Subluxation of the knee may occur during femoral lengthening, especially in patients with congenital shortening (244,245). The subluxation appears to be a posterior subluxation of the lateral tibial plateau, and is always preceded by a loss of extension of the knee. Dysplasia, or absence of the anterior cruciate ligament, and hypoplasia of the lateral femoral condyle are usually found in association with congenitally short femurs (246,247), and contribute to this complication. Routine lengthening of the lateral structures, the biceps tendon and iliotibial band, determined maintenance of knee extension, and avoidance of continued distraction in the face of a knee flexion contracture will avoid knee subluxation.

Dislocation of the hip has been reported, may occur even in the early stages of distraction, and tends to be associated with previous hip surgery and residual instability (248).

Delayed union is difficult to define in this context, but there is no doubt that certain cases take significantly longer to consolidate than others. True nonunion occurs, and is similar in appearance and treatment to posttraumatic nonunion, except that it can occur in narrowed and spindle-shaped bone, so that it is fragile even when united.

It appears that the complication rate is affected by the quality of the underlying bone, but inconsistently so. For example, Naudie et al. showed that the complication rate is higher in patients with an underlying bone disorder (249), but patients with achondroplasia seem to have a lower complication rate. Reasonable lengthening expectations in femoral hypoplasia are unclear (250).

Nerve or artery damage from stretching, entrapment by tense tissues, movement of wires or pins through the tissues, or direct trauma may occur (251). Nerve conduction is affected in one-third or more of patients undergoing lengthening (252).

Karger and colleagues found that femoral lengthenings were more prone to complications than tibias, and that the complication rate increased with lengthenings, exceeding 25% of the initial bone length (253). The author found that the complication rate is significantly higher in children younger than age 8 years, than in older children, and this may reflect the inability of younger children to understand instructions and remain motivated to comply with those of therapists and surgeons (245). Conversely, Noonan found that the complication rate in both femoral and tibial lengthening increased in patients over 14 years of age (222). To some extent, the amount of possible lengthening depends on the length of the bone to start with, and this is another reason to perform lengthening only in older children, whose bones are nearing mature length.

Lengthening affects the subsequent growth of the limb. Price and Carantzas have reported a case of severe growth retardation in the lengthened limb (254). Viehweger has found that lengthening the tibia more than 14% slows its growth, but that this has a negligible effect on the ultimate clinical result, because it is compensated for by femoral overgrowth.

Because of the frequency of concerns, questions, problems, and complications that surround the care of patients undergoing lengthening, it facilitates their management to form a lengthening team in a program with shared responsibilities. A nurse, physical therapist, social worker, and a skilled technician are important members of the team, and should join the surgeon in preparing patients and families for the lengthening. The team can respond to ongoing needs, and offer support during the lengthening. Families never fully appreciate depth and breadth of the hardship they will face, and will require more support than most orthopaedic patients.

There is reason to believe that the complication rate from lengthening is improving with modern techniques and understanding (255) (Fig. 28-36 and Fig. 28-37).

FIGURE 28-36. The course of Ilizarov and Orthofix lengthening. This patient had complex deformities resulting from meningococcemia. The femur was managed by an acute correction of the distal femoral varus deformity and subsequent lengthening, using the Orthofix rail lengthener. The distal pins were placed carefully, before the osteotomy was performed. The tibial deformity required valgus osteotomies both distally and proximally. Because fixation of three fragments was required, the more versatile Ilizarov device was used.

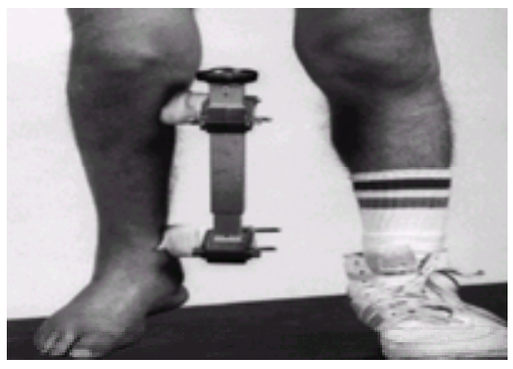

FIGURE 28-37. Patients with the Wagner, Orthofix, and Ilizarov devices can be mobile and undertake partial to full weight-bearing.

CONCLUSION

Excellent care of patients with leg length discrepancy and continuing improvement require comfortable familiarity with the techniques of patient assessment, the methods of prediction of future growth and discrepancy, the factors important in the selection of treatment goals, and the approaches to treatment. Being familiar and up-to-date with respect to the techniques and philosophies of surgical treatment is challenging but the improvement in our capabilities should be an adequate reward.

CHAPTER 29

THE FOOT

VINCENT S. MOSCA

V. S. Mosca: Department of Orthopaedics, University of Washington School of Medicine, Seattle, Washington 98195; Department of Orthopedics, Children's Hospital and Regional Medical Center, Seattle, Washington 98105.

PRINCIPLES OF MANAGEMENT

The foot is a unique part of the musculoskeletal system. Although it is often discussed as if it was another joint in the body, such as the hip, knee, shoulder, and elbow, it is not a joint. There are 26 bones in the foot with countless articulations. The foot of a child looks different from that of an adult. In fact, there is so much variation in shape that the foot of one child may look quite different from that of another child. This feature of physiologic variation is also seen in the long bones of the child's lower extremities, in conditions such as genu varum, genu valgum, femoral anteversion, and tibial torsion (1,2). There are average shapes and normal ranges of shapes. The natural history is for spontaneous change from the normal shapes of the child to those of the adult through normal growth and development. Externally applied forces cannot modify these physiologic variations. And the long-term health consequences of persistent physiologic variations of the long bones have yet to be proven. Physiologic variations of the child's foot, such as flexible metatarsus adductus, positional calcaneovalgus, and flexible flatfoot, must be identified as normal, but not average, shapes to avoid inappropriate and potentially harmful interventions. Conversely, congenital and developmental abnormalities of the child's foot must be identified as such, and managed with the nonoperative and operative methods that have been shown to be effective.

An orthopaedist managing congenital and acquired deformities of the child's foot must have:

1. an appreciation of the age-related physiologic variations in the shape of the foot;
2. an understanding of the natural history of each variation and deformity;
3. an appreciation of the effect of a chosen intervention on the growth and development of the foot, as well as the effect of growth and development on a chosen intervention;
4. a thorough and working knowledge of the most unique “joint” in the human body, the subtalar joint complex, which is a combination of the talocalcaneal or subtalar joint plus the talonavicular and calcaneocuboid or transverse tarsal joints (Chopart joint);
5. an understanding of joint positions and motions that supersedes the confusing and inconsistent terminology in the literature;
6. the ability to obtain, and the commitment to evaluate, only weight-bearing or simulated weight-bearing radiographs;
7. a dedication to preserving joint motion by using soft tissue releases and osteotomies, instead of arthrodeses; and
8. a complete understanding of the phrase “the foot is not a joint.”

Some of the physiologic variations in the shape of the child's foot include metatarsus adductus, calcaneovalgus, and flexible flatfoot. There are also anatomic variations in the structure of the child's foot, including accessory navicular and tarsal coalition.

An understanding of the natural history of each variation and deformity is of paramount importance. Eighty-five to 95% of feet with metatarsus adductus correct spontaneously, with little if any long-term disability, even with mild to moderate residual deformity (3,4 and 5). Essentially all calcaneovalgus “deformities” correct spontaneously (6). Flexible flatfoot is almost ubiquitous at birth, and is present in approximately 23% of adults, most of whom are asymptomatic (7). The height of the longitudinal arch increases spontaneously during the first decade of life in most children (8,9). There is a wide range of normal arch heights at all ages, particularly in young children (8,9). There is no proven benefit from shoe modifications and inserts over spontaneous natural improvement in the development of the longitudinal arch (10,11). Most feet with accessory naviculars (12,13), and approximately 75% of feet with tarsal coalitions (14) are asymptomatic, and do not need treatment. Conversely, congenital clubfoot and congenital vertical talus persist and cause disability, unless treated.

The natural history of the intervention must also be fully appreciated and considered in relation to the natural history of the disease or condition. Unfortunately, although there are few good natural history studies on deformities and variations of the child's foot, there are fewer good long-term follow-up studies on operative interventions for these conditions. It seems most reasonable that the default should logically go to the natural history of the disease.

A unique challenge facing clinicians who manage foot deformities in children is the consideration of the effect of a chosen intervention on the growth and development of the foot, as well as the effect of growth and development on a chosen intervention. Early reconstruction of pathologic foot deformities in children normalizes the stresses on the bones and joints, to allow more normal development. Delay results in the development or persistence of abnormalities in the shapes of the bones and joints, which makes reconstruction more difficult. Furthermore, procedures that affect, or potentially affect, growth in a positive or an adverse way must be used judiciously. Conversely, one must consider how the early positive results of an intervention may change as the child grows. Cavus foot deformity is most commonly a manifestation of muscle imbalance from an underlying neuromuscular disorder. In some cases, the disorder is static (cerebral palsy) or can be stabilized, but may recur (tethered cord in myelomeningocele). In others, the disorder is progressive, and the rate and extent of neuromuscular deterioration may not be predictable (Charcot-Marie-Tooth disease). It is difficult to establish precise muscle balance in any cavus foot, and it is well known that growth, as well as neurologic deterioration, can undo an excellent early result of intervention. The child and family must be aware that there are no panaceas, and that more surgery may be needed in the future. The surgeon must remember this as well, avoid burning bridges, and keep reasonable options available for future procedures.

Congenital vertical talus and many congenital clubfeet are released operatively in the first year of life, when the foot is 8 to 9 cm in length. The hope is that the

correction of these deformities, located at the foundation of the human body, will be maintained through 14 to 16 years of growth and a doubling to tripling in the length of the foot. Problems, including recurrence and overcorrection, as well as plans for their management, should be anticipated.

There is no other “joint” in the human body with the unique anatomy and three-dimensional motion of the subtalar joint complex. This complex consists of two components, the talocalcaneal or subtalar joint, plus the talonavicular and calcaneocuboid or transtarsal joints. The latter is also known as the midtarsal or Chopart joint. Terms that apply to sagittal and coronal plane alignment and motions, such as varus, valgus, abduction, adduction, flexion, extension, supination, and pronation, do not necessarily apply to the subtalar complex, because its axis of motion is in neither the sagittal nor the coronal plane. Inversion and eversion are terms that, in the author's opinion, define the motions of this complex, but they need to be better defined and understood by all who use them. Interestingly, the joint in the body with the most similarity to the subtalar joint complex is the hip. Scarpa (15) identified that similarity almost 200 years ago, when he referred to the talocalcaneonavicular joint as the pes acetabulum. The subtalar complex is malaligned in all significant deformities of the child's foot, including clubfoot, vertical talus, cavus foot, and severe flatfoot. It is essential, therefore, that all who manage these deformities have a thorough and working knowledge of this most unique joint complex.

It is important to evaluate deformity, both clinically and radiographically, with the foot in the weight-bearing position. That is the baseline against which the corrected foot will be judged. A flexible flatfoot appears to have an arch and a normal foot may appear to have a cavus or clubfoot deformity when dangling in the air.

Deformities of the child's foot should be corrected by means of soft tissue releases to align the joints and osteotomies to correct residual deformities. Arthrodesis should be reserved for the older child, adolescent, or adult with established degenerative arthrosis of a joint, or with such severe deformity that correction cannot be achieved with releases and osteotomies. Long-term follow-up studies have demonstrated that arthrodesis of even the small joints of the child's foot should be avoided, because of the risk of developing degenerative arthrosis at the adjacent unfused joints (16,17 and 18). Arthrodesis of the subtalar joint, particularly triple arthrodesis, leads to stress transfer to the ankle (19,20,21,22,23,24,25 and 26). The development of degenerative arthrosis at that important joint is a potentially disastrous outcome.

Correction of foot deformity must be combined with balancing of muscle forces to help prevent recurrence. Balancing muscle forces in a mobile foot is much more challenging than in a foot that has undergone arthrodesis. This challenge must be accepted.

Finally, one who chooses to manage deformities of the child's foot must fully understand the phrase “the foot is not a joint.” It is extremely unusual for only one portion of the foot or only one joint of the foot or ankle to be congenitally or developmentally deformed. Its many joints are usually deformed in opposite directions, as if the foot was wrung out. As examples, note that there is inversion of the subtalar joint and pronation of the forefoot on the hindfoot in a cavus foot; there is eversion of the subtalar joint and supination of the forefoot on the hindfoot in a flatfoot. And one cannot ignore the ankle joint as a potential site of additional deformity. The child's foot usually has multiple deformities, and the orthopaedist must identify all of them preoperatively, and have a treatment plan that addresses each one. There is no justification for creating a compensating deformity, or incompletely correcting a deformity, to avoid an additional procedure, particularly one that can usually be carried out during the same operative session. Consider the analogy of a child with varus deformities of the distal femur and proximal tibia secondary to rickets. One would never overcorrect the distal femur to a valgus alignment and create valgus orientation of the knee joint, to avoid performing an osteotomy of the proximal tibia. The same principle must apply to the foot.

There is a great need for more natural history studies on deformities and variations of the child's foot, as well as for long-term follow-up studies on the interventions used to treat these conditions. The message must be to exhibit caution with interventions, until it is clear that the treatment is not potentially worse than the condition.

All of these principles apply to the congenital and developmental deformities that are now presented individually. Many of the principles apply as well to the other conditions that are also described in this chapter.

CONGENITAL DEFORMITIES

A congenital deformity is characterized by malalignment of bones at their joints, which is present at birth. Deformations of one or more bones are often present, and may be primary or secondary findings.

Clubfoot (Congenital Talipes Equinovarus)

Definition

“Clubfoot” is the term used to describe a complex, congenital, contractural malalignment of the bones and joints of the foot and ankle. The individual deformities include equinus of the hindfoot, varus (or inversion) of the subtalar joint complex, cavus (plantar flexion of the forefoot on the hindfoot), and adductus of the forefoot on the midfoot (Fig. 29-1). Congenital talipes equinocavovarus is a more descriptive term, although certainly more cumbersome.

FIGURE 29-1. Infant clubfeet.

There are four recognized classes of clubfoot. This section focuses on the idiopathic variety, which is found in otherwise normal children, and does not resolve without intensive treatment. A second class is the postural variety. These resolve completely with manipulation, or with one or two casts. Neurogenic clubfoot refers to clubfoot seen in children with myelomeningocele. Syndromic clubfoot is seen in children with other anomalies (Table 29-1). These tend to be rigid and quite resistant to treatment.

Arthrogryposis
Constriction bands (Streeter's dysplasia)
Prune belly
Tibial hemimelia
Möbius syndrome
Freeman-Sheldon syndrome (whistling face) (autosomal dominant)
Diastrophic dwarfism (autosomal recessive)
Larsen syndrome (autosomal recessive)
Opitz syndrome (autosomal recessive)
Pierre Robin syndrome (X-linked recessive)

TABLE 29-1. SYNDROMES WITH WHICH CLUBFOOT IS COMMONLY ASSOCIATED

Epidemiology

The incidence of clubfoot is 0.93 to 1.5 per 1,000 live births in whites (27,28 and 29), 0.6 per 1,000 in Orientals, and 6.8 per 1,000 in Hawaiians, Polynesians, and Maoris (30). Boys are affected twice as often as girls, and bilateral involvement is seen in approximately 50% of cases (27).

Wynne-Davies (28,29) made several important observations regarding the incidence of clubfoot. The occurrence rate is 17 times higher than in the normal population for first-degree relatives, 6 times higher for second-degree relatives, and approximates the normal population risk for third-degree relatives. Unaffected parents with an affected son have a 1 in 40 chance of having another son with the disorder, whereas the risk to a subsequent daughter is very low. Unaffected parents with an affected daughter have a 1 in 16 chance of having a son with clubfoot and a 1 in 40 chance of seeing the deformity in another daughter. The chances are about 1 in 4 that a subsequent child will have a clubfoot if both a parent and a child have the disorder. There is a 32.5% rate of concordance in monozygotic twins and a 2.9% rate in heterozygotic twins. These observations led Wynne-Davies to propose that clubfoot is inherited as a dominant gene with reduced penetrance or multifactorial inheritance.

Cowell and Wein (31) concluded that the data could be accounted for using a multifactorial inheritance model. Complex segregation analysis, using a regressive logistic model, was used by Rebbeck et al. (32) to conclude that the probability of having clubfoot was explained by the Mendelian segregation of a single gene with two alleles, plus the effects of some other factors that have yet to be elucidated.

Pathogenesis

Clubfoot is probably etiologically heterogeneous. Genetic factors clearly play a part. Environmental factors may modulate the genetic expression of the disorder. The proximate cause is debated with fervor, based on a small number of personal observations by a large number of investigators. There may be validity in many of the discordant studies if, in fact, clubfoot is a clinical manifestation that can result from multiple causes and mechanisms. Among the proposed theories are *in utero* molding (33), primary muscle lesion (34), primary bone deformity (germ plasm defect) (35), primary vascular lesion (36), intrauterine enteroviral infection (37), developmental arrest (38), primary nerve lesion (39), abnormal tendon insertion, retracting fibrosis (40), and abnormal histology (41).

Clinical Features

The clubfoot is characterized by equinus of the hindfoot, varus (or inversion) of the subtalar joint complex, cavus (plantar flexion of the forefoot on the hindfoot), and adductus of the forefoot on the midfoot. These deformities are not passively correctable. The severity of the deformities and associated findings vary from foot to foot, even in bilateral cases. There is a single (occasionally double) posterior skin crease (Fig. 29-2). The calcaneus is difficult to palpate within the fatty heel pad. A deep transverse skin crease crosses the midfoot and extends under the longitudinal arch. Assessment of tibial torsion in a newborn with a clubfoot is unreliable. The head of the talus can be seen and palpated on the dorsolateral aspect of the midfoot/hindfoot just anterior to the ankle joint. This is attributable to excessive inversion of the subtalar joint complex around the talus. An examiner's thumb can be placed on the dorsolateral aspect of the head of the talus, as a solid fulcrum around which the foot can be externally rotated and everted. In idiopathic clubfoot, the navicular will not fully align with the head of the talus and displace the examiner's thumb.

FIGURE 29-2. Clubfoot (**left**) with single heel crease and normal foot (**right**) with multiple heel creases.

The foot and calf are smaller than the contralateral side. Little and Aiona (42) noted that leg-length discrepancy of greater than 0.5 cm exists in 18% of children with unilateral clubfoot and in 4% with bilateral deformities. The tibia is short in 89% and the femur is short in 43% of children with unilateral deformity with discrepancy.

A complete physical examination of the child is indicated to rule out a neurogenic or syndromic cause for the deformity. A finding as subtle as adducted and contracted thumbs across the palms will identify a child with clubfeet as having arthrogryposis. Examination of the hips in a newborn is an important part of the musculoskeletal screening examination, but there is no reported increased risk for developmental dysplasia of the hip in children with clubfoot.

Classification of the severity and rigidity of the clubfoot is vital to the assessment of treatment modalities. Several classification systems have been proposed (43,44,45,46,47 and 48), but none has been universally accepted. They all suffer from excessive subjectivity and poor reproducibility.

Radiographic Features

There is no consensus on the role of radiography in the diagnosis and management of clubfoot (48,49). However, it should be stated that the diagnosis of clubfoot in the newborn can and should be based solely on clinical findings. The intended role of radiography is to demonstrate the relationships between bones. This is accomplished by first drawing the axis of each bone, and herein lies the limitation of this imaging modality. There is little ossification of the bones of the normal newborn foot, and there is a delay in ossification in the clubfoot (50). The ossific nucleus of the talus is not centrally located in the cartilaginous anlage (51,52). The ossific nucleus of the talus is between the head and neck, and may be spherical in shape for the first several weeks of life. Ossification of the navicular does not begin until the age of 3 to 4 years in children with clubfoot, and even then it is eccentric. Brennan et al. (53) identified an even more fundamental problem when they showed very poor reproducibility in positioning the clubfoot for radiography. These factors make it unrealistic to consider radiographs of the newborn and infant clubfoot as containing objective data. The age or point at which radiographs become reliable is unclear.

Despite these limitations, there may be a role for radiography to confirm correction, or to help identify the site(s) of residual deformity in the child who is several months old and has been undergoing serial manipulation and casting. In the latter situation, the information can be helpful for surgical planning, particularly if one subscribes to “a la carte surgery” (54,55 and 56). The anteroposterior view is obtained with the foot pressed against the radiograph plate with a dorsiflexion and external rotation force (49,57) (Fig. 29-3A). This will place the subtalar joint in its most everted and corrected position. The lateral radiograph is obtained with the foot dorsiflexed and everted maximally, but also with the leg internally rotated, to ensure a true lateral view of the ankle (manifested by the projection of the fibula within the posterior half of the tibia) (Fig. 29-3B). The talocalcaneal and talus–first metatarsal angles are measured on both views (9). The axes of the talus and the calcaneus normally diverge from each other, and the axes of the talus and the first metatarsal normally form a nearly straight line on both views. The tibiotalar and tibiocalcaneal angles are measured on the lateral view (9). The axis of the talus normally aligns almost perpendicularly to the tibia, and the calcaneus dorsiflexes above a right angle with the tibia. The alignment of the calcaneus and the cuboid is assessed on the anteroposterior view (58).

FIGURE 29-3. A: Simulated weight-bearing anteroposterior radiograph of clubfoot. The talus (*small straight arrow*) and calcaneus (*large straight arrow*) are parallel, rather than divergent. The metatarsals are markedly adducted in relationship to the talus. The cuboid ossification center (*curved arrow*) is medially aligned on the end of the calcaneus, rather than in the normal straight alignment. **B:** Maximum dorsiflexion lateral radiograph of clubfoot. The talus and calcaneus are somewhat parallel to each other and plantar flexed in relation to the tibia.

A second point at which radiography may be helpful is intraoperatively, to confirm the adequacy of correction of the deformities. The low-dose radiation and the convenience of Fluoroscan images make that technology desirable. The third indication for radiography could be, at some substantial time after surgery, to confirm maintenance of deformity correction. Alternatively, the third point at which radiographs are obtained is when recurrence or other secondary deformity is clinically identified.

Other Imaging Studies/Diagnostic Studies

The diagnosis of clubfoot is often made prenatally on the maternal abdominal ultrasound examination, which is now being performed fairly routinely at 16 to 20 weeks of gestation (59) (Fig. 29-4). The sensitivity and specificity are very high, but not 100%. Ultrasonographers have recently been more thorough in their evaluation of the limbs of the fetus. Identification is increasing, and accuracy is improving. The outcome of prenatal diagnosis has been the desire on the part of many parents to receive prenatal counseling, a service that cannot be provided by most primary care physicians, radiologists, or obstetricians at the level desired by the parents (60).

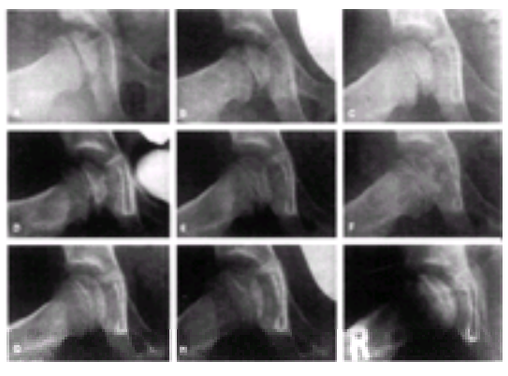

FIGURE 29-4. Maternal abdominal ultrasound image of clubfoot.

In response to the limitations of radiography, ultrasound techniques are evolving for the assessment of the clubfoot during nonoperative and operative treatment (61,62,63 and 64). Early results seem promising; however, the availability of the technology in the orthopaedic outpatient clinic is currently limited. Arthrography, computed tomography (65), and magnetic resonance imaging (51,66,67) may have roles in research or special circumstances, but they do not have roles in the routine management of the idiopathic clubfoot.

Pathoanatomy

The deformities of the clubfoot are created, in part, by malalignment of the bones at the joints, and, in part, by deformation in the shapes of the bones (35,51,65,66,68,69,70,71,72,73,74,75 and 76). The neck of the talus is short and deviated plantar-medially on the body of the talus (35,72,73,75,76). This directs the articular cartilage of the head of the talus in the same plantar-medial direction. Anatomic dissections (73) and magnetic resonance images (66,67) confirm that there is a varus deformity of the distal end of the calcaneus, creating a medial tilt of its articular surface at the calcaneocuboid joint. Howard and Benson (72) and Epeldegui and Delgado (70,77) found that the anterior facet of the calcaneus is tilted medially, in relation to the middle facet in the clubfoot, indicating that the location of the varus deformity is between the two facets (Fig. 29-5). Epeldegui and Delgado (70) performed elegant microdissections of the feet of 75 stillborn infants, some of whom had clubfoot deformities. They specifically studied the bony and soft tissue anatomy of the talocalcaneonavicular joint, which they, like Sarrafian (77), called the acetabulum pedis (AP) and Scarpa (15) termed the “pes acetabulum.” The AP is an ellipsoid articular cavity that holds and rotates around the head of the talus, comparable to the relationship between the pelvic acetabulum and the femoral head at the hip joint. Its bony elements are the posterior articular surface of the navicular and the anterior and middle articular facets of the calcaneus. Epeldegui and Delgado found that the soft tissues of the AP were likewise markedly different in shape and orientation in the clubfoot, compared with the normal foot. The shape of the medial cuneiform has not been studied in the newborn, but it is trapezoid-shaped in the older child with residual forefoot adductus deformity. The subtalar joint complex is severely inverted, a combination of internal rotation, supination, and plantar flexion. The axis of rotation appears to be in the interosseus talocalcaneal ligament. The AP is inverted around the plantar-medially deviated head and neck of the talus, thereby aligning the navicular at or near the medial malleolus. The calcaneus is rotated downward and inward, resulting in parallel alignment with the talus in the frontal and sagittal planes. The posterior part of the calcaneus is tethered to the fibula by the calcaneofibular ligament. There is a varus deformity of the distal end of the calcaneus, with medial deviation of a congruous calcaneocuboid joint, in many clubfeet (66,67,70,71,72 and 73,75,77,78). There may be medial subluxation of the cuboid on the distal calcaneus in some feet (58,69). The plantar fascia, short plantar muscles, and spring ligament are contracted. The Achilles, tibialis posterior, flexor hallucis longus, and flexor digitorum longus tendons are contracted. The posterior capsules of the ankle and talocalcaneal joints are contracted.

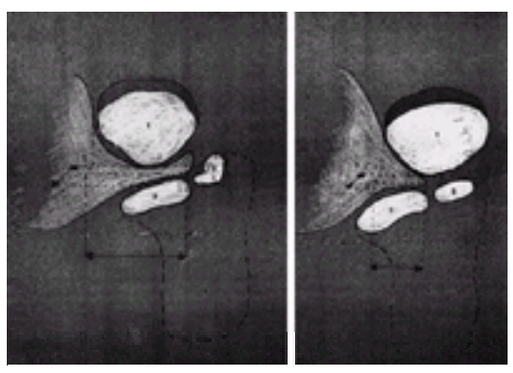

FIGURE 29-5. Navicular. *(1)* The axis of the anterior facet of the calcaneus (*2*) is tilted medially in relation to the axis of the middle facet (*3*) in the clubfoot (**left**) compared with the normal foot (**right**). (From ref. 77, with permission.)

Tibial torsion and the position of the talus in the ankle are debated. McKay (74) believes that the talus is in neutral alignment, Goldner (79) believes that it is internally rotated, and Carroll and associates (68,69,71) believe that it is externally rotated. A recent three-dimensional magnetic resonance imaging study of clubfoot revealed an externally rotated position of the talus in clubfeet, compared with normal feet (51).

Natural History

The untreated clubfoot persists as a rigid, unsightly deformity. A large, callused bursa develops over the dorsolateral aspect of the hyperflexed midfoot, which functions as the weight-bearing surface of the foot (Fig. 29-6). In the most extreme cases, the toes point backward during ambulation. Specially made footwear is required to accommodate the deformity. Surprisingly, untreated adults in certain cultures and environments have little pain for many years, and can function adequately. Their function is similar to that of individuals with Syme amputations when not wearing their prostheses. City-dwelling adolescents and adults with untreated clubfoot experience pain and disability with ambulation on paved sidewalks and hard floors.

FIGURE 29-6. Untreated clubfoot in an adult migrant farm worker.

Treatment

The goal of treatment is to achieve a plantigrade, supple, painless foot that looks normal, although it is not normal, and provides adequate function. The initial treatment of clubfoot, regardless of its severity or rigidity, is nonoperative. The goal of nonoperative treatment is to achieve the stated goal of treatment or, at a minimum, to achieve partial correction of the deformity, and thereby decrease the extent of surgery. Modalities include serial manipulation and casting (81,82,83,84 and 85), taping, physical therapy and splinting (86), and continuous passive motion with a machine (55). Manipulation and casting (81,82,83,84 and 85) is the technique used most frequently in the United States, based on experience, practicality, convenience, and cost. The technique is exacting and requires training, experience, and practice. Poor technique can result in an unnecessary failure of nonoperative treatment. It can also create complications that include rocker-bottom deformity, with spurious correction of the deformity and crushing of the cartilage anlage, with resultant joint deformity and stiffness.

Manipulation and casting should begin early. There is no evidence that a delay of several days makes a difference in the rate of success, and it seems a more holistic approach to let the parents hold and bond with an uncasted child for a short period of time. The technique of manipulation and casting, described by Ponseti and colleagues (83,84 and 85), is the gold standard, and should be studied in detail and practiced regularly. The first ray is dorsiflexed to stretch the plantar fascia and unlock the talonavicular joint. Next, the forefoot is abducted and the hindfoot is everted through the subtalar complex around the talus. Finally, after all other deformities are corrected, the hindfoot is dorsiflexed, while avoiding excessive dorsiflexion stress on the forefoot. Long-leg plaster of Paris casts are used to ensure that the pressures are maintained where they are applied, that the forces are directed appropriately, and to prevent the short-leg component from slipping down on a fat, conical leg.

Semirigid fiberglass has recently been shown by Coss and Hennrikus (87) to be statistically superior to plaster of Paris in its durability, convenience, performance, and ease of removal. The parents can remove the casts and bathe the child the night before (or the morning of) remanipulation and casting, which should occur weekly until no further improvement is seen. If good correction is not achieved by 3 months, it is unlikely that further nonoperative treatment will be successful.

The efficacy of manipulation and casting is attributable to the viscoelastic, or rate-dependent, behavior of the ligaments and tendons (88). The creep phenomenon occurs during manipulation. A constant stress (force per unit area), or load, is applied. The tissues undergo deformation (strain) relatively quickly at first, then more slowly, until there is little additional elongation possible at that time. The cast is applied with the same load used during manipulation. Stress relaxation takes place in the cast. The tissues undergo a small additional amount of elongation in the cast. As soon as that occurs, the stress on the tissues effectively decreases, and will not increase again until the next manipulation. The ability to correct the clubfoot deformity completely with this technique depends on the unique stiffness of the individual child's foot, the age at which the treatment is initiated, the skill of the practitioner, and the definition of complete. This last point is crucial, and is based on the premise that it is not possible to make a clubfoot normal by any combination of techniques. Controlling for the child's age and the practitioner's skill, the clinical and radiographic results for any clubfoot depend on the severity, rigidity, or some other unique biologic feature(s) that has yet to be elucidated. The lack of a valid, reliable, universally accepted, and universally applied classification system for clubfeet has resulted in the inability to compare treatment methods. There is no consistency in the indications for abandoning nonoperative treatment for operative treatment, nor for considering a second operative procedure.

Kite (81,82) believed that most clubfeet could be corrected with serial casting, but that has not been the experience of others. Bensahel et al. (86) reported 77% good and fair results with daily physical therapy and splinting, whereas Dimeglio and colleagues (55) reported high success rates with the use of a continuous passive motion machine. These two approaches are difficult to implement in the health care environment.

Surgery is indicated if there is failure to achieve satisfactory clinical and radiographic evidence of deformity correction by nonoperative methods. The definition of satisfactory is debated. Also debated are the timing of surgery, the technique of surgery, the importance and type of short-term and long-term postoperative management, the definition of recurrence or other secondary deformity, and the indications for additional surgery. The definition of satisfactory deformity correction is also debated for clubfeet that are treated operatively. These debates will not be resolved until there are more comparative long-term data on clubfeet that have been treated by the different modalities in use at present. Cooper and Dietz (89) reported the only truly long-term results of a single treatment method for clubfoot. They evaluated 45 patients with 71 clubfeet, at an average age of 34 years (range, 25 to 42 years), who had been treated from infancy by Ponseti's method (83,84 and 85). This method is the least invasive of the proposed surgical methods. All feet undergo a total of five to eight manipulations and castings at intervals of 5 to 7 days. More than 90% of clubfeet undergo percutaneous tenotomy of the Achilles tendon in the clinic at between 2 and 3 months of age after the manipulations and castings, initiated at birth, have corrected all but the equinus deformity. Full-time bracing is replaced by nighttime bracing that continues for 2 to 3 years. Somewhat less than 50% of patients undergo transfer of the tibialis anterior to the lateral cuneiform, after walking age. Cooper and Dietz (89) used pedobarographic and electrogoniometric analyses, in addition to clinical and radiographic assessment. With the use of pain and functional limitations as the outcome criteria, 35 of the 45 patients (78%) had excellent or good outcomes, compared with 82 of 97 individuals (85%) who did not have congenital foot deformities. The authors reported that excessive weakening of the triceps surae might predispose patients to poor results, and that outcomes could not be predicted from the radiographic results.

For reasons that are not clear, most orthopaedic surgeons are unable to achieve the degree of deformity correction with manipulation, casting, and Achilles tenotomy that has been reported by Cooper and Dietz using Ponseti's method. Most authors report the need for a more extensive operative procedure involving multiple tendon lengthenings and capsulotomies in 75 to 100% of clubfeet that have failed nonoperative treatment (30,79). There are no reported long-term studies on any of these procedures that are comparable to the Cooper and Dietz series with regard to length of follow-up, criteria for evaluation, and rate of excellent and good outcomes. It is hoped that such studies are forthcoming. In the short term, one should learn to master Ponseti's method, reserving one's standard operative approach for failures.

The more extensive surgical approaches are each attributed to an individual. Each is based on a slightly different understanding of the pathoanatomy, with an often dramatically different approach to management of the soft tissues, yet the reported short-term results are almost identical **[➥7.1]**.

The Turco procedure (90,91) was very popular in the 1970s. A medial incision was used to achieve posteromedial release. The subtalar joint was opened like a book with its binding along the lateral border of the foot. Excessive internal rotation of the foot and valgus deformity of the hindfoot were commonly seen in follow-up.

The Goldner procedure (47,79) is based on the premise that the primary deformity is internal rotation of the talus in the ankle joint. Correction requires lengthening of the deltoid ligament. The subtalar joint is not circumferentially released.

Carroll and colleagues (68,69,92,93) and McKay (94) agreed that circumferential release and rotation through the subtalar joint were necessary to correct the deformity. They believed in the importance of preservation of the talocalcaneal interosseus ligament, if possible. They disagreed with Goldner and with each other on the alignment of the talus in the ankle joint. Carroll and colleagues (68,69,71) believed that it was externally rotated, and McKay (74) believed that it was in neutral alignment.

Simons (95) presented the most extensive release yet described for management of the clubfoot. His was a circumferential release of the subtalar joint, with release of the talocalcaneal interosseus ligament, and often with circumferential release of the calcaneocuboid joint. This release completely destabilizes the bones and joints, risking the creation of gross translational deformities, from which it is extremely difficult to recover. Simons (58) brought attention to the alignment at the calcaneocuboid joint. Debate surrounds the implication of the apparent or real medial subluxation at that joint. His approach is to release the joint circumferentially, and realign it. Others perform a partial plantar-medial release, allowing the joint to open without complete destabilization (69,92). The Hueter-Volkmann law may work in this situation to correct the pathoanatomy, which in many cases is a varus deformity of the anterior calcaneus with a medial tilt of the calcaneocuboid joint.

Although some authors have an all-or-none approach to surgery (96,97), many support an a la carte approach (54,55 and 56). It makes sense that if there is a spectrum of severity for clubfeet, and some do not require surgery at all, there should be a spectrum of releases that can be performed, regardless of the pathoanatomic approach chosen. Wientroub and Khermoush (98) have written an excellent review and comparison of several of the most popular surgical procedures for clubfoot.

The type of skin incision is debated, but this is certainly less important than the procedures performed under the skin **[➥7.1]**. Most surgeons use the Cincinnati incision, because it is safe, extensile, and cosmetic (99). It can be used for revision surgery, even crossing longitudinal scars from previous operations. Another approach is Carroll's two-incision technique (69,92). It is safe and extensile, but less cosmetic.

In a severe clubfoot that has not responded well to casting, it may not be possible to immediately approximate the edges of the Cincinnati incision with the foot in the fully corrected position without compromising the circulation of the skin. It has been suggested to leave the skin edges separated with the foot in the fully corrected position, and allow for wound closure by secondary intent (100). Alternatively, the skin edges can be approximated, a pin can be inserted across the talonavicular joint, the cast can be applied with the foot in plantar flexion, and the foot can be manipulated safely into further dorsiflexion during a cast change under anesthesia 1 to 2 weeks later (90,91,95,99). Variable success in stretching the soft tissues has been reported with the use of a preoperatively inserted tissue expander (101,102 and 103).

Debate also surrounds the need for internal fixation with wires. Procedures that are more extensive, with regard to capsular releases, tend to require fixation. Among the challenges of wire fixation is the determination of the proper alignment of bones that cannot be seen well clinically or radiographically.

Unfortunately, a review of the short-term and intermediate-term follow-up studies on these procedures does little to help one choose the best operative approach. A basic problem created by the lack of a universal classification system for clubfeet is that the studies cannot be compared. The clubfeet in the studies may not be comparable with regard to severity, rigidity, or some other important factor(s). Other variables that may have significant influences on the outcome, such as age at initiation of casting, number of casts, age at surgery, type and duration of postoperative cast management, type and duration of postcast splinting, and length of follow-up, are not controlled or comparable between studies. Ponseti (84,85), for example, believed that the prolonged splinting that followed Achilles tenotomy was critical to the success of the method. Finally, evaluation rating systems vary from study to study.

These factors force one to choose an operative approach based on one's understanding of the pathoanatomy of the deformity, an impression of the results seen in one's training, and one's own experience. The pathoanatomy is one of severe inversion of the subtalar joint complex around the talocalcaneal interosseus ligament, with equinus, adductus, and cavus deformities. The techniques described by Carroll (69,92) and McKay (94) best address the pathoanatomy. They both stress the importance of preserving the talocalcaneal interosseus ligament which, if released, puts the calcaneus at risk for lateral translation—a disastrous complication. The alignment of the talus in the ankle joint is probably a moot point, because the talus rotates spontaneously during the release and repositioning.

Controversy surrounds the age at which clubfoot surgery should be performed. The argument for early surgery and realignment is that it allows for better remodeling of the cartilage anlage. Neonatal surgery has been reported (104,105 and 106). The technique is demanding, the results are variable, and the anesthetic risks are higher than for the older child. This approach obviates the avoidance of surgery that might result from manipulation and casting. Data do not support an optimal age range during which clubfoot surgery should be performed. Most surgeons operate on the child between 3 and 12 months of age (91,92,97,107,108). Anesthetic risks, difficulty with venous access, and the technical challenge related to foot size are greater with children younger than 6 months of age.

General anesthesia, with supplemental caudal epidural anesthesia, has been shown to decrease the postoperative narcotic requirement, provide good pain control for several hours after surgery, and shorten the hospital stay (109).

The need for additional surgery after the first operation is reported to range from 5 to 50% (91,93,110,111,112 and 113). These data are not helpful, because there are no strict indications for additional surgery. Painless recurrent or residual deformity might be an indication for surgery at one center, but not at another. The data are also of limited validity, because of the different lengths of follow-up in these studies.

The complications of nonoperative treatment were discussed above. There are many potential complications of surgical treatment (110,114,115). They include wound problems, neurovascular injury, bone/cartilage damage, avascular necrosis of the talus or navicular, residual deformity, recurrent deformity, dorsal bunion, and overcorrection at the talonavicular, talocalcaneal, and talocalcaneonavicular joints.

The Cincinnati incision is safe if it is placed at least 1 cm proximal to the deep posterior skin crease. Lower placement may risk slough of the heel pad. The posterior tibial artery is usually the most important and possibly the only blood supply to the clubfoot (36). It should be isolated early and protected throughout the procedure.

Residual and recurrent varus deformity of the hindfoot in the young child is treated with repeat soft tissue release. Painful residual adductus of the forefoot in the older child is treated with opening-wedge osteotomy of the medial cuneiform (116,117), closing-wedge osteotomy of the cuboid, or both (118,119,120 and 121) **[➥7.6]**. The choice depends on the radiographically determined site(s) of deformity and the age of the child. In residual adductus deformities of the forefoot, the medial cuneiform is usually trapezoid-shaped, with medial deviation of the first metatarsocuneiform joint. Opening-wedge osteotomy will correct this deformity, but it cannot be performed until there is adequate ossification of the cartilaginous anlage, which is often not until after 4 years of age. There is also often a varus deformity of the cuboid, although it is more difficult to document the site of the deformity along the lateral border of the foot. The cuboid ossifies very early, and can undergo closing-wedge osteotomy to improve adductus deformity in the younger child. The ideal situation is to wait until the child is old enough to undergo the combined procedure. There are other techniques for correcting the shape and length of the lateral column of the foot (78). The correction of forefoot adductus can be combined with hindfoot soft tissue release in the older child with residual or recurrent deformity at both sites.

There is imbalance of the tibialis anterior and the peroneus longus and tertius in up to 50% of clubfeet (85). This is manifest as a dynamic, then rigid supination deformity of the forefoot. There may be accompanying adductus of the forefoot and inversion of the hindfoot. This imbalance ultimately leads to the development of a dorsal bunion. Lateral transfer of the tibialis anterior to the lateral cuneiform (85) will improve muscle balance and prevent the development of a dorsal bunion. This transfer can be combined with midfoot osteotomies, as described above, if there is rigid adductus deformity of the forefoot. If a rigid and symptomatic dorsal bunion has already developed in the older child, tendon transfer is indicated, in addition to other procedures (122). These include plantar release of the first metatarsophalangeal joint, transfer of the flexor hallucis longus to the neck of the first metatarsal, and plantar flexion osteotomy of the medial cuneiform or the base of the first metatarsal.

Overcorrection is a worse complication than recurrence, and can occur at different sites. Dorsal subluxation of the navicular on the head of the talus can occur as a result of excessive release of the talonavicular joint, external rotational malalignment of the joint, and residual cavus deformity secondary to failure to release the

plantar fascia. The Third Street procedure, described by Barnett (123), is an effective method for realigning the joint in the young child, but the long-term results have not been reported. This procedure entails capsulotomy of the talonavicular joint, continuing between the cuboid and navicular, the cuboid and lateral cuneiform, and finally between the base of the third and fourth metatarsals. The medial column of the foot is thereby separated from the lateral column, which allows the navicular to align completely and without tension with the head of the talus. Treatment in the older child must be individualized, and includes resection of the prominent dorsal portion of the subluxated navicular, talonavicular arthrodesis, and triple arthrodesis **[➥7.9]**.

Overcorrection of the hindfoot can occur as an excessive eversion of the subtalar joint complex or as a lateral translation of the calcaneus under the talus. The latter is more likely to occur if the talocalcaneal interosseus ligament has been transected. Painful impingement of the calcaneus and lateral malleolus can be treated with posterior calcaneus medial displacement osteotomy (181). The calcaneal lengthening osteotomy described by Evans (124) is effective for management of the overcorrected clubfoot attributable to excessive eversion around an intact interosseus ligament.

Finally, it is important to evaluate the alignment of the ankle joint in cases of apparent overcorrection of a clubfoot. The subtalar joint may be well aligned. Valgus deformity of the ankle joint may account for the deformity seen. Medial malleolus screw hemiepiphysiodesis is a safe, simple, and effective treatment for the skeletally immature individual (125,126). Supramalleolar osteotomy is necessary after closure of growth plates.

Metatarsus Adductus

Definition

Medial deviation of the forefoot on the hindfoot, with neutral or slight valgus alignment of the hindfoot, is the most common congenital foot deformity (Fig. 29-7). The terminology used to describe this deformity has been inconsistent and confusing, and has included metatarsus adductus, metatarsus varus, metatarsus adductovarus, and skewfoot.

FIGURE 29-7. Metatarsus adductus in an infant. Note convex lateral border and neutral hindfoot alignment.

Epidemiology

Wynne-Davies (28) reported the incidence of metatarsus varus at 1 per 1,000 live births and 1 per 20 siblings of patients with metatarsus varus. Hunziker et al. (127) documented an overall frequency of 12% in full-term single births, and an even higher frequency for twin births. The actual incidence is unknown, because of the lack of a strict definition of the condition. The increased reported incidence during the past century is probably attributable to an increased awareness of the condition by primary care physicians (4,128,129 and 130). Although earlier studies (131,132) indicated an association of metatarsus adductus with hip dysplasia, more recent studies (133,134) have shown no significant association between these two conditions.

Pathogenesis

The cause of metatarsus adductus is unknown. The theory that it is the result of *in utero* positioning is supported by the high rate of spontaneous resolution (5) and the strong association with twin pregnancies (127,135). Variations in anatomy have also been proposed as possible causes. Some authors have proposed the cause to be muscle imbalance resulting from contracture and anomalous insertion of the tibialis anterior (129,136,137) or tibialis posterior (138). Two studies on cadavers with metatarsus adductus have documented an abnormality in the shape of the medial cuneiform (139,140). The bone is trapezoid-shaped, and the first metatarsal–medial cuneiform joint is tilted medially, i.e., in varus alignment (141) (Fig. 29-8). It may be that the position theory applies to those feet that correct spontaneously, and the anatomic theories apply to those that do not.

FIGURE 29-8. Metatarsus adductus in an older child with trapezoid-shaped medial cuneiform. (From ref. 141, with permission.)

Clinical Features

Adduction of the metatarsals creates a concave medial border of the foot, a convex lateral border, and prominence at the base of the fifth metatarsal. There may also be varying degrees of forefoot supination. The hindfoot is in neutral or slight valgus alignment, and there is full and free motion at the ankle and subtalar joints.

Bleck (142,143) published two classification systems: one based on the severity and one on the flexibility of the deformity. The severity of metatarsus adductus is determined with the use of the heel bisector method (142) applied to a photocopy of the child's foot in the weight bearing position (144) (Fig. 29-9). The other classification system (143) defines a foot with metatarsus adductus as flexible if the forefoot can be passively abducted beyond the midline heel bisector while holding the heel (Fig. 29-10). A partly flexible foot can be abducted only to the midline, and an inflexible, or rigid, foot cannot be abducted to the midline.

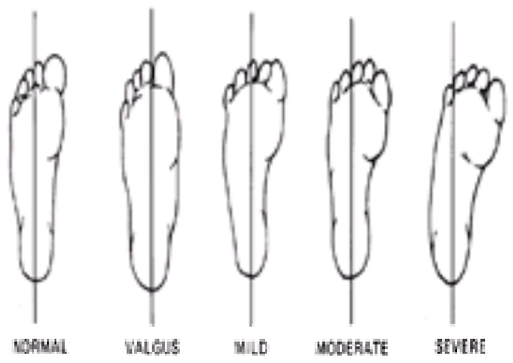

FIGURE 29-9. The heel bisector method. The severity of metatarsus adductus is determined by the relationship between the toes and the distal end of the line bisecting the heel. The severity does not correlate with prognosis. (From ref. 142, with permission.)

FIGURE 29-10. Bleck's (143) flexibility classification of metatarsus adductus. **A:** Metatarsus adductus in an infant. **B:** A flexible foot can be passively overcorrected into abduction with little effort. **C:** A partly flexible foot can be passively corrected only to the midline. **D:** An inflexible foot cannot be passively corrected to the midline. (From ref. 141, with permission.)

Radiographic Features

Radiographs are not necessary, nor indicated, to diagnose metatarsus adductus in infants. Berg (145) developed a classification system for metatarsus adductus and skewfoot based on radiographs of the feet of a small group of children between the ages of 2 and 17 months. The system is inherently flawed, because it is strongly dependent on assessment of the relationship between the talus and the navicular. The navicular does not ossify until 4 to 5 years of age. Cook et al. (146) documented poor interobserver and intraobserver agreement using this system, and showed no correlation between classification and response to treatment.

Radiographs are indicated for the older child or adolescent with severe residual deformity, pain, or other disability, when operative intervention is being considered. A standing anteroposterior radiograph will show the trapezoidal shape of the medial cuneiform and the medial deviation, or adductus, of the metatarsals on the tarsal bones. The severity of adductus decreases from the first to the fifth metatarsal.

Normal hindfoot alignment is seen on the anteroposterior and lateral views.

Natural History

Rushforth (5) prospectively studied the natural history of metatarsus adductus in 83 children with 130 affected feet who received no treatment. Eighty-six percent were normal, 10% were moderately deformed and asymptomatic, and 4% were deformed and stiff at an average follow-up of 7 years. Rushforth stated that it was not possible to determine prognosis before the age of 3 years.

Ponseti and Becker (4) followed 379 children with metatarsus adductus, and documented improvement by 3 to 4 years of age in 335 patients who had flexible feet, as defined by Bleck (143). Forty-four patients (11%), with partly flexible and inflexible deformities, underwent treatment with corrective plaster casts. Farsetti et al. (3) rated 26 of 29 feet (90%) in this treated group as good, at an average follow-up of 32 years. There were no poor results or long-term functional disabilities in patients with mild or moderate residual deformity. No patient required surgical correction, and hallux valgus was not an identified problem.

The percentage of feet with metatarsus adductus that undergo spontaneous correction without treatment may actually be even higher than reported in these studies, because of the likelihood of underreporting of mild, flexible cases.

Treatment

The proposed nonoperative management for metatarsus adductus includes observation, stretching exercises, splints/braces, corrective shoes, and stretching casts. Many types of operative procedures have been recommended for resistant deformities, including soft tissue releases and osteotomies.

The prognosis for spontaneous correction of flexible deformities without treatment is excellent (3,4,136). The efficacy of passive stretching exercises is not documented. Kite (129) believed that stretching exercises performed by the parents were not effective, and Ponseti and Becker (4) believed that they were potentially harmful.

The efficacy of shoes, braces, and splints in correcting foot deformities in children has never been shown. The Denis-Browne bar has no ability to concentrate corrective forces at the site of deformity, the tarsometatarsal joints. Furthermore, some authors believe that it can do harm by creating valgus deformity of the hindfoot (4,144).

Ponseti and Farsetti and colleagues (3,4), Bleck (143), Berg (145), and others have documented the efficacy of manipulation and serial casting for the correction of partly flexible and inflexible deformities. The upper age limit for this treatment modality is not known, but most authors recommend initiation in children younger than 1 year of age (4,143,145). Anecdotal experience indicates no need to begin this treatment before 6 months of age. The details of the casting technique are important. Care must be exercised to avoid excessive valgus stress on the hindfoot (4,129). Long-leg casts are preferred. Holding casts or postcast splints and shoes have been recommended to decrease the risk of recurrence after casting, which has been reported at 8 to 37% (129,143,147).

Surgery is rarely if ever indicated for metatarsus adductus (3). Spontaneous resolution of the deformity can occur up to 4 years of age (3,4), and minor residual deformity does not necessarily lead to disability (3,5). There are no reported series examining long-term disability from residual deformity. Nevertheless, many different operative procedures have been proposed to correct the deformity. Release of the abductor hallucis has been associated with the development of hallux valgus (148). Medial midfoot capsulotomies have been reported without clearly stated indications or natural history controls (136,149).

Heyman et al. (150) described mobilization of the forefoot by capsulotomy of the tarsometatarsal joints and release of the intermetatarsal ligaments. Long-term follow-up studies (151,152) showed a 41% failure rate, with complications including skin slough, avascular necrosis of the second and third cuneiforms, dorsal prominence of the first metatarsal–cuneiform joint, and early degenerative arthrosis of those joints with pain. Osteotomies at the base of the metatarsals have been used as an extraarticular alternative approach to avoid the complications of capsulotomies (153,154). However, shortening of the first metatarsal from a nonunion or

physeal injury, a devastating complication, has been reported in 5 to 30% of patients (153,155,156).

In the rare situation of an older child with disability related to residual deformity, it seems logical to perform the operative correction at the site of the deformity. An opening-wedge osteotomy of the medial cuneiform will change the malformed bone from a trapezoid to the normal rectangular shape, and, thereby, correct the orientation of the first metatarsal–cuneiform joint (116). This procedure **[➥7.6]** can be combined with closing-wedge osteotomy of the cuboid (Fig. 29-11), or with osteotomies at the bases of metatarsals two through four, in the more severe and resistant case (118,119,120 and 121). These osteotomies have been shown to be safe and effective, although they are rarely indicated. Careful preoperative assessment of the hindfoot is necessary to determine if the apparent metatarsus adductus is, in fact, a skewfoot deformity.

FIGURE 29-11. Correction of symptomatic metatarsus adductus in an older child with an opening-wedge osteotomy of the medial cuneiform and a closing-wedge osteotomy of the cuboid.

Skewfoot

Definition

"Skewfoot" is the term used most commonly to designate a rare and poorly defined foot shape that combines adduction deformity of the forefoot with valgus deformity of the hindfoot, i.e., metatarsus adductus plus flatfoot. This is a consensus definition that has been adopted recently in the medical literature (157,158,159,160 and 161), but it has not been officially adopted in medical dictionaries. It is not known how much valgus deformity of the hindfoot is necessary to reclassify a foot with presumed metatarsus adductus as a skewfoot, or how much forefoot adductus is required to reclassify a presumed flatfoot as a skewfoot. Skewfoot is generally discussed in the literature in relation to metatarsus adductus; however, disability caused by this condition is most often related to the hindfoot deformity (159). Inconsistent terminology was used in the three seminal articles on this deformity in the English literature. Peabody and Muro (137) labeled it "congenital metatarsus varus," McCormick and Blount (130) coined the term "skewfoot," and Kite (128) called it "serpentine metatarsus adductus." Interestingly, McCormick and Blount (130) used the term "skewfoot" to describe a group of deformities of the foot that included the shape that is now called skewfoot. Consistency was found in these articles in the reported rarity of the deformity, and in the difficulty of correcting and maintaining correction of the deformity.

Epidemiology

The lack of a strict definition has contributed to the lack of information on this deformity, including its incidence, pathogenesis, natural history, and treatment. It has been stated, without verification, that the diagnosis cannot be made in the newborn. Some researchers have stated that the deformity occurs as a result of improper cast treatment of metatarsus adductus and clubfoot. There are, however, clearly idiopathic cases.

Pathogenesis

The cause is unknown. Some authors believe that a skewfoot deformity can be created in a foot with metatarsus adductus by applying abduction pressure to the forefoot without stabilizing the hindfoot (4). Most cases, however, are idiopathic. The medial cuneiform in a skewfoot is trapezoidshaped, as it is in metatarsus adductus (157,158). A thickened portion of the tibialis anterior courses along an oblique dorsal-to-plantar groove on the concave medial border of the medial cuneiform (157,158). The etiologic significance of these findings is unknown.

Clinical Features

It is challenging to differentiate metatarsus adductus from skewfoot in an infant. The forefoot is adducted on the midfoot, there is frequently the presence of a medial skin crease, and there is normal ankle mobility. Slight valgus and severe valgus are difficult to quantify in a tiny foot with normal baby fat. In some infant feet with forefoot adductus, however, the subtalar joint is sufficiently everted that the head of the talus can be visualized and palpated medially (Fig. 29-12). The author would label such a foot a skewfoot. Valgus deformity of the hindfoot, with adductus of the forefoot, can be better appreciated in older children, adolescents (Fig. 29-13), and adults, although the deformity is often misclassified, even in the orthopaedic literature.

FIGURE 29-12. Probable skewfoot in an infant. Apparent metatarsus adductus, but with the head of the talus visible and palpable medially. This indicates coexistent eversion of the subtalar joint with abduction of the navicular on the head of the talus. (From ref. 157, with permission.)

FIGURE 29-13. Adolescent skewfoot, i.e., valgus deformity of the hindfoot with adductus of the forefoot. **A** and **B:** Photographs. **C** and **D:** Radiographs.

The types of disability associated with skewfoot in the older individual are not well documented. Callusing develops under the head of the talus (Fig. 29-14), as it does in a flatfoot, and at the base of the fifth metatarsal, as it may in severe metatarsus adductus (157,158 and 159). Shoes may wear unevenly, as occurs with a severe flatfoot. Pain develops under the callused head of the talus when there is a coexistent contracture of the Achilles tendon. This is identical to the pain and callus experienced in a flexible flatfoot with a short Achilles tendon (157,158,159 and 160).

FIGURE 29-14. Painful callus that developed under the head of the talus in a skewfoot with contracted Achilles tendon.

Radiographic Features

Radiographs are not indicated for the diagnosis of skewfoot in the infant. Berg (145) attempted to classify metatarsus adductus and skewfoot radiographically, but his system was based on assessment of the relationship of the navicular to the talus at a time of life when the navicular in not ossified. The classification system was found to have poor interobserver and intraobserver reliability, by Cook et al. (146).

Standing anteroposterior and lateral radiographs of the foot in the older child, adolescent, and adult will confirm the deformities that are appreciated clinically, i.e., adductus of the forefoot on the midfoot and valgus deformity of the hindfoot. Mosca (157) was the first author to stress that the skew, or zigzag, deformity is present in both the frontal and sagittal planes (Fig. 29-15). Previously, only the frontal (anteroposterior) plane deformity was assessed and discussed in the literature. Mosca (159) also identified the flaw in using the standard talus–first metatarsal angle to assess deformity between the forefoot and the hindfoot. The skewfoot has two deformities, in opposite directions from each other, between the talus and the first metatarsal, in both the frontal and sagittal planes. These angular deformities tend to cancel each other out when the talus–first metatarsal angle is measured. For that reason, a skewfoot with severe valgus deformity of the hindfoot will appear less deformed than a flatfoot with less valgus deformity, when both are assessed clinically and radiographically.

FIGURE 29-15. Anteroposterior (**A**) and lateral (**B**) radiographs of a skewfoot demonstrating skew, or zigzag, deformities in both planes. (From ref. 159, with permission.)

Natural History

The natural history of skewfoot is unknown. One would assume that some children undergo spontaneous correction of their skewfoot deformities with age, as occurs with metatarsus adductus (4,5) and flexible flatfoot (8,9), when each exists as an isolated deformity. The prevalence of long-term disability attributable to residual deformity is unknown, but some children have pain, callosities, and difficulty wearing shoes, as early as the end of the first decade of life (128,129 and 130,137,157,158,159,160 and 161).

Treatment

Despite the inability to definitively differentiate metatarsus adductus from skewfoot in infancy, it is reasonable to treat all feet with partly flexible and inflexible forefoot adductus with serial long-leg casting. Several authors have reported success with this approach, noting that it takes longer to correct a skewfoot, and that additional care must be exercised to avoid valgus stress on the already deformed hindfoot (4,128,129 and 130,143,145). Berg (145) cautioned against the use of reverse last shoes and Denis-Browne bars, for the same reason.

Some older children, adolescents, and adults with skewfoot deformity will report pain and callusing under the prominent head of the plantar-flexed talus (157,158,159 and 160). Invariably, they have contracture of the Achilles tendon, and symptomatically resemble patients with flexible flatfoot with a short Achilles tendon (157,158,159 and 160). Attempts can be made to stretch the Achilles tendon by means of exercises or casts. Rigid orthoses increase the pressure under the head of the rigidly plantar-flexed talus, and should be avoided. Nonoperative management generally holds little hope of relieving symptoms. Less commonly, children with skewfoot will present with isolated or coexisting pain and callosities at the head of the first metatarsal or the base of the fifth metatarsal (160).

Surgery is indicated when nonoperative management fails to relieve the pain and callosities (157,158,159 and 160). Suggestions for operative management can be found in the literature, but most are based on theory, and not on reviews of operative results. Historical recommendations have included tarsometatarsal capsulotomies or osteotomies at the base of the metatarsals to correct the forefoot deformity (137) and subtalar or triple arthrodesis for the hindfoot (152,153,161). Reported complications from these procedures on the forefoot are enumerated in the section of this chapter on metatarsus adductus (151,152 and 153,155,156). Reported complications and disability from subtalar and triple arthrodesis are enumerated in the section of this chapter on flatfoot (19,20,21,22,23,24,25 and 26). Mosca (158) proposed correction of symptomatic skewfoot by combining the best and safest methods for correcting the individual deformities of the forefoot and hindfoot. In 1993, he reported the short-term results of the largest series of operatively treated skewfoot deformities using a single technique. The technique consists of calcaneal lengthening osteotomy, modified from the technique of Evans **[➥7.5]** (124,159); medial cuneiform opening-wedge osteotomy, according to Fowler et al. (116); and lengthening of the Achilles tendon (Fig. 29-16). Nine of 10 severe skewfoot deformities achieved satisfactory clinical and radiographic outcomes while maintaining joint mobility.

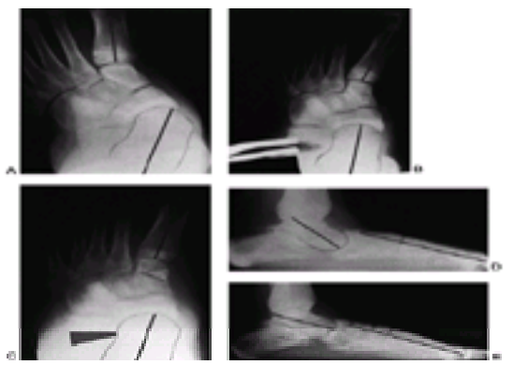

FIGURE 29-16. Preoperative, intraoperative, and postoperative radiographs of a painful skewfoot in a 13-year-old adolescent. **A:** Preop anteroposterior (AP) view. **B:** Intraop distraction of calcaneal osteotomy. **C:** Corrected deformity on AP radiograph with grafts in place. **D:** Preop lateral. **E:** Postop correction. Calcaneal lengthening osteotomy, medial cuneiform opening-wedge osteotomy, and Achilles tendon lengthening were used. (From ref. 157, with permission.)

Flexible Flatfoot

Definition

"Flatfoot" is the term used to describe a weight-bearing foot shape in which the hindfoot is in valgus alignment, the midfoot sags in a plantar direction with reversal of the longitudinal arch, and the forefoot is supinated in relation to the hindfoot. "Flexibility" refers to the mobility of the subtalar joint and the longitudinal arch, and the ability of both to reverse their malalignment.

Epidemiology

The true incidence of flexible flatfoot is unknown, primarily because there is no agreement on strict clinical or radiographic criteria for defining a flatfoot. Nevertheless, it is believed that most children (8,9) and at least 20% of adults (7) have flatfeet, most of which are flexible. Harris and Beath (7) used their own criteria when they identified flatfoot in approximately 23% of the 3,619 adults whom they examined. They classified them into three types and emphasized that the flatness of the arch in weight bearing is less important than the mobility of the joints and tendons. The flexible, or hypermobile, type of flatfoot was characterized by good mobility of the joints and tendons. It accounted for two-thirds of the flatfeet, and was found to be of little or no clinical concern as a potential cause of disability. Contracture of the Achilles tendon was associated with a flexible, or hypermobile, flatfoot in 25% of the total. This type was found to be a cause of pain and disability (7,162). The least common type was the rigid flatfoot, which was characterized by restricted mobility of the subtalar joint. This type was usually caused by a tarsal coalition, and painful disability was sometimes observed. Flexible flatfeet are said to run in families, although there are, to my knowledge, no data to support this statement. The frequency of flatfeet may be the basis of this observation.

Pathogenesis

There are two main theories explaining the pathogenesis of flexible flatfoot. Duchenne (163) used faradic stimulation of the peroneus longus muscle to produce a longitudinal arch in a child's flatfoot. He felt that subclinical muscle weakness was responsible for the flexible flatfoot, a theory that has been supported by other authors. That theory was fairly decisively refuted by Basmajian and Stecko (164), who demonstrated little or no electromyographic activity in the muscles of the foot and ankle, when physiologic loads were applied to the static plantigrade foot in study subjects. They concluded that the bone–ligament complex determines the height of the longitudinal arch, whereas the muscles maintain balance, accommodate the foot to uneven terrain, protect the ligaments from unusual stresses, and propel the body forward. Mann and Inman (165) confirmed this theory. They also found that the intrinsic muscles are the principal stabilizers of the foot during propulsion, and that greater intrinsic muscle activity is required to stabilize the transverse tarsal and subtalar joints in a flatfooted individual than in an individual with an average height arch.

Harris and Beath (162) and others supported the theory that the shape and function of the foot is dependent on the design, configuration, and relative position of the tarsal bones. They were unable to determine whether the abnormal shape of the bones and joints was primary or secondary to the lax ligaments.

The effects of extrinsic factors on the shape and development of the longitudinal arch is suggested by studies from developing countries. Sim-Fook and Hodgson (166), in China, and Rao and Joseph (167), in India, found a higher prevalence of flatfeet among children who wore shoes compared with children who did not.

Clinical Features

The clinical assessment should consist of a general examination of the musculoskeletal system in addition to the specific foot and ankle examination. The general examination is aimed at assessing ligament laxity, torsional and angular variations of the lower extremities, and the walking pattern. Assessment of the foot and ankle begins with the recognition that a flatfoot is not a deformity. It is a combination of deformities that includes a valgus deformity of the hindfoot and a supination deformity of the forefoot. There is a lateral rotational deformity as well. The axis of the subtalar joint complex is in an oblique plane, such that eversion creates valgus, external rotation, and dorsiflexion of the so-called pes acetabulum around the talus. The mobility, or flexibility, of the subtalar joint in a flexible flatfoot is revealed by toe standing (Fig. 29-17), and by the Jack toe-raise test (168) (Fig. 29-18). These two maneuvers take advantage of the windlass action (169) of the plantar fascia to mobilize the subtalar joint into inversion and create a longitudinal arch (Fig. 29-19). Supination deformity of the forefoot on the hindfoot is revealed when the hindfoot deformity is passively corrected by inversion. Functional motion of the ankle joint, as assessed by excursion of the Achilles tendon, is important yet difficult to evaluate accurately. A component of eversion of the subtalar joint is dorsiflexion of the calcaneus in relation to the talus. Therefore, the subtalar joint must be held inverted to neutral to isolate and assess the motion of the talus at the ankle. The knee is then flexed, the ankle is dorsiflexed, and the knee is extended while trying to maintain maximum dorsiflexion of the ankle. Dorsiflexion is measured as the angle between the lateral border of the foot and the anterior tibial shaft.

FIGURE 29-17. The arch elevates and the heel corrects from valgus to varus in a flexible flatfoot during toe standing, as a result of the windlass effect of the plantar fascia. (From ref. 157, with permission.)

FIGURE 29-18. The arch elevates in a flexible flatfoot with the Jack toe-raise test, as a result of the windlass effect of the plantar fascia. (From ref. 157, with permission.)

FIGURE 29-19. The windlass effect of the plantar fascia. The drum of the windlass is the head of the metatarsal. The handle is the proximal phalanx, and the cable wound onto the drum is the plantar aponeurosis, through its attachment to the plantar pad of the metatarsophalangeal joint. Dorsiflexion of the toes creates elevation of the longitudinal arch. (From ref. 169, with permission.)

A family history of flatfeet should be ascertained, with particular attention paid to the existence of pain or other disability.

Radiographic Features

Radiographs of the flatfoot are not necessary for diagnosis, but they may be indicated for the assessment of pain or decreased flexibility, and for surgical planning. Weight-bearing anteroposterior and lateral views are generally sufficient to evaluate the flexible flatfoot, whereas the addition of the oblique and axial, or Harris, views is necessary to evaluate the rigid flatfoot. Radiographs can define the static relationships between bones, but they cannot provide information on flexibility or function. They should not be used as an indication for treatment. This was the conclusion of the study on radiographs of the adult foot by Steel et al. (170) and the study on radiographs of the child's foot by Vanderwilde et al. (9).

The lateral radiograph of a flatfoot reveals plantar flexion of the calcaneus, measured by the calcaneal pitch, and an even greater degree of plantar flexion of the talus, measured by the talus–horizontal angle (Fig. 29-20). Dorsiflexion of the navicular on the head of the plantar-flexed talus creates a midfoot sag with lowering of the longitudinal arch that can be quantified using the talus–first metatarsal angle. Meary (171) determined that the normal talus–first metatarsal angle is zero degrees, or a straight line, but there is in fact a range of normal values. The lateral view can also be used to identify alternative or additional sites of midfoot sag.

FIGURE 29-20. Weight-bearing lateral radiograph. The calcaneal pitch (CP) and the talus–horizontal angle (T-H) are the best measurements to assess valgus deformity of the hindfoot. *T-1MT*, talus–first metatarsal angle. (From ref. 159, with permission.)

The anteroposterior radiograph is less helpful in quantifying flatfoot deformity in a child. The subtalar complex in a flatfoot is excessively everted, a malalignment that combines external rotation and dorsiflexion of the calcaneus, in relation to the talus, with abduction and dorsiflexion of the navicular on the head of the talus. The axis of the calcaneus is frequently difficult to assess on the anteroposterior radiograph, because of technical considerations. Therefore, assessment of the relationship at the talonavicular joint is critical. Unfortunately, the child's navicular ossifies eccentrically beginning laterally, making it unreliable for positional assessment. The anteroposterior talus–first metatarsal angle has been used as an alternative means of evaluating that relationship, but it is unreliable as well. As discussed in the skewfoot section of this chapter, abduction or adduction at the tarsometatarsal joint will falsely exaggerate or minimize the apparent deformity at the talonavicular joint if assessed using the talus–first metatarsal angle (159).

Radiographs can also be used to determine if a painful midfoot prominence is the head of the talus or an accessory navicular.

Natural History

Flatfeet are ubiquitous in infants. Footprint (8) and radiographic (9) studies have confirmed that the average arch height is lower in the child than in the adult. The height of the longitudinal arch generally increases spontaneously during the first decade of life in most children. And there is a wide range of normal arch heights at all ages (particularly in young children) (Fig. 29-21).

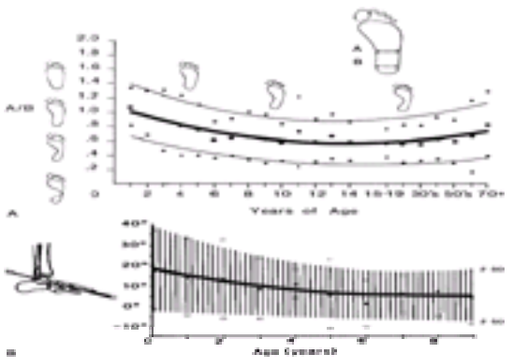

FIGURE 29-21. A: Footprints from individuals of all ages show that children are more flatfooted than adults, that there is a wide range of normal arch heights, and that the arch generally elevates spontaneously during the first decade of life. (From ref. 8, with permission.) **B:** Radiographs from children of all ages confirm the footprint data. The drawing and graph represent the lateral talus–first metatarsal angle. (From ref. 9, with permission.)

Treatment

There are no long-term, prospective clinical studies on the natural history of flexible flatfoot. The information that has been presented is cross-sectional and inferential. Much of the understanding of the benign nature of flexible flatfoot has only recently been elucidated. Most authorities now agree that the flexible flatfoot is an anatomic variant, and not a potentially disabling deformity (7,157,170). Nevertheless, controversy abounds.

Earlier, uncontrolled studies indicated an efficacy of orthotic devices and shoe modifications in the development of the arch in the child's foot (172). More recent, prospective, randomized, controlled studies revealed no benefit from shoe modifications and inserts, compared to spontaneous development of the longitudinal arch (10,11,173). Driano et al. (174) reported long-term negative psychologic effects on adults who had worn shoe modifications as children compared with controls. Therefore, one must conclude that the management of the asymptomatic flexible flatfoot is education of the child and family.

Some children with flexible flatfoot have activity-related pain in the leg or foot. The pain is usually diffuse and nonlocalized, and it is believed to represent an overuse, or fatigue, syndrome. This is consistent with the findings of Mann and Inman (165) that flatfooted individuals demonstrate greater intrinsic muscle activity than normal. Over-the-counter and custom-molded shoe inserts have been shown to relieve or diminish symptoms, and to increase the useful life of shoes without a simultaneous permanent increase in the height of the arch (175). There is no scientific justification for surgery in these children.

Some children with flexible flatfoot have pain with weight bearing and callosities under the head of the plantar flexed talus. The Achilles tendon is contracted in these children. The contracted Achilles tendon prevents normal dorsiflexion of the ankle joint during the midstance phase of gait, and shifts the dorsiflexion stress to the subtalar joint complex. The talus remains rigidly plantar flexed. The soft tissues under the head of the talus are subjected to excessive direct axial loading and shear stress. Firm or hard arch supports exaggerate these pressures. An aggressive stretching program for the Achilles tendon, performed with the subtalar joint inverted, may relieve the symptoms in this clinical situation. Failure to relieve this localized pain with prolonged attempts at conservative management is an indication for operative reconstruction of the foot (159).

Surgery is rarely, if ever, indicated for flexible flatfoot. Nevertheless, numerous surgical procedures to correct flatfoot have been proposed during the last century. The indications for these procedures, whether for correction of deformity, relief of symptoms, or prophylaxis, are difficult to ascertain from a review of the literature. The procedures can be categorized as soft tissue plications, tendon lengthenings and transfers, osseous excisions, osteotomies, arthrodesis of one or more joints, and interposition of bone or synthetic materials into the sinus tarsi. Any procedure should be judged by its ability to achieve and maintain relief of pain and correction of even severe deformity. There have been very few long-term outcome studies on any of these procedures. Nevertheless, those that have been reported have helped to narrow the surgical choices. Mosca (157) recently reviewed the literature, and can be referred to for more detail on these procedures.

Procedures that rely entirely on soft tissue plications and tendon transfers fail in the short term. Osseous excisions were abandoned years ago, because of their obvious destructive nature. Arthrodesis of one or more of the joints in the subtalar complex has been abandoned, because of the detrimental effect of eliminating the shock-absorbing function of that important joint complex. Subtalar and triple arthrodesis shift stress to the ankle and midtarsal joints, leading to premature degenerative arthrosis at those sites (19,20,21,22,23,24,25 and 26). The most popular procedures used during the last 60 to 70 years are the many modifications of Hoke's limited midtarsal arthrodesis (16,17 and 18,168,176,177 and 178). These procedures combine arthrodesis of one or more midtarsal joints with soft tissue plication across the talonavicular joint. Favorable short-term results have been reported consistently, but unsatisfactory long-term results were reported in 68 of 138 cases (49%) by Butte (16), 16 of 32 cases (50%) by Seymour (18), and 7 of 9 cases by Crego and Ford (17). The unsatisfactory feet in these series frequently showed degenerative changes at the talonavicular joints, in addition to persistence or recurrence of pain and deformity. Furthermore, the originators of these procedures acknowledged that the procedures were not capable of correcting severe valgus deformities. They recommended triple arthrodesis for those feet.

“Arthroereisis” is the term applied to procedures that limit, but do not eliminate, the motion of a joint with abnormal mobility. Arthroereisis of the subtalar joint in flexible flatfeet has been reported using bone, silicone, and ultrahigh-molecular-weight polyethylene pegs in the sinus tarsi (179,180). The bone grafts frequently undergo resorption. Reported complications of the prosthetic implants include pain, malpositioning, breakage, extrusion, infection, and reactive synovitis. Most orthopaedists prefer a biologic approach to deformity in children.

Osteotomy is the last category of procedures. This is a biologic approach that avoids arthrodesis and its known complications. There are two types of osteotomies of the calcaneus that address valgus deformity of the hindfoot. Medial displacement of a posterior calcaneal osteotomy (181) will improve the valgus appearance of the hindfoot by creating a compensating deformity. It does not correct the malalignment of the subtalar joint, which includes external rotation of the foot under the talus and dorsolateral displacement of the navicular on the head of the talus. Rathjen and Mubarak (182) reported good correction of flatfoot deformities by combining this osteotomy with closing-wedge osteotomy of the medial cuneiform, opening-wedge osteotomy of the cuboid, and medial reefing of the talonavicular joint.

The other osteotomy for correction of valgus deformity of the hindfoot is the calcaneal lengthening osteotomy **[➥7.5]** described by Evans (124). It has been shown to correct all components of even severe eversion of the subtalar complex (valgus deformity of the hindfoot) at the site of deformity (124,159,183,184 and 185). Additionally, it restores the function of the subtalar complex, relieves symptoms, and, theoretically, protects the ankle and midtarsal joints from early degenerative arthrosis by avoiding arthrodesis (124,159,183,184 and 185). Based on the stated pathology and the indications for treatment, lengthening of the Achilles tendon is always necessary **[➥7.16, 7.17]**. Supination of the forefoot is an additional deformity in a flatfoot that is rotationally in the opposite direction from the hindfoot deformity. If it is a structural deformity, it must be treated with an additional procedure on the medial column of the foot, such as a plantar-based closing-wedge osteotomy of the medial cuneiform (159,183). It is only when all three deformities are corrected that the flatfoot has been corrected (159) (Fig. 29-22). There are few indications for surgery for flexible flatfeet, except in those with tight Achilles tendons. There are no surgical panaceas, but the combination of procedures just described has the best chance of long-term success, while leaving other surgical options for the future.

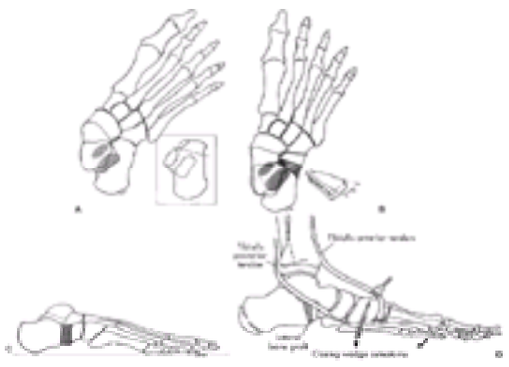

FIGURE 29-22. A: Calcaneal lengthening osteotomy. *Dashed line* indicates the position of the oblique osteotomy between the anterior and middle facets of the calcaneus. **B** and **C:** Insertion of the trapezoid-shaped tricortical iliac crest bone graft corrects all components of the valgus deformity of the hindfoot. **D:** A plantar-based closing-wedge osteotomy of the medial cuneiform corrects the supination deformity of the forefoot. Lengthening of the gastrocnemius or the Achilles tendon is almost always necessary. (**A**, **B**, and **C** from ref. 159, with permission; **D** from ref. 183, with permission.)

Congenital Vertical Talus (Congenital Convex Pes Valgus)

Definition

Congenital vertical talus is a dorsolateral dislocation of the talonavicular joint, and occasionally the calcaneocuboid joint, associated with extreme and rigid plantar flexion of the talus, eversion of the subtalar joint, and fixed dorsiflexion of the midfoot on the hindfoot (186). Other historic terms used to describe this deformity include congenital rocker-bottom foot, congenital convex pes valgus, and congenital flatfoot with talonavicular dislocation.

Epidemiology

The incidence of this deformity is unknown. Several large series have reported that this rare deformity occurs as an isolated congenital abnormality in approximately half of all cases, and is associated with neuromuscular and genetic disorders in the rest (187,188,189 and 190). There is no sex predilection, and approximately 50% of children have bilateral involvement (189).

Pathogenesis

There are probably multiple causes of this deformity. There is evidence that some cases of the isolated deformity are transmitted as an autosomal dominant trait with incomplete penetrance (190,191). Cases associated with neural tube defects, such as myelomeningocele, sacral agenesis, and diastematomyelia, are attributable to muscle imbalance (192). It is a different type of muscle imbalance that creates the deformity in children with arthrogryposis.

Clinical Features

Congenital vertical talus has a rigid, convex plantar surface, giving the foot the appearance of a Persian slipper (Fig. 29-23). Lloyd-Roberts and Spence (193) described the clinical appearance as “a prominence in the sole from which the heel and forefoot rise in a gentle curve.” The Achilles tendon is contracted, and the hindfoot is in a fixed equinovalgus position. There are few posterior heel creases. The head of the talus is palpable on the plantar-medial aspect of the midfoot. The midfoot is dorsiflexed and abducted on the hindfoot, and cannot be plantar flexed. There is a crease overlying the narrow, concave sinus tarsi. The hallmark finding in congenital vertical talus is that none of the deformities is correctable by manipulation. The arch cannot be created, nor can the head of the talus be covered by the navicular.

FIGURE 29-23. Congenital vertical talus in an infant. **A:** Medial. **B:** Lateral.

Oblique talus is a term often mentioned in discussions of congenital vertical talus. To the author's knowledge, there is no consensus definition of this deformity or any primary literature on the subject. The author's belief is that oblique talus exists as a milder and more flexible form of congenital vertical talus, but that it is a more severe and rigid deformity than flexible flatfoot with a short Achilles tendon.

It is important to differentiate congenital vertical talus from positional calcaneovalgus, congenital posteromedial bowing of the tibia, and equinovalgus foot deformity associated with fibula hemimelia. The feet in these conditions are flexible, and the arch can be exaggerated by manipulation.

Radiographic Features

Lateral radiographs of the foot, obtained with the foot in maximum plantar flexion and maximum dorsiflexion are recommended to confirm the diagnosis, notwithstanding the limitations of radiographs discussed in the section on clubfoot (192). The talus, calcaneus, and metatarsals are ossified at birth, and the cuboid generally ossifies within the first month of life. These centers of ossification enable one to confirm the diagnosis radiographically soon after birth. The maximum dorsiflexion view shows the persistence of plantar flexion of the talus and calcaneus, caused by contracture of the Achilles tendon and posterolateral joint capsules (Fig. 29-24A). In a normal foot, the talus dorsiflexes to a right angle with the tibia and the calcaneus dorsiflexes at least 20 degrees past a right angle with the tibia (Fig. 29-24B). The maximum plantar flexion view shows persistent dorsal translation of the forefoot on the hindfoot, caused by fixed dorsal dislocation of the navicular on the head of the talus (Fig. 29-24C). In a normal, unstressed foot, the axes of the talus and first metatarsal create a nearly straight line. In a normal foot that is maximally plantar flexed, those lines intersect in the midfoot, creating an apex dorsal angle (Fig. 29-24D). The position of the cuboid in relation to the calcaneus should also be noted, because it may be dorsally subluxated to varying degrees in congenital vertical talus.

FIGURE 29-24. A: Lateral dorsiflexion radiograph of congenital vertical talus, showing persistent plantar flexion of the talus and calcaneus. **B:** Lateral dorsiflexion radiograph of a normal foot, showing full dorsiflexion of the talus and calcaneus. **C:** Lateral plantar flexion radiograph of congenital vertical talus, showing persistent dorsal translation of the forefoot on the hindfoot. **D:** Lateral plantar flexion radiograph of a normal foot, showing good alignment of the forefoot on the hindfoot.

The author believes that an oblique talus can be characterized radiographically, although there is no literature to confirm or refute this statement. With manipulation of an oblique talus deformity, the talus will partially dorsiflex and the midfoot will plantarflex to an improved, but not complete, alignment at the talonavicular joint.

Pathoanatomy

Postmortem dissections have provided some consistent pathoanatomic findings. Several authors have reported abnormal contractures of the extrinsic muscles, but reached different conclusions on the primary muscle imbalance that leads to the deformity (194,195,196 and 197). Most found contractures of the tibialis anterior, extensor hallucis longus, extensor hallucis brevis, peroneus tertius, peroneus longus, peroneus brevis, and Achilles tendon. The peroneus longus and peroneus brevis were anteriorly subluxated at the lateral malleolus. The tibialis posterior was noted to be atrophied and anteriorly subluxated at the medial malleolus. There was dorsal extension of the articular cartilage of the talar head, to accommodate the proximal articular surface of the navicular, which was wedge-shaped with a hypoplastic plantar segment. The severe plantar flexion of the talus resulted in minimal contact of only the most posterior aspect of the talar dome with the tibia. The head of the talus was oval-shaped. The calcaneus was severely externally rotated and everted, and in close proximity to the lateral malleolus. The sustentaculum tali was hypoplastic, and the anterior subtalar facet was absent. The posterior facet of the subtalar joint had an increased lateral tilt. The dorsal capsule of the talonavicular joint was thickened and contracted, whereas the plantar calcaneonavicular (spring) ligament was attenuated. The plantar half of the cuboid was hypoplastic, and the entire bone was dorsolaterally subluxated on the calcaneus.

Natural History

Congenital vertical talus persists and causes disability if untreated. The rigidly plantar-flexed head of the talus becomes the predominant weight-bearing surface of the foot, with the development of callosities and pain. The heel does not contact the ground. There is no push-off. The gait simulates that of someone with a Syme amputation, but without the well-cushioned heel pad under the weight-bearing bone. If one accepts the author's definition of oblique talus as existing on a continuum between congenital vertical talus and flexible flatfoot, with a short Achilles tendon (but closer to the vertical talus), the prognosis for the untreated foot is poor.

Treatment

As with clubfoot, treatment for the congenital vertical talus and the oblique talus begins with manipulation and serial casting, but with the forces applied in exactly the opposite direction. The foot is stretched into plantar flexion and inversion, in an attempt to elongate the contracted dorsolateral tendons, joint capsules, and skin. It is not possible to concurrently manipulate the hindfoot into dorsiflexion and inversion, because of its small size and dense capsular contractures. Essentially 100% of vertical talus deformities and an undocumented percentage of oblique talus deformities will fail to achieve deformity correction with casting, and will require surgery. Nevertheless, casting is considered important to stretch the dorsal soft tissues and, thereby, decrease the complexity of the operation (189,190,192,196).

Surgical treatment options include one-stage or two-stage circumferential release, talectomy, naviculectomy, subtalar arthrodesis, triple arthrodesis, and lateral column lengthening. Talectomy was recommended by Lamy and Weissman in 1939 (186), but was soon abandoned. It is a destructive, rather than a reconstructive, procedure that does not address the pathology. Additionally, it leaves no options for treating future problems that may arise. The primary choices for operative treatment of congenital vertical talus in a child younger than approximately 2 years of age are one-stage and two-stage circumferential release and reduction. The first stage of the two-stage procedure consists of lengthening of the contracted dorsolateral tendons and release of the contracted dorsolateral joint capsules, with reduction of the forefoot on the hindfoot. The second stage consists of posterolateral release of the contracted capsules and lengthening of the Achilles and peroneal tendons. The one-stage procedure simply combines the two steps into one. Ogata et al. (190) found an increased incidence of complications with the two-stage procedure, including avascular necrosis of the talus. Most authors now recommend the one-stage procedure (190,192,198,199,200 and 201), reporting results that are comparable to or better than those reported with the two-stage approach (189,202,203). Several authors have reported the addition of a full or split transfer of the tibialis anterior to the head or neck of the talus (192,198,199,204,205). Although the efficacy of these transfers has not been scientifically proven, the split transfer adds little time and no morbidity, and makes sense theoretically. The peroneus longus, the plantar flexor of the first ray of the foot, is congenitally contracted and strong. Complete transfer of the tibialis anterior, the dorsiflexor of the first ray, could lead to muscle imbalance and the progressive development of a cavus foot deformity. The split transfer leaves some dorsiflexion power on the first ray, while adding supplemental support to the head of the talus.

It is not clear if there is an upper age limit for this reconstructive approach. There is disproportionate growth of the medial and lateral borders of the foot with chronically unreduced vertical talus. Physiologic compression that is normally associated with a reduced talonavicular joint is lacking. Longitudinal overgrowth of the medial border occurs according to the Hueter-Volkmann law. Excessive compression along the lateral border of the foot inhibits normal longitudinal growth. This phenomenon may be seen as early as 2 to 3 years of age. It manifests as an inability to fully reduce the deformity, or as residual deformity, despite full reduction of the talonavicular joint. Shortening of the medial column and lengthening of the lateral column of the foot are two approaches to management. Some authors (206,207) have recommended naviculectomy as both a primary and a salvage procedure for congenital vertical talus. It is an effective technique for shortening the medial column of the foot. The proximal articular surfaces of the cuneiform bones have a combined configuration almost identical to that of the proximal articular surface of the navicular. They create a reasonably congruous articulation with the talar head, which is further improved over time according to the Hueter-Volkmann law. Posterolateral release is combined with naviculectomy for full deformity correction in this group of slightly older children (Fig. 29-25). The upper age limit for this procedure is unknown. The alternative approach of lengthening the lateral column for the older child with residual vertical talus deformity has not been reported. The congenitally contracted skin along the lateral border of the foot limits the applicability of this technique.

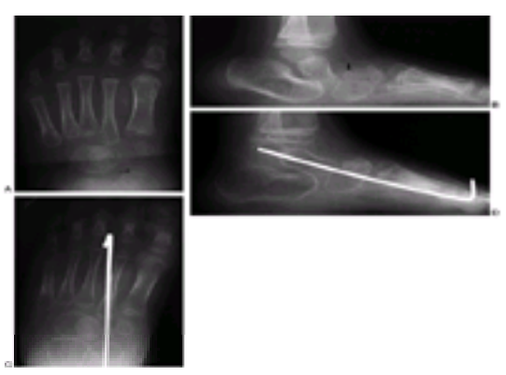

FIGURE 29-25. Radiographs before (**A** and **B**) and after (**C** and **D**) naviculectomy for congenital vertical talus in an older child. *Arrow* indicates the navicular.

Early diagnosis and treatment should eliminate the need for other surgical options in young children. Nevertheless, subtalar (204,205) **[➥7.10]** and triple arthrodeses **[➥7.9]** have been reported for this condition, as they have for almost every major foot deformity in the child. The literature clearly shows that these techniques are associated with a high rate of complications, including the development of degenerative arthritis at the ankle and midtarsal joints (19,20,21,22,23,24,25 and 26). Napiontek (208) reported overcorrection of the valgus deformity in half of his patients who underwent peritalar reduction combined with subtalar arthrodesis. Arthrodeses of the joints of the hindfoot, therefore, should be reserved as salvage procedures for the adolescent and adult with painful recurrent deformity or painful degenerative arthritis.

Positional Calcaneovalgus

Definition

Positional calcaneovalgus deformity is characterized by marked dorsiflexion of the entire foot at the ankle joint with mild and flexible eversion of the subtalar joint (Fig. 29-26). The soft tissues of the dorsal and lateral aspects of the foot are contracted and limit, but rarely prevent, plantar flexion and inversion. The dorsum of the foot is

often in contact with the anterior shin.

FIGURE 29-26. Positional calcaneovalgus foot deformity.

Epidemiology

Wetzenstein (209) reported the incidence at 30 to 50%, and Wynne-Davies (135) reported it at 1 per 1,000 live births. The true incidence figures are not known, but positional calcaneovalgus may be the most common deformity of the foot seen at birth. It is more common in girls, first-born children, and children of young mothers.

Pathogenesis

The probable cause is intrauterine malpositioning.

Clinical Features

The importance of discussing this condition is to differentiate it from other, more serious deformities. Congenital vertical talus is the most important condition from which to differentiate positional calcaneovalgus. In contrast to the latter condition, congenital vertical talus is characterized by fixed equinus and valgus of the hindfoot, rigid dorsiflexion of the midfoot on the hindfoot, and the inability to create a longitudinal arch by manipulation. Congenital posteromedial bowing of the tibia may also be confused with positional calcaneovalgus, but physical examination and radiography can easily differentiate it. Paralytic calcaneovalgus, due to lack of active plantar flexion, can be seen at birth in children with myelomeningocele. The underlying diagnosis should be apparent.

Radiographic Features

Radiographs of a foot with positional calcaneovalgus deformity show normal interosseus relationships, and are not necessary for diagnosis. They can be used to rule out congenital vertical talus, and to confirm congenital posteromedial bowing of the tibia.

Natural History

The prognosis for spontaneous correction is excellent (6,210).

Treatment

Larsen et al. (6) found no difference between calcaneovalgus feet that underwent manipulation and bandaging versus observation alone, when assessed at 3 to 11 years of follow-up. The majority of the feet were normal. The severity of contractures found at birth appeared to have no influence on the final results. Wetzenstein (209) noted a high degree of correlation between the severity of calcaneovalgus deformity in the newborn and flexible flatfoot in the older child. Flexible flatfoot is a normal foot shape, so there should be no negative implication from this finding. Based on this information, one can conclude that positional calcaneovalgus is a benign deformity with excellent prognosis without treatment. Certainly no treatment is required for a mild deformity in which the foot can be plantar-flexed and inverted beyond the neutral position. In an attempt to hasten correction, passive stretching exercises can be performed by the parents for a moderate deformity in which there is difficulty in manipulating the foot to the neutral position. It is a rare foot that requires serial casting to hasten correction of the contracted tissues. Surgery is never required.

Congenital Overriding Fifth Toe

Definition

Congenital overriding fifth toe is a dorsomedial subluxation of the metatarsophalangeal (MTP) joint of the fifth toe that is present at birth. The entire toe is dorsally and proximally displaced, adducted, and externally rotated, lying across the base of the fourth toe (Fig. 29-27A and Fig. 29-27B).

FIGURE 29-27. A and **B:** Congenital overriding fifth toe. **C–E:** The Butler procedure for congenital overriding fifth toe. Double racket-handle incision with dorsal V-to-Y advancement and plantar-lateral Y-to-V advancement.

Epidemiology

The incidence is unknown, but congenital overriding of the fifth toe is a common condition. There is no sex predilection. Bilateral involvement is seen in 20 to 33% of cases (211,212 and 213).

Pathogenesis

The cause is unknown, but there is a familial tendency (212).

Clinical Features

The toe has a characteristic appearance that is different from that of other congenital and developmental deformities of the toes. The interphalangeal joints are in normal full extension. The skin in the web between the fourth and fifth toes is out of alignment with the other web spaces, yet there is no stress or tension on the skin. The toe was formed in that position, not secondarily contracted. The toenail is normal, and the toe has active flexion and extension. Except for possible bilaterality, this is an isolated deformity.

Radiographic Features

Although difficult to image, radiographs would show dorsolateral subluxation at the MTP joint.

Pathoanatomy

There is contracture of the dorsomedial capsule of the fifth MTP joint, but the toe is not clawed. There is also shortening of the extensor tendons to the fifth toe that matches the degree of proximal positioning of the toe. The toe seems to have emerged from the end of the foot, translated more proximally and dorsally than the other toes.

Natural History

Approximately half of affected individuals experience pain and disability (212).

Treatment

Conservative measures, such as stretching, taping, and strapping, have no proven efficacy. This is not surprising considering the pathoanatomy. Therefore, education about the reasonably good prognosis is the recommended early treatment.

Surgery is indicated for the roughly 50% of adolescents and adults who experience difficulty with shoe-fitting because of pain over the dorsum of the fifth toe (212). Numerous surgical procedures have been proposed. Those involving partial and complete excision of the proximal phalanx, with syndactylization to the fourth toe, have had only fair results, and have led to secondary deformities (214). Amputation should be considered a salvage procedure. The Butler procedure **[➥7.20]** originally reported by Cockin (212), is the most successful procedure available (Fig. 29-27C,Fig. 29-27D and Fig. 29-27E). A double-racket-handle incision is used to release the contracted soft tissues and mobilize the neurovascular bundles. The toe is then translated plantar-laterally, which is like “changing gear in a car” (212). There is a risk of neurovascular compromise, but that complication has not been reported.

Curly Toe

Definition

Curly toe is a congenital deformity of one or more of the lesser toes, in which there is flexion, varus, and lateral rotation of the interphalangeal joints, causing the toe to curl under the adjacent more medial toe (Fig. 29-28).

FIGURE 29-28. Curly third toe.

Epidemiology

This is a very common deformity, although the incidence has not been reported. It is usually bilateral and symmetric (215,216). There is a high familial incidence.

Pathogenesis

The cause is unknown.

Clinical Features

The third and fourth toes are most frequently involved. The distal phalanx or the distal and middle phalanges underride the more medial toe, because of the flexion, varus, and external rotation of the distal and/or proximal interphalangeal joints. The nail plate of the affected toe faces laterally. Contrary to the situation seen with congenital overriding fifth toe, the skin in the web spaces is normally aligned. The deformity is flexible in early childhood. The interphalangeal joints can be extended fully when the MTP joint is flexed. This maneuver indicates that the deformity is caused by contracture of the flexor tendon(s).

Radiographic Features

Radiographs are not needed or helpful.

Pathoanatomy

The flexor hallucis longus and/or flexor hallucis brevis tendons to the affected toe are contracted (217). Joint capsules are not contracted.

Natural History

Curly toes are asymptomatic in young children. Many improve in shape spontaneously (216,217). They may become symptomatic in older children, adolescents, and adults, as a result of exaggerated pressure on the skin and nails of the malaligned toes.

Treatment

Stretching, taping, and strapping have no proven efficacy in correcting curly toes (216). The family should be educated regarding the fact that most affected

individuals will have no long-term disability, even with residual deformity.

Surgery is indicated for pain, callosities, and blistering resulting from pressure on the tip of the curly toe or over the interphalangeal joints of the more medial toe that overrides the curly toe. Another indication is an unacceptable problem with growth of the nail on either or both toes. Tenotomy of the flexor hallucis longus **[🛏7.21]**, with or without tenotomy of the flexor hallucis brevis, has been successful in 95 to 100% of cases (215,217). A double-blind, randomized, prospective study, comparing simple tenotomy of the flexor hallucis longus with transfer of the flexor hallucis longus to the extensor mechanism (Girdlestone-Taylor procedure), showed no difference in outcome (218). Simple tenotomy of the flexor hallucis longus is the recommended procedure for individuals with symptoms.

CONGENITAL MALFORMATIONS

These are conditions in which the structure(s) was formed improperly. Examples include too large, too small, improperly connected, too many, too few, wrong shape. In some cases, the abnormality does not manifest for several years.

Accessory Navicular

Definition

"Accessory navicular" is the term applied to plantar and medial enlargement of the tarsal navicular bone beyond its normal size. It may consist of a separate ossicle connected to the main body of the navicular by fibrous tissue or cartilage, or it may be a solid bony enlargement of the bone. Other terms for the separate ossicle include os tibiale externum, navicular secundum, and prehallux.

Epidemiology

The accessory tarsal navicular is the most common accessory bone in the foot, occurring in between 4 and 14% of the population (7,12,219). It is frequently bilateral, and occurs more commonly in females.

Pathogenesis

McKusick believed that the accessory navicular was inherited as an autosomal dominant trait (220).

Clinical Features

The accessory navicular produces a firm prominence on the plantar-medial aspect of the midfoot. There may be a coexistent flexible flatfoot (221,222,223 and 224), but there is no conclusive evidence of a cause-and-effect relationship between the two conditions, which was historically believed (13). The prominence of an accessory navicular is in close proximity to the head of the talus, which is prominent in a flexible flatfoot. Inverting and everting the subtalar joint, with one's thumb on the prominence, is helpful for differentiating the two. If the prominence moves, it is an accessory navicular. If it remains stationary, it is the head of the talus.

Individuals with an accessory navicular may present for evaluation because of the prominence, but more commonly they present because of pain at the site. The typical patient is an active adolescent girl with a history of minor trauma, who presents with pain, callus formation, tenderness, redness, and, occasionally, swelling over the bony prominence. Because of the frequency of this anatomic variation in the general population, one must be careful not to assume that a radiographically confirmed accessory navicular is the cause of the foot pain, without thorough evaluation (225).

Radiographic Features

An accessory navicular can usually be seen on standing anteroposterior and lateral radiographs, but an internal oblique view may be necessary for identification. There are three types of accessory naviculars (226) (Fig. 29-29). Type I is a rarely symptomatic, pea-sized sesamoid bone located in the center of the most distal portion of the tibialis posterior tendon. Type II, the most frequently symptomatic type, is a bullet-shaped ossicle joined to the tuberosity of the navicular by a syndesmosis or synchondrosis. Type III is a large, horn-shaped navicular that probably results from fusion of a type II accessory navicular with the body of the navicular.

FIGURE 29-29. Accessory navicular. **A:** Type I. **B:** Type II. **C:** Type III.

Pathoanatomy

There is proliferating vascular mesenchymal tissue, cartilage proliferation, and osteoblastic and osteoclastic activity in the tissue between the ossicle and the main body of the navicular in painful type II accessory naviculars (226). These histologic findings are consistent with healing microfractures, substantiating the opinion that pain at this site is related to chronic, repetitive stress. There are at least two other possible sources of pain. One is pain from pressure on the skin overlying the bony prominence. The other is tendinitis in the tibialis posterior, the tendon in which the ossicle resides. Any or all of these sources may exist in the same painful foot.

Natural History

Most accessory naviculars are asymptomatic (223).

Treatment

Nonsurgical treatment will often relieve symptoms. Pain is caused by inflammation of the skin, tendon, or cartilage. Strenuous, pain-exacerbating activities should be curtailed. Shoes should be examined to assess the area of contact with the prominence. Shoes can be stretched. Alternatively, shoes that provide softness in that area should be purchased. An over-the-counter orthotic device can be used to elevate the arch and change the site of contact between the prominence and the shoe. This may also decrease the stress on the tibialis posterior, and relieve the tendinitis. If pain is acute and persistent, the foot can be immobilized in a below-knee cast for 4 to 6 weeks.

Surgery is indicated for relief of symptoms after the failure of prolonged attempts at conservative management. The Kidner procedure was developed as a means of removing the ossicle and reestablishing the support of the arch by advancement of the tibialis posterior tendon (221,222). This was based on Kidner's belief that the height of the longitudinal arch was related to its muscular support, a theory that has since been disproved (164,227). Several studies have shown good to excellent results in 90% or more of cases by simple excision of the ossicle and shaving of the medial enlargement of the main body of the navicular through a tendon-splitting

approach (13,219,228,229,230 and 231). The incision should be placed slightly dorsomedially to avoid creating a painful scar.

Tarsal Coalition

Definition

Tarsal coalition is a fibrous, cartilaginous, or bony connection between two or more tarsal bones, which results from a congenital failure of differentiation and segmentation of primitive mesenchyme.

Epidemiology

Tarsal coalition has been described in the archeologic remains of several civilizations since pre-Columbian times (232). The association of the anatomic abnormality with the clinical syndrome of a painful flatfoot occurred 26 years after the introduction of radiographic imaging in 1895. In 1921, Slomann (233) linked the so-called "peroneal spastic flatfoot" with calcaneonavicular coalitions seen on radiographs. Almost three decades later, Harris and Beath (234) linked peroneal spastic flatfoot with talocalcaneal coalition. Tarsal coalition has also been linked, since 1965, with the infrequently occurring tibialis spastic varus, or cavovarus, foot (235,236).

Some tarsal coalitions are associated with other congenital disorders, such as fibular hemimelia (237), clubfoot (238), Apert syndrome, and Nievergelt-Pearlman syndrome. They tend to be quite extensive in terms of the number of tarsal bones involved and the percentage involvement of the subtalar joint. Their natural history and prognosis, although not well studied, seem to be good.

The focus of this section is on the more common types of tarsal coalitions that occur as isolated anomalies in about 1% of the general population (234). The most common sites of coalition are the middle facet of the talocalcaneal joint and between the anterior process of the calcaneus and the navicular. These talocalcaneal and calcaneonavicular coalitions occur with about equal frequency, and together they account for approximately 90% of all coalitions (239). They coexist in a small percentage of feet (240), and are bilateral in 50 to 60% of cases (241,242). Talonavicular, calcaneocuboid, naviculocuneiform, and cubonavicular coalitions are uncommon (239). The true incidence of tarsal coalition, the relative frequency of affected joints, and the frequency of bilaterality are not known, because most affected individuals are asymptomatic and go uncounted.

Pathogenesis

Wray and Herndon (243) suggested an autosomal dominant pattern of inheritance with variable penetrance, based on a single-family study. Leonard (14) confirmed an autosomal dominant pattern with almost full penetrance in a study of 31 index patients and 98 first-degree relatives.

Clinical Features

Progressive flattening of the longitudinal arch, with valgus deformity of the hindfoot, generally predates symptoms, but it is rarely the presenting complaint. The insidious onset of vague and aching pain, in the region of the sinus tarsi or the medial aspect of the hindfoot of a child between the ages of 8 and 16 years, is characteristic. The pain is usually aggravated by activity and relieved by rest. Occasionally, children will report recurrent ankle sprains. Pain under the head of the plantar-flexed talus, which is induced by weight bearing, as occurs in flexible flatfoot with a short Achilles tendon, is often reported in feet with the most severe valgus deformities. There is usually tenderness at the site of coalition, and there may be tenderness on the dorsal aspect of the talonavicular joint.

The flatfoot deformity has been variously described as rigid and peroneal spastic. Rigidity refers to restriction of subtalar joint motion, which can be assessed in several ways. It is important to isolate and manipulate the subtalar joint with the ankle joint held in neutral alignment. The subtalar joint will not invert, and the arch will not elevate during toe standing (244) (Fig. 29-30) and with the Jack toe-raise test (168) in a foot with a talocalcaneal coalition. Feet with calcaneonavicular coalitions are generally less rigid and less flat than feet with talocalcaneal coalitions, which makes inherent sense, because the former type does not cross the subtalar joint and the latter does.

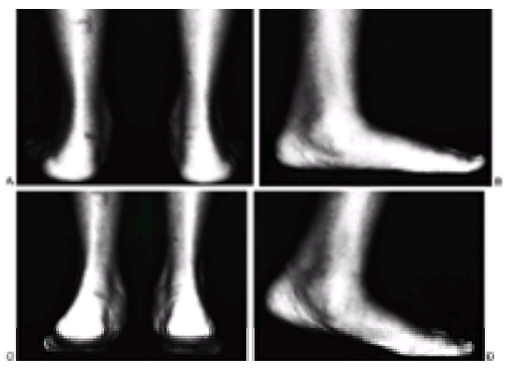

FIGURE 29-30. A,B: Rigid flatfoot. **C,D:** The arch will not elevate, and the hindfoot valgus will not correct to varus during toe standing, because of immobility of the subtalar joint. (From ref. 244, with permission.)

Radiographic Features

A calcaneonavicular coalition is best seen on an oblique radiograph of the foot (Fig. 29-31A). A cartilaginous coalition has the appearance of an articulation with somewhat undulating subchondral bone surfaces. An osseous coalition is obvious. Its presence is suggested on the standing lateral radiograph by an elongated process of the anterior calcaneus, which is called the "anteater nose sign" (245; Fig. 29-31B).

FIGURE 29-31. A: A calcaneonavicular coalition (*arrow*) is best seen on an oblique radiograph of the foot. (From ref. 244, with permission.) **B:** Lateral radiograph demonstrating the anteater nose sign (*arrows*), indicating a calcaneonavicular coalition.

Other radiographic findings that are best seen on the lateral view may include dorsal beaking on the head of the talus, broadening and rounding of the lateral process of the talus, and narrowing of the posterior talocalcaneal facet joint (242,246). The C sign, a C-shaped line formed by the medial outline of the talar dome and the

inferior outline of the sustentaculum tali, is a very reliable indicator of a talocalcaneal coalition (Fig. 29-32) (246A). An anteroposterior radiograph of the ankle should also be obtained. A ball-and-socket ankle may be seen in cases of long-standing tarsal coalition, particularly with the large coalitions seen in the nonidiopathic types (242,246).

FIGURE 29-32. A dorsal talar beak (*white arrow*) in a foot with a talocalcaneal coalition. This represents a traction spur, not degenerative arthritis. The C-sign of Lefleur (*black arrows*) is a very reliable indication of a talocalcaneal coalition.

A talocalcaneal coalition can be seen on an axial, or Harris (234), radiograph, but the best way to assess a coalition in this location is with computed tomography (247,248). The images must be obtained in the coronal plane using 3to 5-mm-thick slices (Fig. 29-33). A computed tomography scan should be obtained before resection of a calcaneonavicular coalition, because of the known risk of a coexisting talocalcaneal coalition (240).

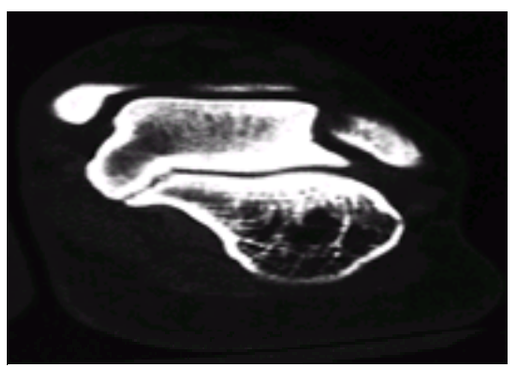

FIGURE 29-33. Talocalcaneal coalitions are best seen on computed tomography scans taken in the coronal plane. The middle facet is narrow, irregular, and down-sloping. (From ref. 244, with permission.)

Other Imaging Studies

Magnetic resonance imaging can be used to identify a symptomatic tarsal coalition that is still in the fibrous stage of differentiation, if the plain radiograph and computed tomography scan are nondiagnostic (249). It should not be a first-line study. A bone scan can help to identify the true cause of pain in a foot that has radiographic evidence of a tarsal coalition, but an atypical history or pain pattern (247).

Other Diagnostic Studies

Other causes of rigid flatfoot include juvenile rheumatoid arthritis, septic arthritis, and osteomyelitis. A complete blood count, with differential, estimated sedimentation rate, C-reactive protein, antinuclear antibody test, and rheumatoid factor may be warranted, if evaluation fails to confirm a suspected tarsal coalition.

Pathoanatomy

In genetically programmed individuals, a tarsal coalition begins as a syndesmosis with fibrous tissue between two bones of the foot that do not join together in 99% of people. The fibrous tissue undergoes metaplasia to cartilage to become a synchondrosis, then to bone, to become a synostosis. This process occurs during late childhood and early to middle adolescence (234,250).

Restriction of subtalar motion caused by a coalition blocks the normal eversion of the subtalar complex that occurs during gait. A component of eversion is dorsiflexion of the pes acetabulum (anterior calcaneus, spring ligament, and navicular), which occurs as it rotates and glides around the head of the talus. When rotation and gliding are eliminated by the coalition, the dorsiflexion force is concentrated at the talonavicular and calcaneocuboid joints (251). They are converted to hinge joints that widen inferiorly and narrow superiorly. The dorsal proximal edge of the navicular impinges on and overrides the head of the talus. This overriding causes elevation of the talonavicular ligament and periosteum on the neck of the talus. The osseus repair of this periosteal elevation leads to the talar beaking that is visible radiographically. The reason for progressive flattening of the longitudinal arch is not established. The author theorizes that this occurs because the eversion forces that are applied during loading in early stance are greater than the inversion forces that exist when the load is eliminated later in the gait cycle. The joint cannot recover its position as it gradually loses motion.

The cause of the pain is unknown (234,239). It has been attributed to ligament sprain, peroneal muscle spasm, sinus tarsi irritation, subtalar joint irritation, fracture through the synchondrosis, stress shift to adjacent mobile joints, and degenerative arthrosis (232). A recent histologic evaluation of nonosseous tarsal coalitions suggested that repetitive stress seemed to induce pain via free nerve endings in the periosteum and the articular capsules surrounding the coaliton (251A). There was evidence of microfracture, repair, and remodeling in the boundary between the coalition and the bone.

Natural History

According to Leonard (14), only about 25% of individuals with tarsal coalitions become symptomatic. The onset of pain usually coincides with metaplasia of the coalition from cartilage to bone, but it may occur earlier in its evolution. This generally occurs between 8 and 12 years of age for children with calcaneonavicular coalitions, and between 12 and 16 years of age for children with talocalcaneal coalitions. Metaplasia of the coalition also coincides with the development of progressive valgus deformity of the hindfoot, flattening of the longitudinal arch, and restriction of subtalar motion. All of these findings are more severe in feet with talocalcaneal coalitions (242,250).

Treatment

The goal of treatment is the relief of pain, not the elimination of the coalition or the reestablishment of the longitudinal arch. Treatment is, therefore, indicated only for symptomatic tarsal coalitions (234,241,242). It is not clear what causes some coalitions to become painful, but inflammation underlies the pain. An attempt should be made to relieve symptoms by nonoperative means, including activity modification, nonsteroidal antiinflammatory drugs, over-the-counter shoe inserts, and immobilization in a cast-type walking boot or a below-knee walking cast. Pain is generally relieved completely within 24 to 48 hours of cast application. Approximately

30% of patients remain free of pain after cast removal 6 weeks later (250). An over-the-counter shoe insert may help to maintain pain relief.

Surgery is indicated for patients with recurrent and disabling symptoms. Surgical options include resection of the coalition, osteotomy, and arthrodesis. Resection of calcaneonavicular coalitions **[➥7.2]** was first reported by Badgley (252) in 1927. Interposition of the extensor digitorum brevis was added to the resection procedure, and reported by Bentzon (253) in 1930. The combined procedure, compared with resection alone, has been shown to decrease the incidence of recurrence, and to increase the incidence of long-term pain relief (254,255 and 256). According to one report, resection of a calcaneonavicular coalition with muscle interposition is indicated in a patient younger than 16 years of age who has a cartilaginous bar with no other coalitions present, and no degenerative arthrosis, and who has undergone unsuccessful nonsurgical treatment (255). However, the age limit, the coalition tissue type, and the influence of coexisting coalitions have not been scientifically established. The presence of a talar beak is not indicative of degenerative arthrosis, and is not, by itself, a contraindication for resection (257,258,259 and 260).

The role of surgical resection of a talocalcaneal coalition **[➥7.3]** is less clear. This coalition is located on the tension side of the valgus deformity of the hindfoot, and additional progressive flattening of the arch may occur after resection. Investigation has only recently focused on a historically frequently quoted, but unproven, statement in the literature, that a talocalcaneal coalition should not be resected if it occupies greater than half of the width of the subtalar joint surface (257). Wilde et al. (260) reported unsatisfactory results of resection in feet in which the ratio of the surface area of the coalition to the surface area of the posterior facet was greater than 50% (as determined by computed tomography mapping of the entire joint). There was excessive valgus deformity of the hindfoot in all of these feet. Many of the feet with poor outcomes also had narrowing of the posterior facet and impingement of the lateral process of the talus on the calcaneus. The independent influence of the size of the coalition was not determined in this or any study to date. These are, however, the most objective criteria for determining the resectability of a talocalcaneal coalition.

Degenerative arthrosis should be considered a contraindication to resection, but that diagnosis is difficult to establish. Historically, the presence of a dorsal talar beak was considered to be evidence of degenerative arthrosis (Fig. 29-32). That theory has been replaced with the belief that the beak represents a traction spur, because it recedes with successful resection of the coalition. Its presence, therefore, is not a contraindication to resection (257,258,259 and 260).

Successful resection and interposition grafting of talocalcaneal coalitions have been reported in up to 89% of cases at 10 years of follow-up (261), although most published and unpublished studies have documented a lower success rate at even shorter follow-up (258,260,262). The poor results have been attributed to poor indications, and indications are evolving. Interposition can be with fat (257,263) or a split portion of the flexor hallucis longus tendon (262).

Documented degenerative arthrosis, particularly in adults, and persistent or recurrent pain after resection of a coalition, represent reasonable indications for triple arthrodesis (232). However, one should establish which joint or joints are arthritic. If the talocalcaneal joint is the only one that is degenerated, it is reasonable to perform a subtalar arthrodesis and avoid arthrodesis of the talonavicular and calcaneocuboid joints (263A). Those joints can help compensate for the loss of subtalar joint mobility and provide some stress relief for the ankle joint. They can be fused at a later time if they develop painful degeneration.

Osteotomies may have a role in treating symptomatic tarsal coalitions as an alternative to arthrodesis. A medial closing-wedge osteotomy of the posterior portion of the calcaneus has been shown to improve foot shape and relieve symptoms in certain feet with severe valgus deformity for which arthrodesis was being considered (263B).

An additional surgical procedure that has been shown to relieve symptoms in certain feet with tarsal coalitions and to correct even severe valgus deformity of the hindfoot, is the calcaneal lengthening osteotomy **[➥7.5]** described by Evans (124). It corrects valgus deformity of the hindfoot, even with osseous coalitions in the middle facet of the talocalcaneal joint. It should be considered for the rigid flatfoot with severe valgus deformity and contracture of the Achilles tendon, pain under the head of the talus, and no degenerative arthrosis. It can be performed as an isolated procedure, if the coalition is too large to resect. Or it can be performed with concurrent or staged resection and interposition grafting in a foot with a resectable cartilaginous coalition and severe foot deformity. Long-term studies have not been reported, but short-term anecdotal experience has been good, and must be considered in light of the known poor long-term results of triple arthrodesis (19,20 and 21,26).

Congenital Hallux Varus

Definition

Congenital hallux varus is a medial deviation of the hallux on the first metatarsal that is present at birth. It may be an isolated deformity, but very often it is associated with other malformations of the foot. These include a short and thick first metatarsal, longitudinal epiphyseal bracket of the first metatarsal (264), accessory metatarsals and phalanges, duplication of the hallux, and a fibrous band that extends from the medial side of the hallux to the base of the first metatarsal (265,266).

Epidemiology

This is a rare condition, but the incidence has not been reported. Sex predilection, bilaterality, and genetic factors are unknown.

Pathogenesis

Congenital hallux varus is a deformity that has been reported to be associated with multiple malformations. There are probably multiple causes, none of which have been identified.

Clinical Features

The hallux is adducted by as much as 90 degrees, and cannot be aligned by passive manipulation (Fig. 29-34A). There is a broad web space between the hallux and the second toe. A firm subcutaneous band of fibrous tissue may be palpable along the medial forefoot. There may be duplication of the hallux as a separate toe, or it may be associated with simple or complex syndactyly. Congenital hallux varus with complex polysyndactyly is commonly seen in Apert syndrome.

FIGURE 29-34. A: Clinical appearance of congenital hallux varus. **B:** Fibrous band between the hallux and the cartilaginous duplicate tarsal anlage.

Radiographic Features

An anteroposterior radiograph will provide only partial anatomic detail of the abnormalities. The varus alignment will be obvious. Duplication of the phalanges in a hallux associated with polysyndactyly will also be apparent. A rudimentary metatarsal duplication at the base of a fibrous band may not be visible because of the lack of ossification at birth. A longitudinal epiphyseal bracket will be suggested by the “D” shape of the metatarsal, with no cortical differentiation along the convex medial

border of the diaphysis (264) (Fig. 29-35A).

FIGURE 29-35. A: Radiographic appearance of congenital hallux varus with a metatarsal longitudinal epiphyseal bracket. **B:** Pins mark the extent of the resection of the longitudinal epiphyseal bracket. **C:** Radiographic appearance 5 years after resection and fat grafting of the longitudinal epiphyseal bracket. The metatarsal has grown normally.

Pathoanatomy

A possible explanation for a single toe varus deformity is that two great toes, and perhaps a metatarsal, originate *in utero,* but the medial or accessory one fails to develop. The rudimentary medial structure forms a fibrous band that acts as a taut bowstring and pulls the more fully developed hallux into a varus position, creating an incongruous first MTP joint (267) (Fig. 29-34B).

In the foot with a longitudinal epiphyseal bracket, there is a varus deformity of the metatarsal, creating the varus alignment of the hallux with the foot. The MTP joint may be congruous, although there have been no published anatomic studies on this aspect of the deformity. The MTP joint congruity is similar to that seen in the opposite direction with juvenile hallux valgus, and, as with the latter condition, it requires an operative approach that preserves joint congruity.

Natural History

Shoe fitting would be difficult or impossible without treatment (266).

Treatment

There is no role for conservative management of this deformity. Surgical management is mandatory, and depends on the individual pathoanatomy. The literature is not particularly helpful in providing direction for operative treatment because of the historical failure to appreciate the frequency with which a longitudinal epiphyseal bracket is associated with the hallux varus.

Soft tissue release and resection procedures with or without syndactylization to the second toe, as described by McElvenny (265) and Farmer (268), are appropriate when the metatarsal is normal. Mills and Menelaus (266) found that unsatisfactory surgical results using these techniques were generally caused by the shortness of the first metatarsal and rarely by symptoms or recurrent deformity. Longitudinal epiphyseal bracket was not recognized at the time of that study, as indicated by the radiographic images in the article.

Mubarak et al. (264) demonstrated that resection and interposition grafting of a longitudinal epiphyseal bracket **[➥7.15]** is an effective technique that leads to gradual correction of the varus deformity of the first metatarsal, and allows longitudinal growth of the bone (Fig. 29-35B and Fig. 29-35C). The interposition material can be fat, Silastic, or methyl methacrylate. With adequate resection of the abnormal epiphysis and good anchoring of the graft, fat is an excellent choice, and avoids the risks and potential complications of the foreign materials. This procedure is combined with distal soft tissue release and resection of duplicated parts, as indicated. Hypercorrection of the first MTP joint should be avoided to prevent joint incongruity and progressive hallux valgus.

Late onset of degenerative arthrosis of the first MTP joint can be managed by arthrodesis (266). Residual shortening of the metatarsal, with pain, callosities, or metatarsalgia, can be addressed with metatarsal lengthening or amputation.

Polydactyly/Polysyndactyly

Definitions

Polydactyly is a congenital condition in which one or more toes are duplicated. The metatarsal may be fully or partially duplicated as well. With polysyndactyly, the duplicate toe is joined to the more normal toe by soft tissue (simple) or bone (complex).

Epidemiology

The incidence of polydactyly is 0.3 to 1.3 per 1,000 live births in whites, and 3.6 to 13.9 per 1,000 live births in blacks (269,270). There is no sex predilection. Approximately 50% of cases are bilateral, and 62% of bilateral deformities are symmetric (271). There is polydactyly of the hands in 34% of patients (271). Polydactyly is seen in genetic syndromes, but most often it occurs as an isolated trait. It has an autosomal dominant inheritance pattern with variable expressivity (272). Thirty percent of affected individuals have positive family histories (271).

Pathogenesis

The cause is unknown. Polydactyly has been experimentally induced in rats by *in utero* exposure to radiation and cytotoxins, and by folic acid deprivation. The limb bud mesoderm is disturbed, leading to failure of differentiation of the apical ectodermal ridge during the first trimester (271). The implications of this information for humans are not known.

Clinical Features

Temtamy and McKusick (272) classified polydactyly as preaxial, if the hallux was duplicated; postaxial, if the fifth toe was duplicated; and central, if there was duplication of the second, third, or fourth toe. Phelps and Grogan (271), in their review of 194 supernumerary toes in 125 patients, found that 79% were postaxial, 15% were preaxial, and 6% were central. More than one type may exist in a foot (Fig. 29-36). Polydactyly can be further classified as well-formed and articulated (type A) or rudimentary and vestigial (type B). The duplicate toe may be entirely separate, or there may be simple or complex syndactyly. The toenails may be separate or conjoined in cases of polysyndactyly.

FIGURE 29-36. Preaxial and postaxial bilateral polydactyly.

The central and postaxial duplicate toes are usually well aligned with the other toes. The preaxial duplicate toe is often deviated medially. One must consider the possibility of a longitudinal epiphyseal bracket of the first metatarsal in the presence of preaxial polydactyly and polysyndactyly (see section on congenital hallux varus) (264,273).

Radiographic Features

Venn-Watson (274) proposed a morphologic classification of the abnormalities of the metatarsals and phalanges in polydactyly of the foot (Fig. 29-37). Unfortunately, there often is not enough ossification of the phalanges, even in the first few years of life, to accurately classify the deformity before surgical treatment. There is clearly no indication for radiography at birth. To help with surgical planning, an anteroposterior radiograph is obtained immediately before surgical ablation. It will reveal a metatarsal abnormality and may suggest the true pathoanatomy of the phalanges.

FIGURE 29-37. Venn-Watson classification of polydactyly. **A:** Postaxial. **B:** Preaxial. (From ref. 274, with permission.)

Natural History

Untreated polydactyly will commonly cause shoe-fitting problems, particularly when the hallux is duplicated.

Treatment

A child and family may choose to retain the duplicate digit if it is well formed, well aligned, and does not extend beyond the border of the foot. Wide shoes may be all that is required.

Surgical treatment, performed at about 1 year of age, is indicated to improve shoe tolerance. Improved cosmesis is a by-product. The most malaligned toe is resected, which is usually the medial duplication in preaxial polydactyly and the lateral duplication in postaxial deformity (271,275). Division of a synchondrosis at the base of the proximal phalanges is quite safe. It is reportedly safe to reduce the size of an enlarged metatarsal head by performing osteotomy perpendicular to the physis (271). However, one may choose a safer approach, and shave down the cartilaginous epiphysis, with care taken to avoid the perichondrial ring. A duplicate metatarsal, as well as the abnormal limb of a Y-shaped metatarsal, should be resected. The MTP joint capsule should be repaired if possible.

In cases of polysyndactyly, the most malaligned phalanges and the associated toenail are enucleated through a dorsal racket-handle incision (271,274,275). The nail fold must be carefully recreated to prevent chronic ingrowth. A common pattern of postaxial polysyndactyly involves medial duplication of the middle and distal phalanges of the fifth toe, wedged into a simple syndactyly that includes the fourth toe (Fig. 29-38). If surgery is elected, the medial duplicate phalanges should be resected without disturbing the syndactyly between the fourth and fifth toes. Otherwise, lateral deviation of the fifth toe might result (275).

FIGURE 29-38. Postaxial polysyndactyly. Clinical (**A**) and radiographic (**B**) appearance.

One can expect close to 100% good and excellent results with surgical treatment. Most of the reported poor results were in patients with residual hallux varus and a short first metatarsal after resection of a preaxial duplication. Some or all of these patients may have had a longitudinal epiphyseal bracket, which with present knowledge, would have undergone resection and interposition grafting (264), with a better outcome expected. Resection of central ray duplication does not reliably narrow the foot (271).

Syndactyly

Definition

Syndactyly of the toes may be classified in two types. Zygosyndactyly is cutaneous complete or incomplete webbing, usually between the second and third toes (Fig. 29-39). Polysyndactyly has been described in the preceding section.

FIGURE 29-39. Clinically benign zygosyndactyly.

Epidemiology

Zygosyndactyly is a common and often inherited trait that is frequently bilateral.

Pathogenesis

The cause is unknown.

Clinical Features

The webbing may be complete to the ends of the toes or it may be extremely subtle and shallow. There is rarely deviation or deformity of the toes, and there is no widening of the forefoot.

Radiographic Features

Radiographs are not indicated, because there will be no findings.

Natural History

Zygosyndactyly remains asymptomatic throughout life. It does not cause shoe-fitting or functional problems.

Treatment

Surgical treatment is not warranted, because of the excellent prognosis for comfort and function. The surgical scars are less cosmetic than the condition itself.

Macrodactyly

Definition

“Macrodactyly” is the term used to describe enlargement of the digits of the feet or hands. The term means large digit, but the metatarsal or metacarpal may also be enlarged.

Epidemiology

Macrodactyly may occur as an isolated phenomenon or as part of a syndrome, such as neurofibromatosis, Klippel-Trenaunay-Weber syndrome, lymphangioma, and Proteus syndrome. In 1988, Kalen et al. (276) reported the largest series, and reviewed the English language literature to date on the isolated type that is the focus of this discussion. The incidence is extremely low. There is a slight male predominance. The second digit is most commonly involved (Fig. 29-40A and Fig. 29-40B), followed by the third digit. Multiple digit involvement is seen in approximately 50% of cases.

FIGURE 29-40. A: Second ray macrodactyly with some enlargement of the hallux and third toe. **B:** Radiographic appearance. **C:** Clinical appearance after second ray resection and third toe interphalangeal disarticulation. **D:** Radiographic appearance 1 year later.

Pathogenesis

The cause is unknown. There is no evidence that inheritance plays a role (276). Turra and colleagues (277) and others hypothesized a nerve trunk disease as the cause for macrodactyly, but this theory has not been confirmed (276).

Clinical Features

The enlarged digit is apparent at birth. Features of Klippel-Trenaunay-Weber syndrome and neurofibromatosis should be sought, although features of neurofibromatosis are rarely present at birth. The relative size of the entire extremity should also be assessed to rule out hemihypertrophy as the underlying disorder.

Radiographic Features

Standing anteroposterior and lateral radiographs are useful for monitoring the relative growth rates of the digits, and for surgical planning.

Pathoanatomy

There is enlargement in length and circumference of the involved bones. An overabundance of fibrofatty tissue makes up the bulk of the soft tissue enlargement.

Natural History

Macrodactyly may be static, in which the digit is enlarged at birth and growth is proportional to that of the normal digits, or it may be progressive, in which the involved digit grows disproportionately faster than the normal digits (278). The latter type is more common in the foot (276). Although the appearance is often quite grotesque, the main disability is with shoe fitting.

Treatment

Treatment must be individualized. The goal is not cosmesis, per se, but the ability to wear shoes of similar size comfortably. Surgical options include soft tissue debulking, ostectomy, epiphysiodesis, complete or partial toe amputation, and ray resection, either as isolated procedures or in combination (276,277,279,280,281 and 282). Ray resection has had the best reported results for decreasing the rate and risk of recurrence and achieving the goal of improved shoe-fitting (276,277,281) (Fig. 29-40C and Fig. 29-40D). Most patients, even those who undergo ray resection, will need more than one operative procedure, because all of the pathologic soft tissue cannot be removed. An aggressive approach, therefore, is desirable.

A combination of soft tissue debulking and epiphysiodesis of the proximal phalanx, the metatarsal, or both, is recommended for mild, static deformities. Repeated debulking procedures may be necessary.

Cleft Foot (Ectrodactyly)

Definition

Cleft foot, or split foot, is the accepted term for a congenital malformation of the foot in which there are varying degrees of central longitudinal fissuring and central ray deficiency (283). The term “ectrodactyly,” which means congenital absence of all or part of a digit, is an acceptable synonym. “Lobster-claw foot,” coined by Cruveilhier in 1829 (283), is no longer acceptable.

Epidemiology

Cleft foot is a rare congenital anomaly with an incidence of 1 per 90,000 live births (284). In the typical form, the malformation is bilateral, usually associated with cleft hands, and has an autosomal dominant pattern of inheritance with incomplete penetrance (284,285 and 286). In the less common presentation, the cleft foot is unilateral without associated hand malformation, and with no evidence of familial inheritance. The incidence of this form is 1 per 150,000 live births (284). Ten percent of patients have no family history (287). Boys are affected more often than girls.

Pathogenesis

The apical ectodermal ridge (AER) induces the normal development of limb buds by interaction with the underlying mesenchyme (288,289). A defect of the AER, caused by genetic or toxic influence, could induce osseous syndactyly by deficient differentiation, polydactyly by excessive differentiation, or a central defect by some other mechanism. Watson and Bonde (290) proposed a hypothesis for cleft formation as selective damage of the AER localized at the second or third ray, the typical central location of the defect. They further proposed that the extent of damage to the AER in the transverse direction would determine the width at the base of the conical defect, and that the time and duration of the damage to the AER would determine the proximal extent of the defect.

Clinical Features

Variations of the malformation known as cleft foot range from a mere deepening of the interdigital commissure to the typical central ray deficiency to the monodactylous foot (288). The width of the foot at the metatarsal heads is excessive, compared with the hindfoot, particularly in those feet with greater deficiency of rays. Associated anomalies include cleft hand, cleft lip and palate, deafness, urinary tract abnormalities, triphalangeal thumb, and tibial hemimelia.

Radiographic Features

Blauth and Borisch (288) have classified cleft foot into six groups based on the number of metatarsal bones (Fig. 29-41). They identified two additional forms, a polydactylous type and a diastatic type. The latter is characterized by monodactyly with lower-leg diastasis, tibial aplasia, or both. Other variations of morphology in this condition, such as crossbones and synostoses, are well described in their article.

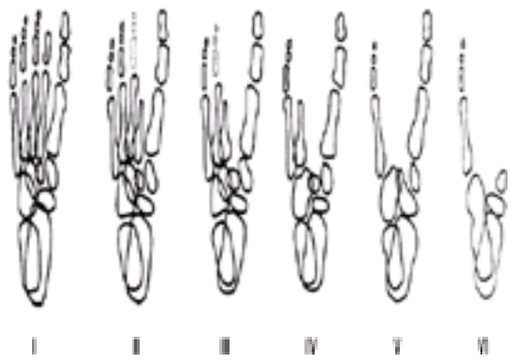

FIGURE 29-41. Cleft foot classification according to Blauth and Borisch. (From ref. 288, with permission.)

Other Diagnostic Studies

Renal ultrasonography is indicated to rule out renal anomalies that are occasionally present in individuals with cleft foot.

Pathoanatomy

The pathoanatomy is one of variable degrees of failure of formation, with occasional duplication and malorientation of bones. Synostoses may be seen at the margins of the cleft and in the tarsals (288).

Natural History

Most patients with cleft foot function well without pain with the use of accommodative shoes. This is certainly the case for feet with shallow clefts and few ray deficiencies. Marked splaying of the forefoot may develop, making it difficult or impossible to find shoes that fit comfortably. Painful callosities develop over the medial and lateral metatarsal heads.

Treatment

Treatment begins with education of the physician on the treatment used in the family member(s) from whom the malformation was inherited (Fig. 29-42). All patterns of cleft foot malformation can be accommodated in shoes during the first few years of life. Thereafter, the width of the forefoot may make it impossible to wear standard shoes without creating painful callosities over the medial and lateral metatarsal heads. At that point, custom-made shoes are an expensive option. The alternative is surgical reconstruction. Interestingly, functional disability is rarely a problem with cleft feet.

FIGURE 29-42. Father and son with cleft feet.

Surgical techniques for the symptomatic cleft foot must be individualized. The problem of symptomatic splayfoot can be addressed effectively with an osteotomy or osteotomies at the base of the lateral, and occasionally the medial, ray of the foot (Fig. 29-43). The soft tissues in the cleft can be partially plicated to improve the appearance and help maintain the corrected deformity (291). Hallux valgus and digiti minimi varus deformities are often severe. Soft tissue reconstructions, such as those used to correct hallux valgus, are ineffective. Distal osteotomies of the metatarsals can be used to improve the malalignment, but recurrence of these distal deformities is common, even after osteotomies. Complex plastic surgery procedures that create the appearance of toes have not added sufficient functional benefit or cosmetic improvement to justify their use (292).

FIGURE 29-43. Preoperative (**A**) and postoperative (**B**) radiographs of symptomatic cleft foot treated with osteotomies.

DEVELOPMENTAL DEFORMITIES

Developmental deformities consist of malalignment of bones at their joints that develop over time.

Cavus

Definition

Cavus refers to a fixed equinus (plantar flexion) deformity of the forefoot in relation to the hindfoot, resulting in an abnormally high arch. The high arch may be along the medial border of the foot or across the entire midfoot. The heel may be in a neutral, varus, valgus, calcaneus (dorsiflexed), or equinus position. There may be an accompanying clawing of the toes. There are two common patterns of cavus deformity (293). Cavovarus, or anterior cavus, is the most common pattern. Calcaneocavus, or posterior cavus, occurs less frequently.

Pathogenesis

Cavus is a manifestation of a neuromuscular disorder with muscle imbalance, until proven otherwise. At least two-thirds of patients who seek treatment for a painful high arch will have an underlying neurologic problem, and half of these will have Charcot-Marie-Tooth disease (294). There are many other causes of cavus foot deformity. It is helpful to consider those that cause unilateral versus bilateral deformity when evaluating the patient (Table 29-2).

Bilateral	Unilateral
Charcot-Marie-Tooth disease	Traumatic injury of a peripheral nerve or spinal root nerve
Friedreich ataxia	Poliomyelitis
Dejerine-Sottas interstitial hypertrophic neuritis	Syringomyelia
Polyneuritis	Lipomeningocele
Roussy-Lévy syndrome	Spinal cord tumor
Spinal muscular atrophy	Diastematomyelia
Myelomeningocele	Spinal dysraphism (tethered cord)
Syringomyelia	Tendon laceration
Spinal cord tumor	Overlengthened Achilles tendon
Diastematomyelia	Cerebral palsy—hemiparesis
Spinal dysraphism (tethered cord)	Clubfoot/recurrent clubfoot
Muscular dystrophy	Compartment syndrome of the leg
Cerebral palsy—paraparesis or quadriparesis (although usually planus deformities)	Severe burn of the leg
	Crush injury of the leg
Familial (consider Charcot-Marie-Tooth disease)	
Clubfoot/recurrent clubfoot	
Idiopathic (exclude diagnosis of exclusion)	

TABLE 29-2. CAUSES OF CAVUS FOOT DEFORMITY

Calcaneocavus deformity is seen almost exclusively in children with myelomeningocele and poliomyelitis (Fig. 29-44).

FIGURE 29-44. Calcaneocavus deformity in a child with myelomeningocele. **A:** Transtarsal cavus with thick callosities under the calcaneus and the metatarsal heads. **B:** Radiograph of the calcaneocavus “pistol-grip” deformity.

Epidemiology

The incidence of cavus is variable, and is related to the prevalence of neuromuscular disorders at any time.

Clinical Features

The clinical features depend on the underlying pathogenesis. Some of the underlying neurologic abnormalities are known at the time of presentation and some are not, some are treatable and some are not, and some are static and some are progressive. The resultant muscle imbalance, however, always leads to progressive foot deformity. The clinical manifestations are instability of gait with frequent falling, a feeling that the ankle is “giving out,” and a history of repeated ankle sprains. Painful callosities develop under the metatarsal heads, lateral to the base of the fifth metatarsal, and over the dorsum of the proximal interphalangeal joints of the progressively clawing toes. In the calcaneocavus foot, callus formation occurs almost exclusively under the calcaneus.

A history of progressive change in foot shape and function must be ascertained, even in situations of a known underlying neurologic abnormality. A sudden increase in cavus deformity in a child with myelomeningocele or lipomeningocele could represent evidence of a tethered spinal cord.

A family history of cavus foot deformity should be investigated as an aid to diagnosis. Charcot-Marie-Tooth disease, an autosomal dominant disorder with variable manifestations, is one of the most common causes of cavus foot deformity (294).

A detailed neurologic examination of the upper and lower extremities, including motor, sensory, and reflex testing, is mandatory. The spine must be examined for midline defects, hairy patches, dimples, or other evidence of spinal dysraphism.

The foot is examined with the child seated, standing, and walking. The longitudinal arch is excessively elevated along the medial border of a weight-bearing cavovarus foot (Fig. 29-45). The lateral border of the foot is convex and plantigrade, and the base of the fifth metatarsal is prominent and often callused. The hindfoot is in varus alignment. Atrophy of the intrinsic muscles is apparent. There may or may not be contracture of the gastrocnemius or the triceps surae. In many cases, as in most cavovarus deformities secondary to Charcot-Marie-Tooth disease, the forefoot equinus gives the false impression of a hindfoot equinus. The thigh-foot angle is usually neutral, despite the internal rotation deformity in the subtalar joint. The reason is that external tibial torsion is always associated with a developmental cavovarus deformity. The two rotational deformities are in opposite directions and cancel each other out. It is important to discuss this with the patient and family, because the external tibial torsion will become obvious after correction of the foot deformity.

FIGURE 29-45. Cavovarus deformity in a child with Charcot-Marie-Tooth disease. **A:** The arch is elevated only along the medial border of the foot. **B:** Varus and adduction can be appreciated.

Despite differences in the patterns of muscle imbalance that lead to cavovarus, the pattern of deformity development is fairly constant (295,296 and 297). The first metatarsal becomes plantar flexed, giving the appearance of pronation of the forefoot on the hindfoot. The deformity is flexible at first but becomes rigid with time. The plantar fascia and the other plantar soft tissues become contracted. The incompletely ossified bones change shape as a result of excessive compression on their plantar aspects (Hueter-Volkmann law). The normal tripod structure of the foot becomes unbalanced. Bearing weight on the plantar-flexed first metatarsal causes the forefoot to supinate, thereby driving the subtalar joint into inversion, or varus (296) (Fig. 29-46). The flexible hindfoot varus deformity eventually becomes rigid as the medial soft tissues of the subtalar joint contract. The cavovarus foot, therefore, has two major rotational deformities in opposite directions from each other: pronation of the forefoot, and supination (varus and inversion are other descriptive terms) of the hindfoot. It appears as if the foot is wrung out. Determination of the flexibility or rigidity of each deformity is important when planning an operation. Flexible deformities are treated with tendon transfers, and inflexible deformities are treated with soft tissue releases, osteotomies, and, occasionally, arthrodeses. Coleman and Chesnut (298) devised the block test to help evaluate the flexibility of the hindfoot (Fig. 29-47). The patient stands with a block of wood under the lateral border of the foot to recreate the tripod while allowing the first metatarsal to plantar flex. A flexible varus deformity of the hindfoot will correct to valgus alignment, whereas a varus deformity that is already contracted and rigid, will not. In the first situation, surgery for deformity correction is confined to the forefoot. In the latter case, forefoot and hindfoot procedures are needed.

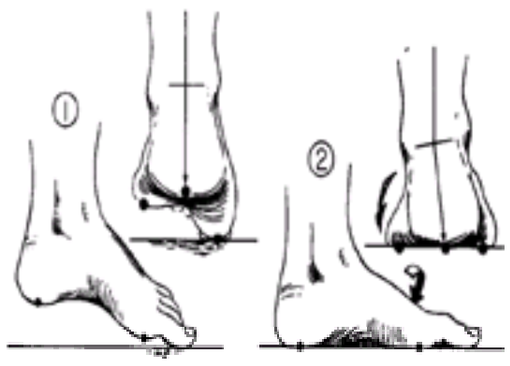

FIGURE 29-46. The tripod effect. The hindfoot must assume a varus position when weight bearing if the first metatarsal is fixed in plantar flexion. (*1*) Initial contact of plantar-flexed first metatarsal. (*2*) Fifth metatarsal makes contact through supination of the forefoot (*arrow*), which also drives the hindfoot into varus. (From ref. 296, with permission.)

FIGURE 29-47. The Coleman block test for determination of hindfoot flexibility. The flexible varus deformity of the hindfoot will correct to valgus when the plantar-flexed first metatarsal is allowed to drop down off the edge of the block of wood. Failure to correct to valgus indicates the need for surgical correction of the hindfoot, in addition to the procedures on the forefoot. (From ref. 298, with permission.)

The arch is elevated across the entire midfoot in the calcaneocavus deformity (Fig. 29-44). The calcaneus is dorsiflexed and vertically aligned, giving it the appearance of posterior truncation. The plantar heel pad is thickly callused from excessive pressure over a small surface area.

Radiographic Features

Standing anteroposterior and lateral radiographs of the foot are indicated on initial evaluation. There is normally a straight-line relationship between the axis of the talus and that of the first metatarsal on the lateral view (171). An apex dorsal angulation between those lines indicates a cavus deformity. Varus is indicated on the anteroposterior radiograph by parallelism between the talus and the calcaneus, and by adduction between the talus and the first metatarsal.

The author obtains a standing anteroposterior Coleman-type block-test radiograph to document the flexibility of the hindfoot. The author finds that the clinical and radiographic block tests are more reliable if a Plexiglas block is placed under the lateral metatarsal heads alone (Fig. 29-48).

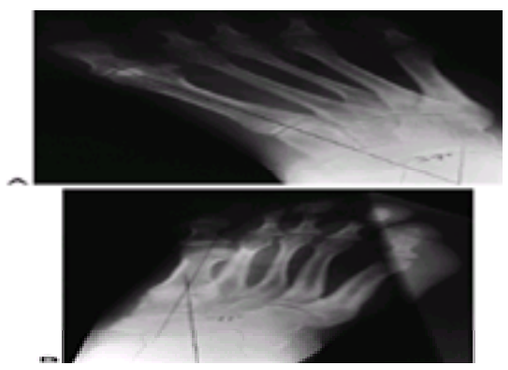

FIGURE 29-48. Standing block test radiograph with Plexiglas under the lateral metatarsal heads. The flexibility or rigidity of the subtalar joint can be documented by assessing alignment at the talonavicular joint using the talus–first metatarsal angle. **A:** Without block. **B:** With block, the hindfoot varus is corrected.

Standing anteroposterior and lateral radiographs of the spine are indicated if any physical examination findings suggest spinal dysraphism, spinal cord tumor, or diastematomyelia.

Other Imaging Studies

Magnetic resonance imaging of the spine may be indicated.

Other Diagnostic Studies

The DNA blood tests for Charcot-Marie-Tooth disease, electromyography with nerve conduction studies, and muscle biopsy are other possible investigations. Consultation with a pediatric neurologist is appropriate.

Pathoanatomy

Several patterns of muscle imbalance can create the cavovarus deformity. A common pattern is that seen in Charcot-Marie-Tooth disease (295,297). Denervation begins in the intrinsic muscles of the foot (297). The weakened lumbricals allow the long toe extensors to extend the metatarsophalangeal joints and the long-toe flexors to flex the interphalangeal joints, thereby creating claw toe deformities. These same forces create elevation of the longitudinal arch during gait, by the windlass effect of the plantar fascia (169) (Fig. 29-19). The intrinsic muscles undergo atrophy, fibrosis, and shortening, which lead to secondary contracture of the plantar fascia. This creates a bowstring between the anterior and posterior pillars of the arch, which draws them closer and produces equinus of the forefoot on the hindfoot. The tibialis anterior, a dorsiflexor of the first metatarsal, becomes weak, whereas the peroneus longus, a plantar flexor of the first metatarsal, remains relatively strong (293). The extensor hallucis longus is automatically recruited in an attempt to provide additional dorsiflexion strength along the medial column of the foot, but it creates a paradoxical effect of plantar flexion, as a result of the windlass effect of the plantar fascia. The first metatarsal starts to plantar flex, and with time, this creates more contracture and shortening along the plantar-medial than along the plantar-lateral border of the foot. The forefoot becomes rigidly pronated in relation to the hindfoot. The tripod effect (296) accounts for the varus position that the hindfoot must assume during weight bearing, as a result of the fixed pronation of the forefoot. Also contributing to the varus deformity of the hindfoot is the muscle imbalance between the tibialis posterior, an inverter of the subtalar joint, which remains

strong, and the peroneus brevis, an everter of the subtalar joint, which becomes weak (295). The subtalar joint eventually becomes rigidly deformed in varus, because of contracture of the plantar-medial soft tissues, including those of the subtalar joint complex. Although the triceps surae does not become contracted in Charcot-Marie-Tooth disease, it does in some of the other diseases that cause cavus.

The calcaneocavus deformity develops when there is little or no strength in the triceps surae, but strength exists in the muscles that plantar flex the forefoot and toes. The tibialis posterior, peroneus brevis and longus, flexor hallucis longus, and flexor digitorum longus bypass the calcaneus and plantar flex the entire forefoot on the hindfoot, without creating varus. Contracture of the plantar fascia, elongation of the paralyzed triceps surae, and preservation of functional strength in the tibialis anterior contribute to the dorsiflexion posture of the calcaneus.

Natural History

Muscle imbalance from both static and progressive neurologic disorders leads to progressive cavus foot deformity.

Treatment

Treatment of the underlying neurologic disorder should precede treatment of the foot deformity. Unfortunately, there is no known treatment or cure for many of the neurologic conditions that lead to cavus deformity. Furthermore, established muscle weakness and imbalance are not reversible, even with successful arrest of the neurologic deterioration. The foot deformity, therefore, progresses.

There is little role for nonoperative management of cavus deformities, because most are progressive and of an advanced degree of severity at the time of diagnosis. The complexity of reconstruction increases with the severity and rigidity of the deformities (296). Inexpensive, accommodative arch supports and shoe modifications may be used to ameliorate symptoms during the time it takes to diagnose and, if possible, treat the underlying cause.

Operative indications include evidence of progressive deformity, painful callosities under the metatarsal heads or the base of the fifth metatarsal, and ankle instability. There are three principles of operative management: correct all of the segmental deformities, balance the remaining muscle forces, and leave reasonable treatment options available for the recurrence of deformity and pain. There is also a principle of patient management: educate the patient and family that there are no treatment panaceas, and that more surgery may be required in the future (19,20 and 21,293,296,299,300 and 301).

There is a very long list of operative procedures that can be used to correct the individual deformities and balance the muscle forces in the cavus foot (293,296,299,302). No single procedure can accomplish both goals. Although some authors have tried (296,299), no one has yet developed an algorithm to help one choose the combination of procedures that will best address the unique pathology in any particular case.

The cavus foot deformity must be classified based on the flexibility of the segmental deformities. Correction of the deformity begins with soft tissue releases, such as fasciotomies, capsulotomies, and muscle or tendon lengthenings, with the goal of realigning joints. For the cavovarus foot, this means plantar fasciotomy, proximal release of the abductor hallucis, and possibly talonavicular joint capsulotomy and tibialis posterior tendon lengthening (296). Some of the bones in the child's foot will grow abnormally when unbalanced muscle forces are placed on them for a prolonged period of time. Osteotomies are used to correct these bone deformities, which can be identified only after soft tissue release and realignment of the joints. The first ray becomes plantar flexed early in the course of development of the cavovarus foot deformity. The site of that deformity is the medial cuneiform. Treatment with a plantar-based opening-wedge osteotomy of the medial cuneiform is safe, effective, reliable, and inherently stable without the need for internal fixation (116,296,303) (Fig. 29-49). Osteotomy of the first metatarsal (304) **[➥7.7]** is less desirable because it puts the growth plate at risk for arrest, requires internal fixation, puts the second metatarsal head at risk for a stress transfer lesion, and is not located at the site of deformity. The lateral column of the foot may require shortening if adductus and varus persist after the procedure(s) on the medial column (78). Alternatively, posterior calcaneus lateral displacement (181) or closing-wedge osteotomy (305,306) can be used. With these techniques, all but the most severe and rigid cavovarus deformities can be corrected with preservation of motion in the subtalar joint.

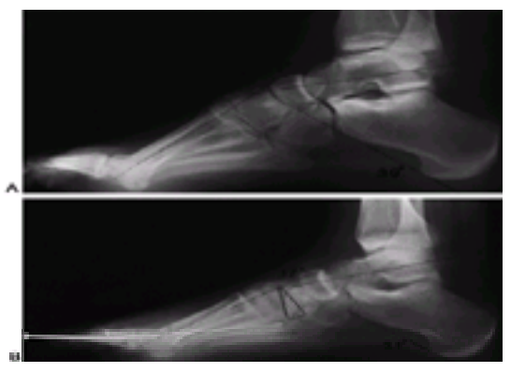

FIGURE 29-49. Lateral radiograph of a cavovarus foot deformity before (**A**) and after (**B**) a medial cuneiform plantar-based opening-wedge osteotomy. The axis lines of the first metatarsal and the talus cross each other in the body of the medial cuneiform, indicating that as the site of deformity. (From ref. 303, with permission.)

Midfoot osteotomies **[➥7.8]**, such as those described by Cole (307), Japas (308), Jahss (309), and Wilcox and Weiner (310), correct the cavus deformity by sacrificing the midtarsal joints to arthrodesis. These procedures, therefore, should be considered second-line treatment for the cavovarus foot. Triple arthrodesis should not be used as a primary, or perhaps even a secondary, reconstructive technique in a child or adolescent with a cavus foot deformity. It causes stress shifting and premature degenerative arthrosis (19,20 and 21,26) or Charcot arthropathy (311) in adjacent unfused joints. Furthermore, it cannot by itself correct the coexisting deformities of the forefoot and the hindfoot. Arthrodesis should be reserved as a salvage procedure in cases of existing severe arthritis or recurrent deformity in older individuals. Mild recurrences in younger individuals may be amenable to additional tendon transfers with or without deformity correction.

Deformity correction in the calcaneocavus foot requires radical plantar fasciotomy and release, as well as bony procedures. Dorsal displacement of a posterior calcaneal osteotomy lowers the longitudinal arch by elevating the heel. It is an effective procedure that has the added benefit of preserving joint motion. Alternatively, midfoot wedge resection osteotomies (307,308,309 and 310) can be used. Joint preservation is the goal when treating all deformities in the child's foot. The elimination of midtarsal joint motion has fewer negative long-term consequences than the elimination of subtalar joint motion.

Correction of deformity lends itself more readily to an algorithm than does muscle balancing. And balancing muscles in a mobile foot is more challenging than in a foot that has undergone subtalar or triple arthrodesis. The challenge must be accepted.

There are several principles of tendon transfers. A transfer should eliminate a deforming force and bring strength to a site of weakness. It should not leave behind weakness that could shift the balance of forces in the opposite direction. Phasic transfers are better than transfers that are out of phase. Dynamic tendon transfer cannot correct static bony deformity. The deformity must be corrected concurrently. One must know the present strength of all muscles. A tendon will lose at least one grade of strength when transferred. When choosing tendons to transfer, one must also anticipate the future strength of the muscles if there are underlying neurologic disorders in which there will be progressive deterioration. And always leave treatment options available for the next operation.

Juvenile Hallux Valgus

Definition

Juvenile hallux valgus is defined as greater than 14 degrees of lateral deviation of the hallux on the first metatarsal that has its onset in the preteen or teenage years, when the growth plates of the first metatarsal and proximal phalanx are still open. This age of onset applies regardless of the age at the time of treatment. Other features include minimal bursal thickening over a relatively small medial eminence, and good range of motion and lack of degenerative changes in the first

metatarsophalangeal joint.

Epidemiology

The incidence is unknown. It is much more common in girls than in boys, with girls accounting for greater than 80% of operative cases (312).

Pathogenesis

The cause is also unknown. There is maternal inheritance in more than 70% of cases (313,314). Studies and case reports indicate that juvenile hallux valgus may be associated with X-linked dominant, autosomal dominant, or polygenic transmission (312,315).

Controversy surrounds each of the many extrinsic and intrinsic factors purported to influence the development and progression of juvenile hallux valgus deformity. Studies in developing countries have shown an increased risk of hallux valgus in children who wear shoes, compared with children who do not (166,316). However, the majority of evidence supports the conclusion that, in most cases, juvenile hallux valgus deformity does not appear to be influenced by a history of constricting footwear (313,314,317). Poorly fitting shoes play a small role in the cause of this condition.

Pes planus and ligamentous laxity have been reported to be associated with the development of juvenile hallux valgus, based on patient populations that included children with collagen and neuromuscular disorders (318). Studies by Trott (319) and Coughlin and Roger (313) in normal children concluded that pes planus in juveniles had no significant association with the magnitude of the hallux valgus deformity. Coughlin and Roger (313), Kilmartin and Wallace (320), and Canale et al. (321) found no correlation between pes planus and the success rate of surgical correction of juvenile hallux valgus. These data, however, should not be used to completely discount the effect of severe valgus deformity of the hindfoot and significant ligamentous laxity on the development and progression of the juvenile hallux valgus deformity.

The association of juvenile hallux valgus with the length of the first metatarsal is also controversial. An excessively long (313,322,323), as well as an excessively short (80), first metatarsal has been implicated in the incidence, severity, and recurrence of juvenile hallux valgus deformity. Coughlin and Roger (313) have recently provided data showing that the relative lengths of the first and second metatarsals in children with juvenile hallux valgus are statistically similar to those of the normal population.

The shape of the first metatarsal may be an etiologic factor in the development of juvenile hallux valgus. The articular cartilage on the distal end of the first metatarsal normally aligns almost perpendicularly with the long axis of the bone. Lateral deviation, or orientation, of the articular cartilage can occur, thereby effectively creating a very distal valgus deformity of the metatarsal. The distal metatarsal articular angle (DMAA) quantifies this alignment (312,313,324,325) (Fig. 29-50). A higher angle indicates greater valgus deformity of the metatarsal. Coughlin and Roger (313) reported that 48% of juveniles with hallux valgus had an increased DMAA with a congruous first metatarsophalangeal joint, significantly greater than the percentage of adults with this finding (324). The remainder of his juvenile patients had lateral joint subluxation with a nearly normal DMAA, the usual finding in adults (Fig. 29-51). Coughlin and Roger (313) noted that the DMAA was significantly higher in patients with positive family histories, in patients with early onset of hallux valgus (younger than 10 years of age), and in patients with long first metatarsals.

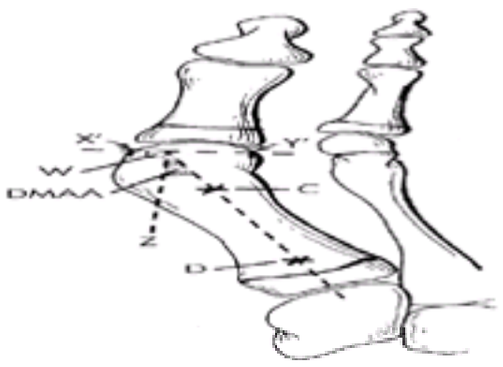

FIGURE 29-50. The distal metatarsal articular angle (*DMAA*) quantifies the angular relationship between the articular surface and the shaft of the metatarsal. The DMAA is the angle between the metatarsal shaft (C–D) and the line (W–Z) that is perpendicular to the articular surface (X'–Y'). (From ref. 312, with permission.)

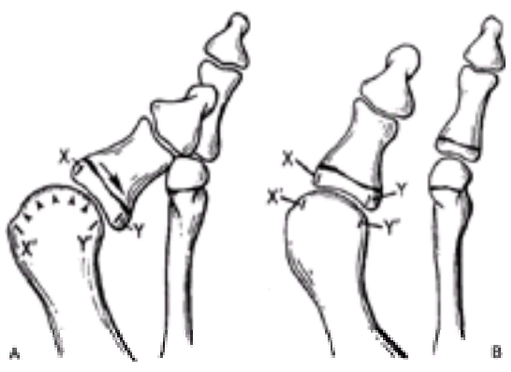

FIGURE 29-51. Subluxated (**A**) and congruous (**B**) first metatarsophalangeal joint. *X'* and *Y'*: extent of metatarsal articular surface; *X* and *Y*: extent of proximal phalanx articular surface. (From ref. 312, with permission.)

The orientation and flexibility of the first metatarsocuneiform (MTC) joint may be etiologic features of juvenile hallux valgus (312,314,322,326,327). Medial deviation of the MTC joint creates metatarsus primus varus. Metatarsus primus varus, or a 1st–2nd intermetatarsal angle (Fig. 29-52) of greater than 8 degrees, is abnormal, and is frequently seen in children with juvenile hallux valgus. The literature is inconsistent in identifying an association between adductus of all of the metatarsals and juvenile hallux valgus (313,328).

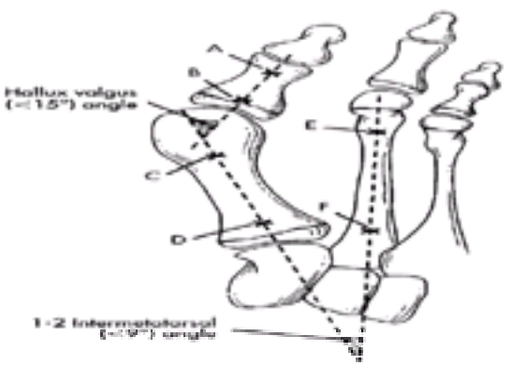

FIGURE 29-52. Hallux valgus and 1st–2nd intermetatarsal angle. *A–B*: axis of proximal phalanx; *C–D*: axis of 1st metatarsal; *E–F*: axis of 2nd metatarsal. (From ref. 312, with permission.)

Clinical Features

Most adolescents with hallux valgus are asymptomatic and have learned to choose their shoes to avoid pressure and pain on the medial aspect of the first metatarsal head. Some are merely dissatisfied with the appearance of the foot. Others report pain only when wearing certain stylish shoes that fit poorly and are biomechanically inferior. Still others are symptomatic despite attempts to modify their shoe wear. The pain is located in the superficial soft tissues, because of pressure from the shoe on the bony prominence of the first metatarsal head. There may also be pain associated with the overlapping of the second toe on the distal end of the hallux. Intraarticular pain is rare in juvenile hallux valgus. Likewise, it is rare to find restriction of motion of the metatarsophalangeal joint.

Although it is difficult to quantify, the mobility of the MTC joint should be evaluated. The foot should be assessed in weight bearing to determine the alignment of the midfoot and the hindfoot, with particular note being made of the presence or absence of valgus deformity. Contracture of the Achilles tendon must be ascertained. A thorough motor and sensory examination is performed. Gait is observed, with a focus on the position of the forefoot during push-off. The shoes are inspected for the pattern of wear. Most importantly, the child's major concerns, symptoms, expectations, and goals must be elicited.

Radiographic Features

Standing anteroposterior and lateral radiographs of the foot are necessary to evaluate juvenile hallux valgus. Assessment of overall foot alignment, including the midfoot and the hindfoot, is important. Forefoot assessment includes measurement of the hallux valgus angle, the 1st–2nd intermetatarsal angle, DMAA, MTP joint congruity, relative lengths of the metatarsals, MTC orientation, proximal phalanx articular angle, and lesser metatarsal orientation (312) (Fig. 29-50,Fig. 29-51 and Fig. 29-52). The importance of determining the DMAA has been stressed. Unfortunately, identification of the extent of the articular cartilage of the metatarsal head is difficult in children and many adolescents. Additionally, a radiographic study on cadavers by Vittetoe et al. (329) showed that, although intraobserver reliability for DMAA measurement was high, interobserver reliability for this measurement technique was poor.

Pathoanatomy

Valgus alignment of the hallux on the first metatarsal is the final deformity that may result from one or more anatomic variations.

Natural History

The natural history of juvenile hallux valgus is not known. Piggott (324) concluded that congruous joints with juvenile hallux valgus were stable and less likely to progress than those with subluxation. In this situation, the degree of hallux valgus is equal to the DMAA. Nevertheless, a hallux valgus deformity with a congruous first MTP joint may require surgical correction if the severity of the deformity leads to disability. A congruous first MTP joint is found in 9% of adults (324) and 47% of juvenile patients (313) with hallux valgus. Joint incongruity leads to progressive deformity and degenerative arthrosis at an unpredictable rate.

Treatment

The reason for seeking treatment must be ascertained. The natural history of juvenile hallux valgus is not known, and the complication rate from surgery is high. Cosmetic surgery, therefore, is contraindicated. Such treatment could be far worse than the condition itself.

Treatment can be divided into those methods that relieve pain and those that relieve pain through deformity correction. Nonoperative and operative modalities may be successful in relieving pain. Deformity correction can obviously be achieved through operative means. Contrary to expectations, Kilmartin et al. (330) found that hallux valgus deformity increased more in patients who used rigid, thermoplastic, biomechanical foot devices than in patients who did not. There is only one report indicating a possible nonoperative means for correcting deformity. Groiso (331) demonstrated improvement in the hallux valgus and 1st–2nd intermetatarsal angles in approximately 50% of feet that were treated with a moldable thermoplastic night splint, in combination with daytime active and passive stretching exercises. Others have not reproduced this experience.

Conservative measures will relieve symptoms without correcting the deformity in most patients with juvenile hallux valgus. The object is to make the shoe look like the foot, rather than vice versa. Shoes with an adequate toe box, a soft upper, and a low heel are most likely to provide pain relief. A running shoe is the most acceptable shoe that meets these requirements for this age group, although it is not appropriate for all social situations. Bunion stretchers are available where shoes are sold and repaired. When contemplating the purchase of a pair of shoes, the weight-bearing foot should be traced on a piece of paper, and compared with the outline of the shoe.

Surgery is indicated when prolonged attempts at conservative management have failed to relieve the pain over the first metatarsal head. The age of the patient at the time of surgery is a consideration. Poor results with high complication rates have been reported consistently in 30 to 60% of cases of surgery for juvenile hallux valgus (323,332,333,334 and 335). These results have been attributed to several factors. They include recurrence of deformity as a result of further epiphyseal growth (336), growth arrest secondary to injury of the growth plates at the proximal ends of the first metatarsal and the proximal phalanx, and the application of a single technique that did not take into consideration the unique pathoanatomy of each foot (334). Coughlin and Roger (313) and others (80,335) have performed successful surgical reconstruction with few complications in adolescents with open growth plates with juvenile hallux valgus. These authors have stressed, however, that there is rarely urgency in performing the surgery and that it should be delayed, if possible.

Perhaps the most challenging management decision to be made concerns the adolescent athlete who is performing at a high level, albeit with pain. In this patient, surgery, with its known risks and complications, could have a deleterious effect on future performance.

No single surgical procedure is suitable for all patients with juvenile hallux valgus deformity. All elements and components of the deformity must be analyzed clinically and radiographically. The goal is to correct the deformity to relieve pain and functional disability, while maintaining a flexible first MTP joint and a normal weight-bearing pattern of ambulation. The principle is to correct all components of the deformity at the site(s) of deformity without creating compensating deformities. Knowledge of the DMAA and the congruency of the first MTP joint is central to appropriate surgical planning, for it is this information that determines whether the correction will be intraarticular or extraarticular. The surgeon must have the knowledge and skills to perform the many and varied techniques that may be needed to address the pathoanatomy at all sites.

Surgical treatment for a juvenile hallux valgus deformity with a subluxated MTP joint consists of distal soft tissue realignment. A medial cuneiform or base of the first metatarsal osteotomy should be combined with the soft tissue realignment, if the subluxation is combined with an intermetatarsal angle greater than 8 degrees, i.e., metatarsus primus varus (312,313,333). An opening-wedge osteotomy of the medial cuneiform is a particularly good choice if the MTC joint is medially deviated, the metatarsal growth plate is open, and the first metatarsal is shorter than the second.

The treatment of a juvenile hallux valgus deformity with a congruous MTP joint involves osteotomies to correct the bone deformities and to realign both the joint and the first ray. A distal metatarsal osteotomy is used to correct the DMAA, whereas a proximal metatarsal osteotomy or a medial cuneiform osteotomy is used to correct the metatarsus primus varus (312,337) **[➥7.12–7.14]** (Fig. 29-53). In some cases, an additional osteotomy at the base of the proximal phalanx is indicated. The distal metatarsal osteotomy can be a simple closing-wedge procedure or a more complex biplanar chevron (312) or Mitchell osteotomy (312,321,332,334,336,338,339,340 and 341). Standard uniplanar chevron and Mitchell osteotomies do not correct the DMAA. There is a risk of interrupting the blood supply to the metatarsal head, with resultant avascular necrosis, when a lateral soft tissue release is combined with a distal metatarsal osteotomy (342).

FIGURE 29-53. A: Preoperative radiograph of juvenile hallux valgus. *IMA*, intermetatarsal angle. (From ref. 303, with permission.) **B:** Radiograph after medial cuneiform opening-wedge osteotomy and distal first metatarsal closing-wedge osteotomy.

Postoperative complications are frequent after surgical correction of juvenile hallux valgus. Recurrence, overcorrection to hallux varus, avascular necrosis of the metatarsal head, metatarsalgia, joint stiffness, and growth arrest are among the most serious complications.

The most reasonable approach to the adolescent with symptomatic hallux valgus is to exhaust all modalities of conservative management to treat the pain before considering surgery. Then, carefully assess the deformity both clinically and radiographically, and choose the combination of techniques that addresses each of the segmental deformities in that individual. Pay particular attention to the DMAA and the congruity of the MTP joint. Have a plan for the potential complications.

ACQUIRED AFFECTIONS

Kohler Disease

Definition

In 1908, Kohler described a self-limited painful condition of the tarsal navicular in young children that was characterized on radiographs by flattening, sclerosis, and irregular rarefaction. Diagnosis is dependent on the clinical and radiographic findings.

Epidemiology

This condition is uncommon. It occurs four times more frequently in boys than in girls (343,344), and it may be bilateral (344,345).

Pathogenesis

Kohler disease is considered an osteochondrosis, an idiopathic condition characterized by disordered endochondral ossification, including both osteogenesis and chondrogenesis, which arises from a previously normal growth mechanism (346). More specifically, it has been classified by Siffert (346) as a secondary articular osteochondrosis, because involvement of the articular and epiphyseal cartilage, if any, is a consequence of avascular necrosis of the subjacent bone. The navicular is located at the apex of the arch of the foot, and is subjected to compressive forces during weight bearing that could disrupt its blood supply. There is evidence that the disease develops in navicular bones that are constitutionally and biologically inferior and, therefore, vulnerable to damage by mechanical forces that normal bone is able to withstand (347).

Clinical Features

Typically, a child younger than 6 years of age presents with an antalgic limp, bearing weight on the lateral border of the foot. Pain is reported to be located over the dorsomedial aspect of the midfoot. There may be tenderness, swelling, redness, and warmth, signs that might suggest an infection or an inflammatory arthropathy. Range of motion of the joints is normal.

Radiographic Features

Standing anteroposterior and lateral radiographs reveal the characteristic findings of sclerosis, fragmentation, and anterior-to-posterior flattening of the navicular bone (Fig. 29-54). The tarsal navicular is the last bone of the foot to ossify. The average age of appearance of its ossific nucleus is 18 to 24 months in girls and 30 to 36 months in boys (348). Irregularity in the ossification of this bone is common, and may manifest as multiple ossification centers that subsequently coalesce (348). This should not be mistaken for Kohler disease if the clinical picture does not correlate. Abnormalities of ossification are more frequent in boys, and are more common in naviculars that ossify late. Radiographs of both feet should be obtained for comparison if the changes are subtle.

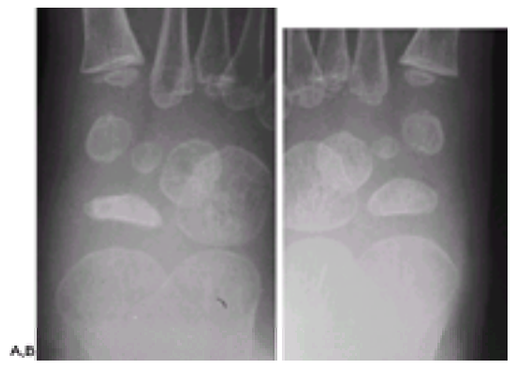

FIGURE 29-54. Kohler disease of the right tarsal navicular. **A:** Manifest as sclerotic and flattened. **B:** Normal left navicular.

Other Imaging Studies

No other imaging studies are indicated when the clinical presentation and radiographic findings are typical, although the use of bone scanning has been reported. The clinical findings may suggest infection, which is extremely unlikely in this location without a penetrating injury. Complete blood count, sedimentation rate, and C-reactive protein should be obtained, if that possibility exists.

Pathoanatomy

Waugh (349) investigated the vascular anatomy of the navicular and found two patterns of blood supply. The most common pattern was a diffuse network supplied by five or six arteries. A less common pattern was a single dorsal or plantar artery. He felt that compressional forces could occlude the vessels and produce avascular necrosis of the bone. Histologic examination of affected bones has disclosed areas of necrosis, resorption of dead bone, formation of new bone, and interference with normal ossification.

Natural History

This is a self-limiting condition that never has its onset in later childhood, adolescence, or adulthood. The navicular reconstitutes itself in 4 months to 4 years, and is normal at skeletal maturity (343,344 and 345). There is no residual deformity or disability in adults who were affected as children.

Treatment

Treatment is symptomatic. An over-the-counter longitudinal arch support may relieve mild symptoms. More intense pain can be relieved with a below-knee cast. Borges et al. (345), Ippolito et al. (343), and Williams and Cowell (344) found that treatment with a below-knee cast for a minimum of 8 weeks reduced the duration of symptoms to approximately 3 months. The duration of symptoms was 7 to 15 months for patients casted for less than 8 weeks and patients treated with other regimens. A walking cast was as effective as a nonwalking cast. Except for the duration of symptoms, treatment had no effect on the final outcome of the disease (343,344 and 345). There is no role for surgery.

Freiberg Infraction

Definition

In 1914, Freiberg (350) reported on a painful condition affecting the second metatarsal head, which was characterized radiographically by flattening of the articular end of the bone. He labeled the condition an infraction, because he postulated a traumatic origin.

Epidemiology

The incidence is unknown, but the condition occurs most commonly in adolescent girls. Freiberg infraction is the only osteochondrosis with a predilection for females. The second metatarsal is most commonly affected, followed by the third; the first, fourth, and fifth metatarsals are rarely involved. Less than 10% of affected individuals have bilateral involvement.

Pathogenesis

The cause is unknown. Like Kohler disease, Freiberg infraction is considered an osteochondrosis, an idiopathic condition characterized by disordered endochondral ossification. However, unlike Kohler disease, it has been classified by Siffert (346) as a primary articular osteochondrosis that may or may not progress to disruption of the subjacent bony epiphysis. These histologic changes occur in constitutionally and biologically susceptible metatarsal heads for unknown reasons. Proposed theories include trauma, repetitive stress, vascular anomalies, and high-heel shoe wear (347,351).

Clinical Features

Typically, a midto late adolescent girl presents with forefoot pain that is exacerbated by weight-bearing activities and is relieved by rest. There is soft tissue swelling, tenderness, and restriction of motion of the involved metatarsophalangeal joint. When the pain, swelling, and tenderness are located more proximally on the metatarsal shaft, and there is full motion of the metatarsophalangeal joint, the diagnosis is more likely to be metatarsal stress fracture.

Radiographic Features

Radiographic findings are evident on anteroposterior and oblique radiographs of the forefoot within several weeks of the onset of symptoms. The radiographic findings of Freiberg infraction, like the physical findings, are varied and tend to correlate with the pathologic stage of the disease, but not necessarily with the physical complaints. The prognosis cannot be determined by the extent of involvement seen radiographically. Various authors have proposed different staging schemes (351,352 and 353), correlating physical and radiographic findings to various treatment options (Fig. 29-55).

FIGURE 29-55. A: Freiberg infraction of the second metatarsal head. Early stage with crescent sign. **B:** Later stage with collapse of the metatarsal head. The patient, a young woman, was asymptomatic.

Pathoanatomy

There are three stages of pathologic changes (354). The intraarticular and periarticular soft tissues are thickened and edematous during the first stage. In the second stage, the cells of the epiphysis, which receive nutrition by diffusion from the joint fluid, are deprived as a result of the edematous pressure from chronic synovitis. Blood vessels within the epiphysis are incompetent secondary to thrombosis or microfractures of the trabeculae. The epiphyseal contour becomes deformed because of this disordered osteogenesis and chondrogenesis. Repair takes place during the third stage, with gradual replacement of the necrotic bone. Alternatively, the necrotic bone segment(s) may separate as an intraarticular loose body, leaving a defect in the articular surface.

Natural History

The disease can either progress through the various stages of involvement, or it can be arrested at any level by healing of the subchondral bone. The distribution of cases is unknown. The long-term result depends on the final severity of the deformity and the integrity of the articular cartilage.

Treatment

Nonoperative treatment is indicated to relieve symptoms and to allow healing, as will occur in many cases. Modalities include restriction of activities, avoidance of weight bearing, cast immobilization, use of metatarsal bars and other shoe inserts to relieve pressure under the metatarsal head, and modification of shoe wear.

Surgery is indicated when prolonged attempts at nonoperative management have failed to alleviate the symptoms; however, there is no consensus on the best technique. Surgical options include joint debridement with removal of loose bodies (350,352,355), elevation of the collapsed head with bone grafting (353), excision of the metatarsal head, excision of the base of the proximal phalanx, metatarsal shortening (356), metatarsal dorsiflexion osteotomy (351,352,355), and joint replacement. Debridement of the metatarsal head is a minimally morbid procedure that preserves the length and function of the metatarsal, and usually gives satisfactory symptomatic relief (350,352,355). Satisfactory restoration of joint motion has been reported. In more advanced stages of the disease, joint debridement alone might not be sufficient. The addition of a distal metatarsal dorsiflexion osteotomy (351,352,357) has been reported to relieve symptoms and to restore joint motion and patient function at any stage of the disease. Attention to the details of the procedure is important to avoid iatrogenic disruption of the vascularity of the

metatarsal head and the creation of transfer lesions to adjacent metatarsal heads (351).

Sever Apophysitis

Definition

In 1912, Sever (358) described an inflammatory disorder of the apophysis of the os calcis, which caused heel pain in the growing child.

Epidemiology

Sever calcaneal apophysitis is the most common cause of heel pain in the immature athlete (359). The average age of clinical presentation is 11.5 years, with the majority of patients presenting between 10 and 12 years of age. It is two to three times more common in boys than in girls. Bilateral involvement occurs about 60% of the time (359).

Pathogenesis

The cause is unknown. Sever apophysitis is considered a nonarticular osteochondrosis (346). Repetitive microtrauma, or overuse, results in injury to the apophysis in constitutionally susceptible children (359).

Clinical Features

The typical patient with Sever apophysitis is a 10to 12-year-old avid male soccer player with activity-related heel pain, who has recently undergone a growth spurt. The child continues to play despite the pain. There is no redness, swelling, warmth, or night pain. The classic physical finding is pain on medial-to-lateral compression of the apophysis. Other possible causes of heel pain can usually be diagnosed with careful and specific palpation (360) (Fig. 29-56). The child with calcaneal apophysitis will usually have mild contracture of the Achilles tendon.

FIGURE 29-56. Sites of heel pain: Achilles tendinitis (*A*); calcaneal apophysitis (*B*); retrocalcaneal bursitis (*C*); calcaneal stress fracture (*D*); plantar fasciitis/calcaneal bursitis (*E*); and fat-pad shear syndrome (*F*). (From ref. 360, with permission.)

Radiographic Features

The diagnosis of Sever apophysitis is a clinical one, because there are no diagnostic or pathognomonic radiographic features. Irregularities of ossification, with sclerosis and fragmentation, represent the normal radiographic appearance of the apophysis of the os calcis in the growing child (361) (Fig. 29-57). Lateral and axial (Harris) radiographs are not necessary in the face of a classic history and physical examination, but they can be used to rule out other causes of heel pain, particularly if there is local swelling, redness, warmth, or a history of night pain.

FIGURE 29-57. Lateral radiograph showing the normal irregularities of ossification of the apophysis of the os calcis in the growing child.

Other Imaging Studies

A bone scan can be helpful in localizing the site of pathology in cases of heel pain when symptoms, physical findings, and radiographs are nondiagnostic. It is particularly helpful to rule out a stress fracture.

Pathoanatomy

The apophysis of the os calcis experiences opposing traction forces from the Achilles tendon and the plantar fascia during weight bearing (346,362,363). It is also subjected to powerful compressive forces at right angles to the traction forces during heel strike. Siffert (346) believed that, in constitutionally susceptible children, mechanical disruption of the endochondral mechanism might be evident as microfractures that do not heal because of repeated trauma. He felt that the disruption of chondrogenesis and osteogenesis could account for the clinical symptoms and the radiographic changes that, although not diagnostic, are often seen with Sever apophysitis. Liberson et al. (363) had the opportunity to study pathologic specimens of the apophysis of the os calcis in children. Their histologic and computer-aided analyses supported the hypothesis of a stress remodeling process that occurs subclinically in every child at a certain stage of apophyseal development. They determined that it is caused by bending of the apophysis under the repetitive stresses of traction and impact. They concluded that pain, radiographic changes, or both, result when remodeling exceeds certain rates.

Natural History

Sever apophysitis is a self-limited and age-limited condition. It cannot occur after maturation and closure of the apophysis of the os calcis.

Treatment

Treatment is symptomatic. It includes restriction of activities that cause pain, Achilles tendon stretching exercises, strengthening of the anterior compartment muscles, and the addition of a soft heel pad and lift. Nonsteroidal antiinflammatory medications and/or a short-leg cast can be used for a brief time if the pain is significant. This is the same treatment regimen recommended for most causes of heel pain in the child. The average time to symptomatic relief with this regimen is 2 months, with a range of 1 to 6 months (359). Recurrence of symptoms is possible before skeletal maturation. There is no evidence that continued participation in painful activities has any long-term sequelae. There is no role for surgery in this condition.

C. Coulter-O'Berry: Department of Orthotics and Prosthetics, Children's Healthcare of Atlanta at Scottish Rite, Atlanta, Georgia 30342.

EPIDEMIOLOGY

There is little information on the incidence of congenital limb deficiency in the population, and what is reported varies widely from 1 per 4,264 in Canada (1), to 5 per 10,000 in Australia (2), to 310 per 10,000 in Tayside, Scotland (3). This illustrates that caution needs to be used in the interpretation of the information, since the methods of gathering the information vary.

Although such figures, if available, would be of use to health planning agencies, the fact for the orthopaedic surgeon, is that the child with a limb deficiency will not be a common problem. The majority of limb deficiencies seen in childhood are congenital in origin. This is followed at a distant second by trauma, and lastly as a result of tumors; thus, there is a need for these patients to be seen in an organized program where knowledge and experience are available.

Fibular deficiency is the most common long-bone deficiency. The incidence is between 7.4 to 20 per million live births (4,5). The prevalence of tibial deficiencies is far less, and is reported to be approximately 1 per million live births. The incidence of proximal femoral focal deficiency (PFFD) ranges from 1 in 50,000 to 200,000 live births. Although this is a more common anomaly than fibular deficiency, the explanation lies in the difficulty in separating congenital short femur from true PFFD.

The incidence of upper-extremity amputations is not precisely known. However, two general facts are easily accepted. Although upper-extremity amputations of all types are unusual, in children, congenital amputations are far more common than acquired amputations. In one multicenter review, 85% of bilateral deficiencies were congenital (6). Few physicians, other than those working in a limb deficiency program, will have much experience with these amputations.

CLASSIFICATION

The attempt to classify congenital anomalies has taken many paths, and most clinics choose to use some combination of these classification systems to best categorize the child's deficiency. These different classifications are an attempt to more precisely convey the particular anomaly.

The first attempt to devise a classification system for congenital anomalies was that of Frantz and O'Rahilly (7) (Fig. 30-1). This system was widely adopted in the United States and is still widely used by clinicians today to describe longitudinal deficiencies. However, it was not acceptable to European physicians, because of problems created in translating terms, e.g., “hemimelia.” This resulted in the classification system devised by the International Standards Organization (ISO) and the International Society for Prosthetics and Orthotics (ISPO) (8).

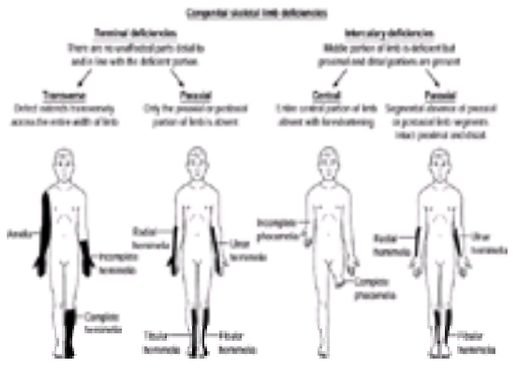

FIGURE 30-1. Diagrammatic representation of the Frantz and O'Rahilly classification of congenital limb deficiencies. (From ref. 7, with permission.)

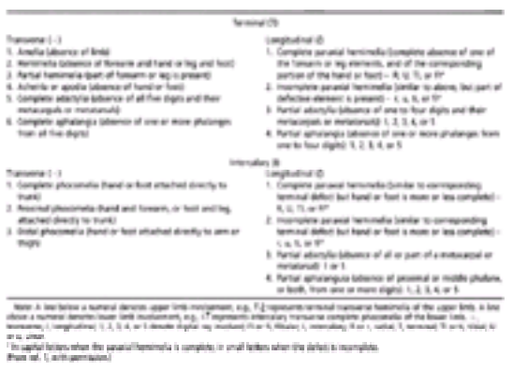
The classification of Frantz and O'Rahilly begins with seven descriptive terms derived from Greek root words. Three of the terms are from the root word *melos*, meaning limb: amelia, absence of a limb; hemimelia, absence of a large part or half of a limb; and phocomelia, or a flipper-like limb (*phoke*; seal). The hemimelias can be divided into complete, partial, and paraxial. The remaining four terms refer to the hands (*cheir*), feet (*pous*, *podos*) metacarpals (*daktylos*), and phalanges (*phalanx*) (Table 30-1).



Terminal (T)	
Transverse (–)	Longitudinal (l)
1. Amelia (absence of limb)	1. Complete paraxial hemimelia (complete absence of one of the forearm or leg elements, and of the corresponding portion of the hand or foot) – R, U, T, or F*
2. Hemimelia (absence of forearm and hand or leg and foot)	2. Incomplete paraxial hemimelia (similar to above, but part of defective element is present) – r, u, t, or f*
3. Partial hemimelia (part of forearm or leg is present)	3. Partial adactylia (absence of one to four digits and their metacarpals or metatarsals): 1, 2, 3, 4, or 5
4. Ectromelia or ajoodia (absence of hand or foot)	4. Partial aphalangia (absence of one or more phalanges from one to four digits): 1, 2, 3, 4, or 5
5. Complete adactylia (absence of all five digits and their metacarpals or metatarsals)	
6. Complete aphalangia (absence of one or more phalanges from all five digits)	
Intercalary (I)	
Transverse (–)	Longitudinal (l)
1. Complete phocomelia (hand or foot attached directly to trunk)	1. Complete paraxial hemimelia (similar to corresponding terminal defect but hand or foot is more or less complete) – R, U, T, or F*
2. Proximal phocomelia (hand and forearm, or foot and leg, attached directly to trunk)	2. Incomplete paraxial hemimelia (similar to corresponding terminal defect but hand or foot is more or less complete) – r, u, t, or f*
3. Distal phocomelia (hand or foot attached directly to arm or thigh)	3. Partial adactylia (absence of all or part of a metacarpal or metatarsal): 1 or 5
	4. Partial aphalangia (absence of proximal or middle phalanx, or both, from one or more digits): 1, 2, 3, 4, or 5

Note: A line below a numeral denotes upper limb involvement, e.g., T $\underline{2}$ represents terminal transverse hemimelia of the upper limb. A line above a numeral denotes lower limb involvement, e.g., I $\overline{4}$ represents intercalary transverse complete phocomelia of the lower limb. –, transverse; l, longitudinal; 1, 2, 3, 4, or 5 denotes digital ray involved; R or r, fibular; U, intercalary; R or r, radial; T, terminal; F or f, tibial; R or r, fibular; or u, ulnar.

* In capital letters when the paraxial hemimelia is complete; in small letters when the defect is incomplete.

(From ref. 7, with permission.)

TABLE 30-1. CLASSIFICATION OF CONGENITAL SKELETAL LIMB DEFICIENCIES

The hemimelias can have three additional descriptions: complete, when the entire distal one-half of the limb is missing; partial, when only a portion of the distal half is missing; and paraxial, when either the preaxial or postaxial side of the distal portion of the limb is missing. The hemimelia is named after the missing portion of the limb. Thus, a complete absence of the fibula is a fibular hemimelia.

Next, the deficiencies are either terminal, in which all of the parts of the limb distal to and in line with the defect are affected; or intercalary, in which the parts of the limb proximal and distal to the defect are present. Finally, the terminal and intercalary deficiencies are further divided into transverse, where the defect extends across the entire limb; and longitudinal, where only the pre- or postaxial portion is affected.

The ISO/ISPO system of classification of deficiencies present at birth (ISO 8548-1 Method of Describing Limb Deficiencies Present at Birth) was adopted by the International Organization for Standardization (ISO) and the International Society for Prosthetics and Orthotics (ISPO) (8,9). In this system, the deficiency is first described as transverse, in which all of the limb distal is missing, or longitudinal, in which all or part of one or more bones in a limb is missing. In a longitudinal deficiency (“paraxial” in the Franz and O'Rahilly classification), there may be parts of the limb present distal to the deficiency. In the transverse deficiencies, the part of the segment in which the limb ends is named, and an amount may be stated. A complete loss of the limb distal to the tibial tubercle would be “transverse leg upper third.” In a longitudinal deficiency, the bone or bones missing is named and described as “partial” or “total.” Thus, a fibular deficiency with part of the distal fibula present would be described as “longitudinal fibula partial.” Because this system does not characterize deficiencies, e.g., proximal femoral focal deficiency, phocomelia, and amelia, these terms may still be used.

A second system for describing acquired (traumatic or surgical) amputations (ISO 8549-2.1) uses three adjectives: trans, disarticulation, and partial. Trans is used to describe any amputation across the axis of a long bone. A child who has an amputation performed through the upper third of the tibia is not a below-knee (B-K) amputation in this classification, but a “transtibial, upper third.” “Disarticulation” is any amputation through a joint. Thus, a Syme amputation is an ankle disarticulation. Partial is any amputation distal to the wrist or ankle joint. Thus, a Boyd amputation is a partial foot amputation, with qualifiers added to distinguish it from a Chopart amputation.

ETIOLOGY

There are at least three ways in which limb deficiencies can be caused: errors in the genetic control of limb development, disruption of the developing arterial supply, such as “the subclavian artery supply disruption sequence” (10), and intrauterine amputation from amniotic bands.

The oldest and most commonly held etiology for congenital amputation in the past was the mechanical amputation of limbs by amniotic bands. Streeter, whose name is attached to this mechanical concept of limb deficiency, actually felt that the bands and constrictions were due to an intrinsic defect in the growth of the fetal limb (11). There is, however, evidence that amniotic bands can form a constriction around the developing limb that interferes with the growth of the limb. The resulting constriction can result in any degree of damage, from a constriction band around a limb that is otherwise normal, to a complete transverse amputation. The previously developed limb has actually been recovered at the time of birth, indicating the mechanism (12). Most children with amniotic band syndrome have either craniofacial abnormalities or other evidence of band formation.

Modern genetics has shown that the development of the limb is a complex phenomenon that requires the precise interaction of a large number of genes and their effects, which are described in Chapter 1 and other review articles (13,14). The opportunity for errors in this system is great, and animal experimentation has identified the probable mechanism in several limb anomalies.

The disruption of the subclavian artery and its supplied tissue explains the overlap of many of the common orthopaedic conditions seen, e.g., Poland syndrome, Klippel-Feil syndrome, Mobius syndrome, Sprengle deformity, and transverse limb deficiencies. There are several possible mechanisms by which this disruption may occur. For more detail, the reader is referred to an excellent review article (15).

This understanding of the various etiologies has importance for the clinician. With genetic control and vascular disruptions playing a large role in the development of the limb and having consequences in other organs and systems, the association of limb deficiencies with other abnormalities creating syndromes is likely. The implications are two: When children present with limb deficiencies, a thorough examination for other abnormalities is necessary; and any heritable genetic defect should be identified. The possibility of a teratogen always arises in the parent's mind. Although there may be many suspected agents, to date, thalidomide remains the only drug proven to have caused a large number of congential limb deficiencies. The role of retinoic acid and low cholesterol on gene expression are discussed in Chapter 1.

Although the vast majority of congenital limb deficiencies are sporadic and not transmissible (transverse below-elbow), a small number are (tibial deficiency and cleft hand and foot). For parents, this is often something they desire to know. Understanding the cause of the deficiency is important to the resolving of the guilt that parents will initially feel. The possibility of a transmissible defect is certainly something their affected offspring will need to know. A recent study from the Medical Birth

Registry of Norway showed that children born to a mother with a limb deficiency had a relative risk of 5.6 of having the same defect as the mother (16). This is similar to the relative risk of clubfoot. For the physician, knowing the existence of other problems and the natural history of the syndrome, is necessary for the care of the child.

THE CHILD WITH AN AMPUTATION

Psychosocial Development

The child with an amputation is essentially different—something that no child wants to be. However, almost all children are different in various ways. Some differ in physical appearance, some in physical ways that are not immediately visible, and some in personality and intellectual development. The more the child perceives him- or herself different from peers, the more they understand their disability. Children's understanding of their disability is general and incomplete at 6 years of age, but within a few years, around the age of 8 or 9 years of age, they come to a much more complete understanding of their handicap (17). Thus, if parents have not discussed this with the child, they can expect the more difficult questions to begin at this age.

All children with disabilities are vulnerable to social isolation. This in turn can have negative effects on the development of self-esteem, body image, and the child's identity, which are developed through the interaction with parents, teachers, friends, classmates, and others. As children develop these interactions, the issue of “first appearance” becomes important, because it serves as a clue to perceived personal characteristics, and can be an obstacle to further healthy interaction. Children in peer groups tend to devalue those with handicaps, a factor that may greatly interfere with these relationships (18). Parents especially understand this and fear for their child in this regard.

There has been a great deal of study on the nonhandicapped child's reaction to various handicaps, showing that children prefer other children without handicaps, and that they dislike some handicaps more than others (19,20 and 21). In addition, it is known that young adults show signs of anxiety when face to face with a handicapped person. However, there is some evidence that young children do not share their parents values toward various handicaps when young, but between the ages of 6 to 18 years of age, they gradually develop values almost identical to their parents (20). This would suggest that among young children, these values may be subjected to modification, and emphasizes that organized discussions with classmates in school about the child's handicap may be of great value.

Despite the negative “first impression” that physical differences hold for children, there is evidence that demonstrates that the age of the patient, the gender, the degree of limb loss, or socioeconomic status are not predictors of low self-esteem or depressive symptoms. Rather, social factors, e.g., stress and hassle, parental discord, social support from classmates, parents, and teachers, along with the child's own perceptions of competency and adequacy, gained through peer acceptance, scholastic achievement, and athletic accomplishments, play the largest role in the development of self-esteem (22,23 and 24).

The importance of this information for parents, physicians, therapists, prosthetists, and teachers is that, while the limb deficiency is the visible problem, and subject to little modification, the important factors in the development of self-esteem are independent of the deficiency, and can be positively affected.

Differences in Amputees

The difference between the juvenile amputee and the adult are as different as are the child and the adult. Acquired amputation in the adult is usually lower extremity and involves only one limb. The child is most often congenital, and more frequently has upper- and multiple-limb involvement.

The more important difference, however, lies in the fact that children are born dependent, and are naturally in the process of becoming independent, whereas adults and older children are independent and far less changeable. The child with a congenital amputation or congenital deformity requiring an amputation will adapt far better to a missing limb than will an older child or adult who suddenly loses a limb. In addition to adaptability in the physical arena, they will have far more adaptability in the psychologic arena.

Similar differences apply to congenital and acquired juvenile amputees. The congenital amputee has a difference; the acquired amputee must adjust to a loss. The difference is dependent on the age and the deficiency. A child born with bilateral amelia will learn to use the feet for all activities of daily living, as will a child with traumatic loss of both upper limbs at an early age. However, bilateral upper-extremity loss in the older child who has functioned with both hands for years will not be well compensated for by use of the feet.

THE PARENTS

When a child with a congenital deformity or congenital amputation first presents, one of the first concerns has to be the parents. The child does not need a doctor yet, but the parents do. The issues around the child's deficiency, especially if amputation or surgery is required, are not urgent. However, the mental turmoil in the parents' lives is urgent. They did not expect to give birth to anything but a healthy normal child, unless forewarned by ultrasound. They are now there to see a doctor with the certainty that their child is anything but normal and with the unrealistic desire for an expert to make the limb normal.

One of the earliest emotions the parents will have is guilt. What did I take or do during my pregnancy to cause this? Even worse, they may be wondering from which side of the family did this affliction come. It is a time of anticipated joy that has turned into a period of great stress for both the individuals, and often for the marriage. Taking time at the first visit, and again looking for the opportunity later, to explain what is known about the cause of these problems is essential. Obtaining a genetic consultation, even when the deficiency is not known to be hereditary or caused by teratogens, can be therapeutic in this regard. It is usually much more thorough than what one can do, and is done by an expert in that particular area, giving the parents additional reassurance.

Quickly, the feeling of guilt will be mixed with anxiety about the child's future. Will he walk? Can he play sports? Will she have children of her own? The parents probably have never known an amputee, and have no frame of reference to answer these questions. Although one may try to anticipate and answer many of their questions, one is unlikely to have much success in alleviating their fears. The best one can do during the first visit is gain their confidence and give them realistic hope. Fortunately, there are usually no emergent decisions to be made, and there is time to help the parents answer these question for themselves.

Because “seeing is believing,” the next several months are a good time for the parents to meet children with similar deficiencies, and their parents to see what their child might actually be like in the future. This makes known the previously unknown, and the problems become easier to deal with. In addition, the parents can see the various surgical options that might be recommended for their child. Because there is not a need for intervention in the congenital deficiency for a few months to a few years, the parents have time to learn about their child's problem. Introducing the family to other families who have children with similar limitations is one of the most important interventions.

With information from the lay press or the Internet, and encouraged by well-meaning friends, many parents will ask about a miracle cure: sew on a new arm, for example. Carefully listening to and explaning what they have read or heard will usually suffice for most. Seeing other patients and talking to their parents is also of great help, because they are parents who went through the same thing, and they likely asked the same questions.

During this initial period physicians also need to be careful about what they tell the parents. In an effort to help the parents feel better, while not knowing how to deal with this difficult role, physicians may offer false hope and mention treatments that are totally unrealistic. Physicians who do not know, or who do not wish to take on this role should assure the parents that they are referring them to the best possible care.

The relationship between the parents and the physician (as well as all members of the team) is important. In that regard, the first thing the parents must be made to understand is that all of the decisions will be theirs. No one will make them do anything they do not wish to do. In this regard, it becomes the role of the physician to educate the parents. This occurs through repetitive explanation and answering of patient's questions. It is helpful if this occurs, not only with the physician, but also with the therapist and prosthetist, who all should be working together. Again, nothing helps like seeing other patients and parents.

Parents will often refuse a recommendation, e.g., an amputation (25). It is important for the treating physician to recognize the factors that affect their decision and do his or her best to educate the parents. Frequently, the child will have a near normal–appearing foot, and all the parents see is a small amount of shortening. The child may be able to walk in the first few years of life, and the parents may not understand the progressive shortening that will develop. Along with these observations, they share the popular public belief that modern science can cure everything; next year, if not now. They have all heard of miraculous lengthening of limbs in the popular

press, and more recently, the “successful” transfer of limbs.

Finally, it may need to be constantly reinforced that the child with a limb deficiency is more normal than abnormal. During this first year, the parents need to resolve their disappointment and loss, accept the child, and see the potential for the future. They need to bond to the child and begin to think of the child as an independent person. Most parents will begin to see their children this way as they grow and develop. Again, this process can be accelerated by seeing other children with similar problems. One recommendation that often needs repeating to the parents is that children tend to acquire the fears of their parents, and that support to participate in any activity the child expresses interest in will allow the child to develop his or her natural abilities to the fullest.

ORGANIZATION OF CARE

The management of pediatric limb deficiency is considered a specialized area of practice. There are several reasons for this. First, these anomalies are rare to any one practitioner outside of a limb deficiency center. The experience of an orthopaedic surgeon, therapist, or prosthetist who has treated several of these different anomalies can be important. Second, all patients and parents benefit by knowing they are not alone. In particular the new parent, and later the children, will benefit immeasurably by seeing other parents and children like themselves. No amount of explanation, pictures, or movies can educate parents like talking to other parents like themselves, and seeing children like their own.

The team should be made up of a physician and surgeon, prosthetist, physical and occupational therapist, and social worker or child psychologist, all of whom are knowledgeable in normal childhood development, and who can anticipate the deviations in development that will occur. The acquired adult amputee knows what he or she had and what he or she wants. The child and parents of a congenital amputee know little, and need education and guidance that usually can not be provided by an orthopaedic surgeon referring the patient to a prosthetist. The parents will be making decisions for their child that the child will live with for the remainder of their life. The professionals caring for the family must provide the necessary education and framework in which the parents can make these decisions.

Family involvement is the essential setting of the treatment program (26). The child has a condition he or she will accommodate to. This is not a disease that will be cured. Hence, the condition should not be “medicalized,” but rather treated within the context of family, home, school, play, etc.

GENERAL CONSIDERATIONS

Growth

It has been observed that the percentage of shortening in a congenital limb deficiency remains relatively constant. The principle has been established for congenital short femur (27,28 and 29), and fibular hemimelia (30,31). Clinical experience would indicate this to be true for the tibial hemimelias also. It is important for the clinician and the parents to be aware that this percentage difference will translate into significant differences as the limb grows. Thus, in discussing centimeters of shortening and planning treatment, it is important to calculate what the discrepancy will be at maturity.

Because the percentage of shortening remains relatively constant, it is possible to calculate the ultimate discrepancy in centimeters at an early age. Knowing the percentile height of the child, the length of the femoral and tibial segments of the normal limb can be estimated from the Green and Anderson growth charts (32) (Table 30-2 and Table 30-3). Then, knowing the length of the normal segments and the percentage by which the affected segments are short, the length of the affected segments at maturity can be estimated.

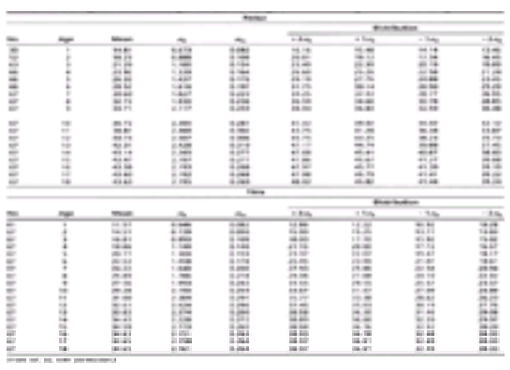


TABLE 30-2. GIRLS: LENGTHS OF THE LONG BONES INCLUDING EPIPHYSES

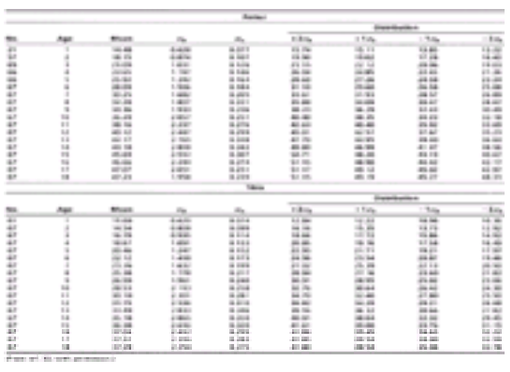

TABLE 30-3. BOYS: LENGTHS OF THE LONG BONES INCLUDING EPIPHYSES

Although the above method of calculating the eventual discrepancy at maturity is clinically valid, the clinician should be aware of the effect surgical procedures could have on the growth of the limb. Following amputation, the epiphysis of the bone may not grow at the normal rate. Christi et al. showed that in 20 below-knee amputations in children, only three tibias grew at the expected rate (33). The congenital group grew 36% of what would have been expected, and the acquired group at 53%. Various reasons for this may be the lack of stress across the growth plate, the decreased blood flow to the bone, or the result of the congenital insult producing the limb deficiency.

Timing of Amputation

The timing of an amputation in a congenital limb-deficient child is best understood in the context of the purpose of the amputation and the development of the child. The amputation is done to provide improved function, compared to what is provided by the deficient limb, correct a severe discrepancy in length, or to facilitate prosthetic fitting, so that the child can keep pace with normal motor milestones.

In general, elective lower-extremity amputations, designed to aid prosthetic fitting of congenital deficiencies, are performed at the time the child is ready to walk as indicated by their pulling to stand. For children with tibial and fibular deficiencies who will be treated with amputation, pulling to stand and cruising are the signals that the child is ready to begin walking. This would be the time for an amputation and prosthetic fitting, so the child can maintain normal developmental sequence. In some unusual cases in which the deformed extremity is interfering with crawling and other prewalking activities, amputation may be performed earlier. However, prosthetic fitting should wait until it will be of some value. It is very difficult to keep a prosthesis on a crawling child.

In other cases, e.g., proximal femoral focal deficiency, prosthetic fitting will usually be done when the child is ready to walk, but definitive surgical treatment to permit a more functional prosthesis will be done later for technical reasons.

Finally, there will be cases in which leg lengthening is the treatment of choice, but the difference in length must be compensated for prior to lengthening at a later age. Occasionally, it will be necessary to fit such patients with nonconventional prostheses, when shoe lifts are not sufficient.

Although it is poorly documented, there is the impression among both parents and surgeons that with early amputation the child does not suffer the loss in body image that accompanies amputation at a later stage. Also important is that as a general rule, the earlier the amputation, the better the child's neurologic plasticity adapts to the alteration.

COMPLICATIONS

Overgrowth

Bony overgrowth at the end of the residual limb is the most common problem in juvenile amputees. Its occurrence is reported to be between 4 and 35 percent, and depends on the age of the patient at the time of amputation, and of the bone involved (34,35 and 36). The condition has not been reported after the completion of growth. Overgrowth occurs most often in below-knee amputations, with the fibula being the problem more often than the tibia, and in transhumeral amputations.

Contraction of the soft tissue and growth of the bone, pushing it through the skin, were the most common reasons given for the problem. Aitken disproved these theories when he demonstrated by implanting metallic markers that the overgrowth took place distal to the end of the bone (34,37). Experimental and clinical work that has demonstrated that plugging of the medullary canal can prevent bony overgrowth is explained by the normal occurrence of wound contracture. This mechanism has been demonstrated by Speer (38).

The patient will often notice pain on weightbearing or prosthetic use. An antalgic gait with decreased stance time may be noticed. Decreased range of motion, to limit pulling of the skin at the end of the limb, is an additional symptom. Clinically, the patient presents with tenderness and pain at the end of the residual limb. There may be inflammation, bursal formation, or the bone end may be protruding through the skin. Commonly, the bony spike can be palpated within a small, tender bursa. Careful medical supervision can often anticipate the problem, which in turn allows the patient to plan for surgical correction.

Various plastic and metallic devices have been used to cap or plug the end of the bone. However, these have been abandoned because the results have not been as good as with biologic material (39,40). Marquardt reported in the mid-1970s, in the German literature, on the capping of the bone end with a cartilage-bone graft. Various reports for both acquired and congenital amputees would indicate generally favorable results, with most revisions being for technical reasons (39,40,41 and 42).

When a patient presents with pain and bursa formation, prosthetic modification and other conservative measures should be used first, unless a bony spike is felt. Once overgrowth occurs in a limb, it is likely to recur during remaining growth, and may possibly result in shortening of the residual limb. If revision surgery is necessary, consideration for a capping procedure should be given. Age is a paramount factor in the decision, since bony overgrowth is very unusual after the age of 12 years. In the case of a primary amputation, it is advisable to use available parts from the amputated portion of the limb to cap the end of the bone, if conditions permit. The most common procedure is the use of the proximal fibula to cap the tibia. As in any revision, adequate resection of bone, to provide a healthy soft tissue envelope, is essential (Fig. 30-2).

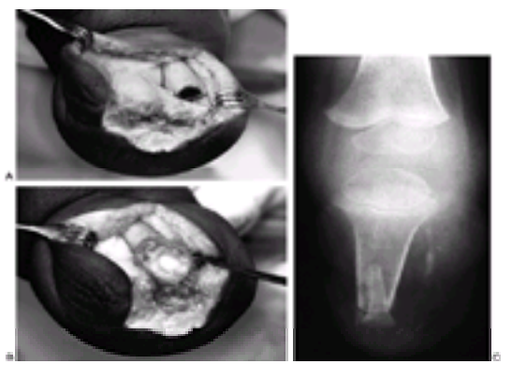

FIGURE 30-2. The end of the tibia with the bony overgrowth removed with the head of the fibula inserted into the medullary canal of the tibia (**A**) and (**B**). **C:** The anteroposterior view of the tibia six weeks after the Marquardt procedure.

Following surgery, the therapist should supervise and educate the child and parents in edema control to hasten return to prosthetic use. In addition, range of motion and strengthening exercises speed, and may even be necessary to regain, full function of the prosthesis. Myoelectric users may need readjustment of their electrodes, and may have difficulty for a while activating the prosthesis. This is because of swelling and reshaping of the limb, which may alter the optimal sites for electrode placement.

Phantom Sensation/Pain

The term “phantom limb” was coined by the neurologist Silas Weir Mitchell in the middle of the 19th century. He described these sensations as replicas of the lost limb, some being painful and some not. Phantom sensation of the limb is often described by the patient as the feeling that they can move the part, tell how the part is positioned, itching, or tingling. Phantom pain, however, is perceived by the patient as just that: painful. It often is the same as the pain before an amputation, or may be cramping, shooting, burning, or of any other characterization.

It has been a general teaching that children born without limbs do not have sensations of them, nor do these children experience phantom pain or phantom sensation as seen in the acquired amputee (43). Recent reports call this commonly accepted truism into question (44,45). Whatever this pain is, it will be recognized by those who care for children with limb deficiencies that these children do not have the same problem as the true chronic phantom pain seen in adult amputees.

Melzak and colleagues reported that phantom limb was present in at least 20% of the congenitally limb-deficient children, and in 50% of those who underwent amputation before age 6 years (45). In addition, 20% of the congenitally deficient group described the sensations as painful, whereas 42% of the acquired amputees described them as painful. To explain the phenomenon of phantom limb in a child who has never had a limb, Melzack et al. have proposed that there is a genetically or innately determined neural network that is distributed in the cortex (not focal), which is responsible for the representation of the limb, even though the limb bud development was not normal.

Phantom pain and stump pain are also associated, and in general, seen to be associated with other pains, e.g., headache, bone, or joint pain (44,46). The phantom sensations may occur frequently or rarely. They are often triggered by a wide variety of stimuli. Feeling nervous or happy, not wearing a prosthesis, being cold, or being ill are frequent. Fortunately, these sensations do not interfere with the child's usual activity, and most say they just try to ignore the sensations (47).

There is no single highly successful treatment of phantom limb pain, most likely because there is usually not one single cause. Because many of these problems resolve with prosthetic alterations or physical therapy modalities, a multidisciplinary team approach has proven to be the best intervention in evaluating and properly treating phantom limb phenomenon when it becomes a problem.

A properly fitting socket, with appropriate suspension and sock thickness, is the best and first treatment of choice (47,48). A heavy, tight shrinker, either worn inside

the prosthesis or when the prosthesis is off, may give relief. Physical therapy interventions including weightbearing and graduating pressures, such as tapping, rubbing, and massage to the residual limb, have been reported to give temporary or permanent relief. Rubbing and massaging the uninvolved limb at similar points to those in which they are experiencing the phantom limb sensation may provide relief. Various physical modalities have been utilized in the treatment of phantom sensations in children, including transcutaneous electrical nerve stimulation (TENS), biofeedback, ultrasound, and the physical agents of heat and cold (49).

For the occasional adolescent amputee who has problems with phantom pain following an amputation, gabapentin (Neurontin, Park-Davis) has proven a useful medication.

CONGENITAL DEFICIENCIES OF THE LOWER EXTREMITY

Fibular Deficiency

Classification

According to the ISO terminology, fibular deficiency is longitudinal deficiency that is either partial or complete. But this does little to accurately portray the spectrum of deficiency that is seen.

Numerous classifications specific for fibular deficiency have been proposed (25,30,50,51 and 52). To be useful a classification should guide treatment or aid in prognosis. As treatment changes, it may be reasonable to expect that classifications change.

Most classifications are anatomic, and are based on the radiographic appearance. Maffulli and Fixsen describe total aplasia of the fibula and a *forme fruste* of the same condition in which the fibula and tibia are short to varying degrees (53,54). A more specific classification, which is probably the most widely used today, was proposed by Achterman and Kalamchi (30) (Fig. 30-3, Fig. 30-4 and Fig. 30-5). They correlated the classification with the discrepancy in length, and recommended treatment based on the classification.

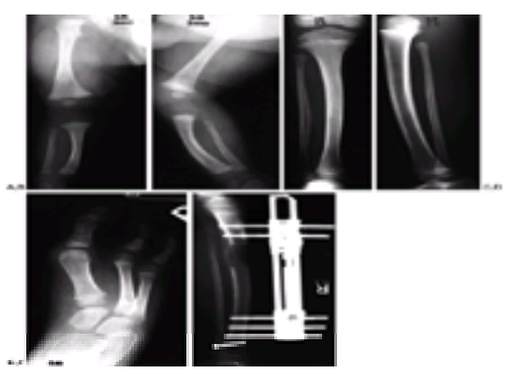

FIGURE 30-3. A, B: The radiographs of a 3-month-old boy with type IA fibular deficiency of Achterman and Kalamchi. Although the bones may seem normal to the casual observer, the proximal fibula is short. **C, D:** Anteroposterior and lateral radiographs of the same patient at age 7 yr 6 mo. The shortening of the fibula is more apparent and the ball-and-socket ankle joint is easily seen. **E:** The foot at the same age, with the lateral two rays missing. **F:** At age 13 yr, the leg was lengthened 7 cm.

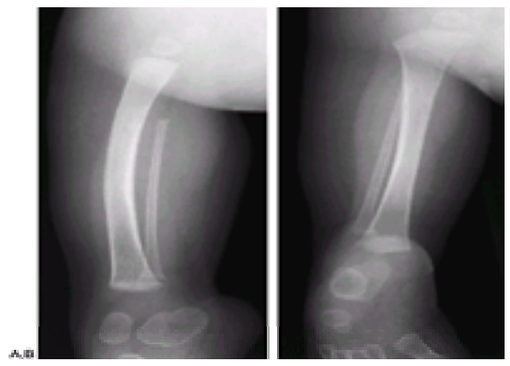

FIGURE 30-4. A, B: Type IB fibular deficiency, in which the proximal fibula is missing. This type is often associated with proximal focal deficiency, as it is in this child.

FIGURE 30-5. A, B: Anteroposterior and lateral radiographs of a type II fibular deficiency, in which the entire fibula is missing. Note the missing lateral rays of the foot and the severe angulation of the tibia. **C, D:** The limb 6 weeks after Syme amputation and an anterior closing-wedge osteotomy of the tibia. Placing the pin through the anterior cortex of the proximal fragment provides rigid fixation, which is not obtained if the pin is simply passed up the medullary canal. The pin was removed in the office at the time of cast removal. The clinical appearance of the same deficiency at the time of surgery in another patient is seen in **E** and **F**. Note the short tibial segment, the valgus knee and foot, and the dimple over the tibia.

Recently, Birch et al. have proposed a functional classification based on the functionality of the foot and the limb-length discrepancy as a percent of the opposite side (55). As they point out, however, the problem is picking the correct treatment for the individual patient. Given the large variation in the different aspects of fibular deficiency, including the parents' desire, it remains unlikely that classifications will provide anything more than a rough guide and a method of comparing patients in different reports.

Clinical Appearance

The appearance of a limb with fibular deficiency can vary from barely detectable to severely deformed. The typical limb is characterized by a valgus foot, shortening of the leg, variable anterior bowing of the tibia with a dimple over the apex, and variable valgus of the knee. The foot is often deformed, missing one to several lateral

(post axial) rays (Fig. 30-5E and Fig. 30-5F).

Examination of the limb will demonstrate anteroposterior instability of the knee, a small patella, variable degree-of fixed valgus and equinus of the ankle, and rigidity of the hind foot.

The appearance and physical findings of the leg are indicative of the widespread abnormality that may be present, along with hypoplasia or absence of the fibula, which gives the deficiency its name.

Frequently, the femur is short as well as the tibia. The femoral shortening may be slight to severe, with the associated diagnosis of proximal femoral focal deficiency. Amstutz (28) reported femoral deficiency in 15% of those with fibular deficiency, whereas Bohne and Root (56) reported femoral deficiencies in almost two-thirds of their patients. Kalamchi noted that 70% of type I and 50% of type II deficiencies were associated with shortening or deformity of the femur (57).

The abnormality extends into the knee joint, where the condylar notch of the femur is shallow, the tibial spines small, and there is laxity in the anteroposterior direction (58).

There is also a valgus deformity of the knee, which is not associated with varus/valgus instability (58), but reflects from a small hypoplastic lateral femoral condyle (59). The natural history of this deformity is that it usually worsens with growth (31,56,60,61). In some cases, the degree of valgus is more severe than can be explained by the smaller lateral femoral condyle alone.

The anterior bow of the tibia is variable, being more severe in the more severe deficiencies. It is not always of clinical significance.

The ankle may appear normal in some patients with mild deficiencies. The classic appearance is the ball-and-socket ankle joint, which is seen in less-severe deficiencies (Fig. 30-3C and Fig. 30-3D). There is disagreement about the origin of this abnormality: some authors feel that it is congenital in nature (62), while others feel that it develops secondary to the tarsal coalitions (63). If caused by the tarsal coalition, it is difficult to explain its absence in tarsal coalitions without fibular deficiency.

In more severe cases, if the fibula is present, it is short and may not reach the level of the ankle joint. The distal tibial epiphysis shows a triangular appearance.

The foot may appear normal, but more frequently is missing one or more lateral rays. It is a common and paradoxical observation that it is the shorter, more severely involved limbs that are usually missing four or five rays, whereas the less involved longer limbs are frequently missing only three rays or less (31).

Although not seen on radiographs at birth, tarsal coalitions are present in the majority of the feet associated with fibular deficiency. Grogan et al. noted such coalitions in 54% of anatomic specimens, although the abnormality could be seen on only 15%, radiographically because of the cartilaginous nature of the coalition (64).

Treatment Options

The main problems in the treatment of fibular deficiency are the limb length discrepancy and the deformity and instability of the foot and ankle. It is very important to realize that the discrepancy will become worse with growth, and it is the ultimate discrepancy at maturity that is important.

Amputation. Until the 1960s, amputation for fibular deficiency was recommended only as a last resort (65). Based on the results of these early attempts to save the limbs, several reports emphasized the advantages of amputation for severe cases (31,66,67 and 68). The indications are based primarily on the length difference and the functionality of the foot. Wood et al. recommended amputation for a discrepancy of three inches or more at the time of decision, or if predicted at maturity, for a nonfunctional foot, for a limb that would have severe cosmetic or functional problems, or for children who cannot endure the psychologic trauma of repeated hospitalizations and surgery (68). These recommendations were reaffirmed in a later publication from the same institution, following many of the same patients (31).

More recent recommendations begin to stretch the amount of length that can be restored, reflecting improvements in limb lengthening. Westin et al. suggested amputation for any discrepancy that would be greater than 7.5 cm at maturity (31). For Letts and Vincent, the number was greater than 10 cm (25), and for Hootnick et al. it was between 8.7 and 15 cm (69).

Although modern prosthetics have made amputation a somewhat more acceptable alternative, the improved ability to lengthen limbs has also made limb salvage a more feasible option. The recommendations of Birch et al. are an effort to account for these changes (55). They would recommend amputation for those with a nonfunctional foot, regardless of length, unless the upper extremities were non-functional. For those with a functional foot, but a length discrepancy of 30% or more, amputation would be recommended. For those with a functional foot and a discrepancy less than 10%, epiphysiodesis or lengthening is reasonable. There is little disagreement about these indications today.

It is between these two groups where the controversy regarding treatment lies today, and the greater the discrepancy in length, the greater the controversy. According to Birch et al., those patients with a functional foot, and a discrepancy between 10 and 30%, are candidates for either amputation or lengthening (55). The parents who are the decision-makers are weighing the hope for their child to retain their limb against what that will entail. They most likely have never seen a child or adult with an amputation; they visualize something horrible. They cannot really know what a lengthened limb will be like at the end of treatment; they see the limb as normal. Although they may understand that they will need two or three lengthening procedures, they cannot know what the impact will be on their child or their family, what complications they will encounter on the way, nor how their child will look or function at the end of treatment.

As yet, there are but a few preliminary reports of lengthening in fibular deficiencies with discrepancies greater than 10 cm. These preliminary reports, using the Ilizarov methods, deal mainly with the amount of length achieved, often before maturity, but with little information on cosmetic and functional result (70,71,72,73 and 74).

One way to begin to assess the problem is to look at what amount of length is required. The combined femoral and tibial length for a girl of average height at maturity will be approximately 80 cm (32) (Table 30-2). A 10% discrepancy would be approximately 8 cm, a 20% discrepancy would be 16 cm, and a 30% discrepancy would be 24 cm. To achieve greater than 10 cm of length in a congenital limb deficiency with anteroposterior knee instability, ankle instability, foot deformity, and congenitally short soft tissues, is a significant undertaking (75,76 and 77).

Reports comparing Syme amputation with lengthening are few and incomplete, but begin to give an appreciation for the problems associated with lengthening severe deficiencies (50,78,79). These authors conclude that lengthening should be reserved for those with more normal feet and less discrepancy in length, while early Syme amputation is the best treatment for the more severe problems. Herring gives a philosophical perspective on the dilemma (80). Birch et al. reviewed a series of adults who were treated with Syme amputation in childhood. They performed physical examination, prosthetic assessment, psychologic testing, and physical performance testing, and commented that the results of multistaged lengthenings for this condition would have to match these results to be justified (80a). They currently offer lengthening to patients whose limb length discrepancy is 20% or less.

Bilateral. In patients with bilateral fibular deficiency, the three problems are the foot deformity, the discrepancy in length between the two limbs, and the overall shortening in height as a result of two short limbs. Without extenuating circumstances, e.g., nonfunctional upper extremities, disarticulation of the foot and prosthetic fitting is the best solution. For those children with nonfunctional upper extremities who will use their feet for many of the activities of daily living, amputation of the feet is not an option.

In children with bilateral fibular deficiency, there is usually little discrepancy between the two limbs, but rather a discrepancy in their height, compared to what it should be. As they enter into their peer group this becomes an increasing problem. This problem is most easily solved by the prosthetist. If there is a significant difference between the length of the two limbs that cannot be solved by prosthetic adjustment, lengthening of the short limb becomes an attractive option.

It is easy to miss a patient with bilateral deficiency when the deficiency on the opposite side is mild. The focus on the severe deficiency distracts the examiner. The deficiency will become apparent with time, causing disappointment and loss of confidence.

Syme and Boyd Amputation

The amputation described by Syme (81) **[➥7.22]** seems to have been accepted for adults before children, and its use in boys was advocated before its use in girls because it was said that the Syme amputation produced an unsightly bulkiness around the ankle. This resulted in many children receiving a transtibial amputation, rather than a Syme amputation. It was subsequently learned, however, that the ankle does not enlarge following amputation in a young child, and the cosmetic appearance is excellent as the child grows.

Thompson et al. were the first to recommend the Syme amputation, rather than transtibial amputation, although only as a last resort (65). Subsequent reports by Kruger and Talbott (67) and Westin et al. (31) not only confirm the advantages of the Syme amputation in both boys and girls, but also advocated its early use for severe deficiencies. Several studies now confirm the value of Syme amputation (61,67,80,82,83,84,85 and 86).

One of the major advantages of the Syme amputation is the ability to bear weight on the end of the residual limb. One of the major complications of the Syme amputation is migration of the heel pad off the end of the residual limb. This is particularly true in congenital limb deficiencies, in which the heel may be on the back of the tibia, making repositioning of the heel pad on the end of the limb difficult or impossible. Although suggestions to remove a piece of the Achilles tendon, suture the extensor tendons into the anterior portion of the heel pad, or fix the heel pad with a Kirschner wire, may each have their place, most authors agree that migration of the heel pad does not produce any insurmountable problem for the patient or the prosthetist (60,82). Most other problems in patients with Syme amputation are caused by the other effects of the underlying disorder (60,61,82,84).

In the most complete study to date on the outcome of Syme amputation in children, Herring et al. examined the functional and psychologic status of 21 patients with a Syme amputation (60). They noted that family stress was the factor that had the greatest influence on the patients' psychologic functioning, and that children who had amputation after several failed attempts at salvage were at considerable risk for emotional disturbance. Functionally, the patients were able to function at the average for their age group, and they did not find that adolescents were less likely to participate in athletics (as Green and Carey also found) (87). In summary, they concluded that Syme amputation may be compatible with the athletic and psychologic function of a nonhandicapped child.

A variation of Syme amputation was described by Boyd (88). In the Boyd amputation **[➥7.23]**, the talus is excised and the retained calcaneus with the heel pad is arthrodesed to the tibia. The operation was initially devised to avoid the complication of posterior migration of the heel pad seen in some children with Syme amputation. However, the main complication of the Boyd amputation is the migration of the calcaneus if arthrodesis is not achieved. This requires an additional operation, which is often conversion to a Syme amputation. A real advantage of the Boyd amputation is that with the retained calcaneus the heel pad tends to grow with the child, rather than remaining small as in the Syme amputation. The Boyd amputation also adds additional length. This can be a problem in children who do not have significant shortening of the limb, when fitting various prosthetic feet, and may require a shoe lift on the normal side.

Eilert and Jayakumar (83) compared the two operations, and found the migration of the heel pad to be the only complication in the Syme amputation, whereas the Boyd amputation had more perioperative wound problems and migration or improper alignment of the calcaneus. In the authors' clinic, all of the children, even bilateral amputees, can and do walk on the ends of their residual limbs, either with or without the heel pad in place. If the heel pad migrates posteriorly, it may alter the weight bearing aspects of prosthetic fitting, especially as the child gets older.

In fitting a Syme amputation, there are two prosthetic advantages to having the deficient limb shorter. The first is the ability to make a narrower and more cosmetic ankle in the prosthesis. The second is that some shortening, rather than additional lengthening, makes it easier to fit more durable energy-storing feet. In fibular deficiencies, length is never a problem, because these limbs are always short.

Correction of Tibial Bow

The anterior bow in the diaphysis of the tibia varies from nonexistent to severe. Severe bowing is usually seen in the more severe deficiencies with complete absence of the fibula. Westin et al. reported this to be of little consequence (31). However, observations in the authors' center have shown this to be a frequent prosthetic problem, requiring osteotomy during the first decade.

With the tibial bow, the foot is displaced posterior to the weight-bearing axis that passes through the knee. If the foot is placed at the distal end of the tibia (which the parents want for cosmetic reasons), the ground reaction force places a large moment through the toe-break area, leading to premature failure of the foot component and skin problems caused by abnormal pressure. The problem is then blamed on the foot component or the prosthetist.

A reasonable recommendation would be to correct any significant bow at the time of Syme amputation. A small anterior incision, removal of an anterior-based wedge of the tibia, and fixation with a temporary Steinmann pin, placed up through the heel pad, solves the problem, and does not result in any delay in prosthetic fitting (Fig. 30-5). When correction of the bow is necessary in older children who are already in their prosthesis, the authors have preferred the Williams rod technique **[➥6.11]**, because this speeds resumption of prosthetic wearing.

Correction of Valgus

Development of progressive genu valgum has long been known as a complication of fibular deficiency. It is one of the major problems seen in gait in children with this problem. At first, it is merely cosmetic, and can be accommodated with prosthetic alterations. However, if it becomes more severe, it will increase the forces on the lateral compartment and make good alignment impossible.

The cause of the deformity has been controversial. Initially, it was thought to result from tethering by the fibular anlaga; however, release of this lateral band did not prevent or lessen the deformity (28).

Westin et al. noted that the tibia often developed an anterior flexion along with the valgus, and attributed the problem to an abnormality in growth in the lateral and posterior portions of the proximal tibial physis (31). This is separate from anterior bow in the diaphysis of the tibia.

Most recently, Boaks et al. documented a decrease in the height of the lateral femoral condyle that was not present prior to walking, and correlated with the amount of valgus (59). They suggested that tibial osteotomy **[➥6.1–6.5]**, to correct the anteromedial bowing, might prevent the changes in the lateral femoral condyle. If the deformity was present in the lateral femoral condyle, they suggested temporary stapling of the medial femoral condyle **[➥4.21]**, since osteotomy had a very high recurrence rate unless performed near the end of growth.

Ankle Reconstruction

Any attempt to save the limb of a child with significant fibular deficiency will require efforts to realign and stabilize the ankle. There is renewed interest in this subject with attempts to lengthen the leg.

The Gruca procedure is designed to provide lateral stability to the foot in the absence of the fibula. Serafin gives the first report of the technique in the English literature, and recounts the various attempts at bone grafting and other procedures that were described before Gruca developed his technique (89).

In the Gruca procedure the tibia is split longitudinally. The medial segment is displaced proximally with the talus, leaving the lateral fragment as a lateral buttress. Thomas and Williams describe the early results in nine patients treated with this procedure. The follow-up is short, and the evaluation of function incomplete (90). The operation has not been widely used, and would seem to have little to recommend it.

Arthrodesis of the talus to the distal tibia is a logical plan in conjunction with leg lengthening, but there are no reports on its outcome. It is likely that this would also require release of all of the tendons crossing the ankle joint to prevent foot deformity.

The ball-and-socket ankle joint, seen in the Kalamchi type IA deficiencies, usually require no treatment. The authors have, however, seen several children with increasing valgus during adolescence or following leg-lengthening, who become symptomatic with normal athletic activity. These have been successfully treated by a

Wiltse osteotomy **[➥6.6]** of the distal tibia.

Prosthetic Management

Prosthetic management of the fibular-deficient limb is treated differently than a comparable traumatic adult with a Syme disarticulation. In the child, the prosthesis is designed to accommodate growth, and to help stabilize knee laxity and hyperextension through socket design and alignment. Emphasis is placed on socket alignment and minimizing rotational forces acting on the knee.

The socket fitting for a Syme amputation may be designed to take all of the weight on the end of the residual limb, as intended, all of the weight on the patellar tendon and flare of the proximal tibial condyles, as in a transtibial amputation, or both. As the child grows, it is a good idea to begin to shift some of the weight bearing to the proximal structures, to prepare the child for the time when full weight bearing on the end may not be possible. Failure to shift weight bearing proximally with age usually results in problem fittings resulting from tolerance issues. This discomfort probably arises from the small distal weight bearing surface seen in many of the congenital limbs. This is an important consideration in the bilateral amputee, in whom disproportionate weight shifting to the sound side is not possible for comfort.

As with most amputations done at a young age, the condyles will be small at the time of amputation, will not grow to normal size, and therefore, do not need to be trimmed as in the adult. The brim of the socket is designed with supracondylar medial and lateral trim lines, in an effort to control any knee valgus instability and/or patellar instability. The type of suspension will depend on the size of the distal end of the residual limb. If very large, an obturator or window may be necessary. With further growth, the distal end may not be sufficient for suspension, and a different design will be necessary. These are discussed later.

To best utilize current prosthetic feet in children who are older and large enough to take advantage of them, it is necessary that at least 4 cm of space be available at the distal end. If the prosthetist is to offer the latest in technologic advances in components, greater residual limb length differences will be required. This need can be anticipated and an arrest of the distal or proximal tibial and fibular physes performed at the appropriate time. This length differential is usually not a problem in children with congenital limb deficiency, because the deficient limb will usually be shorter than the opposite. It is relevant in children with acquired deficiency treated by Syme or, more often, Boyd amputations. Although the longer lever arm of the Syme amputee tends to compensate for the lack of more elaborate components, when fit is possible, they can be an advantage.

Tibial Deficiency

Classification

There are two classifications specific for tibial deficiencies, both based on the radiographic findings. Anatomic studies of available specimens have not proven of value (91,92).

The simplest classification is that of Kalamchi and Dawe (93). Type I is complete absence of the tibia (Fig. 30-6). Type II is absence of the distal tibia, with a proximal portion that forms a relatively normal articulation with the femur (Fig. 30-7). Type III is distal tibiofibular diastasis (Fig. 30-8).

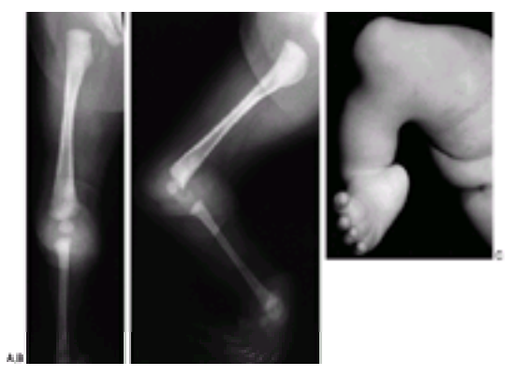

FIGURE 30-6. A, B: Radiographs of an infant with a type I tibial deficiency of Kalamchi and Dawe (Type 1a of Jones et al.), in which the entire tibia is absent. There was no extensor mechanism and no proximal tibia. If there were a proximal remnant of tibia that would later ossify, this would be a type 1b deficiency of Jones et al. **C:** The clinical appearance with the medial deviation and severe equinus of the foot, and the absence of any tibial structure below the distal femur.

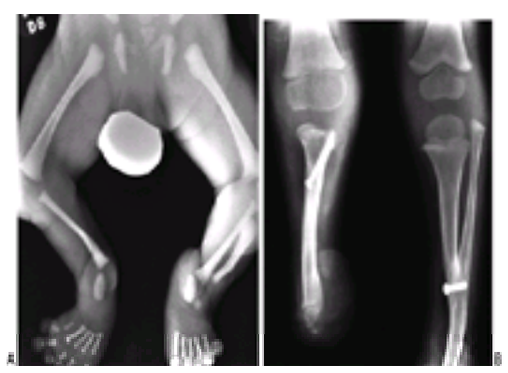

FIGURE 30-7. A: Anteroposterior radiographs of a 4-month-old child with type I tibial deficiency of the right leg and type II deficiency of the left leg. **B:** On the right leg, he underwent a Brown procedure. Despite the favorable radiographic appearance 4 years after surgery, he developed a severe valgus/flexion deformity, and subsequently had a knee disarticulation on this side. On the left leg, he underwent a synostosis of the fibula to the tibia and a Syme amputation. It is best to excise the proximal remnant of the fibula when performing this procedure, because the continued growth of the proximal fibula produces a large prominence that will interfere with prosthetic fitting. This was resected at the time of his right knee disarticulation.

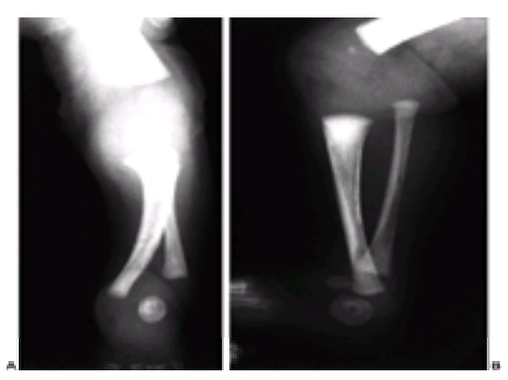

FIGURE 30-8. A, B: Anteroposterior and lateral views of a type III of Kalamchi and Dawe, or type 4 of Jones et al. This is sometimes referred to as a diastasis of the ankle mortise. Notice the shortened tibia and the disruption of the normal relationship between the tibia and the fibula.

The classification of Jones et al. divides the type I of Kalamchi into 1a and 1b. In neither is the proximal tibia visible radiographically at birth. In type 1a, it is actually absent and without an extensor mechanism, whereas in type 1b, it is present as a cartilaginous remnant that will later ossify, and which suggests that the extensor mechanism is intact.

The Jones classification adds an additional type: a very unusual variant, with a diaphyseal and distal remnant of tibia, but no proximal tibia, is type 3. The diastasis of the distal tibiofibular joint is now type 4 in this classification.

The most important point in deciding on the treatment is the presence of active knee extension, which implies an adequate active quadriceps muscle and insertion on the tibia. This usually depends on the presence of a proximal tibial segment. Because this proximal portion of the tibia may be present, but not visible in the Jones Type 1b deficiencies, some authors have recommended direct surgical exploration, sonography (94), or magnetic resonance imaging, to detect its presence. This should seldom be necessary, because it is extension power to the tibial segment that is important, not the presence of a tibial segment. A good radiographic clue is that, in those with the presence of a proximal portion of the tibia, the distal femoral condyle will be wider, and the ossification of the epiphysis better, than if it is not present.

An unusual type of tibial deficiency is that seen in association with fibular dimelia. Kumar and Kruger summarized the sporadic reports until 1993, and presented the findings, associated anomalies, and treatment in six patients (95). In this deficiency, the tibia is absent and there is a duplication of the fibula. There is a high incidence of other anomalies, including visceral anomalies in these patients. These authors recommended knee disarticulation, if the femur is of normal length, and fusion of the fibula to create a sufficient lever arm, if there is associated PFFD.

Clinical Appearance

The characteristic appearance of an infant with tibial deficiency is a markedly shortened tibia with a rigid equinovarus-supinated foot pointing toward the perineum (Fig. 30-6C). Preaxial polydactyly is relatively characteristic of tibial deficiencies, although absence of the preaxial rays can also be seen. The fibula is relatively long. Other congenital limb anomalies will frequently be seen in association with tibial deficiency.

Children with congenital tibial deficiencies, regardless of type, frequently have other associated abnormalities, frequently musculoskeletal (96,97). The incidence of associated anomalies is reported to be between 60 and 75% (93,98,99). Although the majority of these anomalies are in the musculoskeletal system, there may occasionally be problems in other organ systems (100).

In addition, many of the children with tibial deficiency and other anomalies will represent an inherited syndrome (96,97,101,102). Although it is not necessary for the orthopaedic surgeon to know all of these syndromes, he or she must be aware of the need for a thorough examination of affected children, and of the high potential for genetic transmission of the disorder (102,103).

Treatment

The treatment of the type I of Kalamchi and Dawe or the 1a of Jones is knee disarticulation. Without the presence of active knee extension, there is no possibility for reconstruction of the leg. Notwithstanding this common orthopaedic principle, there have been attempts to centralize the fibula under the femoral condyle.

Adopted from others (104,105), and popularized in the United States by Brown (106), the Brown procedure, as it is commonly known in the United States, is the centralization of the fibula under the femur. It was Brown's recommendation that fibular centralization be done only with active extension. Apparently, there are occasional deficiencies in which some part of the extensor mechanism inserts into the fibula. In reviewing the literature on the results of Brown's procedure, it is not apparent that this is always present before surgery. The operation has now been evaluated in several clinical trials (96,97,107,108,109,110 and 111). This procedure is distinct from synostosis of the fibula to a tibial remnant, a point that may not always be clear in reports on the subject.

The majority of those reporting on the procedure recommend against it, preferring the early function obtained with knee disarticulation (96,97,108). Loder (112) examined 87 cases from the literature using the minimal requirements for a good result, suggested by Jayakumar and Eilert of acceptable gait, active knee motion of –10 degrees to 80 degrees of flexion, varus/valgus instability less than 5 degrees, and no flexion contracture (113). He found that 53 of the 55 cases of Jones type 1a deficiency treated by Brown's procedure had a poor result because of flexion contracture. This echoes the reported experience of most others, and emphasizes the need for strong, active knee extension, which is usually not present without a remnant of the proximal tibia (96,107,108,110,111). Simmons et al. were satisfied with their results (109). Their satisfaction was based more on the patients feelings than objective assessment.

It has been said that it is difficult to assess active quadriceps function clinically, prior to surgery (96). However, it might be a wise clinical decision to consider quadriceps function at least inadequate if not absent, if it cannot be observed during the first year of life by an experienced physician and therapist.

In patients with Jones type 1b deficiency, in which a radiographically invisible cartilaginous remnant of tibia is present, it is important to assess it over time for ossification and development, as well as to verify good active extension. It is possible that this remnant will be present, but good active extension will be absent and/or it will not ossify. If there is active extension, but the remnant is not sufficiently ossified by 1 year of age, the surgeon may choose to attempt to transfer the fibula to the unossified segment or perform a Syme amputation, fit with a prosthesis, and wait for ossification before performing the transfer.

In those patients with type I deformities and proximal femoral deficiency, with a very short limb, the best option may be to arthrodese the fibula to the distal end of the femur. The goal of this procedure is to increase the lever arm of the femoral segment, for the same reasons that a knee fusion is performed in children with PFFD.

In type II deficiencies in either classification, the tibial remnant will ossify and form a satisfactory joint. In these cases it is usually best to create a synostosis between the existing fibula and the tibial remnant, to increase the length of the lever arm. A Syme amputation **[➥7.22]** is performed at the same time, and the patient is fit with a below-knee prosthesis. In performing the synostosis, it is important to achieve good alignment of the fibula in relation to the knee joint. The residual proximal fibula should be removed to avoid problems with prosthetic fit.

Type 3 deficiencies of Jones (not classified by Kalamchi and Dawe) are very unusual, and there is not a lot of published experience. Jones et al. reported one case that was bilateral (114). They described a cartilaginous portion of the tibia proximal to the ossified portion, and that it was “under voluntary muscle control.” Their patient was treated with excision of the proximal fibula and Syme amputation. Fernandez-Palazzi et al. had two cases in their report. Both were treated with Syme amputation, implying that there was an active quadriceps mechanism (115).

Type III deficiency of Kalamchi (Type 4 in the Jones classification) presents a unique problem. At birth, the foot is deformed, often appearing like a clubfoot to the inexperienced. In addition, the amount of tibial shortening that will result is not apparent. All of this makes it difficult for the parents to accept amputation. The difficulty for the surgeon is that this deformity is a spectrum of deformity. Garbarino et al. have emphasized the distinction between a short tibia with a varus foot and a true congenital diastasis of the ankle joint (116). The former is usually amenable to reconstruction according to Schoenecker (99), whereas the true type 4 deficiency with diastasis of the ankle joint usually is treated with amputation (114,117).

There are reports of reconstruction for the type 4 deficiencies, but in general the follow-up is short and the problems of a plantigrade foot and limb length discrepancy just beginning (116,118,119). The only long-term follow-up of a reconstruction is that of a girl followed to age 15 years of age, with what was described as satisfactory ankle function and 6.5 cm of shortening (120).

In their review of tibial deficiencies, Schoenecker et al. reported on ten Jones type 4 deficiencies, of which nine had initial reconstruction of the foot. A Syme amputation was subsequently done in six, usually at the parents' request. Of the four who retained their foot, two had contralateral deficiencies in which the prosthesis accommodated the length discrepancy. One had lengthening of 4.6 cm and one remained 4.8 cm short.

From the available information it would seem reasonable to attempt to retain the foot, if the deformity is at the less severe end of the spectrum, or if there is a significant contralateral deficiency. In most other cases, Syme amputation seems most reasonable.

Prosthetic Management

With various surgical interventions dependent on the severity of the anomaly, there are several prosthetic approaches to management. In those children with type I tibial deficiency who have been treated with knee disarticulation and have a flare at the condyles, the prosthetic socket consists of a nonischial weightbearing design with rotational control achieved through the intimate fit of the distal end of the socket over the femoral condyles and a well-formed gluteal impression. Suspension is usually achieved with the use of a segmented liner or bladder design that allows the wider condyles to pass through, while maintaining pressure over the femur just proximal to the condyles.

In cases in which the condyles are absent, or there is the need to fit with a transfemoral socket, rotational control is achieved through proper contouring of the socket relative to the femur—the musculature surrounding the femur has a slight triangular shape in a cross-sectional view, and the more proximal one moves on the lateral side, the flatter the shape. This allows a locking of the musculature, and with proper socket fit, decreases rotation. In addition, a silicone sleeve suspension may be used in conjunction with a pull-through strap to secure the liner. If all else fails, a standard Silesian belt (around the pelvis) may be utilized. However, this will interfere with toileting and potty training.

In the knee disarticulation (or transfemoral) prosthesis for children, there are differences of opinion as to when young children are able to handle an articulated knee. Current established practice is to first fit with a locked knee, and allow an articulating knee at approximately 3 to 5 years of age. In contrast, Wilk et al. (121) advocate the use of articulating knees in children as early as 17 months. It is the authors' experience that the very early installation of articulated prosthetic knees, when the children begin to pull-to-stand around 10 to 12 months of age, has proven clinically successful. The children learn how to handle the knee very quickly, and there is very little need for any type of device to temporarily stabilize the knee. The use of a knee joint at this stage permits more normal development, allowing bent-knee sitting, side sitting, crawling and kneeling on hands and knees, and easier pull-to-stand.

In type II cases, in which a tibial segment has been preserved or the fibula has been joined to the tibial remnant, a modified transtibial prosthesis or a Syme prosthesis is utilized. Unlike the standard transtibial design, the socket will incorporate supracondylar and suprapatellar proximal brim lines that will aid in the control and stability of the knee and prevention of a hyperextension moment, respectively. In some instances in which knee stability is less than optimal, outside joints and a thigh cuff or lacer may be required. These are used as a last resort, and often contribute to increased weakening of the musculature as a trade-off for increased control and alignment.

Femoral Deficiency

Classification

There have been numerous classifications of proximal femoral focal deficiency (PFFD) (27,29,52,122,123,124,125 and 126). These classifications range from attempts to unify all radiographic defects of femoral development to a simple two-part classification based on limb length inequality. Some classifications are radiologic, some functional, and some are designed to suit the authors' preferred treatment. In addition, no classification is able to account for the length, radiographic, and muscle abnormalities, all of which are important in the treatment and outcome.

The most widely used classification is that proposed by Aitken (122). It divides the true PFFD cases into four categories based on the radiographic findings. It is important to keep in mind that in PFFD, as in other congenital deficiencies, the bone may be late in ossifying, and thus may be present but unseen on radiographs. Also, these different groups are not distinct, but rather form a continuous spectrum.

In class A, the femur is short, with its proximal end at or slightly above the acetabulum (Fig. 30-9). There is a defect in the subtrochanteric region. The femoral head may be absent, but will later ossify, and its presence is indicated by a well-developed acetabulum. The subtrochanteric defect will eventually ossify, establishing bony continuity, although usually with considerable varus deformity. The location of this varus deformity in the subtrochanteric region, rather than the femoral neck, is what distinguishes PFFD from congenital coxa vara.

FIGURE 30-9. Anteroposterior pelvis of an 18-month-old child with bilateral proximal focal femoral deficiency. The right hip is an Aitken class A, and demonstrates the presence of the ossific nucleus and a good acetabulum. The femoral metaphysis lies above the level of the ossific nucleus. There is a cartilaginous connection between the metaphysis and the femoral head, which will usually ossify by skeletal maturity, but often with a significant varus deformity. The opposite hip is a class C PFFD. This patient demonstrates the difficulty with limb length difference in some patients with bilateral PFFD.

In class B, there is a more extensive defect or absence of the proximal femur (Fig. 30-10). The femoral head is present, although its ossification may be delayed. There is usually a bony tuft on the proximal end of the femoral shaft. The defect will not heal spontaneously, and the proximal end of the femur will be above the acetabulum.

FIGURE 30-10. A: Anteroposterior radiograph of the pelvis and limbs of a newborn female with Aitken class B proximal focal femoral deficiency. Note the short femoral segment and the well-developed acetabulum, although the femoral head is not visible. **B:** By 5 years of age, the femoral head is ossified and the cartilaginous connection between the femoral head and the subtrochanteric region of the femur has undergone considerable ossification. However, a pseudarthrosis persists and a significant varus deformity has developed. **C:** The femur after correction of the varus with a spike type of osteotomy **[➥4.4]**. The result 1 year later is seen in **D**. Now faced with a projected discrepancy of 20 cm, the parents elect a van Nes rotationplasty. This was done with part of the rotation through the knee arthrodesis, and the remainder through the tibia. The radiographic result is seen in **E**. The patient had one additional derotation performed through the midtibia at age 10 years.

In class C, the femoral head is absent, and will never ossify. The acetabulum is severely dysplastic (Fig. 30-11). The femoral shaft is shorter than in class B, and the entire proximal portion of the femur, including the trochanters, will not appear.

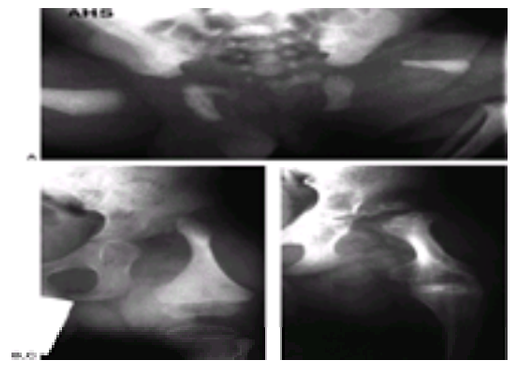

FIGURE 30-11. The anteroposterior pelvis and limbs of a newborn boy (**A**) and at 3 years of age, just before surgery (**B**), with Aitken class C proximal femoral focal deficiency. Note the very short femoral segment and the lack of acetabular development. The same patient is seen in **C** at the age of 12 years, following a Syme amputation and knee arthrodesis with preservation of the proximal tibial physis. There is still no appearance of a proximal femoral ossific nucleus.

In class D, the femoral shaft is extremely short, often with only a tuft of irregularly ossified bone proximal to the distal femoral epiphysis (Fig. 30-12). The lateral pelvic wall is flat, without hint of an acetabulum.

FIGURE 30-12. Anteroposterior radiograph of the pelvis and femur of a 1 yr 5 mo old male with Aitken class D proximal focal deficiency. There is little femur present, and no sign of acetabular development. He underwent knee arthrodesis and Syme amputation at 2½ years of age.

Gillespie (124) proposed classifying femoral deficiencies into three groups for purposes of treatment. Group A are those with congenital short femur indicated by clinical hip stability, lack of significant knee flexion contracture, and the foot of the affected extremity lying at or below the mid-point of the opposite tibia. These patients may be candidates for limb-lengthening. His group B patients include those classified as Aitken class A, B, and C, whereas his group C represents the Aitken class D patients. He recommends lengthening for his group A patients, and prosthetic treatment for his group B and C patients.

An unusual variant of PFFD is that seen with a bifurcated (not duplicated) femur. In this condition, the femur has two distal ends, which form a “Y” (127). There is always an associated type I tibial deficiency without active extension, and treatment is by knee disarticulation and removal of the segment of femur in poorest alignment.

Clinical Appearance

The appearance is classic and should be easily recognized. It will be bilateral in 15% of the cases. The femoral segment is short, flexed, abducted, and externally rotated. The hip and knee joint exhibit flexion contractures. The proximal thigh is bulbous and rapidly tapers to the knee joint. Fibular deficiencies are so common in association with PFFD that the valgus foot and other characteristics of fibular deficiency are almost a part of PFFD (Fig. 30-13). PFFD is associated with fibular deficiency in 70 to 80% of cases (128). In addition, about 50% of the patients will have anomalies involving other limbs (122,128).

FIGURE 30-13. This photo of a 12-month-old female who is pulling to stand demonstrates the clinical features of proximal focal femoral deficiency: a very short and bulbous femoral segment, which is flexed, abducted, and externally rotated.

Examination of the hip joint is difficult because of the bulbous thigh and short femoral segment. Pistoning may be apparent because of associated hip instability. The knee is always unstable in the anteroposterior direction.

Treatment

The treatment aims to compensate for the functional problems the patient experiences. The most obvious of these is the shortening of the limb. Less obvious is the problem with hip function and its relationship to alignment of the limb. Because of the flexed and externally rotated femoral segment, the knee remains flexed, and the leg and foot are anterior to the axis of the body (Fig. 30-13 and Fig. 30-14D). With or without skeletal hip stability, there is deficiency of the muscles around the hip, resulting in significant lurch, to shift the center of gravity in single-leg stance. The knee will have varying degrees of instability. The function of the foot will depend on the severity of any associated deficiencies of the leg, e.g., fibular deficiency.

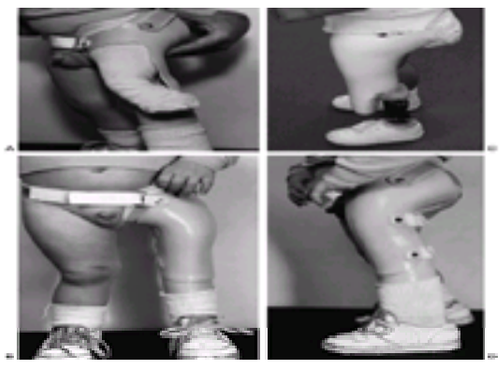

FIGURE 30-14. The nonconventional or extension prosthesis allows the child to “stand” on the prosthesis, extending his limb to the floor and accommodating the deformity. **A** and **B** show this prosthesis without a knee joint, which is usual. It is possible to add a knee joint to the prosthesis. **C:** The children rapidly learn to control the knee joint. **D:** Lateral view of the patient in the prosthesis, demonstrating why this prosthesis is not a good long-term solution. The knee is at the brim of the socket, is poorly contained, and provides a very poor lever arm. The weightbearing line of the leg remains anterior to the axis of the body; the flexion and external rotation of the hip persist.

There are more options and variations in the treatment of PFFD than almost any other congenital limb deficiency. Fortunately, most of these decisions can be postponed until 2½ to 3 years of age, because this is the best age to perform these surgical options. Prior to this time, several important decisions need to be made. The first is whether or not the child is a suitable candidate for limb-lengthening.

According to most literature on this subject, the limb may be judged to be suitable for lengthening if the predicted discrepancy at maturity is not greater than 20 cm, the hip is or can be made stable, and there is a good knee, ankle, and foot. In such cases, multiple staged lengthenings can be planned. The timing and staging of these procedures depends on the choice of the physician, but will usually not start before the age of 3 years. Although it is possible to obtain this much length, there are as yet no good reports on the functional outcome of such lengthenings in patients followed to maturity and into adulthood.

If the discrepancy is predicted to be greater than 20 cm at maturity, or for any other reason lengthening is not chosen as a treatment, a decision should be reached about the best approach to prosthetic fitting.

This initial treatment of children with unilateral PFFD is, as in other congenital deficiencies, to parallel normal development. Therefore, when the child is ready to stand, regardless of the treatment planned for the future, he is fitted with a prosthesis to equalize the leg lengths and permit standing and walking. The prosthesis is often called a “nonconventional” or “extension” prosthesis. It is designed to fit the extremity without any surgical modification to the extremity (Fig. 30-14). The flexion, abduction, and external rotation of the proximal segment (the femur) are accommodated in the alignment. Although it is usual to omit a knee joint, the authors have found that if there is sufficient room, a knee joint can be used in the initial prosthesis.

In the authors' clinic knee joints are placed, whenever possible, within limits of the short prosthetic tibial section. This is to allow the infant knee flexion during all developmental functions: one-half kneel, squat, pull-to-stand and climb on toys and furniture. The authors' have found that infants who are fitted with knees learned very rapidly to extend their hips to control knee extension throughout all their movements. Less vaulting and deviations on the nonprosthetic side are also noted if a knee joint is placed within the prosthesis. There is no knee joint in the prosthesis if the length of the limb is too long to fit a prosthetic foot, including a knee.

This nonconventional prosthesis will permit ambulation for the young child. However, as the child grows older, the limitations of this prosthesis soon become apparent (Fig. 30-14D). The continued flexion, abduction, and external rotation of the femoral segment, with limb alignment anterior to the body's axis, along with the hip instability and the flexed knee, which is difficult to contain within the prosthesis, are all factors that make a very poor lever arm to move the prosthesis. The foot frequently lies at the level of the midcalf of the opposite limb, making the placement of the knee joint less than ideal. Surgical correction of these problems is designed to make the limb a more efficient lever arm for the prosthesis. Among the usual surgical choices are knee arthrodesis, amputation of the foot, rotationplasty of the limb, and reconstruction of the hip. Additional possibilities are iliofemoral arthrodesis with or without rotation, and prosthetic fitting without modification to the limb. Thigh reduction by surgical resection and liposuction are of great value in prosthetic fitting as the patient grows older.

The treatment of children with bilateral PFFD is very different. In these children, the feet should be preserved, and knee fusion is not indicated. This is because these children will spend the majority of their lives walking without prostheses. The two biggest problems in these children are foot deformities and unequal limb lengths. Surgical release of the foot and long-term orthotic use can usually provide for a useful foot. Limb length discrepancy when significant is more difficult, because of the problem of shortening the child more, on the one hand, and the difficulty of lengthening these limbs, on the other. No firm recommendation can be made regarding this, and each case should be decided on its own merits.

Knee Arthrodesis

Arthrodesis of the knee joint is a standard procedure in children with PFFD. It creates a single longer and more efficient lever arm, which is easier to contain within the prosthesis. This will greatly enhance prosthetic function and lower energy consumption. Within 6 months of knee fusion and prosthetic fitting, the abduction and flexion deformity at the hip joint will correct, thus aligning the limb under the axis of the body.

Depending on the length of the femoral segment and the limb as a whole, it is usually desirable to remove at least one of the growth plates at the knee at the time of fusion. This is usually the case in Aitken class A, B, and C deformities. If this is not done, the limb will remain too long for fitting of a suitable knee joint at maturity. In some cases, depending on the length, it may be advisable to remove both or neither growth plates (129). Calculation of the anticipated length of both limbs at maturity by means of the Green-Anderson growth charts (Table 30-2 and Table 30-3), as described earlier, will help with the answer.

The fusion is usually performed between 2 and 3 years of age. After excision of the epiphysis and physis from one side, usually the femur, and the joint surface from the other, the femur and tibia are fixed with a rigid rod, e.g., a Rush rod placed from proximal to distal. This is supplemented with a spica cast. The patient is usually ready for prosthetic fitting in 6 weeks and ambulation as soon as the prosthesis is ready.

Amputation of the Foot

With the knee fused, ablation of the foot is desirable in most situations. One reason is length: the new lever arm, consisting of the femur and the tibia, needs to be short enough to accommodate an internal knee joint when the child is older. The foot adds unnecessary length. In addition, as the foot grows, it becomes increasingly difficult to accommodate in a cosmetically acceptable socket. The advantages and disadvantages of the Syme and Boyd amputations have been discussed. Amputation is best performed at the time of knee fusion.

van Nes Rotationplasty

In the van Nes rotationplasty, the limb is rotated 180 degrees, either through the knee arthrodesis, the tibia, or a combination of both. The goal is to have the ankle of the short limb at the level of the knee on the long limb at maturity. The foot now functions like the residual tibia in a below-knee amputation, thus giving the patient function more like a B-K amputee than a knee disarticulation (Fig. 30.15). An obvious prerequisite is reasonable function of the foot and ankle. Because this procedure is also used in the treatment of both malignant skeletal tumors around the knee and traumatic loss of the knee with its corresponding growth plates, it is important to keep in mind that these patients are very different from those with PFFD. Although some lessons from one group are applicable to the other, care must be taken.

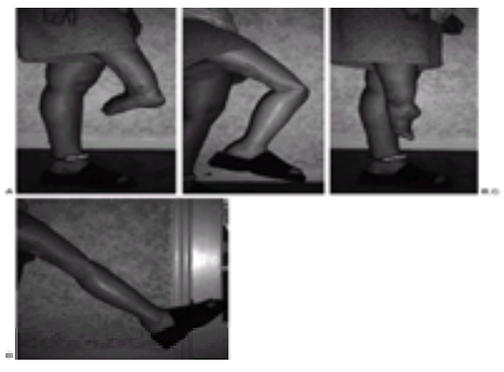

FIGURE 30-15. The results of a van Nes rotationplasty are seen in this 17-year-old female with PFFD (same patient as Fig. 30-10). With the ankle rotated 180 degrees, dorsiflexion of the ankle (**A**) results in flexion of the prosthetic knee (**B**), and plantar flexion (**C**) results in extension of the prosthetic knee (**D**).

The rotationplasty was first described in 1930 by Borggreve (130) for an acquired limb length discrepancy, and later by van Nes (131) for three cases of congenital deficiency of the femur. Initial reports of rotationplasty for treatment of PFFD by Kostuik et al. (132), and Torode and Gillespie (133) have been followed by more recent reports by Friscia et al. (134) and Alman et al. (135).

The main complication of the procedure is either failure to achieve sufficient rotation at surgery or subsequent derotation with growth. Kostuik et al. (132), in one of the earliest reports on this procedure, recommended waiting until the child was older to perform the operation. However, this delays the procedure many years beyond when the patient can learn to use the prosthesis and benefit from the procedure. Because the complication is easily treated, there seems little reason to wait. Subsequent reports have not found this to be so great a problem.

A potential problem that is of concern to patients, parents, physicians, and prosthetists, when this procedure is considered, is the cosmetic appearance. It appears, however, that the problem is overrated by medical staff, compared to the patients themselves. The procedure has been more widely used and accepted in Canada than the United States, and in large limb deficiency centers. Alman et al. found no difference in the perceived physical appearance of children treated with rotationplasty, compared to knee arthrodesis and Syme amputation (135). In the report of Friscia et al., one patient subsequently had a Syme amputation at the parents' request (134). This emphasizes the importance of proper preparation of the parents, and patient if old enough. This is best accomplished by seeing other patients with a rotationplasty, along with using videos of patients, teaching dolls, etc.

It needs to be emphasized that the ankle must be sufficiently normal to serve as a knee. This is particularly important, because up to 70% of children with PFFD will also have a fibular deficiency on the same side. Although some valgus alignment of the foot and ankle can be compensated for in the prosthetic alignment, the deformity may tend to become greater with age. Severe valgus and equinus deformities, with a deficient foot, is a contraindication to the procedure.

Additional preoperative preparation includes toe and ankle strengthening, in particular, since these are the structures that will power the new knee joint. Equinus position should be emphasized, because this will place the foot in the best mechanical position. Children who have mild equinus contractures of 30 degrees or less will usually stretch these out with prosthetic use, and do not need special attention preoperatively. Crutch training should be done preoperatively, as in all elective surgery that will require crutch use postoperatively.

The improvement in function with the rotationplasty, compared to other procedures, has been documented both for tumor patients (136,137 and 138) and for those with PFFD (135,139). These studies demonstrate that those with rotationplasty function better than those with knee arthrodesis and Syme amputation, not quite so well as those with a below-knee amputation, and not as well as those who have rotationplasty for noncongenital conditions, e.g., tumor.

Stabilization of the Hip

Most patients with PFFD who are to be managed with prosthetic fitting will have hip instability. This is not only because of the deficient bony anatomy, but also the deficient musculature. This has resulted in some controversy about the value of surgical procedures to stabilize the hip. Some feel that nothing of functional value is gained and surgical intervention is not warranted (128,129,140), whereas others feel that surgical correction can be of value (27,141,142 and 143). It is the authors' opinion that, in Aitken class A and B patients, who have a femoral head within the acetabulum, surgical correction of the pseudarthrosis, with correction of the varus deformity, is beneficial **[➥4.4]** (Fig. 30-10B, Fig. 30-10C and Fig. 30-10D).

There are two problems to consider: the pseudarthrosis and consequent malalignment, and the bony stability of the femoral–pelvic articulation. In those patients for whom lengthening is planned, it is necessary to obtain good containment of the femoral head, which may require an acetabular procedure. In these patients, retroversion and varus are usually present, and should be corrected prior to lengthening.

In patients with Aitken class B PFFD, there will be a pseudarthrosis of the femoral neck. This can be repaired while, at the same time, restoring more normal alignment. It may not be necessary to wait until complete ossification of the femoral neck to perform this procedure (144). Ossification may accelerate after realignment.

Iliofemoral Arthrodesis

There are two types of iliofemoral arthrodeses described. These procedures are an attempt to address the problem of hip instability.

In 1987, Steel described arthrodesis of the distal femoral segment to the pelvis, in the region of the acetabulum in four patients (145). The femur was flexed 90 degrees, so that it was perpendicular to the axis of the body. This results in knee extension being equivalent to hip flexion, and knee flexion equivalent to hip extension.

More recently, Brown has described a rotationplasty in conjunction with iliofemoral arthrodesis (146). In this procedure, the distal end of the femur is rotated 180 degrees, before it is joined to the ilium with its axis in line with that of the body. The knee now functions as the hip joint, and the ankle now functions as the knee joint, as in a van Nes rotationplasty.

Both of these procedures have had limited use. There are significant problems in achieving an arthrodesis, and the distal femoral segment cannot be allowed to grow too long. Additional surgical procedures are to be expected. As yet, there are only very limited reports on the functional advantages (145,146 and 147).

Thigh Reduction

The bulbous proximal portion of the thigh makes prosthetic fitting difficult in some patients, and results in discomfort for others. This problem can be resolved by thigh reduction with a combination of surgical excision and liposuction.

Prosthetic Management

Initial prosthetic management of the child presenting with PFFD begins with the extension or nonstandard prosthesis, with or without an activated knee joint (Fig. 30-14). With the foot positioned in plantar flexion, the limb is cast proximal to the hip joint, and the prosthesis fabricated with a prosthetic foot positioned under the shortened limb. The socket was commonly referred to as a “ship's funnel” design with ischial containment, because of the resemblance to the engine air intake funnels of ocean vessels. This drastic socket design is necessary because of the flexed hip and knee that must be contained within the socket while attempting to gain ischial support.

The purpose of the extension-type prosthesis is to equalize the length between the prosthetic and sound limb, in preparation for early ambulation, while affording time for surgical decisions. There are four indications that have been identified relating to the fitting of nonstandard prostheses (148):

1. While awaiting the proper age for surgical conversion.
2. When the patient or parent refuses surgical intervention, and a prosthesis is necessary for ambulation.
3. In bilateral cases, when extra height or better balance is the goal.
4. When there is lower-extremity involvement, combined with bilateral upper-extremity absence, requiring the feet for ADL.

When a Syme amputation with knee fusion option is chosen, the prosthesis resembles a knee disarticulation prosthesis, except for the need for ischial weight bearing and high lateral brim containment to aid in hip stability. Weight bearing is divided between the ischium and the distal heel pad. Full distal weight bearing would severely compromise hip function over a period of time, because of the inherent instability of the hip with possible proximal migration of the femur. Prosthetically, fusion of the knee, with correction of the angular deformities, results in improved gait and ease of fitting, because of a single skeletal lever arm (149). During growth, the child should be evaluated periodically for the relative length of the two limbs so that, if needed, distal femoral epiphysiodesis can be performed. This will allow fitting of an optimal knee joint when the patient is fully grown, while maintaining the knees at the same level.

In the small child, and when the residual limb is longer than the opposite femoral segment, external knee joints may be used. As the child grows, an internal four-bar knee can be used. More about the indications and selection of knee joints is discussed later in the chapter.

A Syme amputation without knee fusion results in difficulty with prosthetic management. Movement within the prosthesis, at the level of the anatomic knee, and the increased need for an intimately fitted socket, fosters a decreased stride length and increased pelvic movement. However, in the child with an Aitken class D PFFD and only a remnant of distal femoral epiphysis in which knee fusion will have little to offer, this may be a suitable choice.

The van Nes rotationplasty requires a nonconventional prosthesis with the ankle functioning as the new knee. This is a very difficult prosthesis to align and fit, although it gives excellent function (134,150). The prosthesis has a lower padded foot socket that contains the rotated foot in full plantar flexion. Lateral and medial external joints are attached to the upper thigh section, to increase stability and to prevent hyperextension of the lower shank (150). The original design incorporated a laminated thigh section with ischial weight bearing. With good hip stability, e.g., in tumor and trauma patients, the laminated section is often replaced with a leather thigh lacer and no ischial weight bearing. It is imperative for proper function that the external joints be aligned with the axis of rotation of the ankle/subtalar complex, while maintaining the line of progression. Failure to ensure this alignment, regardless of the anatomic joint, will result in a poor gait pattern and skin breakdown. The prosthetist should incorporate mechanical joint placement with slight external rotation on a new prosthesis, in anticipation of the mild internal derotation inevitable during growth.

CONGENITAL DEFICIENCIES OF THE UPPER EXTREMITY

Some of the differences between upper- and lower-extremity amputations have been discussed previously. One additional difference requires emphasis here: upper-extremity amputations are very visible. The hand is one of the most noticed parts of the human body. Thus, unlike the child with a below-knee amputation who walks without a limp and can often match his peers in physical activity, the child with an upper-extremity amputation is more easily seen as different.

This section deals with those congenital deficiencies of the upper extremity that are transverse in nature. The longitudinal deficiencies, e.g., radial club hand and the other classic anomalies that are confined to the hand, are discussed in Chapter 22.

Most transverse deficiencies of the upper extremity will be treated by prosthetic fitting, if they are treated at all. An upper-extremity prosthesis is a way to improve the ability of the deficient limb to assist the intact limb in its activities; it does not replace the function of the missing part as adequately as it does in the lower limb.

The main purpose of the upper extremity, or a prosthetic substitute, lies in the function of the hand, with the rest of the limb used to position the hand. In addition, the upper limb, or a prosthesis also plays a role in support, balance, and trunk stability. In these latter functions, the prosthesis can do well, but in the main function of prehension, it functions poorly when compared to the normal hand. A prosthesis has no sensory feedback, which requires that the child watch the prosthetic hand in use. This, plus the thought and mental practice that goes into making a mechanical device work, makes the upper-extremity prosthesis a far less efficient tool than the lower-extremity prosthesis.

It is important to recognize that many transverse upper-extremity deficiencies will not be well served by prosthetic prescription. If the prosthesis does not afford the child a functional gain or cosmetic benefit, he or she will be quick to reject it. The prosthesis must aid the child in some function he or she wishes to do, i.e., age-appropriate functions that require the use of two hands. The reasons for some children becoming good users of a prosthesis, whereas others with the same characteristics reject it, are not well understood. Although the parent's acceptance and compliance are important, this is not the whole answer. The inability of the prosthesis to substitute for a normal limb, and the hand in particular, is also a partial explanation. These facts, coupled with the incredible ability of the young child to learn to use one hand assisted by the residual limb with so little concession to activities that are assumed to require two hands, must also be a significant factor.

Judging the success of an upper-extremity prosthesis is very specific to the particular patient, and difficult to quantify. The hours of use alone is not a good criterion. Many children will use the prosthesis for specific tasks (riding a bike), and prefer to remove it for others (swimming). Some children will wear it very little during the summer while playing, but will wear and use it every day in school, when bimanual motor tasks are a significant part of the activity.

What the child can do with the prosthesis when asked, and what they actually do with it in their normal activities, can be very different. Although some children develop an amazing facility with the prosthesis in their everyday activities, many will demonstrate this facility in the medical setting, but continue to use the prosthesis much as they would their residual limb, and not as a prehensile tool, during daily activities. Standardized tests have been developed to measure spontaneous use versus voluntary control as it relates to age-appropriate activities. The University of New Brunswick test of myoelectric control is used by therapists to assess the child's ability to use the prosthesis in a controlled situation. The Prosthetic Upper Extremity Functional Index is a self-reported measure of the child's functional abilities during daily activities.

Although children often will not use a hand for functional purposes, the importance of the hand in appearance must be remembered. Besides the face, it (or its absence) is the most readily noted feature of the body. Good cosmetic hands can be of great help to children, especially adolescents, who desire them, and should not be minimized because of their nonfunctional nature.

The higher the deficiency, the more the disability, the harder it is to replace the function with a prosthesis, and the less will be the patient's acceptance of it. Lack of heat dissipation, weight, energy expenditure, concentration necessary to work it, and lack of functionality are all reasons why children with more proximal deficiencies will be less likely to use a prosthesis.

The main purpose of the upper extremities is grasp and manipulation of objects. Early in infancy the upper extremity reaches and touches objects within the visual fields and provides a rich sensory feedback to the child. This sensory feedback is an essential element of upper-extremity function. For the child with a limb deficiency or high-level amputation, especially if bilateral, sensation seems to be the single most desirable attribute of the extremities. Thus, if the upper extremities meet in the midline, the child will usually reject a prosthesis. If the extremities will not meet, or sometimes, when they meet where they cannot be seen, the patient may prefer a prosthesis for the function it affords.

The fitting of an upper-extremity prosthesis is much more individualized than a lower-extremity prosthesis. For those with a unilateral below-elbow amputation, fitting with a passive hand around 4 to 6 months of age is an easy decision because it is relatively inexpensive, well-tolerated by the patient, and helpful in deciding on later fitting with a more complex prosthesis. However, in cases of high-level amputations, especially bilateral, such a program of routine fitting will frequently result in failure (6).

The age for fitting is based on the normal development of the child. By 4 months of age, the child brings the hands to midline while supine, and props on elbows while prone. Eye–hand coordination develops as the hands are brought into the visual fields. By 6 months, the child is beginning to prop on the extended arms when sitting, and is rolling in all directions. Early prosthetic fitting between 4 and 6 months allows the infant to incorporate the prosthesis in all gross and fine motor functions that

are developing.

Children with bilateral high level amputations will primarily use adaptive performance techniques with their mouth, chin, neck, shoulder, and feet. Therapeutic interventions should focus on promoting these techniques first, and secondarily adapting the environment to assist the child in age-appropriate activities. Attempts should not be made at this point to modify the child with prosthetics. Children with high levels or complete absence of the upper limbs will use their feet to accomplish everyday two-handed activities. The use of the foot in play, and in activities of daily living appropriate for the child's stage of development, should be incorporated in all therapy home programs. It may take considerable persuasion to win the parents to this view.

Children with bilateral high-level amputations should probably be given an opportunity for prosthetic use. In addition to possible functional gains, the families experience a significant benefit in knowing that all has been tried, and the patients gain a valuable experience in having tried prostheses. A multicenter review of bilateral upper-limb deficiencies showed that 50% were still wearing a prosthesis at age 17 years or older (6). Fitting in such children should rarely be attempted before 1 year of age, despite the parent's anxieties. Fitting should be done to help the child perform appropriate tasks for his or her stage of development, or to aid in certain specific activities. It is usually best to fit a child with only one prosthesis at a time, because the problems with two may lead to early rejection.

Amelia

The child with unilateral absence of the arm will be less likely to fully accept a functional prosthesis than those with lower levels of amputation. If body-powered components are used, the patient has difficulty in controlling the devices, because there is no lever arm. Externally powered prostheses are heavy. The weight, and the increased body heat, because of the necessary suspension, make this a difficult prosthesis to wear. When coupled with the problems of function in using an artificial shoulder, elbow joint, and hand, the child will usually choose to function without the prosthesis.

Many children with amelia of the upper extremity are bilateral. The choices for these children are to help them develop their lower extremities to substitute for the upper extremities, to fit them with prostheses, or to attempt a combination of both. There is universal agreement that there is no place for attempting to limit the child's use of their feet and attempting to provide all of their upper extremity function with prostheses. The feet are the best substitute for the hands. Children with bilateral amelia and relatively normal lower extremities can usually master all of the activities of daily living, while leading full lives with a family, children, and employment. Until the physician becomes acquainted with a child or, preferably, an adult with bilateral amelia, she or he cannot understand the extent to which the legs and feet can substitute for the arms and hands. Most of these children will reject prostheses.

The question of prosthetic fitting most often arises in the child with bilateral amelia and significant lower-extremity anomalies that limit their substitution for upper-extremity function. In such cases, unilateral fitting may be indicated, but is likely to gain limited acceptance, and then only after many years of struggle, coupled with need for the limited function the prosthesis provides.

Children with bilateral amelia will often walk late. They will need help in pushing to stand. In addition, the fear of falling, because they cannot protect themselves, comes early. Helmets or some protective head gear are needed until the child is independent in gait. Therapy is directed at trunk control and strength, along with training in the use of their feet for all activities. These children are also prone to develop a progressive scoliosis, often before adolescence. This presents a difficult problem. Bracing restricts the use of their feet in activities of daily living. Surgical fusion does the same. However, often these curves will require fusion, and in such cases, as short a fusion as possible should be done.

Phocomelia

In phocomelia, the distal portion of the extremities appear to attach directly to the body. There are wide variations in this deficiency. In some, the hands may be close to normal, with some remnants of the arm bones, whereas in others the hand may be no more than a single functionless digit with little residual of the arm. Patients with phocomelia usually have some mobility in their residual limbs, and thus differ in one significant way from the child with bilateral amelia: they have a sensate limb often capable of some grasping function. The function of these limbs depends on the function of the hand and the length and function of the arm itself, and the ability to bring the hands together in the midline or to the face.

Those children who cannot bring their hands to the mid-line or to the mouth will use their feet to substitute in the activities of daily living (Fig. 30-16A, Fig. 30-16B, Fig. 30-16C and Fig. 30-16D). They should be encouraged from an early age to develop their foot skills and the body strength that is necessary to use the feet. In those with better function and length, little else than adaptive equipment to aid in dressing, etc. may be necessary (Fig. 30-16E).

FIGURE 30-16. A child with bilateral amelia or bilateral phocomelia, when the hands cannot meet in the midline, will use the feet for most activities. In such children, the use of the feet should be encouraged and developed from an early age (**A**). When older, these children will need the use of their feet to accomplish the activities of daily living (**B, C**). If there is any motor power in the extremities, they may be capable of useful function assisting the feet (**D**). When the hands can meet in the midline and have good motor power, excellent function is possible (**E**).

Therapy to increase the range of motion of the scapula and limbs, and to strengthen any muscle power in the residual digits, may prove of benefit. Adaptive equipment to aid in the use of their residual limbs can be very useful for some activities, e.g., feeding and dressing as well as other activities. The residual limbs can manipulate switches for powered prostheses, and thus, the temptation for a prosthetic solution to their problem. However, like the child with bilateral amelia, these children will function in most activities by substituting foot function for what they cannot do with their upper extremities. Fitting the older child with a unilateral prosthesis for specific function may be indicated, but routine wear is not common.

Transverse Complete Humeral Deficiency

There is little published experience in this deficiency. Although some children with unilateral above-elbow amputation will develop surprising facility with this prosthesis, they will often wear it only for specific activites, e.g., sports, or for cosmetic reasons. If there is a humeral segment of any reasonable length, the humeral–thoracic pinch provides useful assistance for the normal opposite extremity. Prosthetic use will be in accord with the patient's functional needs, and will generally relate to specific tasks. These may be as limited as riding a bicycle or as broad as full-time use at school. These patients should be offered the opportunity for prosthetic fitting.

Patients with bilateral congenital transhumeral deficiencies are more inclined to use their own body, rather than a prosthesis. These children may benefit more from assistive devices than prostheses for their needs. Such patients will often prefer prosthetic fitting on one side, utilizing the humeral–thoracic pinch, with intact sensory feedback on the other side, along with their feet. It is important to again make the distinction between the congenital and acquired amputee. The congenital amputee will be less inclined to use prostheses and the traumatic more inclined.

For the patient with bilateral above-elbow transhumeral deficiencies, Marquardt has recommended an angulation osteotomy of the humerus (151). The osteotomy angles the distal 3 to 5 cm of the distal end of the humerus anteriorly 70 to 90 degrees. It allows for suspension without the usual shoulder cap, is easier to put on,

permits better shoulder motion, and gives better control of rotation. This procedure should only be performed if the humeral length is sufficient and there is a need for a unilateral prosthesis.

Transverse Complete Forearm Deficiency (Congenital Below-elbow Amputation)

The congenital below-elbow amputation is the most common of all of the upper-extremity deficiencies. It is usually the left arm (Fig. 30-17). It is sporadic and without known cause. Children with this deficiency are the most ideal upper-extremity deficiencies for prosthetic fitting. Children with this deficiency are unlike those with a transverse amputation through the carpal bones, which usually have partial grasping function with sensation. They are also unlike the above-elbow deficiencies, in that they have a normal shoulder and elbow that allows accurate placement of a relatively light prosthetic terminal device.

FIGURE 30-17. A: A typical patient with a congenital below-elbow amputation. There is usually enough length to fit a prosthetic arm and still permit good active elbow motion. **B, C:** Two different children with transverse incomplete forearm deficiency fitted with a myoelectric-powered hand performing common functions of childhood. Many of the children who use the prosthesis develop amazing skill in its use.

Despite the fact that congenital below-elbow amputees are ideal candidates for prosthetic use, not all children will remain good prosthetic users during their childhood. Scotland and Galway reviewed the experience at the Ontario Crippled Children's Center, and found that 32% had stopped using their prosthesis, with follow-up of 7 to 17 years (152). How many of these may resume use of the prosthesis in the work environment is unknown. They, like Brooks and Shaperman (153), noted greater acceptance of the prosthesis if fitting was done before the age of 2 years.

In the congenital group of Brooks and Shaperman (153), 22% of those fitted before 2 years of age, and 58% of those fitted after, had stopped using their prosthesis. However, of those who continued to use their prosthesis, there was no difference in the amount of use between the two groups. The most common age at which patients discontinued use was age 13 years, and the most common reasons were cosmetic, and that they could do everything without it. Sorbye (154) reported that, of the patients in their clinic below age 24 years, 87% were using their myoelectric prosthesis, and 65% of these used it all day and for all activities. Hubbard et al. (155), reporting on the Toronto experience, found that 70% of the below-elbow amputees were using their prosthesis, whereas 30% had rejected it.

With this and other evidence, it is now the usual practice to recommend fitting around the age of 4 to 6 months with a passive hand to aid in normal development. At 4 months, the child brings the hands to midline while supine and props on the elbows while prone. By 6 months, the child will prop on extended arms while sitting and rolling over. This lightweight prosthesis is used to have the child become comfortable with a prosthesis, and to acquaint the child with the two-handed activities that a normal child would use, in an effort to develop the central cortical pathways for bimanual dexterity.

Depending on the child's acceptance and use of this passive prosthesis, and the choice of a terminal device, a more functional terminal device is fit between 15 and 18 months (26,156). Today, there are a number of terminal devices available (157). There are two choices to power the device: battery (myoelectric) and body (cables). Although there will be many factors to consider in the selection (cost and funding, clinic philosophy, and parent choice), virtually all centers today in North America are fitting the majority of children with a myoelectric-powered terminal device (Fig. 30-17). Table 30-4 compares the advantages and disadvantages of a myoelectric and body-powered terminal device for the child with a congenital below-elbow amputation.

Myoelectric	Body-powered
Weight Heavier—however, passive prostheses are weighted to prepare for the myoelectric system	Weight spread across the shoulders
Grip Strength Stronger than a body-powered; built into the system—less work for the child	Strength is provided by rubber bands that increase or decrease tension and force needed to open the hand—more work needed through scapular control
Cosmesis More accepted—resembles the hand—more self-esteem by the child, greater parental acceptance	Hook-like or clawlike in appearance; usually rejected by the child or parent—object of ridicule by other children
Maintenance Requires gloves—maintenance and electronics—electrodes lose contact and require occasional adjustment—adjustments for growth	Requires gloves; frequently requires repair for broken cables caused by friction; requires gloves if mechanical hand used; adjustments for growth on a regular basis
Harness No harness—suspension through socket—no straps on body	Harness—bulky on a toddler; difficult to keep on without pinning to undergarment; children dislike harness especially in summer months
Muscle Control Uses muscles in limb to control terminal device—prosthetic hand—direct "cause and effect"	Uses muscles distant from the terminal device—bioscapular abduction to control hand or hook—very confusing for toddler whose control and balance is developing—easier for older children
Grip Control Maintains grip easier through muscle contraction at the end of the residual limb; is the most successful type of control	Toddlers loose grip very easily, overall gross movements allow the object being grasped to release and fall involuntarily—tension on the cable to the harness does not remain constant—becomes very frustrating for the child

TABLE 30-4. COMPARISON OF MYOELECTRIC- TO BODY-POWERED PROSTHESIS

Terminal Transverse Transcarpal Deficiency

The congenital transcarpal amputation is the second most common deficiency of the upper limb, and occurs in a characteristic pattern, with some or all of the proximal row of carpal bones preserved. The existing flexion of the carpals on the radius allows for limited grasping function that along with normal sensation, makes this an assistive hand for which no prosthesis can substitute (Fig. 30-18). Occasionally, children will benefit from a volar opposition post for certain activities. They will usually wear it only for certain tasks, e.g., a guitar pick adapter or to grasp the handle bars on a bicycle.

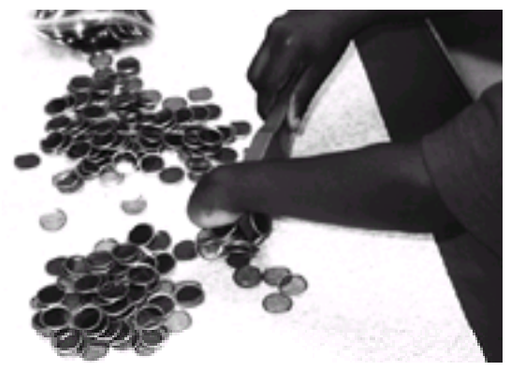

FIGURE 30-18. This young boy with a transverse transcarpal deficiency demonstrates the partial grasp at the flexor crease that, when combined with sensation, usually proves superior in function to a prosthesis.

The authors' experience with such children is that they have much more difficulty with the cosmetic aspect of their deficiency that do those children with transverse amputations at higher levels. In the older child and adolescent, it may be wise to explore the desire for a cosmetic hand that would be used in certain circumstances or provide a psychosocial benefit. Some cosmetic hands have a passive spring grasp to provide limited function.

Prosthetic Management

Generally, upper extremity prostheses and their control systems can be subdivided into three categories: *passive, externally powered,* or *body-powered devices*. The Ballif arm (circa 1400) was the first body powered prosthesis to introduce the use of prosthetic hand operation by transferring shoulder movement to activate the terminal device (158). A harness over the contralateral shoulder is connected with a thin cable and housing to a terminal device. Through the use of scapular abduction, the fixed cable is stretched over a greater distance and causes the prosthetic hook or hand to open or close, depending on the configuration of the terminal device. A good analogy is the braking system on most bicycles. Most parents prefer the cable-operated prosthetic hand over the cantered hook for cosmetic reasons. Unfortunately, the hook is far superior in function, but has fallen from favor, because of parental and public pressure to have the prosthesis look as natural as possible, at the sacrifice of function. Most hooks are canted in design, and this allows a full field of view, compared to the mechanical hand that obstructs the view and results in an awkward arm positions to grasp objects.

The externally powered prosthesis can be further subdivided into *switch control* or *myoelectric control.* In both systems, a battery, relay switch, electric hand, and electronic control system are present. It should be noted that the electric hand is the only terminal device available for children using the externally powered prosthesis. In the myoelectric prosthesis (Fig. 30-19), an electrode placed on the surface of the skin acts to pick up the electromyographic signal (EMG), which in turn is amplified with the help of an electronic relay switch, and this, in turn, operates the electric hand (159). The entire system is generally referred to as a one-site or two-site system. This denotes the number of electrodes that are used for signal recognition.

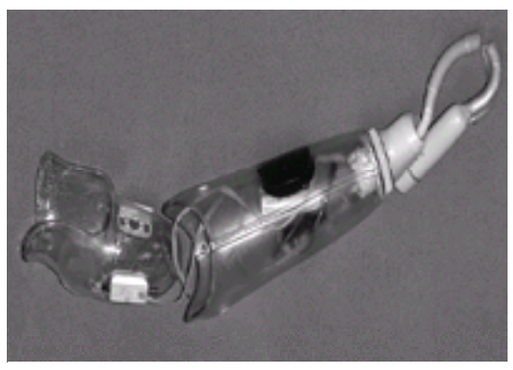

FIGURE 30-19. This example of the myoelectric prosthesis was made with a clear socket for teaching purposes. The proximal portion of the socket, which fits on the residual limb, contains the electrodes that pick up the signals from the muscles. This fits into the prosthesis, which contains the electrical and mechanical working parts of the Otto Bock Electrohand.

The one-site system can be further categorized as voluntary opening—automatic-closing, rate-sensitive, and level-sensitive. The first fitting of a myoelectric arm occurs at under 2 years of age, and utilizes a voluntary opening—automatic-closing (cookie-cruncher) configuration. The muscle signal opens the electric hand, and relaxing of the signal causes the hand to close automatically. This system is used for children under 4 years of age. The rate-sensitive and level-sensitive control systems use one muscle to control two functions, and are generally fitted to children over 4 years of age, when two sites are not available. The choice of a system depends on the muscle signal strength, muscle control, and prosthetic design factors (26).

In the two-site system, each electrode operates a specific task. Children can often operate this more complex system by 3 to 3½ years of age. The EMG signal of the flexors is used to close the hand, while the EMG signal of the extensors is used to open the hand. This system is used when children have established good control and use of their myoelectric prosthesis, and have demonstrated the ability to control both the flexors and extensors independently of each other.

Patients with a higher level of upper-extremity amputation are generally good candidates for switch-controlled externally powered prosthesis. The electrode is replaced with a miniature switch that can be either a push-pull configuration, a force-sensing resistor, or simple on-off design. The incorporation of these switches into the prosthesis depends primarily on the level of amputation and the design of the prosthetic socket or frame.

Multiple Limb Deficiencies

Management of the patient with multiple limb deficiencies, involving both the upper and lower limbs, is a challenge that requires a team with experience, to achieve the maximum function for the patient. The problem of bilateral upper-extremity amputation has been covered earlier. Children with one upper and one lower extremity pose no problems beyond the management of each individual limb. Children with bilateral knee disarticulation or transtibial amputations will walk without support, and thus a unilateral upper-extremity amputation in association poses no special problem, other than donning and doffing the prostheses. With amputations above the knee disarticulation level, however, walking without support, and thus the need for upper-extremity function, becomes a problem, and may require a wheelchair for long distances and to conserve energy.

A special caution needs to be given in regard to those children with bilateral upper-extremity amputation and lower-extremity anomalies that might ordinarily be treated with amputation and prosthetic fitting. No amputations of the lower extremity should be performed until it is certain that the child will not require the use of the feet for grasping activities.

One of the most common types of patients seen in the pediatric age group with this problem is the quadrimembral amputee as a result of meningococcemia. In these patients, it is often necessary to cover the residual extremities with split-thickness skin grafts to maintain length. These grafts, if not adherent to bone, do very well in the prosthesis, and are not a hindrance to fitting. Treatment must be individualized for each patient with certain general guidelines. The first is to help the patient maximize function with his or her residual limbs. This is especially true with the upper extremities, where sensation is so important to function. Although these children will become proficient in the use of bilateral upper-extremity prostheses, if their residual limbs are long enough, they will usually perform many of their daily activities, especially at home, without their prostheses.

A common mistake is to attempt to fit all four extremities of these children with quadramembral loss at the same time. Although the pressure to do so is enormous, it may result in actual delay in functional recovery and rejection of the prostheses. In the vast majority of situations, it is best to first fit the lower extremities and achieve ambulation. After this is accomplished, fitting of the upper extremity is done.

In the child with a congenital quadramembral deficiency, there will usually come a time when the parents, and perhaps the child desire prosthetic fitting. Again, it is best to avoid fitting all four extremities at once, but rather focus on meeting specific needs. Although experience shows that most of these children will use their prosthetic devices in a limited fashion, if at all, they and their parents need and are entitled to the experience at least once (Fig. 30-20).

FIGURE 30-20. This child with congenital bilateral hip disarticulation and transhumeral amputations (**A**) was fitted with four prostheses (**B**), which she quickly abandoned in favor of her power chair and simple assistive devices (**C**).

ACQUIRED DEFICIENCIES

Causes

Children may suffer an amputation for a variety of reasons. Although there are no good statistics, trauma is the major cause of amputation in childhood (160). In this group, power lawnmowers lead the list of causes, and most commonly, it is a child riding with a family member. Motor vehicle accidents, farm injuries, and gunshot wounds follow in that order (161). In war-torn countries, land mines may be the leading cause of amputation. Because amputation of the digits is most often caused by machinery, upper extremity amputations are more common than lower extremity. Boys are affected about twice as often as girls.

Tumors, vascular occlusion caused by meningitis or vascular catheterization, and burns are additional causes, and each has its own unique set of circumstances. Indeed, the differences in acquired amputation defy a detailed analysis. Some are semielective, and allow for some preparation of the patient and the parents, whereas traumatic amputation do not. It is possible, however, to discuss the common principles that are applicable to acquired amputations in children.

Principles

When the surgeon is faced with an acutely mangled extremity, it can be difficult to decide on amputation versus limb salvage. The usual criteria and classifications that are applied to adults are not easily transferred to children. It is often necessary to gain the input of a vascular surgeon and others, to make the best assessment, while always remembering the tremendous healing and adaptive capacity of the child, compared with the adult.

When dealing with feet mangled in a power lawnmower, it is often wise to attempt salvage at the first operation. However, in the case of a mangled leg that will require vascular and nerve repair, along with bone reconstruction and free tissue transfer, the decision needs to be made more realistically. The more energy expended in saving the limb, the higher the parents' expectations of the result.

The surgeon rarely will have options regarding the level of amputation in trauma. The lack of preparation, coupled with the parents' expectations, usually dictates saving as much of the limb as possible. This often results in less functional level of amputation than one more proximal. The most obvious example is preservation of the talus and calcaneus, which the parents and child may see as having at least part of the foot, whereas the result will may be a worse gait, worse cosmesis, and more prosthetic problems than a Syme amputation.

In the child, it is usually advisable to save as much length as possible in amputations of the long bones. This is especially true in the femur, where 70% of the growth of the bone occurs from the distal physis. A 5-year-old child with a midthigh amputation will have less than ideal length as an adult. In the leg, however, little is lost, so long as an adequate portion of proximal tibia, where the majority of the growth occurs, is preserved, and in fact, shortening the bone to achieve good soft tissue coverage may be the best course.

The common teaching that skin grafts do not make suitable coverage for a residual limb that will bear weight in a prosthesis, is not applicable to children, especially very young children. In children, skin grafts do make good coverage so long as they are not adherent to bone. Split-thickness skin grafts are frequently needed to preserve length in meningococcemia, burns, and some cases of trauma. In older children with traumatic amputations, free vascularized flaps can provide excellent coverage.

Where possible, disarticulations will avoid the problem of bony overgrowth. It is not necessary, or perhaps even advisable, to remove the cartilage from the bone end. Tapering of the bone ends, e.g., at the distal tibia, is not necessary, unless the child is approaching adulthood. The bony prominences will not develop to adult proportions, and thus do not represent a prosthetic fitting problem. If a young child has a through-bone amputation, it may be possible to salvage a portion of bone and cartilage from the amputated part for capping the bone. This is similar to performing a Marquardt procedure, and has the potential to substantially reduce problems of overgrowth.

It is important not to forget the child during the acute phase of the amputation. Often the surgeon has enough problems dealing with the parents' emotions, and can easily forget that the child also needs emotional as well as physical attention.

In many circumstances, the amputation will be elective. Such is the case with children who have posttraumatic injuries, and are electing surgical modification for better function and prosthetic fitting. Children with gigantism, Klippel-Trenauney-Weber syndrome, and malignant tumors not suitable for limb salvage, also are in this category. In many cases the need is obvious, and the child and parents have come to their decision after careful consideration.

In the case of tumors, however, it is not so easy, and there is generally not complete acceptance for what is a life-saving procedure. In all cases, the more preparation by the professionals, and the parents and patient talking with other patients the better. It needs to be emphasized that the challenge is to live, and that the operation is necessary for that. The options revolve around the functional and cosmetic aspects of the different procedures.

There remains a difference of opinion as to whether or not it is worthwhile to fit the acquired juvenile amputee in the immediate postoperative period. In the young child with a congenital deficiency, there seems little to be gained. However, in the older child, especially when the amputation is caused by trauma, there can be large psychologic benefits to placing the child in an immediate postoperative prosthesis. This also aids in control of edema and phantom pain.

PROSTHETICS

In the prosthetic fitting of the pediatric amputee, the single most important guiding principle is that function should never be sacrificed for cosmesis. When dealing with the adult population, overall biomechanical forces resulting from prosthetic alignment can do relatively little damage to skeletal integrity. This is not the case for the pediatric patient, in whom skeletal development is ongoing. Incorrect alignment can have far-reaching and often pronounced negative results.

Role of the Prosthetist

The role of the prosthetist is to ensure that the highest level of functional need of the patient is achieved through prosthetic intervention, or the wisdom for no intervention at all. The skilled prosthetist is able to assess anatomic and functional deficiencies, and recommend socket design and component selection. In addition, he or she must possess the clinical skills, medical knowledge, and ability to communicate that will enable timely and appropriate flow of knowledge to the other team members and parents, so that realistic expectations can be identified and achieved. Routine servicing of the prosthesis is extremely important to minimize extensive repairs and anticipate the need for a new prosthesis. Children are generally not happy to be without their prosthesis.

Fitting Techniques

Technique will vary, based on the experience of the prosthetist, team approach, integration of ever-changing technology, and the severity of the deficiency. Physiologically, the child is in a constant state of growth and the prosthetic device must be designed to permit weight bearing, and allow for the greatest amount of growth without compromising fit and function. Most congenital lower-extremity amputees are able to bear some weight on the distal end of the residual limb, and the prosthetist is able to allow for a slightly less intimate fit of the prosthetic socket than might be the case for the acquired amputee. Unlike the adult, the child's skin has greater tolerance for skin breakdown. The increased activity levels of the child amputee place tremendous expectations on the prosthetic devices and the components. All of these factors are constant challenges to the prosthetic prescription, and emphasize the need for a nonstructured approach to fitting. What may be suitable for one child may be unsuitable for a different child with the same anomaly. Rigid time schedules are discouraged, and developmental levels should be used only as a guideline to aid the practitioner.

Fitting the pediatric amputee leads to unique issues not normally seen in the adult population. Disarticulations lead to long residual limbs with knee centers lower than the sound side. Ischial containment sockets are not normally recommended (unless needed because of hip instability) because of problems with soft tissue containment and diapers in infants. Location of bony landmarks is obscured by fatty baby tissue, and casting is difficult and nonexact.

The various stages involved prior to receiving a prosthesis are generally standard within the profession. Upon referral to a clinic, the child is assessed by the team, and a treatment protocol is established. The stages involved in prosthetic fitting include:

1. CASTING of the residual limb.
2. TEST fitting of the modified interfacing socket.
3. DYNAMIC alignment and gait training.
4. DELIVERY of the completed prosthesis.

Socket Design and Suspension Systems

The cast or impression forms the foundation for the prosthetic design (162). It is only after a well-fitting and comfortable socket–skin interface is achieved that the additional componentry can be added and expected to function as designed. Casting usually involves the placing of a casting sock on the residual limb, marking all landmarks and wrapping circumferentially with plaster or synthetic bandage. This becomes the negative impression. It is then filled with molding plaster and stripped, forming the positive cast ready for modification. This positive cast is then modified to distribute forces and relieve pressure in the socket for proper hydrostatic control of the residual limb.

Through the use of a clear test or diagnostic socket, fabricated over the positive mold, the practitioner is able to ascertain the areas of high and low pressure, and to ensure that they are directed over the appropriate areas. Common fitting problems can be flagged and corrected before final socket design.

Computer-aided design–computer-aided manufacture (CAD/CAM) has been used as an alternative tool to plaster casting and modification of the prosthetic socket. In its most simplified form, a residual limb is scanned with an optical laser. The information is relayed to a computer, where modifications can be made to the scanned shape, to allow for increased or decreased weight bearing areas. The finished design is transferred to a computerized milling machine to form a positive model. This, in turn, is used to fabricate the finished device. Slowly, CAD/CAM is becoming more widely used within the profession, because of advantages of design reproducibility, record keeping, and flexibility in remote locations (163). Its advantages in the pediatric setting have yet to be proven. All current CAD/CAM systems rely on surface topography of the residual limb, therefore disregarding crucial data, such as tissue density, tissue mobility, and underlying skeletal structures (164).

During dynamic alignment in the crawling infant, the prosthetist initially focuses on creating a prosthesis that will aid the infant in preparation for ambulation, transitioning from crawling to standing, with little consideration at this point to gait. Sutherland concluded that mature gait patterns were established by 3 years of age (165), whereas others place the time frame closer to 6 years of age. Early infant gait patterns are, in fact, the processes of suppression of primitive reflexes and the acquisition of postural responses (166). Dynamic alignment is the manipulation of relative position of the socket to the foot and knee, while the prosthesis is moving through the various stages of gait. Through the use of alignment mechanisms in the components, the prosthetist is able to shift, tilt, and rotate the knee and foot in relation to the socket. Once independent gait is established in the infant, further refinement to gait can be achieved through prosthetic alignment.

Lower-extremity Socket Design

The design and fitting of lower-extremity prostheses encompasses numerous biomechanical principles and their application to the residual limb–socket interface, and it is the successful manipulation of these forces that ensures a patient's comfort and function. The accommodation for differences in tissue compressibility, pressure tolerance, underlying bony structures, and vascular integrity are factors taken into account prior to socket design. Dynamic forces exerted through ground reaction forces and resulting moments, including torque and shear forces, increase the vulnerability of the skin–socket interface.

Hip Disarticulation

Amputees at the hip disarticulation level require extensive prosthetic intervention. The socket encompasses the amputated pelvic remnant, and encloses the contralateral side for suspension. The traditional socket design rises proximally to the waist, and fits similar to a Boston spinal orthosis. The Diagonal socket is a modified version of the standard design, and it affords a more comfortable fit and increased flexibility. Prosthetic hips are single axis, and are mounted on the outside anterior distal aspect of the affected side. Hip and knee flexion are easy to activate, if the prosthesis is perfectly aligned. The hip is anterior to the weightline and the knee is posterior. This allows for a stable stance and a smooth gait. The endoskeletal system is used exclusively for this level of amputation because of an increased level of cosmesis and decreased weight. Children at this level can achieve remarkable gains, when fitting begins while the child is pulling to stand, and when therapy intervention and parental training are incorporated. It is recommended that the knee be locked, initially, so that hip control can first be learned. Once the child is walking independently, the knee can be activated.

Transfemoral Prosthesis

Transfemoral socket design has evolved significantly over the last 10 years. The quadrilateral socket was the socket design of choice until 1987, when the International Society for Prosthetics and Orthotics (ISPO) formulated recommendations on the narrow medial lateral (ML) socket design (167). Variants of this design (ischial containment socket) continue as the CAT-CAM (contoured adducted trochanteric/controlled alignment method), NSNA (normal shape, normal alignment), and the modified quad design, to name a few (Fig. 30-21). The underlying principle is to adduct the femur, while locking the ischial tuberosity within the socket, thus providing a more anatomically correct alignment during all phases of gait (168). The controversy over these designs has been increasingly dispelled, with further clinical experience.

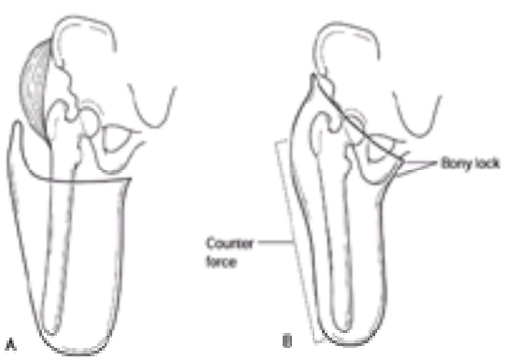

FIGURE 30-21. A: The quadrilateral socket is useful for the young child, especially if end-bearing is possible. However, it fails to stabilize the femoral segment in a transfemoral amputation. **B:** This has led to the popularity of the narrow medial lateral socket design, e.g., the ischial containment socket shown here. This design can

prove impossible in small infants, because of the fatty thigh and buttocks as well as diapers.

There are various suspension mechanisms that may be utilized for the secure attachment of the socket to the residual limb. These devices may be auxillary suspension, which is attached to the socket to suspend or enhance suspension. The suspension may be incorporated in the socket itself, e.g., suction sockets, supracondylar sockets, etc.

Pediatric amputees are usually fitted with a S*ilesian belt* system of suspension (Fig. 30-14A and Fig. 30-14B; Fig. 30-22A), until adequate development of the residual limb allows for silicone suspension, at approximately 2 to 3 years of age. The Silesian belt attaches to the anterior/medial aspect and the lateral aspect of the transfemoral socket, and lays across the pelvis at the waist. Tightening the Silesian belt prevents the socket from slipping distally. The total elastic suspension (TES) belt may be used instead of the Silesian belt. The TES belt is a neoprene suspension system that is applied over the proximal portion of the transfemoral socket, then secures around the waist.

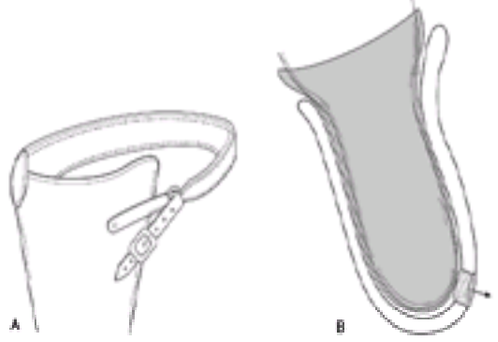

FIGURE 30-22. Methods of suspension for transfemoral prostheses. **A:** The Silesian belt is almost universally used in the young pediatric patient, to suspend a transfemoral prosthesis, and occasionally a knee disarticulation or transtibial prosthesis (see also Fig. 30-15B). **B:** The suction socket is a tight-fitting socket design with a one-way valve that allows air to be expelled with weight bearing to maintains a suction fit on the residual limb. It is best suited for the older child or adolescent, who has a mature limb that is not changing in size.

Suction sockets are not typically used for the pediatric population because of tight tolerances in fitting that cannot be maintained by a growing child. With the suction socket, the residual limb is pulled into a socket that incorporates a one-way valve in its design (Fig. 30-22B). Once the valve is in place, the amputee expels air every time the prosthesis is in contact with the ground. During swing phase, the negative pressure within the socket holds the prosthesis in place. Air that leaks into the socket is quickly expelled through the one-way valve, and a constant negative pressure is maintained. Total contact suction sockets are generally used for the transfemoral amputee with a mature residual limb, and at the completion of skeletal growth. Short limbs, volumetric changes, and severe scarring are contraindications for the suction suspended socket.

Transtibial Prosthesis

The transtibial prosthesis is used the least in the pediatric population. Although most amputations in children are disarticulations, growth changes in the fibular deficiency often result in a transtibial-level residual limb that is distal end weight bearing. The true transtibial socket is most often required for the traumatic amputee. Total contact design allows for increased pressure-bearing over the patellar tendon, medial flare of the tibia, medial shaft of the tibia, and lateral shaft of the fibula, and the anterior and posterior compartments. Similarly, weight-sensitive areas most affected include the tibial crest, fibular head, distal tibia and fibula, peroneal nerve, and the patella. The socket design is comprised of an outer shell, inner soft liner, and a cosmetic cover.

The patellar-tendon-bearing (PTB) socket is the standard socket (Fig. 30-23A). It provides the least suspension, and for that reason, is not often suitable for young children. The supracondylar/suprapatellar (SCSP) transtibial socket design (Fig. 30-23B) allows for suspension without the need for belts or cuffs. The medial, lateral, and anterior walls extend proximally, to fully enclose the patella and femoral condyles. The supracondylar (SC) transtibial socket (Fig. 30-23C) is almost identical to the SCSP design, except the anterior proximal brim does not enclose the patella, and therefore allows greater freedom and range of motion. Contraindications for both the SCSP and SC design include obese or muscular limbs, patients with severe ligamentous laxity, and patients with heavy scarring around the knee.

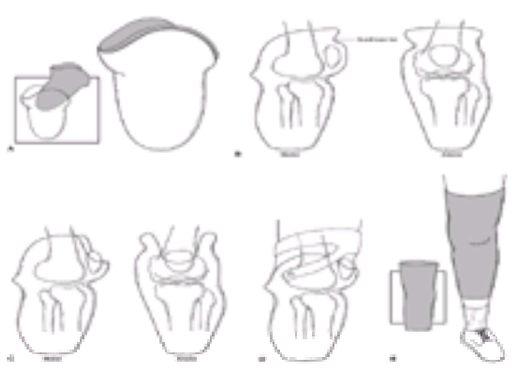

FIGURE 30-23. Common sockets and suspensions for transtibial pediatric amputees. **A:** Patellar-tendon-bearing (PTB) socket is most useful for the mature patient. It gives the most freedom of motion, but the least secure suspension. **B:** The supracondylar suprapatellar (PTB-SCSP) design gives the most secure suspension and best knee control of any of the sockets that incorporate the suspension in the socket. **C:** The supracondylar (PTB-SC) socket eliminates the suprapatellar portion of the socket anteriorly, for better range of motion with less control of hyperextension. **D:** The supracondylar cuff suspension is a common suspension used in the pediatric age range. **E:** The neoprene sleeve suspension provides very secure suspension for the very active amputee. This can also be used for the transfemoral amputee.

Supracondylar cuff suspension is a common form of suspension for the pediatric transtibial amputee (Fig. 30-23D). The cuff is fabricated from leather, and encompasses the femoral condyles and patella. It is attached to the medial and lateral aspects of the socket. The neoprene sleeve suspension is another useful suspension in the pediatric amputee (Fig. 30-23E). It can also be used for the transfemoral amputee. It tends to be hot, and is poorly tolerated by some children for this reason, but for the very active child, it provides a great level of security that the prosthesis will not come off.

Silicone suspension liners have become increasingly popular as a method of suspension without the need for belts or cuffs (Fig. 30-24). The liner is rolled onto the residual limb. At the distal end of the liner is a serrated pin. Inside the distal end of the socket is a shuttle or receptacle mechanism. Once the liner is donned, the amputee places the limb in the socket, and the pin and shuttle engage and lock into place. Pressing of a button hidden on the medial distal aspect of the prosthesis releases the pin and the residual limb can be removed from the socket. Because of the physical characteristics of the liner, the greater the distracting forces placed on the prosthesis, the tighter the liner grips the residual limb. This system is used extensively in young children.

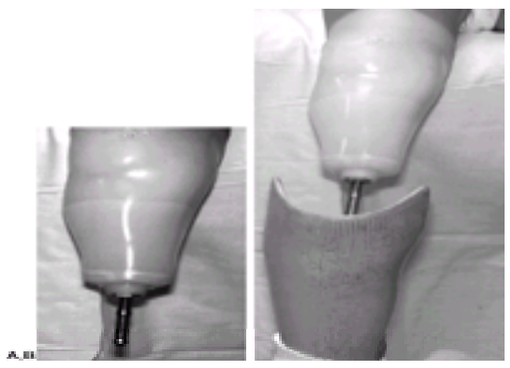

FIGURE 30-24. The silicone suspension liners (Triple S socket) have become very popular. The soft silicone liner has a serrated pin incorporated into the bottom of the liner. The patient rolls the liner on the residual limb (**A**), then inserts the limb into the prosthesis (**B**). At the bottom of the prosthesis is a socket where the pin locks. It is released by pushing the button on the medial side of the prosthesis.

Ankle Disarticulation Prosthesis (Syme)

The obturator (medial opening) design is most often used when the distal bulbous end is large and the medial malleolus is prominent (Fig. 30-25A). The removable or segmented liner socket incorporates a full foam liner that has been built up to the same circumference as the distal bulbous end. A laminated shell is then formed over this insert. The patient dons the liner first, then slips this into the laminated receptacle (Fig. 30-25B). An atrophied residual limb with a small heel pad is best suited for this design, and the degree of cosmetic restoration will be very good. The silicone or bladder prosthesis utilizes an inner elastic area that stretches to permit passage of the bulbous end of the residuum through the narrower circumference of the tibia and fibula, then constricts once the distal end has passed through (Fig. 30-25C). All of the above designs maintain total contact, and the proximal brim is at the level of the patellar tendon. This ensures that the biomechanical forces are adequately spread up to a load bearing landmark to increase comfort and function.

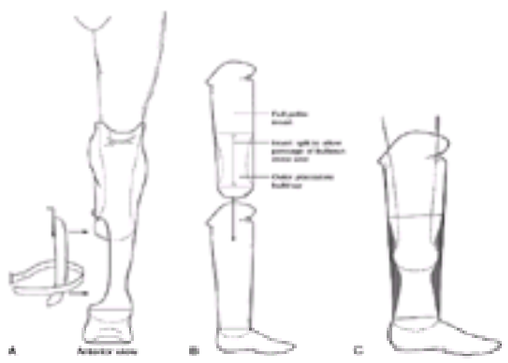

FIGURE 30-25. Common socket designs for Syme amputation. **A:** Obturator design is often needed if the distal end of the residual limb is large and bulbous or the medial malleolus is prominent. It is the least cosmetic. **B:** The removable or segmented liner consists of a complete separate foam liner, which has a split in the side to allow the distal end of the limb to pass. Once the patient applies the liner, they slide the limb covered by the liner into the prosthesis. The patient must have the manual dexterity and strength to use this suspension, which will eliminate some patients with hand anomalies. Limbs with a small heel do best with this system. **C:** The bladder design has a built-up silicone sleeve, which the patient slides the limb past. This socket fits more loosely, and does not stabilize the heel pad as well as the other designs.

Prosthetic Knees

It has been estimated that more than 100 prosthetic knees are commercially available, and the number is growing each year (169). Although the majority of these are for adults, recently there are a number of new knees available for children. The prosthetic knee is comprised of the knee mechanism or frame, and may contain a control unit. The control unit consists of either a pneumatic, hydraulic, or mechanical system, or some combination of these three. The control unit responds to changes in cadence and dampens sudden abrupt changes. The faster a hydraulic or pneumatic unit is compressed, the faster the energy is released, and this helps to regulate the lower shank of the prosthesis. The prosthetic knee unit can be further subdivided into single axis and polycentric.

The maturation of gait from infant to adult carries with it the need for sound practice in selecting the appropriate knee, based on amputation level, functional level, and body size. In general, the single-axis internal knee without any control unit is the first knee to be used on the child, because of its light weight, short lever arm, and simplicity. In the single-axis knee joint, the lower shank rotates around a single point in relation to the socket.

A polycentric knee was introduced in 1998 for the infant and toddler, and may also be used if space permits. Internal polycentric knees move around a center of rotation that varies with the flexion angle of the lower shank (169). The four-bar linkage knee is the most common polycentric knee and the most widely used by prosthetists (170) (Fig. 30-26). The inherent stability during stance, the fluid knee flexion movement, and the mechanical design, to give more ground clearance during flexion, increases patient and practitioner confidence in the unit (170).

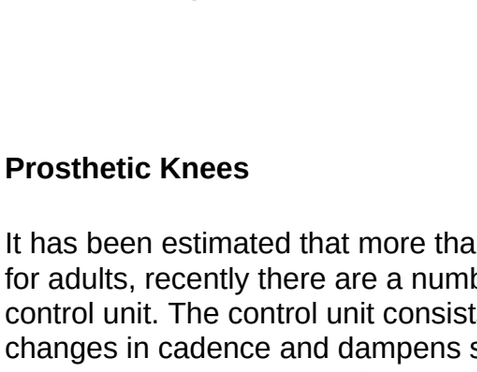

FIGURE 30-26. Four-bar-linkage is an internal polycentric knee that provides many advantages to the patient, e.g., increased stability and better ground clearance during swing phase**.** As indicated in this illustration, the point of rotation varies with the degree of flexion **.** With the knee flexed, the leg folds under the thigh segment, and thus is very useful for longer residual limbs. There is also a hydraulic version of the four-bar linkage for children.

Changes in design and technology have now widened the boundaries and age distinctions for the prescribing of specific knees. Traditionally, an articulating knee would be introduced in a congenital amputee around 3½ to 4 years of age. This age was used, in part, because of limitation in size and function of the components. In the experience at the authors' center, as well as others, introduction of a prosthetic knee without a locking feature can be used in the first prosthesis when the child first pulls to stand. A recent report demonstrated the benefits of early fitting with articulated knees in children as young as 17 months. All children learned to walk with

an articulated knee, despite their age differences (121).

As the child develops and grows, more sophisticated control systems (e.g., hydraulic knees) can be incorporated into the prosthesis. Most components carry specific weight guidelines, and many children reach these ranges well before adulthood. For example, an adult hydraulic polycentric knee is routinely used on 8-year-old boys whose weight has surpassed 100 lb. This does not mean that every child of a certain age and weight should have a particular knee. Placing a sophisticated knee and control system on an individual who has neither the hip range, muscle strength, nor residual limb length to activate the knee, often results in contralateral hip and lower back pain, and patient frustration.

Prosthetic Feet

Variations in the materials, design, and alignment of the foot can have profound effects on the performance of the prosthesis. Functionally, prosthetic feet can be categorized into five main groups (171):

- Solid ankle cushion heel
- Single axis
- Multi axis
- Elastic keel
- Dynamic response

The solid ankle cushion heel (SACH) foot contains no articulating parts, and foot motion depends on the various compressive properties of the materials used between heel-strike and toe off (Fig. 30-27A). It is generally considered when amputees require maximum late-stance stability because of weak knee extensors, knee-flexion contractures, or poor mid- to late-stance balance (172). The SACH foot is used in pediatrics when the foot size is below 12 cm, but has mostly been replaced by the dynamic response or energy-storing feet.

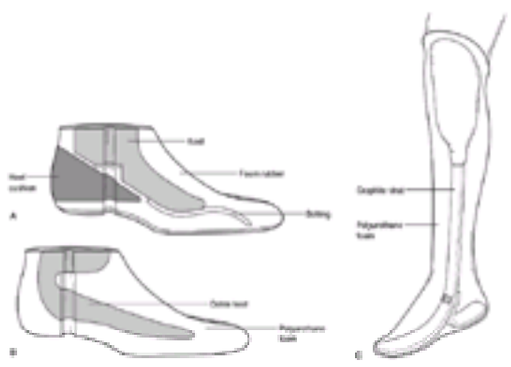

FIGURE 30-27. A: The solid ankle cushion heel (SACH) foot. The length of the keel controls the toe lever arm, and thus the hyperextension moment at the knee, while the compression of the material at the heel absorbs the forces at heel strike. **B:** The Seattle foot is one of the many varieties of energy-storing feet. It incorporates a flexible keel in the foam foot. This is one of the most common feet used in the pediatric amputee. **C:** The Flex-foot is another energy-storing foot, but with much different performance characteristics than the Seattle foot. It is used for the older, stronger, and physically active child who has the physical ability to use such a foot.

The single-axis foot usually contains rubber bumpers that allow passive dorsi- and plantar flexion. By changing the hardness of the bumper, the prosthetist is able to effectively change the properties of the foot. This foot is best suited for the transfemoral amputee, in whom full-foot contact with the ground is necessary to increase stability. The multiaxis foot allows passive dorsi- and plantar flexion, inversion and eversion. The multiaxis foot is best suited for the amputee who requires flexibility in foot position because of uneven terrain, or when lifestyle, such as golfing or various sports, require some rotational control. These feet do not find much use in the pediatric age group.

Once the child's foot size exceeds 12 cm, the prosthetist can move the child into a dynamic-response foot. This group of feet is distinguished by a spring mechanism in the keel that deflects during gait (Fig. 30-27B). Originally called an “energy-storing foot,” this class of foot is ideally suited to the child amputee. Although the variety of componentry for children is still much less than for adults, there is a wide variety of feet with different performance characteristics available. It is important to use components that will maximize performance, and at the same time be appropriate for the patient (173).

At slower walking velocities, there is little difference between the dynamic-response foot and the SACH foot (174). Generally, children are not fitted with highest performance dynamic-response feet, because of constant growth and weight changes, and high costs associated with foot replacement. The involvement in competitive sports is usually a good benchmark to initiate fitting adolescents with highest-performance dynamic-response feet.

In the transfemoral amputee, it is crucial to properly choose a foot that will enhance gait, but, also to choose the complementary knee that will aid in controlling the foot during all aspects of the gait cycle. A common mistake is to prescribe a dynamic-response foot with a simple, friction-controlled knee that is incapable of preventing uncontrolled heel rise. The same is true of the transtibial amputee, who lacks muscle strength to control the foot, often resulting in premature muscle fatigue. In the selection of multiple components, the prosthetist must marry the characteristics of all components, so that maximum benefit can be available to the amputee.

Partial Foot Prosthesis

The most important consideration in the fitting of the partial foot amputee is to ensure that adequate load-bearing is designed into the prosthesis of choice. As a general rule, the more proximal the level of amputation, the higher the prosthesis must fit over the ankle complex and proximal on the tibia/fibula. Tissue condition, function of the remaining foot complex, and activity of the child, all play a role in determining the prescription and design of the prosthesis.

Complete or partial absence of the toes usually requires little more than a shoe filler. A carbon fiber insert, to better control forces from heel to toe-off, may be incorporated in the shoe filler. In the case of the very young child, no intervention may be required until a need has been demonstrated, e.g., the inability to keep the shoe on, especially when the child becomes more active in sports.

The prosthesis most commonly used for the moderate/short partial-foot amputee is the Lange silicone partial-foot prosthesis (Fig. 30-28). This incorporates a cosmetic foot shell, silicone laminated socket with modified foot sole, and a posterior zipper for ease of donning and doffing. The prosthesis is fabricated over a modified model of the patient's partial foot. The socket trim line is proximal to the malleoli, and is fitted intimately, to ensure adequate control. The design of a partial foot prosthesis may also include a removable insert, to accommodate the need for corrective alignment of the residual foot. The prosthesis is then cosmetically finished to resemble the contralateral limb. Overall, this type of prosthesis is perfectly suited for the child amputee, and resists premature wear and tear. If needed, a partial-foot prosthesis should be prescribed once the child is pulling to furniture, so that foot control will begin at an early age. It should be noted that a low-profile insert (distal to the malleoli), used in conjunction with a high-top boot, will offer adequate function and cosmesis until a lower-cut shoe is requested by the parent.

FIGURE 30-28. A: The Lange silicone partial-foot prosthesis is a custom-made prosthesis that can incorporate a keel to aid in foot stability and push-off in gait. **B:** It is useful for children with partial amputations of the foot or congenital longitudinal deficiencies of the foot, shown here. It is not useful in feet with insufficient length, e.g., the Chopart amputation.

The Chopart, or midtarsal amputation is rarely used, except in special instances (175). In the Chopart partial-foot amputation level, the prosthesis is modified to encompass the calcaneus and talus, and this results in a prosthesis that is often longer than the contralateral limb. The prosthesis must encompass the ankle joint, and often rises proximally to the patellar tendon in an effort to reduce forces on the tibial crest–socket interface. Selection of prosthetic feet is compromised, because of the lack of space distally, and commercially available carbon foot plates require permanent attachment with vulcanizing rubber cement. This negates any changes caused by growth, and realignment to compensate for gait changes is virtually impossible.

Terminal Devices for the Upper Extremity

The choices left open to the prosthetist are numerous and, at times, controversial. Where some clinics maintain rigid protocols for terminal device selection, other clinics rely more on patient and parent input, combined with historic success rates for device types. Clinics that maintain very high myoelectric caseloads, for example, will most likely have far more experience in fitting externally powered prostheses, compared to a clinic that may only see a handful of potential myoelectric candidates.

In simple terms, the terminal devices can be divided into hands and hooks, and they can be body-powered (cable and harness) or externally powered (electric). Hands and hooks can be either voluntary opening or closing. Patton lists the functional and prescription criteria for the various terminal devices (175a).

The initial fitting of a child with upper-extremity limb deficiency begins at 4 months of age in a passive prosthesis with a clenched fist passive terminal device (Fig. 30-29A). This allows for equal arm lengths for the development of propping up on the amputated side and greater acceptance by the parents. Following initial sitting balance, the clenched-fist terminal device is exchanged for a small infant passive hand. When the infant begins to reach (at approximately 15 to 18 months of age), the clinic team begins to assess the need for either body-powered or externally powered prostheses. If body-powered is recommended, a cable-operated Hosmer 12P plastic-covered hook (Fig. 30-29B) or an ADEPT infant hand (Fig. 30-29C) will be prescribed. The canted design of the 12P hook allows for greater visual feedback to the wearer. In the event that a myoelectric device is warranted, the Variety Village 0-3 (VV 0-3) electric hand (Fig. 30-29D) or the Otto Bock Electrohand (Fig. 30-19) is used. In the pediatric VV 0-3 hand, the thumb and opposing two fingers operate to form a three-point chuck grip. In the OB 2000 hand, the same principle is applied, except that from the open to close position, the thumb sweeps from a lateral position to meet the two opposing fingers upon close.

FIGURE 30-29. A: The passive fist or hand, which is used as the first hand for a child. This would commonly be fitted between 4 and 6 months of age. The fist has proven more useful than the open spoon-shaped passive hand since it allows the child to prop on the hand. Active hands are divided into two categories: body-powered and externally (electric) powered. **B:** The ADEPT is a voluntary closing body-powered hook that would be fitted around 15 months of age, if the child were ready and a body-powered device was desired. **C:** The Lite-Touch is a voluntary closing hand that would find the same indication as the ADEPT hook. It looks a bit more like a hand, which often makes this the parents' choice. **D:** The Variety Village hand is one of the most commonly used myoelectric hands in the pediatric age group. The Otto Bock Electrohand is shown in Figure 30-19. Both of these electric hands are covered with a cosmetic glove.

Progression from this starting point through the various component sizes and versions allows for a relatively smooth transition into adulthood. Prescription criteria are reviewed during each clinic visit, and changes are made based on the child's changing needs. In today's environment of active children and sports activities, the use of sports or other adaptive terminal devices is essential for the amputee. Therapeutic Recreation Systems Inc. (TRS) has developed numerous devices for use in sports and recreational activities. These can be interchanged on the prosthesis, so that only one socket is required.

Endoskeletal versus Exoskeletal Construction

The structure or construction of a prosthesis is referred to as an endoskeletal (internal structure) or exoskeletal (external structure) prosthesis. Generally, transtibial, partial foot, and transradial prostheses are constructed exoskeletally, and transfemoral, knee disarticulation, hip disarticulation and transhumeral, and shoulder disarticulation levels are constructed endoskeletally.

Exoskeletally finished prostheses are more durable and better suited to the growing child. There are various techniques and materials used in the construction of the exoskeletal prosthesis. Generally, following the completion of dynamic alignment, the ready-to-be-finished prosthesis is placed within a transfer jig that allows the socket to be separated from the foot, while maintaining alignment. A rigid polyurethane foam is added, and the prosthesis is cosmetically shaped to equal the sound limb. The structure is then laminated with acrylic resin forming the outer “shell.” The advantages of this construction are increased durability, easy to clean, and structurally stronger. The major disadvantages are lack of further alignment capabilities, and they are less cosmetically acceptable.

Endoskeletal design was initially used in the immediate postoperative period as a temporary method to initiate ambulation, while maintaining the ability to alter the alignment. This quickly became the norm for fitting in the adult population, and has been used primarily for the knee disarticulation or transfemoral prosthesis. The prosthesis is modular and comprised of a pylon (tube) and connecting hardware, and allows for quick changing of damaged components. In the event that realignment is necessary, the endoskeletal design incorporates alignment jigs within the attachment couplings, and only the cosmetic soft cover needs to be removed for adjustment. In children, advanced components tend to be engineered for use in this system for the above reasons. The disadvantages of the endo system are lack of durability of the cosmetic cover, increased maintenance, and increased costs. This is outweighed by the increase in function and ease of adjusting length.

ROLE OF THE PHYSICAL/OCCUPATIONAL THERAPIST

The role of the physical/occupational therapist in the care of the limb-deficient child is mostly nontraditional, but at the same time, central. In addition to the traditional

role of physical/occupational therapist is the role of teacher, advocate, friend, and liaison (176). In some situations, all but the traditional role of therapist may be filled by a nurse. In some cases, the role may be shared. What is important is to recognize the need for all of these activities.

The first role of the therapist will usually be that of educator. In this role, it is important that the therapist, physician, and prosthetist all be of one mind regarding the patient's treatment. First is the education of the parents. Like nurse practitioners, the therapists will usually have more time and be better heard than the doctor when relaying information to the parents about their child. The therapist will be able to reinforce with the parents the options that have been discussed at the initial meeting with the physician. Most importantly, they can arrange for the family and child to meet others with similar deficiencies during routine sessions. Throughout the child's life, the experienced therapist can be of immense value to the child and young adult, in anticipating problems and helping with solutions.

The therapist's first role as advocate will start with the first meeting with the parents. The importance in this role is to bring the parents to see the normal, as well as the abnormal, and ensure that the initial bonding to the parents occurs. The therapist will frequently need to advocate for the patient to insurance companies and other agencies, to help provide for the patient's needs. When the child starts into day care, then school, the therapist will assist in the child's transition into a new world by educating the teachers and the child's peers about the child's differences. This can be extremely important for the child's acceptance and socialization. Later, the same role may be necessary with physical education teachers and coaches, to ensure that the child can participate in all the activities he or she is able to.

The therapist (or nurse) with these roles is the ideal liaison with the team members. This close teamwork can spare the child and parents countless visits to clinics and delays in treatment: a very important goal in avoiding the medicalization of a condition for which there is no cure, only good management.

The traditional role of the therapist will be far more home/community-based than hospital/office-based, for many reasons. First, the child's condition will be permanent. This means adapting to the environment in which the child exists. None of the child's activities (toileting, eating, dressing, play, sports) will take place in the hospital or an office. Therefore, they should be learned in the normal environment. Second, the parents will be with the child, and are responsible for the child's development and learning. They will have unlimited access to the child for this “therapy.” Finally, the child should not come to think of him- or herself as a medical problem, but rather as a child with a difference that they will successfully adapt to. Unnecessary hospital/clinic/office visits are not a good way in which to communicate this goal of independence.

The traditional medical model does have a role in acute situations, as it does in many diseases or postsurgical situations. These are times when specific therapeutic exercises or the use of new prostheses must be performed, supervised, and taught. During the first months of life in a congenital amputee, the parents are seen by the therapist every 6 to 8 weeks. The child's development is monitored, and the parents are taught activities appropriate for the stage of development, e.g., rolling over and coming to stand from sitting. These visits are used to monitor the parents' coping, to listen and answer questions, review treatment options, and arrange for the meeting with other parents and children.

Following surgical intervention and prosthetic fitting, the medical model is more appropriate, and the frequency of the visits increase briefly, while the child and parent are taught the use of the prosthesis. In addition to the usual goals of increasing or maintaining motion and strength following surgery, the therapist plays a critical role in edema control. This is very important if the patient is to resume prosthetic wear quickly. Teaching and supervising elastic wrapping obtaining shrinkers are important postsurgical issues.

Older children need to be taught ways to become independent in donning and doffing the prosthesis, toileting, and other activities with the prosthesis. Fitting of a new prosthetic component, e.g., a hydraulic knee joint, will usually require specific training to maximize the benefits of the new components.

As the child grows out of infancy, the therapist can be helpful in designing and modifying age-appropriate play activities. With the approach of school age, emphasis switches to independence in the activities of daily living, and later, fine motor skills that may be needed for classroom activities. Adaptations for sports, e.g., special terminal devices, if desired, or a swimming leg, are important, as is the advocacy role to allow the children to participate in all possible activities.

In adolescence the need for specific therapeutic interventions is usually minimal. The child has now become fully aware of his or her differences and their significance. The child will usually dictate the needs. Appearance being important, more cosmetic prostheses and improved gait become important issues.

At this time, driving becomes one of the major issues defining independence. The therapist can play a critical role in directing the child and parents to the appropriate agency for the rules of the state, and to a source for evaluation and modifications to the vehicle. As with any adolescent, the amputee should attend driver education training, using modifications if needed. Modifications can range from simple to complex. Switching the brake and gas pedals to accommodate unilateral lower-limb loss is one of the most common examples. Many amputees, even with bilateral lower-extremity loss, drive without adaptations. This must be closely monitored and evaluated by the state's examiners. Hand controls are used most commonly in bilateral lower-extremity loss. A ring adaptation can be used to modify the steering wheel for upper-extremity amputees. A handicap license is appropriate for individuals whose mobility is limited. The higher-level amputee, and those with multilevel limb loss, may benefit from a handicap parking license. All modifications are listed on the amputee's driver's license.

College is often the patient's first test of complete independence, and the needs may be greater than the child anticipates. The therapist can be of great value in assessing the situation, counseling the patient, and helping with the transition.

ADAPTATIONS FOR ACTIVITIES AND SPORTS

Children of all ages with limb deficiencies or amputations should be encouraged to participate in sports and recreational activities with their peers. The psychologic impact of sports cannot be underestimated. Improving self-esteem and confidence, gaining independence, learning to win and lose, developing decision-making and problem-solving skills, and cooperating as a team member are a few of the benefits that a child carries throughout his/her life. Improving physical fitness, developing balance, strength, coordination and motor skills, increasing endurance, and weight control are benefits of physical activity.

Over the years, there has been an increased awareness of adapted sports and recreation for individuals with physical and mental impairments. The Paralympic and Special Olympics initiatives have been the most obvious, and have sparked an increase in availability of programs for special-needs children. Laws also have been passed for children to receive education in the least-restrictive environments. PL 94-142 provides free and appropriate education for all children with disabilities (Campbell S, Physical Therapy For Children, 1994). Physical therapy and recreation are related services included in this legislation. This allows for adapted physical education to be included in a child's everyday school activities. Physical therapists need to be aware of the resources and adaptations that provide accessibility of a sport to a child within limits of his/her physical abilities in the school and community settings. Gross motor achievements are a measure of a child's development. Learning to toss a ball, jump, run, hop, and ride a bicycle are activities included on standardized developmental screenings and tests. It is important that these activities be included in the child's plan of treatment, so that a child can be offered the same age-appropriate physical challenges as his/her peers.

Special adaptations and specific sports-related prostheses are available, depending on the degree and level of the disability. All of the adaptations are too numerous to mention. Recreational and sports-related terminal devices are available for the upper-extremity amputee (177,178). Adaptations can be as simple as raising the handlebars on a bicycle and adding a toe strap to highly sophisticated prosthetic components specific to each sport (179). Information and resources for sports and adaptive recreation for the amputee can be obtained through the Amputee Coalition of America (e-mail: www.amputee-coalition.org; phone 1-888-267-5669). The Association of Children's Prosthetic and Orthotics Clinics is an excellent resource for services in geographical regions (e-mail: www.acpoc.org; phone 847-698-1637).

CHAPTER 31

SPORTS MEDICINE IN CHILDREN AND ADOLESCENTS

MICHAEL T. BUSCH

M. T. Busch: Department of Orthopaedics, Children's Healthcare of Atlanta at Scottish Rite, Atlanta, Georgia 30342.

CARE OF THE YOUNG ATHLETE

Young athletes sustain musculoskeletal injuries that are different from those of their adult counterparts. Although many of these are the torus fractures, greenstick fractures, and physeal injuries that are common to children, the proliferation of youth athletics has increased the incidence of overuse syndromes and other injuries (1). The role of rehabilitation in the treatment of sports-related injuries is recognized, and there is a growing emphasis on prevention of these injuries (2).

The volume of organized sports activities and levels of intensity for youth training and competition have grown tremendously in recent years. The United States Consumer Product Safety Commission reported that approximately 2 million medically attended sporting injuries occur annually to youths between the ages of 5 and 14 years (3). In response to this problem, preparticipation physical examinations, heat illness education, safety reviews, school athletic trainers, team physicians, and health education programs for grade school and high school sports participants have evolved (4).

Sports have important effects on strength, speed, and stamina. If appropriately organized, sports can be a positive social experience, with opportunity for character growth and development. Competition is often emphasized, but the lifelong values of health, exercise, and recreation should not be overlooked. Particularly during the elementary school years, programs should be available that emphasize the participation by all children, not just the physically advantaged (5). Involving younger children in elite-level sports training and competition should be done with caution, because there is a risk of exploiting the child and producing long-term emotional consequences (6). However, many important behavioral needs of youths can be satisfied by athletic participation and competition (7).

Approximately 2% of children suffer from chronic medical problems that restrict their activity (8). Besides having to live with the inherent aspects of these conditions, these children are often excessively restricted from physical activities. Most children with asthma, cystic fibrosis, congenital heart disease, or juvenile rheumatoid arthritis can benefit from an appropriately structured exercise and sports recreation program (8,9). Recommendations are available from the American Academy of Pediatrics for sports participation by youths with special health conditions, although a physician's assessment of the individual situation should always be considered (10,11).

Programs such as the Special Olympics have grown from the recognition that children with physical impediments can benefit from the personal, social, and physical aspects of sports participation. Children with a variety of chronic illnesses, including asthma, can benefit from exercise conditioning (12); however, this should be done with the advice and direction of their physicians.

Nutrition

Everyone seriously involved with youth sports should be familiar with the facts and myths concerning nutrition. This area has received much attention in the medical and lay literature. Inaccurate nutritional information leaves the impressionable and naive young athlete easy prey for food faddists and nutrition charlatans.

Vigorous training increases the consumption of calories, but does not significantly alter the athlete's need for essential nutrients (13). Minerals and electrolytes are replaced by a normal diet, unless the athlete is experiencing daily fluid losses of 4 to 6% of body weight because of excessive sweating. Nutritional supplements, such as vitamins and protein powder, are unnecessary if the youth eats a basic mixed daily diet consisting of four fruit or vegetable servings, four grain servings, two diary products, and two high-protein foods (13,14). As many as 15 to 20% of menstruating female athletes may require an iron supplement. Children from low socioeconomic backgrounds may also lack adequate iron in their diet (15).

Young athletes have increased energy requirements related to rapid growth and exercise expenditure. The increased need for food energy is best met through complex carbohydrates. A high-carbohydrate and protein diet provides the needed calories, while increasing muscle and liver glycogen stores, which are important for

athletic performance (16). Simple sugars provide a readily available source of carbohydrate calories. They may be a needed component of an active athlete's diet to meet total caloric requirements. The disadvantage of simple sugars is that they are absorbed quickly. This induces an insulin response that can lower serum glucose and result in fatigue.

The recommended caloric intake is 50 to 60% carbohydrate, 10 to 15% protein, and 30 to 35% lipids (17). The ratio of complex carbohydrates to these other components can be achieved with fruits, leafy vegetables, and starches such as potatoes, rice, pasta, and breads. Greasy and salty foods should be discouraged.

Carbohydrate loading during the days before competition can enhance glycogen stores to optimize energy availability for prolonged muscle performance (18,19 and 20). The pre-game meal should consist primarily of light carbohydrate foods consumed approximately 3 h before the activity (19). Foods high in fats and salt slow gastric emptying and increase water retention in the gut (13).

Fats are a rich source of energy, but they are poorly mobilized for a short-term energy expenditure. A diet high in fat fails to enhance the body's glycogen stores, which are important for athletic performance. Excessive consumption of fats also carries the associated risks of elevating serum cholesterol and triglycerides (17).

Proteins are complex amino acids. They are necessary components for building new muscle tissue. Proteins should account for approximately 15% of total caloric intake, and any surplus is metabolized for energy or excreted in urine (17). Most protein supplement preparations are solely expensive sources of calories. Gains in muscle strength and mass are made by training, and have not been proven to result only from providing a high-protein diet (20).

A variety of minerals and vitamins are important. Because potassium is primarily an intracellular ion, losses associated with sports are slow and gradual. Potassium does not need to be replenished acutely, but it is needed over the prolonged course of serial competition and training (17). Magnesium is a key component in the adenosine triphosphate (ATP) cycle. Bananas are an excellent source of magnesium and potassium. Iron deficiency is still a problem in teens, especially females, vegetarians, and individuals from lower socioeconomic groups (14). Adolescents should be encouraged to eat iron-fortified foods, such as whole grain breads and lean red meats. When combined with citrus fruits, the bioavailability of iron increases. Athletic activity theoretically depends on all vitamins, but emphasis has been placed on vitamin C and B complex vitamins, because of their roles in the metabolism of proteins, fats, and carbohydrates for energy (17). However, there is no evidence to suggest that an intake in excess of normal requirements improves performance (17).

Heat Illness and Fluids

Heat illness is almost entirely preventable through awareness and education (21) (Table 31-1). Between 70 and 80% of the energy consumed in muscle contraction is transformed to heat (22). Heat loss is promoted by increased blood flow to the skin, and by increased sweating. Cooling is provided by thermal conduction, convection, radiation, and evaporation. Extrinsic factors affecting heat exchange include ambient temperature, humidity, clothing, sunlight, and wind.

Proper acclimatization at the beginning of the workout season
Evaluate weather conditions for temperature, humidity, and sunlight
Schedule rest in the shade
Identify participants at particular risk
Hydrate before practice and competition
Have chilled fluids readily available at the practice site
Enforce periodic drinking
Never use water restriction as discipline
Discourage deliberate dehydration for weight loss
Make appropriate clothing adjustments
Schedule events to avoid peak hours of heat and sun
Educate the players and parents
Record daily weights to ensure adequate rehydration between practices

TABLE 31-1. GUIDELINES FOR PREVENTING HEAT ILLNESS

The spectrum of heat illness can be divided into four clinical entities: heat cramps, heat syncope, heat exhaustion, and heat stroke (23). Heat cramps are painful muscle spasms that typically occur in the gastrocnemius and soleus, hamstrings, quadriceps, and spine extensors. Because the spasms are primarily caused by fluid depletion, the key elements of treatment are fluid replacement, stretching, and cooling. Heat syncope usually involves a feeling of fatigue and resolves with cooling, fluids, and rest. Heat exhaustion is characterized by extreme weakness, exhaustion, headache, altered consciousness, and profuse sweating. This is a much more advanced stage of the heat illness continuum, and should be treated aggressively with fluid replacement, cooling, and restriction of further participation in sports for the day. Occasionally, intravenous fluids and hospitalization are necessary.

Heat stroke is a true medical emergency resulting from dehydration with severe hyperthermia. There can be severe abnormalities affecting the brain, heart, clotting system, kidneys, and liver. Edema of the brain and meninges, as well as petechial hemorrhage, can lead to loss of consciousness, dysphoria, headache, dizziness, weakness, confusion, euphoria, coma, and seizures. Myocardial injury and increased pulmonary vascular resistance can lead to tachycardia, hypotension, and shock. Systemic petechial, gross tissue hemorrhage, and consumptive coagulopathy are thought to be triggered by thermal injury to the vascular endothelium. Renal tubular dysfunction and acute tubular necrosis can result in severe dehydration and marked hypokalemia and hyponatremia. Occasionally, there is liver damage, including centrilobular necrosis and cholestasis resulting in hyperbilirubinemia and jaundice (24). Maximal cooling efforts should be made at the site, and the victim should be rapidly transported for emergency medical care (23).

Children are less efficient thermal regulators than adults and acclimatize more slowly than adults. They have a lower sweating capacity, especially before puberty. Children also produce more metabolic heat per mass, and have a decreased ability to conduct heat to the skin (25). They have a greater ratio of surface area to mass, which increases heat transfer from the environment on hot days. Additional risk factors for children can include obesity, fever, recent gastroenteritis with dehydration, and cystic fibrosis (26).

Sweat is hypotonic to body fluids, containing 40 to 80 mEq/L of sodium and less than 5 mEq/L of potassium. Sweating increases serum electrolyte concentrations. Electrolyte solutions for replacement are recommended only after 1 or 2 h of rigorous activity (27). Initially, plain water adequately replace these losses. The water should be cooled to stimulate thirst. Cool liquids do not significantly slow gastrointestinal emptying, but delayed motility can be a side effect of electrolyte solutions with high osmolalities. Salt tablets, once popular, are dangerous, because they can produce intracellular dehydration by their osmotic effect in the serum (22).

Situations that increase heat gain include rigorous exercise, bright direct sunlight, and dark clothing. Cooling is inhibited by dehydration, high humidity, high air temperature, a lack of wind, and equipment or clothing that act as insulation. Acclimatization is also important, because it reflects the body's capacity to transfer heat to the skin for convection and the body's ability to produce sweat for evaporation. With this as background, the guidelines in Table 31-1 outline most of the key components for avoiding heat illness.

Strength Training

Weight lifting should be differentiated from weight training. Olympic lifting and power lifting are the two categories of weight lifting. The Olympic lifts consist of snatch and clean-and-jerk lifts. The dead lift, squat lift, and bench press are the three power lifts. In both categories of weight lifting, the object is to perform a one-repetition maximum lift.

Weight training refers to the use of free weights and machines to enhance strength and endurance. Submaximal weights are lifted repeatedly with a large variety of exercises typically intended to enhance performance for other sports, rather than for a specific contest (28).

Children can increase strength by 20 to 40% in a well-supervised program, with a relatively low risk of injury (29,30). Females and prepubescent males do not produce significant hypertrophy of their muscles in response to weight training because of insufficient circulating androgens. The strength gains that occur result from

enhanced recruitment of motor units and synchronization rather than significant muscular hypertrophy.

Common injuries associated with weight lifting include patellofemoral pain, meniscal tears, pelvic apophyseal avulsion fractures, and clavicular osteolysis (31,32). Lumbosacral injuries, including disc herniation and spondylolisthesis, are the most common problems in adolescent weight lifters (33). The most common injuries from weight lifting are muscle pulls, tendinitis, sprains, and other minor injuries (33). Stress fractures and a variety of acute physeal, metaphyseal, and diaphyseal fractures have been reported in weight lifters (28,34,35 and 36). Despite concerns, there does not seem to be any substantial evidence that weight training using submaximal loads harms the physeal plates. However, power lifting or Olympic weight lifting is generally not recommended for skeletally immature youths (37).

Many high schools run successful and safe weight-training programs. A proper strength-conditioning program should be a prerequisite to participation in contact sports. For safe participation, there should be a structured program supervised by an educated and attentive staff. Proper technique should be emphasized, using repetition without maximal weight lifts. Equipment must be in good repair. An attentive partner (i.e., spotter) is important when free weights are used. A conscientious, concurrent stretching program is also important (29,34). Although the scientific documentation is just evolving for warm-up and stretching, they appear to be important for preventing injuries (38,39). Stretching and warm-up exercises apparently enhance muscle, tendon, and ligament elasticity, and may improve performance by nervous system recruitment and psychologic effects (38,39).

Performance-enhancing Substances

The use of drugs with which athletes hope to enhance performance has become common (40). Frequently involved substances include amphetamines, analgesics, tranquilizers, diuretics, anabolic steroids, and creatine. The evidence for actual performance enhancement is questionable, but the potential complications are well known. Most widely abused are the anabolic steroids used in conjunction with weight training and weight lifting. The use of anabolic steroids, for example, has been reported to be as high as 5 to 11% of high school males and 2.5% of females (41,42 and 43). Up to two-thirds of the users start before 16 years of age (41,43).

Creatine supplements are legal, readily available, and increasingly popular with adolescents. Muscles convert creatine to phosphocreatine, which serves as a reservoir for the high-energy phosphate bonds of ATP. The idea behind the supplements is that excess phosphocreatine will lead to a higher rate of ATP synthesis, so the supplements are thought to delay the fatigue that results from ATP depletion. This may have some benefit in activities requiring short bursts of high-intensity muscle contraction; however, there is little evidence that it is helpful in endurance sports (44,45). Some argue that it allows athletes to train more intensely. Because the long-term effects are unknown, the use of creatine is generally not endorsed.

Anabolic steroid use appears to be spreading, despite the known side effects, which include premature epiphyseal closure, jaundice, acne, behavioral changes such as aggressiveness and mood swings, fluid retention, hematoma, hepatocellular carcinoma, testicular atrophy, and female hirsutism (42,46,47 and 48). Physicians dealing with adolescent athletes should be aware and suspicious of these problems. Unfortunately, physicians are occasionally the source for these drugs (41,43,47).

Young athletes are easily influenced, so the health aspects of reputed performance-enhancing substances must be addressed frankly. The efficacy of most of these substances is questionable. Those trying to offer easy alternatives to better conditioning and training rarely explain the risks. Rather than concentrating solely on competition or achievement, sports programs should stress the overall importance of health and activity.

Antiinflammatory Drugs

Nonsteroidal Antiinflammatory Drugs

The principles for using nonsteroidal antiinflammatory drugs (NSAIDs) in sports-produced inflammation include decreasing the pain of inflammation to allow compliance of rehabilitation and to avoid pain-induced atrophy, reducing inflammation in freshly healed and relatively vascular tissues during retraining, and limiting the zone of edema-induced tissue necrosis after acute injury. Although their effects, efficacy, and roles are still being clarified, it is important to be familiar with these medications, because they are commonly used by young athletes.

NSAIDs work primarily through inhibition of cyclooxygenase in the pathway of prostaglandin synthesis (49). The three main clinical features are analgesic, antipyretic, and antiinflammatory effects. In inflammatory conditions, the response may take time. In rheumatoid arthritis, only one-half of the patients have an adequate response to the NSAID within 2 weeks, and an additional 30% respond by 10 weeks (50). Fifty percent of patients who experience no relief from the first type of NSAID improve after another is tried, and a trial of several drugs may be needed before a satisfactory response is achieved. In cases of prolonged use, a drug may become ineffective with time, requiring substitution of another NSAID (50).

The principal metabolic pathway of NSAIDs is hepatic, with renal excretion of the conjugated metabolites. All NSAIDs are extensively bound to proteins, giving them the potential to displace other drugs, but this seldom produces significant potentiation of other drug effects. The potentiation of anticoagulants is therapeutically significant, but these agents are seldom used in children and adolescents. Occasionally, two NSAIDs are used concomitantly, but this should be done under careful scrutiny for toxic side effects.

Aspirin, ibuprofen, naproxen, and tolmetin sodium are the only NSAIDs approved by the U.S. Food and Drug Administration for children younger than 13 years of age. Among the NSAIDs, aspirin is the least expensive, but has the highest rate of minor side effects. Most parents are reluctant to administer aspirin because of the well-publicized association with Reye syndrome. Naproxen has the advantage of twice-daily dosing, and is available in liquid suspension form. Ibuprofen is used widely, because it is relatively inexpensive and available without prescription.

Most of the information available about the use of these agents in younger patients derives from experience in treating juvenile rheumatoid arthritis. Their use in musculoskeletal inflammation secondary to trauma and overuse syndromes is less well documented, particularly in youths. Although these drugs are widely used, their efficacy in sports-related disorders is largely empiric and not well documented in placebo-controlled studies (49).

Occurring in as many as 10% of patients, the most common side effects of NSAIDs are gastrointestinal: gastritis, abdominal pain, nausea, diarrhea, and, occasionally, constipation. Hematuria, proteinuria, and marrow suppression also can occur. Most NSAIDs inhibit platelet function, and can lead to bleeding-related complications. Newly released cyclooxygenase-2 inhibitors avoid these problems, although safety in children is still being studied. Rarely, tinnitus, blurred vision, exacerbation of asthma, mood changes, drowsiness, and mouth ulcers are seen. These side effects usually resolve after discontinuance of the medication. Patients on prolonged NSAID therapy should have a hemogram, urinalysis, and liver function profile at 2 weeks, 6 weeks, then every 6 months after therapy is begun. Rarely, NSAIDs can cause peptic ulcer, severe liver or renal toxicity, or severe allergic reactions (50). The use of NSAIDs in young children, or for prolonged periods in older children and teens, is probably best supervised by a rheumatologist or an experienced pediatrician.

Corticosteroids

Oral and parenterally administered steroids have multiple inhibitory effects on inflammation. Their action is more potent, but they may produce harmful side effects, including the retardation of healing (51).

There are concerns that intraarticular injection of steroids can damage articular cartilage, possibly by inhibiting the synthesis of chondral matrix (52). In adults, there are several reports of adults undergoing rapid radiographically-evident degeneration after intraarticular injections, but these are probably anecdotal. The risk of adult tendon rupture after steroid injection appears to be substantially more founded (51). Intraarticular triamcinolone hexacetonide, in the management on children with juvenile rheumatoid arthritis, has been effective with relatively few side effects (53). Because there is no definitive evidence regarding the safety and efficacy of oral or parenteral steroids for sports-related maladies in children, these treatment options should probably be avoided or used sparingly (54).

OVERUSE SYNDROMES

The term “overuse syndrome” categorizes several musculoskeletal maladies that are characterized by connective tissue failure in response to repetitive submaximal loading. In the course of normal activities, a small amount of tissue breakdown usually occurs. With repetition, musculoskeletal tissue hypertrophies and this is the essence of athletic training. If the rate of tissue fatigue exceeds the reparative response, failure occurs. Inflammation ensues and leads to clinical symptoms (55) (Fig.

31-1).

FIGURE 31-1. Cyclic loading of all tissues leads to tissue fatigue. Normally, these tissues heal and remodel, permitting continued activities. Athletic training involves increasing activity and converting the healing and remodeling process into hypertrophy of the tissues. This strengthens tissue, allowing increased tissue loading and greater performance. Excessive training leads to tissue fatigue by exceeding the rate of healing or remodeling.

Classic Stress Fractures

Stress fractures are partial or complete disruptions of the bone secondary to an inability to withstand repetitive, nonviolent loads. Normally, the bone remodels itself in response to microtrauma. However, with excessive use, the mechanical fatigue and bone resorption can outpace the osteoblastic response. Although the classic example of stress fractures are the “march fractures” of young adult military recruits (56,57), stress fractures do occur in younger athletes, including adolescents and occasionally children (58,59,60 and 61). In a series of 200 stress fractures occurring in all ages, 36.5% occurred in 16- to 19-year-old adolescents, and 6% occurred in youths 15 years of age or younger (60).

Adolescents with stress fractures closely parallel their adult counterparts, with a few exceptions (60,61). The proximal third of the tibia is the most commonly affected site; metatarsal fractures are rare in youngsters (60). There is equal distribution among male and female patients. Although most stress fractures in adolescents are associated with endurance running, the average training distance is typically not excessive (60).

Engh reported stress fractures of the proximal tibia in a series of nine children younger than 12 years of age, with the youngest diagnosed at 21 months of age (59). In many of these cases, there was no clear history of athletic overuse, so these cases likely represent an entity distinct from sports-related stress fractures.

Stress fractures about the knee can involve the distal femoral physis, the proximal tibial physis, and the patella (62,63 and 64). Although the lower extremities are most commonly affected, cases of adolescent athletes with stress fractures of the metacarpal, radius, ulna, humerus, and olecranon have been reported (65,66,67 and 68). Spondylolysis is often the result of a stress fracture of the pars interarticularis, and is most commonly seen in young gymnasts and football linemen (69,70) (see Chapter 20).

The typical history of a stress fracture is one of insidious onset of pain in the area of fracture that is initially relieved by rest. The pain eventually increases. It persists after activity, and affects normal walking. On examination, the tenderness can be localized to the site of fracture in about two-thirds of cases, and swelling occurs in about one-fourth (71).

Approximately 10% of initial radiographs are abnormal (71). With time, the osteoclastic process may lead to cortical disruption, and even to a displaced fracture. Bone scintigraphy is helpful for establishing the diagnosis, especially during early stages. As many as 50% of adolescents with stress fractures show multiple asymptomatic areas of stress response on bone scan (61). If clinically asymptomatic, these other areas of bone scan uptake do not warrant treatment.

Osteoid osteoma, malignancies, and infection can have presentations and radiographic appearances similar to stress fractures. The differential diagnosis of tibial stress fracture includes all of the causes of shin splints. Occasionally, a biopsy is indicated, but this should be avoided if possible, because the surgical defect may delay healing or precipitate a complete fracture. If a biopsy is performed, an adequate sample must be obtained and the interpretation reviewed carefully. A healing fracture can have many features similar to a malignancy.

Stress fractures of the proximal femur can have serious complications, including avascular necrosis if displacement occurs. These occur in young adults, with a few cases reported as young as 16 years of age (56,72). Only rarely has stress fracture of the femoral neck been reported in skeletally immature children (73,74). Other diagnoses, particularly slipped capital femoral epiphysis, should be considered in the young athlete complaining of vague hip, thigh, or groin pain related to activity.

The treatment of most stress fractures involves breaking the cycle of repetitive trauma. This usually can be done by eliminating running, while permitting normal walking. Crutches or a cast can be used for fractures that seem to be at particular risk for displacement or for the uncooperative adolescent (71). Alternative training, such as swimming, cycling, or pool jogging, can be used for maintaining aerobic conditioning in the serious athlete. Compliance is critical in ensuring that a complete fracture does not occur (75). Healing takes 2 weeks to 3 months. Recommending when to return to sports is a complex judgment, and prevention of reinjury by modifying the athlete's training program is essential. Distal fibular stress fractures have little risk of residual complications. For these, the use of a pneumatic leg brace is useful for the early return to sports (76). Tibial stress fractures deserve special attention, because nonunion occasionally occurs, even after 4 to 6 months of conservative care (77). Femoral neck stress fractures should be treated aggressively and may require internal stabilization.

Repetitive Physeal Injuries

Epiphysiolysis of the Proximal Humerus

Adolescents may develop widening of the proximal humeral physeal plate associated with shoulder pain during rigorous upper-extremity activities, such as baseball pitching. Coined by Dotter, the descriptive term “Little League shoulder” is not precise because other overhead sports may be involved (78). The pathology has not been delineated, because biopsy is not indicated for this self-limiting disorder. The pathomechanics are presumed to be repetitive traction or torsional forces at the physis (79). The exact incidence of Little League shoulder is unknown (80).

The typical patient with epiphysiolysis of the proximal humerus is a male baseball player between the ages of 12 and 15 years. Typically, the pain begins during throwing, without an inciting event. Initially, the youth may continue to play despite the pain, with the discomfort resolving between games. Playing ability diminishes as the pain becomes more constant.

Tenderness is primarily in the proximal humerus or shoulder. Pain is elicited with active internal rotation against resistance (80). The shoulder has a full range of motion.

Plain radiographs demonstrate widening and irregularity of the physeal plate (Fig. 31-2A), and a comparison view of the unaffected shoulder is helpful (Fig. 31-2B). Bone scans do not demonstrate greater than normal activity (80). The primary differential diagnoses include rotator cuff tendinitis, acromioclavicular joint injury, shoulder instability, and bony lesions of the proximal humerus, such as a solitary bone cyst.

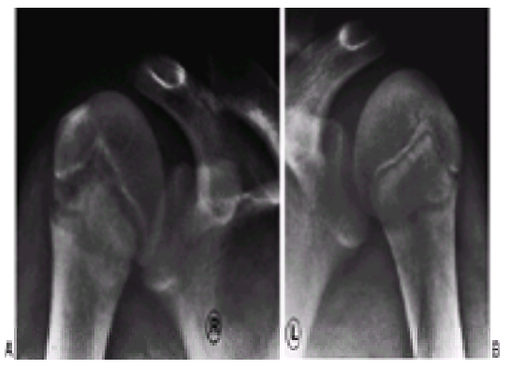

FIGURE 31-2. Radiographs of the proximal humerus in a 14-year-old, right-handed baseball pitcher with shoulder pain that progressed over the final few weeks of the season. **A:** Widening and irregularity of the physeal plate are present in the right shoulder. **B:** Radiograph of the left shoulder is provided for comparison.

Initially, a sling may be indicated if the shoulder is extremely sore, although treatment primarily involves modification of activity. Gradual return to activity can begin within 1 or 2 months. Radiographic resolution may take up to 6 months (80). Callus or periosteal new bone may develop (81). The physeal plate gradually returns to normal.

Initially, the athlete should avoid or minimize the precipitating activity, and symptoms should be monitored as sports are resumed. Baseball pitchers and catchers can usually tolerate infield positions. Permanent restriction of pitching until skeletal maturity is reached probably is not necessary, because there are no known sequelae to this condition (81,82).

Epiphysiolysis of the Distal Radius

Physeal abnormalities of the distal radius have been reported in young female gymnasts (83). These are stress injuries of the physis. Radiographs demonstrate widening of the growth plate, and there are often lucent defects of the adjacent metaphysis and irregularities of the metaphyseal margin (83,84) (Fig. 31-3). Bone scans may be normal (84). This process resolves with rest, although it may take 3 months or longer for resolution of the radiographic abnormality (83) (Fig. 31-4). Mild cases become asymptomatic in as little as 4 weeks, and result in no growth inhibition or residual deformity (83,84). However, more severe cases are slow to resolve, and can lead to premature physeal closure of the distal radius (85). Premature closure can lead to relative overgrowth of the ulna and subsequent carpal impingement. Rest and training modification sufficient for resolution appears warranted.

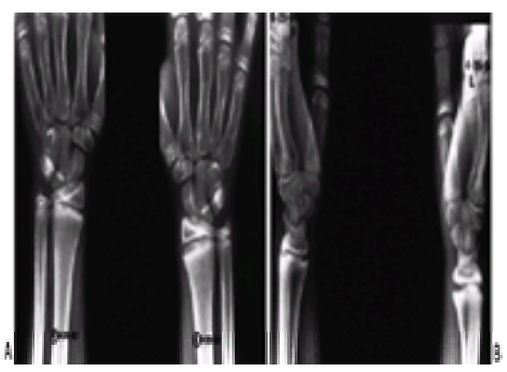

FIGURE 31-3. Bilateral epiphysiolysis of the distal radii in a highly competitive, 11-year-old gymnast. The left is more symptomatic than the right. **A:** The anteroposterior view shows widening of the left distal radial physis, compared with the right. The metaphyseal margins are irregular. **B:** The lateral view of the wrists shows definite cupping of the distal metaphyses, which is greater on the left than the right.

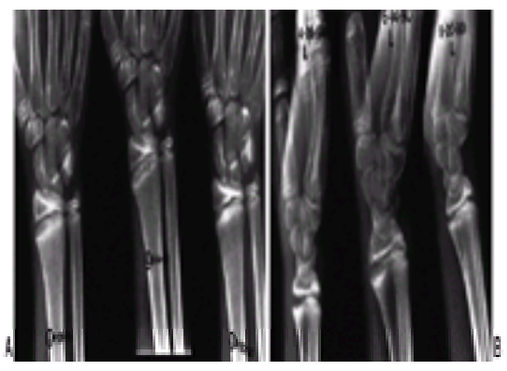

FIGURE 31-4. Sequential radiographs of the patient shown in Figure 31-3. She was asymptomatic 6 weeks after the initial presentation, and gradually returned to activities. She remained asymptomatic. The radiographs demonstrate progressive, but incomplete resolution. **A:** Anteroposterior radiographs were taken at the time of presentation, 6 weeks later and 5 months after initial presentation. **B:** Lateral radiographs show gradual resolution of the physeal widening and metaphyseal cupping.

Apophyseal Conditions

Osgood-Schlatter Disease

In 1903, Osgood and Schlatter separately described the tibial tuberosity disturbance that commonly affects active adolescents. Through membranous ossification, the apophysis of the tibial tubercle is formed anterior to the tibial metaphysis. In Osgood-Schlatter disease, there appears to be a partial avulsion of the developing ossification center and overlying hyaline cartilage from the anterior surface of the apophysis (86).

Patients are usually 10 to 15 years of age at the onset of the disorder, with the lesion typically occurring in girls about 2 years earlier than boys (87,88). Boys are more commonly affected than are girls. Approximately 15% of teenage boys and 10% of teenage girls develop pain in their tibial tubercles (88). The incidence may be as high as 20% in athletic youngsters, compared with 5% in nonathletes (88). The incidence of bilaterality is 35 to 55% in boys and as low as 18% in girls (88,89). There may be a familial component as well, with an incidence of 20 to 30% among youngsters whose siblings had Osgood-Schlatter disease (88). Biomechanical malalignment of the lower extremity, including increased quadriceps angle, genu valgum, femoral anteversion, and forefoot pronation, may be a contributing factor (90). Youths with one of the osteochondroses are likely to develop others; as many as two-thirds of athletes with Sever disease later develop symptoms of Osgood-Schlatter disease (88).

The pain is localized to the tibial tubercle, which is often prominent, and may have some local swelling. Abnormal findings of the joint itself are absent.

In unilateral cases, radiographs are indicated, unless the history is typical of Osgood-Schlatter disease and the findings are directly localized to the tubercle. Radiographs are not usually necessary in bilateral cases. The radiographic findings include prominence and irregular ossification of the tibial tubercle (Fig. 31-5A).

One or more ossicles may exist. The diagnosis should not rely solely on the x-ray film, because fragmentation of the tibial tubercle may be an asymptomatic normal variant. Radiographic blurring of the infrapatellar fat pad has been described, and probably results from the associated inflammatory response (87). Tumor and infection involving the tibial tubercle are rare occurrences, but should be considered in the unilateral case. If there is a history of an acute injury, a tibial tubercle fracture may have occurred, and there is the potential of this becoming displaced (91).

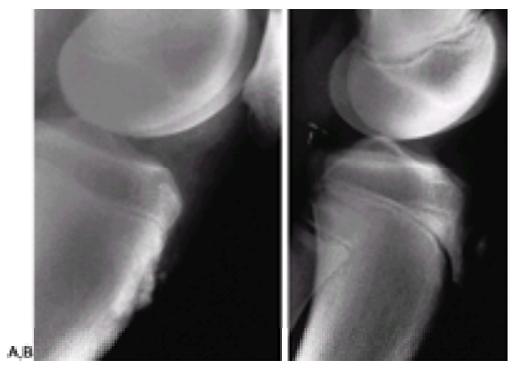

FIGURE 31-5. Osgood-Schlatter disease. **A:** Typical radiographic findings include a prominence of the tibial tubercle with irregularity of the bone at the insertion of the patellar tendon. **B:** In some cases, a separate ossicle may form and not unite. If persistently symptomatic, this ossicle may require excision.

Most symptoms spontaneously resolve with closure of the physeal plate, although as many as 20% of patients have some residual tenderness with kneeling (89). The treatment is primarily reassurance, symptomatic treatment, and occasional activity modifications. After being assured of the benign nature and self-limited course of this problem, most parents and youngsters are satisfied with tolerating some discomfort during certain activities; occasionally, restriction from sports may be necessary to control symptoms. Avulsion of the tibial tubercle associated with Osgood-Schlatter disease has been described in a young athlete (91). This appears to be an uncommon complication, and probably does not dictate that all young athletes must be curtailed from sports in an attempt to eliminate this risk.

Additional measures that may be helpful for young athletes include intermittent NSAIDs and hamstring stretching. Pads or braces may reduce local trauma, and commercially available straps and knee sleeves appear to help. In view of the risks and unsubstantiated efficacy, steroid injection is not recommended. If a significant biomechanical abnormality exists, such as excessive foot pronation, foot orthoses may be helpful (90). Casts are seldom used because immobilization weakens ligament insertions (92).

Occasionally, an ossicle and painful bursa forms deep in the tendon, and this remains symptomatic (Fig. 31-5B). If symptoms persist after physeal closure, excision of the ossicle offers simple and successful treatment (93).

Sinding-Larsen-Johansson Disease

Sinding-Larsen and Johansson independently described a condition in adolescents consisting of painful fragmentation of the patella's inferior pole (Fig. 31-6). Although associated with conditions involving spasticity of the lower extremities, this is more commonly seen in healthy, active, and athletic youngsters (94,95 and 96). Many analogies are made between this entity and the Osgood-Schlatter lesion, and both processes may occur in the same patient (96). In the early stages, there may not be radiographically detectable changes in the inferior pole of the patella, and some youngsters with similar clinical findings never develop abnormal calcification. This latter group is often diagnosed with “jumper's knee,” or patellar tendinitis, and Sinding-Larsen-Johansson disease may represent a specific variant of this disorder. Calcification and ossification at the inferior pole of the patella presumably occur in response to persistent traction in a growing individual.

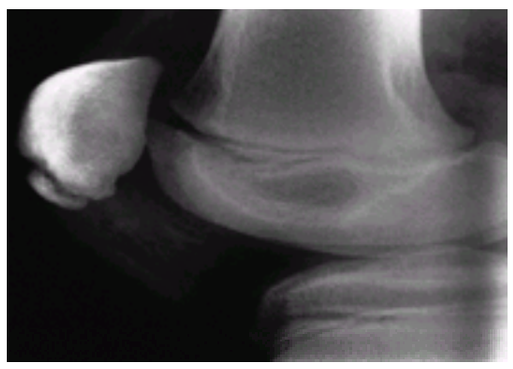

FIGURE 31-6. Sinding-Larsen-Johannson disease. The lateral radiograph best demonstrates the irregularity at the inferior pole of the patella.

The presenting complaints are typically pain in the knee associated with rigorous activities, especially running, climbing stairs, and kneeling. Tenderness is confined to the inferior pole of the patella, with no other significant knee findings. Other conditions that cause inflammation of the fat pad or anterior knee synovium can produce similar findings when the patient is examined with the knee in extension. With 90 degrees of knee flexion, the finding of tenderness at the inferior pole of the patella is more precisely indicative of Sinding-Larsen-Johansson disease or patellar tendinitis. A lateral radiograph of the knee should be able to confirm the presence of a calcified area separated from the patella. An MRI is rarely indicated, but does show edema and irregular calcification at the inferior pole of the patella.

This entity is self-limited. Typically lasting 3 to 12 months, it is shorter in duration than the Osgood-Schlatter condition. Management focuses on reassurance, and for discussion with parents, the term “condition” may be more appropriate than “disease.” Activity modification, ice, and NSAIDs may be helpful. Immobilization is seldom needed, and surgery is not indicated (96). While activity modifications may reduce symptoms, restriction from athletics is not absolutely indicated.

Calcaneal Apophysitis

Heel pain in the area of the calcaneal apophysis is a common complaint in young athletes. The age of onset is typically 9 to 14 years of age (97). The condition is bilateral in 60 to 80% of cases (98).

This was first described by James Sever in 1912, and is often referred to as Sever disease. Although histologic analysis is lacking, the clinical condition is that of an inflammation of the apophyseal growth plate of the calcaneus. It is a self-limited disorder, without documented complications or residual problems. The symptoms resolve after fusion of the apophysis, and treatment is therefore symptomatic. Like the other apophyseal overuse conditions, ice, oral NSAIDs, and activity modification can be helpful. Heel pads or lifts seem to improve symptoms. Cast immobilization may be indicated for the unusual case with severe, unremitting symptoms (98). For athletes such as gymnasts, for whom shoe wear modifications are not practical, taping the heel and arches may provide symptomatic relief (97).

Apophysitis of the Fifth Metatarsal

Often referred to as Iselin disease, apophysitis at the base of the fifth metatarsal is much less common than an apophysitis of the tibial tubercle or calcaneus. Symptoms typically occur in adolescents who have tenderness of the prominence of the proximal fifth metatarsal without acute trauma. Typically, there is a prominence of the tubercle, soft tissue swelling, and pain with resisted eversion. Oblique radiographic views may show enlargement and irregular ossification of the apophysis (99,100).

The natural history is apparently benign. Like the unresolved Osgood-Schlatter lesion, a persistently symptomatic ossicle has been described (99). Treatment is primarily symptomatic, consisting of ice, oral NSAIDs, and reassurance. Arch supports or foot taping may have a role (100). A cast may be indicated if the symptoms are severe (99).

Olecranon Apophysitis

Pain at the tip of the olecranon can occur in young athletes, and may be associated with ossification irregularity (101). This is thought to result from repetitive traction forces (102), or may result from hyperextension impingement, particularly in young gymnasts. Olecranon apophysitis is relatively uncommon (101). It appears to have a benign natural history, and should respond to conservative measures.

Apophysitis of the Hip and Pelvis

There are six major apophyses in the hip and pelvis: iliac crest, anteriosuperior iliac spine, anterioinferior iliac spine, ischial apophysis, greater trochanter, and lesser trochanter. Each of these can be affected by an apophysitis.

The iliac crest is a common site for apophysitis, and it can be troublesome, particularly for young runners (103,104). Tenderness is localized to the iliac apophysis, and it is often bilateral (105). Resisted trunk rotation produces pull by the abdominal oblique muscles, and reproduces the athlete's pain. This is different from an iliac contusion or hip pointer, because there is no history of direct injury. The differential diagnosis should include avulsion of one the iliac spines, Perthes disease, slipped capital femoral epiphysis, tumor, and infection. Radiographs are negative in iliac apophysitis. It is a self-limited disorder that improves with rest and training modifications (103,104 and 105). Likewise, apophysitis of the other growth centers about the pelvis are usually innocent problems.

Tendinosis

Overuse injuries of tendons and their surrounding sheaths have been classified into three groups by Puddu et al. (106). Group I tenosynovitis or tenovaginitis is an inflammation of only the paratenon, whether lined by synovium or not. Tendinitis and tenosynovitis often occur together, and it is difficult to differentiate the two clinically. Group II tendinitis is an injury or symptomatic degeneration of the tendon from a resulting inflammatory reaction of the surrounding paratenon. Group III tendinosis involves degeneration of the tendon, caused by aging, accumulated microtrauma, or both. Although tendinitis is much more common in adults, it is seen in younger athletes. Typically, young athletes have tenosynovitis, and occasionally have tendinitis; degeneration and tendon rupture is rare.

Achilles Tendinitis

Inflammation of the Achilles tendon is typically localized 2 to 6 cm above the insertion of the tendon into the calcaneus (107). Contributing factors include overtraining, sudden changes in training, extreme forefoot pronation, poor gastrocnemius-soleus flexibility, and inappropriate training surfaces or shoes (108,109). Tenderness should be localized to the tendon itself.

The differential diagnosis includes calcaneal apophysitis, retrocalcaneal bursitis, symptomatic pump bumps, and symptomatic os trigonum. Radiographs are usually unnecessary, but they may show minor soft tissue changes.

Treatment in young athletes is almost exclusively nonoperative. Training modification, heel lifts, custom foot orthotics, ice, stretching, and oral NSAIDs are used in combination, depending on the individual circumstances. If an underlying training error is identified, educating the patient and parent about the principles of overuse syndromes is helpful for treatment and prevention of recurrence. Immobilization and surgery are rarely indicated in young individuals.

Popliteus Tendinitis

The popliteus resists internal rotation of the tibia during gait (110). Popliteus tendinitis likely results from overuse of the muscle tendon unit, usually caused by excessive forefoot pronation (111). This is exacerbated by running on banked surfaces and down hills (112). There may be additional irritation of the tendon caused by friction as the popliteus tendon courses beneath the fibular collateral ligament.

Young athletes are particularly prone to tendinitis at the beginning of a sport season, when they are often out of shape, inexperienced, and impatient with proper stretching and warm-up exercises. The lateral joint line pain of popliteus tendinitis is typically brought on by activity. Pain may subside during the workout, only to return after practice. Sitting cross-legged exacerbates the pain.

On physical examination, the course of the popliteus tendon along the lateral femoral condyle and beneath the fibular collateral ligament is tender (Fig. 31-7). Joint effusion or ligamentous instability usually is not present (112). Popliteus tendinitis is occasionally associated with clicking, and may simulate a discoid meniscus or iliotibial band friction syndrome. Although typically negative, radiographs should be obtained to exclude any osseous pathology. Occasionally, a small site of ossification is adjacent to the origin of the tendon (112). Magnetic resonance imaging (MRI) may have a role in excluding other sources of symptoms.

FIGURE 31-7. Popliteus tendinitis is most easily detected with the leg in a figure-four position. The popliteus tendon courses from the proximal tibia to the distal femur, passing beneath the fibular collateral ligament. In this position, the lateral collateral ligament is prominent; tenderness is elicited along its anterior and posterior margins, where the tendon passes.

Treatment of popliteus tendinitis consists of “relative rest.” This involves diminishing the running component of training and, for the serious athlete, substituting other activities, such as swimming, cycling, pool running, and weight training (112). NSAIDs and ice massage are helpful. The runner's shoes should be checked for any obvious imbalance related to uneven wear. A foot orthosis may be helpful to control excessive pronation (113). A graduated, progressive running program with proper warm-up and stretching exercises is begun as symptoms resolve. Steroid injection usually is ineffective for this condition, and not recommended in young athletes; steroids are never injected into the tendon itself.

Shin Pain

Shin pain in young athletes accounts for as many as 10% of all athletic complaints (114,115). These problems can significantly interfere with training and performance, but most forms of shin pain have no long-term sequelae. The term “shin splints” has been applied to a variety of symptom complexes characterized by exercise-induced pain in the middle part of the leg (116). Although there may be multiple factors involved in the etiology of this problem, periostitis is the most common source of the pain. Other common sources of shin pain include chronic compartment syndrome, muscle herniation through the fascia, and superficial nerve

entrapment.

The differential diagnosis of shin pain should also include stress fractures, sciatica, deep venous thrombosis, popliteal artery entrapment, varicose veins, muscle strain, tumor, and infection (116). Shin pain in youths should be evaluated for a specific diagnosis, because shin splints are uncommon in patients younger than 15 years of age (117). Radiographs are likely to be positive if the nonacute symptoms are caused by a tumor or infection. If the radiographs are negative, a bone scan may be needed to rule out subtler pathology or stress fractures (118).

Regardless of the cause of pain, patients with shin splints, and most of those with more specific diagnoses for shin pain, often respond to the same fundamental empiric treatment. The first stage of treatment is to diminish inflammation by relative rest, NSAIDs, and the application of ice after activity (119). An isometric strengthening program can be started early, and the athlete advances to progressive resistance exercises as pain permits. Therapeutic modalities such as ultrasound may help. Crutches may be indicated. Casts are seldom used, but a foot orthosis may be appropriate for the patient with an obvious biomechanical abnormality (120). The issues of good shoe wear, training surface, and exercise program should be addressed before running is resumed. Rest and shoe modifications may be the most effective components of this program (121). After the patient is pain-free during walking and strengthening exercises, a graduated running program is begun and monitored closely.

Periostitis

Medial tibial stress syndrome, also called the “soleus syndrome,” is the most common form of periostitis in athletes, and is characterized by localized tenderness over the posterior medial edge of the distal third of the tibia (122,123). About 75% of running athletes with shin pain have posteromedial tenderness (121). The pain probably results from periostitis, which has been documented histologically and by bone scan (118,122,123). The soleus muscle and its investing fascia originate in this area, and are also implicated in causing the syndrome (122).

The pain is bilateral in as many as one-half of the cases (117). Both sexes are equally affected (123). Predisposing factors include muscle weakness, running shoes with a lack of heel cushion, inadequate arch support, and hard running surfaces. Training errors, such as sudden increases in intensity or mileage, are common factors (120). Contributing biomechanical abnormalities include varus hindfoot alignment, excessive forefoot pronation, genu valgum, excessive femoral anteversion, and external tibial torsion (120).

Initially, the pain is related to activity; later, it persists after the activity is stopped. There is no associated numbness. The history should include the intensity of sports participation, training and competition schedule, any recent change in regimen or shoes, and surface training conditions. The localization of pain, intensity, onset, duration, and any associated numbness are important in the differential diagnosis.

The physical examination should include evaluation of gait, leg lengths, sagittal-plane alignment, rotational abnormalities, muscle laxity or tightness, joint motion, and muscle strength (113,120). An attempt should be made to localize the painful site. The only significant physical finding is tenderness localized to the margin of the bone. The discovery of a fascial defect, for example, may indicate that the pain is secondary to muscle herniation. A positive Tinel sign indicates sensory nerve compression. Tenderness transverse across the subcutaneous margin of the bone may indicate stress fracture, whereas tenderness over the muscle compartments during exercise is suggestive of chronic compartment syndrome.

Radiographs occasionally show periosteal new bone. When positive, bone scans demonstrate a diffuse longitudinal area of uptake along the bone, rather than the transverse pattern characteristic of a stress fracture (122). Radiographs and bone scans are indicated when there is a clinical suspicion that symptoms and findings are not typical of periostitis.

If the patient is unresponsive to the usual treatments for shin splints, release of the periosteum localized to the area of pain may provide relief (115,122,124). Surgery should be undertaken only after a substantial attempt at nonoperative treatment has failed (123).

Chronic Compartment Syndromes

In contrast to the acute compartment syndrome, which results from trauma or arterial insufficiency, chronic compartment syndromes are induced by exertion, relieved by rest, and seldom result in tissue necrosis or residual disability (125). The elevated interstitial pressure of chronic compartment syndromes is secondary to inadequacy of the osseofascial compartments to accommodate exercise-induced volume and pressure changes. When compartment pressures exceed capillary filling pressure, the muscle becomes ischemic and produces pain. The anterior compartment is the most commonly involved, although any of the four compartments in the lower leg may be affected (126).

Typically, the patient complains of aching pain, tightness, or a squeezing sensation brought on by and interfering with athletics (126). A history of bilateral symptoms should be specifically sought. After unilateral surgical release, patients frequently increase their activity levels, only to develop pain on the side that had been asymptomatic (126). The pain usually lasts only a short time after exercise. The athlete may experience transient footdrop. Typically, there are paresthesias across the dorsum of the foot, with an anterior compartment involvement or plantar paresthesias with chronic posterior compartment syndrome. Fascial defects with muscle herniation may be discernible over the anterior and lateral compartments (127).

Mubarak et al. pointed out that the symptoms attributed to a chronic deep compartment syndrome frequently are clinically indistinguishable from periostitis (123). Because the physical findings are nonspecific, the diagnosis is made by measuring compartment pressures (128). In chronic compartment syndrome, resting pressures typically are not elevated. With exercise, the pressures rise to 70 to 100 mm Hg, whereas normal compartments rise to less than 30 mm Hg. The degree of compartment pressure elevation correlates with the level of symptoms (124). All compartments should be assessed, because symptoms may not be adequate to identify all involved compartments.

As in any other form of shin pain, initial treatment includes activity modification, orthoses, physical therapy, and time. About one-third of patients find these efforts to be helpful. Definitive treatment involves fasciotomy, which can be performed by a variety of techniques. All involved compartments should be released. This can be done through limited skin incisions, rather than through the extensive releases suggested for adequate management of the acute traumatic compartment syndrome (125,126,129,130). Care must be taken to protect the saphenous vein, saphenous nerve, and the superficial branch of the peroneal nerve (130).

A success rate of at least 90% can be expected with surgery. Failure can result from not recognizing, preoperatively, that multiple compartments can be involved; from inadequate decompression, especially of the deep posterior compartments; and from excessive scar tissue response (126,130). Few patients require repeat compartment releases (126,130). Recurrence secondary to excessive scarring is best treated by fasciectomy, although this is not recommended as the primary procedure, because it may reduce strength (126).

Muscle Herniation and Superficial Peroneal Nerve Compression

Styf's series of 90 patients with exercise-induced anterior leg pain included 13 patients with documented compression of the superficial peroneal nerve (117). Compression of this nerve can be caused by increased muscle pressure within the compartment during exercise. Muscle herniation through a fascial defect, entrapping the nerve, may also produce these symptoms. Patients typically experience diminished sensation over the dorsum of the foot with exertion, and they have point tenderness where the nerve exits the compartment. Nerve conduction velocities can help confirm the diagnosis, but one-half are normal at rest and require exercise testing for documentation of this problem (117).

Ischemia of the entrapped tissue in cases of muscle herniation has been theorized to cause shin pain during activity. This may occur in as many as 60% of chronic compartment syndromes (127).

Limited fasciotomy is performed for persistently symptomatic peroneal nerve compression or muscle herniation. Specific attention should be directed to the exit point of the superficial peroneal nerve to ensure it is free (125).

Iliotibial Band Friction Syndrome

Iliotibial band friction syndrome is an overuse phenomenon caused by the iliotibial tract rubbing over the lateral epicondylar prominence during repetitive knee motion (131,132). Although most commonly seen in adult distance runners, adolescents involved in recreational and team sports also can be affected (133). Iliotibial band friction syndrome is more common in males.

Symptoms typically commence at the beginning of sports training session. Two-thirds of cases are associated with a recent increase in running intensity or distance (134). The athlete complains of pain over the lateral aspect of the knee, especially during running or cycling, and the pain occurs with every knee flexion (135). Usually, there is no history of injury or mechanical symptoms, such as locking or catching.

Typical physical findings include genu varum, external tibial torsion, pes planovalgus, and pes cavus (133,134 and 135). Slight swelling may occur if a bursitis develops, but there usually is no joint effusion. Tenderness extends from the lateral epicondyle to the joint line from the anterior to posterior margins of the condyle. Frequently, there is a contraction of the iliotibial band that can be detected by the Ober test (Fig. 31-8). This maneuver reproduces pain and demonstrates restricted adduction.

FIGURE 31-8. The Ober test is used to detect tightness of the iliotibial band. With a patient lying on his or her side, the hip is first abducted and extended, with the knee held flexed. The test is then performed by attempting to adduct the knee to the midline. Palpation along the lateral femoral epicondyle typically elicits tenderness at this site, if iliotibial band friction exists.

Radiographs are normal. The differential diagnosis includes lateral meniscus tear, discoid lateral meniscus, stress fracture, popliteus tendinitis, biceps femoris tendinitis, and patellofemoral pain syndrome (136). These usually can be differentiated by careful history and physical examination.

Initial treatment involves relative rest or a change in training habits, ice massage, NSAIDs, and a rigorous iliotibial band–stretching program (135,136 and 137). This condition may take 6 weeks or more to resolve (132,133). Foot orthoses are often helpful, particularly if an alignment abnormality exists. Extraarticular steroid injection may help recalcitrant cases (134), In young athletes, surgical release of the distal iliotibial band and excision of the bursa rarely are required (135,136).

Breaststroker's Knee

Competitive breaststroke swimmers are prone to develop medial knee pain along the course of medial collateral ligament, medial facet of the patella, and the plica (138,139). The whip-kick technique, which is a more powerful modification of the frog kick, has certain variations that are strongly implicated in the cause (138). This condition may begin in the first few years of competitive swimming, and may occur in swimmers as young as 6 years of age (138), although the frequency is related to increasing age of the swimmer, increasing years of competitive swimming, increasing breaststroke training distance, and decreasing warm-up time (140,141). Other than medial knee tenderness, there are no other consistently associated physical or radiographic findings.

Initially, the symptoms are reversible with rest or training alterations, although with time, chondromalacia and medial facet patellar arthritis may occur (138,139,140 and 141). Measures to quiet inflammation of the medial plica, such as ice, NSAIDs, and phonophoresis, may help (141). Most important is altering the swimmer's whip-kick technique, particularly by keeping the legs together during the recovery and rapid extension phase of kicking (138). Arthroscopy is only occasionally indicated, because it typically shows medial synovitis without other significant derangements; it is only occasionally indicated (142).

Valgus Overload Injuries of the Elbow

The most commonly affected athletes are baseball players (particularly pitchers), gymnasts, American football quarterbacks, and potentially, other throwing and racquet sport athletes (143,144). Such activities can lead to a variety of abnormalities of the capitellum, radial head, and medial epicondyle (145).

During the throwing and racquet motions, a significant valgus moment is generated at the elbow (Fig. 31-9). The result is excessive and repetitive compression forces through the radiocapitellar joint, and tension across the medial epicondyle and collateral ligaments. Collectively, these are referred to as Little League elbow.

FIGURE 31-9. Pitching produces a valgus moment (*large curved arrow*) at the elbow. There are compressive forces (*straight arrows*) across the radiocapitellar joint, and tension (*curved arrows*) across the medial epicondyle and medial collateral ligament.

Osteochondral Lesions of the Capitellum

Primarily based on age, repetitive use lesions of the capitellum can be divided into Panner disease and osteochondrosis of the capitellum.

Panner described a lesion of a young boy's capitellum that he compared with Legg-Calvé-Perthes disease (146). In children younger than 10 years of age who have Panner disease, the course is usually benign (147,148). The entire ossific nucleus of the capitellum may demonstrate irregular ossification, but an osteochondral loose body does not form. The lesion completely resolves with reconstitution of the capitellum.

Adolescent baseball pitchers and gymnasts can develop fragmentation of the capitellum's subchondral bone and dislodgment of the articular surface. Based on the belief that a low-grade inflammatory process was responsible, Franz Konig called this condition “osteochondritis dissecans.” Histologically, there are no inflammatory

cells present, so the term “osteochondrosis” is more appropriate (143,149).

The causes of Panner disease and osteochondrosis of the capitellum are unknown. The two entities may represent the same process in persons of different ages, but the course and prognosis contrast sufficiently to consider the disorders separately. Heredity may be a factor (143). Repetitive microtrauma frequently occurs in throwing athletes, and disturbance of the blood supply has also been implicated. By 8 years of age, the capitellum's vascularity is solely from a group of end vessels (150). These vessels traverse the chondroepiphysis posteriorly, with no significant collateral contribution. Upon closure of the physis, the blood supply of the epiphysis and metaphysis becomes interconnected (143).

Patients with Panner disease and osteochondrosis of the capitellum typically complain of pain with throwing. Tenderness is maximal over the radiocapitellar joint, and there may be crepitus. The elbow typically lacks 10 to 20 degrees of full extension, and flexion is mildly limited (147,149).

Initial assessment should include bone detail radiographs with anteroposterior, lateral, and oblique views. There is irregular ossification of the capitellum and rarefaction within a crater (79,147) (Fig. 31-10A). Tomograms or computed tomography (CT) scans are occasionally helpful to better define bony pathology (Fig. 31-10B). Loose bodies may be present. Arthrograms are unreliable for cartilaginous loose bodies, because filling defects related to synovial convolutions can lead to false-positive studies. False-negative results can occur if the loose bodies are completely enveloped by synovium or hidden in joint space recesses (149).

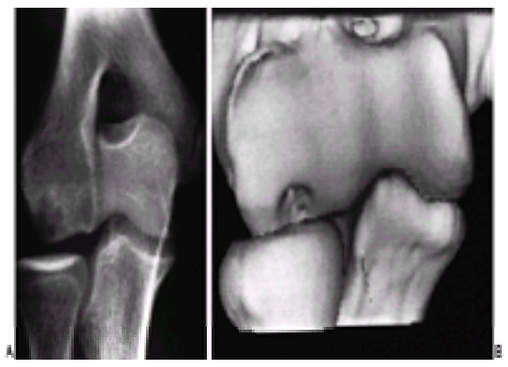

FIGURE 31-10. Osteochondral lesion of the capitellum in a 15-year-old baseball player with a painful elbow. **A:** The subchondral plate of the capitellum appears intact. Subchondral cysts are present. **B:** The computed tomography scan with three-dimensional reconstruction demonstrates the bony defect of the capitellum, including loss of the subchondral plate in that area.

Initial treatment should include restriction of forceful upper-extremity activities, application of ice, and NSAIDs. A sling or splint is occasionally needed (144). It may take 6 or more weeks for the pain to subside, at which time range of motion and strengthening exercises are begun.

After almost full and pain-free range of motion with good strength is achieved, a graduated and well-supervised program for returning to upper-extremity activity is initiated. Throwing technique should be reviewed to minimize unnecessary valgus load to the elbow. The prognosis for return to competitive pitching, however, is guarded (144,147). Baseball players should be switched to a position, such as the infield, that requires less throwing. For gymnasts, particularly stressful maneuvers or “tricks” are modified from their workout, and most can continue to participate.

The athlete is monitored for recurrent symptoms. Radiographs may remain abnormal, and symptoms are followed closely. Activities are gradually advanced, and readjusted if pain recurs (143). Persistent difficulty should prompt further investigation for a loose body or a chondral flap in the articular cartilage. In this situation, given the indeterminate reliability of CT and MRI, arthroscopy may be the most prudent next diagnostic step, and offers the advantage of being potentially therapeutic.

Indications for surgery include a locked elbow, a symptomatic intraarticular loose body, or failure of nonoperative program to adequately diminish pain and restore motion (144,149). Whether open or arthroscopic surgery is performed, loose bodies should be searched for carefully (151). Flaps of articular cartilage from the surface are debrided, because loose chondral fragments produce synovial inflammation (152). Bone grafting and internal fixation of the fragment are rarely indicated, because most procedures other than simple excision have been unfavorable in the elbow (144,147). Drilling of the base of the defects may stimulate a fibrocartilaginous response; however, the advantage of drilling over simple debridement of the lesion is not well documented (144).

The prognosis for the more advanced lesions is less favorable. After surgery, many athletes are unable to resume their prior levels of competitive throwing (144,149).

The most important lesson about this condition is the opportunity for prevention. Junior baseball programs should all have rules limiting the duration that a youngster pitches. Typically, this is a maximum of three innings per game and up to six innings per week. Training and practice are difficult to regulate, making it essential to educate parents, coaches, and physicians about this condition.

Osteochondral Lesions of the Radial Head

Osteochondral lesions of the radial head are much less common than those of the capitellum (153,154). Most patients are boys between 8 and 15 years of age (153). Because repetitive valgus loading occurs, the mechanical stress of throwing is implicated as the cause. Because osteochondrosis of the radial head is an uncommon problem, a more generalized disorder should be considered (153). Radiographs should be obtained of the other elbow, and if abnormal, a radiographic survey should be done of the other major joints. The treatment principles are similar to those for symptomatic lesions of the capitellum.

Injuries of the Medial Epicondyle

Traction on the medial elbow structures is the counterpart to radiocapitellar compression during valgus stress. With excessive throwing, the medial epicondyle may become prominent and intermittently painful. Active adolescent baseball players frequently develop accelerated growth, and widening of the medial epicondylar apophysis and fragmentation of the medial apophysis (154). The prognosis is excellent, with the pain usually resolving after rest (148).

Avulsion of the medial epicondyle can occur with forceful throwing. This results from the tension forces exerted by the ulnar collateral ligament and the pull of the forearm flexor muscles. If the elbow is stable and the fragment is minimally displaced, the elbow is immobilized for 3 weeks, after which range of motion is begun, and the athlete is gradually returned to activity.

Significantly displaced fractures probably should be repaired. Elbow instability can be disabling to throwing athletes, wrestlers, and gymnasts (155). If there is question of valgus instability, a stress radiograph should be obtained (156). Other standard indications for internal fixation include intraarticular incarceration of the fragment and ulnar nerve dysfunction (156).

SPORTS TRAUMA

Epidemiology

The number of youth sports participants, the amount of coaching, the intensity of training, and the level of competition are increasing. Injuries are inevitable, and parents often seek advice regarding the risk of injury from sports participation, particularly contact sports. Most trauma in children occurs from activities such as running, tree climbing, and skate boarding (157). Organized sports account for only about one-third of sports injuries, with the remainder occurring in physical education classes and nonorganized sports (11,158).

In youths 5 to 14 years of age, the sports related to the most total injuries, in order of frequency, are football, baseball, basketball, gymnastics, other ball sports,

soccer, wrestling, volleyball, and ice hockey (3,159). When injury data are adjusted for the number of participant hours, the general trend is for American football to be the highest-risk sport, followed by basketball, gymnastics, soccer, and baseball (157). Injuries occur most frequently in contact sports. Each year, as many as 20 to 40% of high school football players are injured; however, about 75% of these injuries are minor, resulting in a loss of fewer than 7 days of participation (160,161 and 162). The risk of injury in sports must also be weighed against the risk in normal activities. As many as one-third of junior sports participants are sidelined by injuries they sustained outside of their sports program.

Although it may intuitively seem that the younger child is at greater risk in contact sports, the converse is true, with fewer injuries occurring among younger athletes. Soccer, for instance, results in injuries to about 3% of players in elementary school, 7% in junior high school, and 11% in high school (7,163).

In junior American football programs (9 and 15 years of age), the incidence of injury is only 2%. Of an estimated 463,000 football-related injuries treated in 1980, 37% occurred in 5- to 14-year-old children, and 63% occurred in athletes 15 years of age and older (3). Most injuries are mild, with about 10% resulting in hospitalization, 15% requiring minor procedures, and 2% needing reconstructive surgery (164,165).

Contusions, sprains, and simple fractures of the upper extremity account for most injuries in younger athletes (164,165). Teenagers have more lower-extremity trauma, with the knee injuries being common and the knee reinjury rate being as high as 25 to 60% (160,161,166,167).

Tragic injuries do occur occasionally in youth sports. The U.S. Consumer Product Safety Commission reported that almost 1.8 million sports-related, medically attended injuries occurred in 5- to 14-year-old children from 1973 through 1980. Of these, 93 were fatalities. Baseball accounted for 40 deaths, with most related to bat or ball blows to the chest or head. Football resulted in 19 fatalities, almost all secondary to head and neck injuries. Surprisingly, golf was related to 13 deaths, with 11 children being struck by clubs and 2 with balls. Many of these children were not actually participating in golf at the time; they were struck by an adult who was playing or by a playmate. Eight children were killed by equipment falling on them, including four soccer goals, two football goal posts, one baseball backstop, and one trampoline (3).

Prevention

Although the prevention of all injuries related to sports participation is not realistic, the rate and severity of injuries can be reduced significantly. Many sports injuries can be avoided or ameliorated with conscientious supervision, appropriate rules, safe equipment, and adequate rehabilitation of injuries (2,158). Stretching and warm-up exercises are key components of injury prevention, although the scientific basis of these standard training techniques are just starting to be understood (39,168). Because there is significant individual variation in body types, accurate and specific advice is still evolving (169,170 and 171). A preseason conditioning program, consisting of warm-up, stretching, running, weight training, and skill development, appears to have a positive impact on preventing injuries, especially in collision and contact sports (172).

Medical evaluations are commonly required before young athletes are allowed to participate in sporting programs, particularly on the interscholastic level. This is often done through a preparticipation screening evaluation. The principle is to identify young athletes at high risk for sports-related injuries or illness. Unfortunately, there is no consensus of opinion regarding the components of an optimal screening program (173). The yield of identifying disqualifying conditions is low on initial sports screening examinations, and becomes even lower on repeated examination (4,174). Although the cost of doing such screening may appear minimal at first look, unnecessary exclusions and referrals can result in a significant health care cost (175).

To produce a favorable cost–benefit ratio, the screening process must focus on the relevant history and pertinent physical examination. Medical history is the most sensitive and specific component. The history should include prior musculoskeletal injury, neurologic injury, infectious disease, and cardiopulmonary problems. Questions related to general health, immunization status, hospitalizations, and limitations of function are helpful. Athletes should be specifically asked about prior history of concussion, unconsciousness, paresthesias, and prior musculoskeletal treatment or rehabilitation (173). Syncope can be an important clue to undetected heart disease, specifically, idiopathic hypertrophic subaortic stenosis, which is one of the most common causes of sudden death in young athletes (176). Despite conscientious screening, this uncommon but tragic event is not completely preventable. Athletes and parents should always be informed that screening cannot ensure detection and prevention of all problems.

The general medical examination should include blood pressure measurement, cardiopulmonary examination, and review for any contagious skin lesions (177). Ideally, a dynamic evaluation of recovery after exercise should be performed, but this is usually impractical (178).

Since inadequate rehabilitation probably accounts for almost one-fourth of sports-related injuries in children, the musculoskeletal examination should focus on prior injuries and any residual problems from them (4). A screening examination of the ankles, knees, and neck range of motion should be included for all athletes, and other areas of the musculoskeletal system should be examined, based on the individual's prior history.

Evaluation of athletic performance, joint laxity, and visual acuity are optional components. Otoscopy, ophthalmoscopy, and hernia evaluations are probably unnecessary. Routine laboratory testing does not appear to be cost-effective (4,173,174).

Athletic Trainers

Athletic trainers have been caring for sports injuries since ancient times. The education, ability, and role of athletic trainers have evolved considerably since the founding of the National Athletic Trainers' Association in 1950. These allied health professionals have rigorous credentialing requirements. They can provide valuable help in recognition, initial management, triage, prevention, and rehabilitation of athletic injuries. Used effectively, athletic trainers are liaisons between physicians and athletes, and provide important educational information for athletes, partners, and coaches.

Although they are widely used for college and professional sports programs, it is estimated that only about 10% of the U.S. high schools have certified athletic trainers (160). An estimated 636,000 injuries occur annually among American high school football players. Half of these occur during practice, when physician medical coverage is seldom available (160). Many injuries can be prevented through safe equipment, proper supervision, appropriate instruction, training, and injury rehabilitation (2,3,158). To take advantage of this opportunity, the involvement of certified athletic trainers in high school and other youth sports programs should be strongly encouraged.

Ankle Injuries

Ankle Sprains

Ankle sprains are among the most common injuries in sports. They occur in approximately 6% of all high school sports participants, and in as many as 70% of all high school basketball players over the course of 4 years of participation (179). Most ankle sprains involve the lateral ligaments. Approximately 3% of sprains are medial, with wrestling being the only sport that is associated with a significant number of these (179,180). Inversion and supination injuries sequentially tear the anterior ankle capsule, the anterior talofibular ligament, and the calcaneofibular ligament (181,182). Although most ankle sprains are minor, one-third of these injuries lead to more than 2 weeks of disability (183). For severe ankle sprains, a minimal intervention approach is not universally favorable, and treatment does have a positive impact (184,185).

For the purpose of this discussion, the following classification is used:

Grade I: mild sprains involve stretching and minimal interstitial tearing of the ligament, with little swelling, limp, and disability.

Grade II: moderate sprains involve partial disruption of the ligaments, with modest swelling, diffuse tenderness, and difficulty with weightbearing.

Grade III: severe sprains result in complete ligament disruption, often with extensive bleeding swelling, instability, and disability.

Knowing the mechanism of injury may be helpful. The common lateral ligament complex sprain usually results from an inversion injury, whereas anterior tibiofibular sprains (high ankle sprains) typically result from a dorsiflexion injury. Recollection of a popping sensation varies, but a history of prior ankle injuries is important for the

assessment of acute or chronic instability.

If the patient is first seen after considerable swelling has developed, it may be difficult to localize the tenderness. Examination of the acute injury should be directed toward pinpointing the maximally tender structures. The entire length of the tibia and fibula should be inspected, with specific attention to the area of the physeal plates. Gentle percussion of the physis and epiphysis by the examiner's fingertip is a useful technique for differentiating physeal fractures from ankle sprains. A more reliable assessment of tenderness and stability can often be achieved after several days of rest, ice, elevation, and compression.

The anterior drawer maneuver primarily tests the stability of the anterior talofibular ligament complex. This can be performed by securing the distal leg with one hand and applying an anterior pull on the heel, with the foot held in gentle plantar flexion (Fig. 31-11A). Alternatively, with the patient supine on a table, and with the knees flexed about 90 degrees, a posterior force is applied to the lower leg while the foot is held flat on the table top (Fig. 31-11B).

FIGURE 31-11. The anterior drawer test of the ankle is used to evaluate stability of the anterior talofibular ligament. **A:** The heel is pulled anteriorly, with the foot held in gentle plantar flexion. Counter force is applied at the tibia. **B:** Alternatively, the foot is held firmly on a table top, with the hip and knee flexed at 90 degrees, and posterior force is applied to the lower leg.

Routine views of the ankle should include anteroposterior, lateral, and “mortise” views. Clinical judgment ultimately dictates the decision to obtain radiographs. For adults, tenderness along the posterior edge of malleoli, or inability to bear weight, are reliable indicators to prompt ankle radiography. Although not as well studied in youths, similar criteria probably apply. Tenderness over the navicular, cuboid, and base of the fifth metatarsal should prompt additional views of the foot (186).

The indication for other studies depends on the index of suspicion for injury, and treatment philosophy. Anteroposterior or lateral view stress radiographs are intended to demonstrate ligamentous laxity (187). Unfortunately, the reliability is affected by individual variation, timing, muscle spasm, the patient's pain tolerance, foot position, and variability of manual technique (188). Even with an apparatus and local anesthesia, the overlap between normal and abnormal is considerable (189). Ankle arthrography can reliably detect anterior talofibular and calcaneal fibular injuries, although the clinical relevance is unproven (190).

If subtalar motion is limited after resolution of the acute injury, radiographs of the foot should be obtained to look for tarsal coalitions. The athlete's risk for recurrent ankle sprain is increased by the presence of a coalition (191).

The primary differential diagnoses include physeal fracture of the distal fibula, triplane fracture, osteochondral fracture of the talus, subluxation of the peroneal tendons, fracture of the base of the fifth metatarsal, sprains of the midfoot ligaments, and Maisonneuve fracture (181). Accessory ossification centers, at the tip of the medial and lateral malleoli in youths, should not be confused with avulsion fractures (192). Localization of maximal tenderness and radiographs can differentiate most of these.

Nondisplaced Salter-Harris type I physeal fracture of the distal fibula is the most commonly occurring problem that closely imitates an ankle sprain. Fingertip percussion over the physeal plate usually differentiates the two; in cases of fracture it is distinctly positive. If doubt remains, immobilizing the ankle in a cast for 3 weeks adequately treats the fracture, without being overtreatment of a sprain.

Although treatment of ankle sprains varies considerably, a few sound principles have evolved (193). Sprains are initially treated with rest, ice, compression, and elevation (R.I.C.E.). The goal of the initial treatment is to limit bleeding, edema, and any further soft tissue injury. Ideally, these occur at the time and site of injury. After the degree of injury is determined, an appropriate course is planned. Each progressive step of the rehabilitation is based on functional goals, rather than an arbitrary calendar (194).

A grade I sprain is a minor injury. The pain usually resolves, and motion returns in less than 1 week (195). In some cases, the athlete may be able to return almost immediately to sports competition. The athlete must have minimal pain and be able to run, cut, and perform specific tasks relevant to the activity to which he or she is about to return.

Supporting the ankle by taping, a laced stabilizer, or a semirigid orthosis facilitates early return and diminishes the risk of recurrent injury (196,197). Taping restricts extremes of ankle motion and shortens reaction time of the peroneal muscles, probably by affecting the proprioceptive function of the ankle (198). The lace stabilizers and semirigid orthotics may offer an advantage over tape, which loosens after a short period of exercise (197,199,200).

Grade II sprains involve more extensive tissue injury and result in an average of 2 weeks of disability (195). Crutches are often helpful for several days, as weight bearing is progressively increased. For the athlete concerned about an early return to sports, early phases of a supervised rehabilitation program should be directed toward diminishing the swelling and regaining motion. Initially, ice pack and intermittent compression boots are useful modalities (201). Isometric exercises are started immediately, and progressive resistance exercises are subsequently introduced. Satisfactory strength of all muscle groups, particularly the peroneals, must be restored to ensure dynamic protection from a repeat injury. Proprioceptive training may be helpful as well (202).

For the serious athlete, aerobic conditioning is continued during rehabilitation by swimming, using an upper body ergometer, running in a pool, or cycling. Upper body conditioning is continued. The use of ankle supports in grade II sprains is the same as that for a grade I sprain.

Treatment of grade III sprains remains the most controversial. Options include taping, casting, and surgical repair. Tape and immediate motion theoretically minimize stiffness. Treatment with a dorsiflexion cast reduces the talus in the mortise, and theoretically reapproximates the torn ligament fibers to their premorbid location (183). Advocates of surgical treatment feel that other soft tissues may prevent anatomic reduction of the torn ligament fibers, especially if there is an associated bony fragment. Most series reporting surgical outcomes report no difference over immobilization and therapy protocols, or they fail to have an adequate control group to demonstrate a clear superiority of one treatment approach over another (184,203,204).

The author prefers to treat grade III sprains initially with a posterior plaster mold and compression dressing. This controls the initial hemorrhage and swelling. In 7 to 10 days, as swelling starts to resolve, the patient is placed in an articulated ankle orthosis (164). This permits plantar flexion and dorsiflexion but protects against inversion and eversion. An intermittent compression boot device and other physical therapy modalities are used to reduce swelling. Weight bearing progresses as tolerated. The rehabilitation program is advanced in the same fashion as outlined for grades I and II sprains. The orthosis is used continuously for 8 weeks. The athlete may return to competition wearing the device, if pain-free motion and adequate strength have been regained. This typically occurs 4 weeks after injury (205).

Recurrent severe sprains occasionally lead to chronic ligamentous laxity. A variety of reconstructive procedures are available, but are uncommonly needed in youths (206,207). Results of delayed reconstruction are comparable to primary surgical repair, further supporting the approach of nonoperative treatment of most ankle sprains, particularly in young athletes (208).

Anterolateral Ankle Impingement

After ankle sprains, chronic anterolateral ankle pain occasionally develops, because of impingement of the anterior inferior tibiofibular ligament or the synovium in that area (209,210). Tenderness is localized along the anterolateral corner of the joint. Some patients experience popping with dorsiflexion of the ankle. Radiographs are normal. MRI may be helpful to rule out other sources of pain, such as osteochondral injuries and subtalar pathology. Occult instability of the ankle and subtalar should also be considered.

Rest, immobilization, NSAIDs, and physical therapy modalities may be tried to reduce the symptoms (211). Injection of local anesthetic and a steroid can be both diagnostic and therapeutic. If pain persists, arthroscopic inspection debridement of the reactive synovium and resection of the inferior fibers of the tibiofibular ligament should resolve the problem, unless significant instability exists (209,210).

Distal Tibiofibular Sprains

Isolated injuries of the distal tibiofibular syndesmosis are uncommon, but need to be recognized (212). These may be associated with injury of the deltoid ligament. Pain and tenderness are located principally at the anterior aspect of the syndesmosis and interosseous membrane. Tenderness is elicited by squeezing the tibia and fibula together, and by dorsiflexing and externally rotating the foot at the ankle (186,213). Radiographs occasionally demonstrate an osseous avulsion. The CT scan and bone scan are occasionally helpful in demonstrating occult degrees of injury to the tibiofibular ligament complex (214).

Sprains of the distal tibiofibular ligament and syndesmosis are usually treated nonoperatively, with rehabilitation principles similar to those for lateral complex sprains (215). The athlete should be aware that the recovery process is typically twice as long as for a severe ankle sprain (213). Impingement of the ankle joint created by disrupted fibers can cause chronic pain (210). Occasionally, immediate surgical repair or reconstruction of the syndesmosis becomes necessary if there is significant diastasis (215).

Knee Injuries

Collateral Ligament Injuries of the Knee

Ligaments of the knee originate from the distal femoral epiphysis, and insert into the proximal tibial epiphysis, with the exception of the superficial portion of the medial collateral ligament, which inserts into the proximal tibial metaphysis distal to the physeal plate (216) (Fig. 31-12). The ligaments are generally stronger than the physeal plates, so significant bending injuries usually produce physeal fractures, although pure ligament disruption can occur in children. Complete rupture of the medial collateral ligament has been reported in children as young as 4 years of age (217,218 and 219). The results after these injuries are favorable in children and adults.

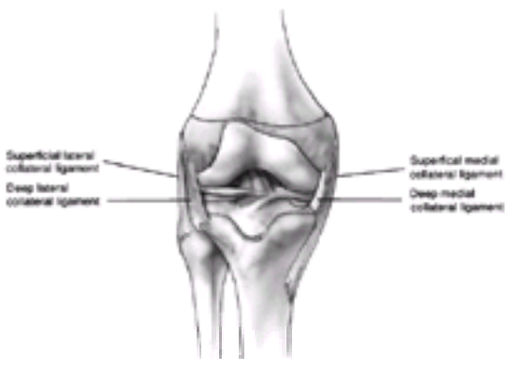

FIGURE 31-12. The collateral ligaments of the knee insert into the epiphyses, with the important exception of the distal insertion of the superficial medial collateral ligament. Bending injuries of the immature knee typically disrupt the physeal plates, which are usually the “weak link in the chain.”

The grading of collateral ligament sprains requires comparison of the injured with the uninjured knee, because the normal degree of laxity varies considerably. A mild sprain (grade I) has little or no disruption of the ligament's mechanical integrity and no increased laxity on examination. Moderate sprains (grade II) result in plastic deformation of the ligament without complete disruption; the examination demonstrates increased laxity, but there is a distinct end point. Severe sprains (grade III) are complete ligament disruptions, resulting in significant laxity, and do not have distinct end points (220).

The history of injury obtained from youngsters is often poor, so the examination must be relied on heavily. Often, tenderness can be localized to the physeal plate or to the path of the collateral ligaments themselves. The collateral ligaments are tested with the knee flexed 20 to 30 degrees, to relax the posterior capsule and posterior cruciate ligament (221). The joint line should be palpated while varus and valgus stresses are applied. Standard radiographs are obtained to look for physeal fractures or bony avulsions.

If there is instability, a stress radiograph must be obtained to differentiate opening of the joint space, because of severe sprain, from motion through the bone, because of an unstable physeal fracture. If an effusion is present in the knee, it can be aspirated, and the area can be infused with a local anesthetic to facilitate the examination.

If a hemarthrosis is detected, a cruciate ligament injury should be suspected. MRI is very useful for defining the injury.

Isolated collateral ligament sprains in the knee are treated according to the degree of injury, and by the same principles that are established for adults. Definitive studies of collateral ligament sprains in children are not available. All partial tears are treated nonoperatively. Most sprains are immobilized only until pain subsides (222). Sports are resumed when there is full motion, good muscle strength, and ability to run, cut, and perform necessary sport-specific activities (220,223,224). The use of these functional criteria is particularly helpful for the adolescent athlete who is anxious to return to sports. Grade I sprains result in an average of 10 days lost from activities, and grade II sprains average 20 days (225). For grade III collateral ligament sprains to the knee, the same rehab principles are applied. The recovery is slower than more mild sprains. Residual laxity is generally well tolerated. Double-upright, hinged functional braces provide medial stability, and therefore have a logical role in the protection of more severe medial collateral ligament sprains as they heal (226).

Although a few studies have suggested operative treatment for grade III collateral ligament sprains of the knee, isolated injuries in adults appear to have good clinical results without surgery (227,228 and 229). Successful nonoperative treatment is predicated on establishing that the grade III sprain is isolated. Concomitant meniscal tears or an anterior cruciate disruption must be considered.

Bony avulsions of the collateral ligaments are best managed operatively (218).

Anterior Cruciate Ligament Injuries

Anterior cruciate ligament (ACL) injuries occur far less commonly in children than in adults. Throughout adolescence and young adulthood, these injuries become more frequent. The principles of evaluation and treatment are very similar to those used for adults, although the specifics must take into account the open physes and high activity level of youngsters.

In children, the collagen fibers of the ACL blend from ligament to perichondrium to epiphyseal cartilage. Adult ligaments insert directly into bone by means of the Sharpey fibers (230). This difference probably accounts for the childhood tibial eminence avulsion fracture, which usually spares the ligament itself, although interstitial tears of the ACL can occur in children. Midsubstance disruption has been reported in a 3-year-old child (231). Avulsion of a bony fragment from the femoral attachments occurs less often, and rarely from both ends of the ligament (232,233). Avulsion from the distal insertion through the chondral–bony interface also may

occur.

Fractures of the distal femoral and proximal tibial physes have a significant incidence of associated ligament injuries (234). The presence of a physeal fracture of the knee does not preclude ligament damage, so ACL injury can easily be overlooked.

Meniscal tears are commonly associated with ACL sprains (235,236). Evaluation of the menisci by MRI may be useful, particularly if nonoperative treatment is being considered (237).

The history of injury in the adolescent is usually one of hyperextension, direct blow, or sudden twisting in the open field or court. Occasionally, a pop is heard, and the early onset of swelling caused by hemarthrosis is common (236). The younger child is typically a poor historian of the event. As in tibial eminence fractures, bicycle accidents commonly cause ACL injuries in children (238,239). The amount of initial pain is variable, with discomfort lasting over the ensuing days. Instability may be noticed if the youngster attempts to return to play.

The physical examination typically reveals effusion, diffuse tenderness, and limited motion. Although the anterior drawer test has been the classic test of anterior cruciate stability, the Lachman test and pivot–shift signs are felt to be more sensitive and specific (221,240,241). Instrumented knee laxity testing is useful, if the physical examination is equivocal (242). The degree of inherent or congenital laxity must be considered in grading these tests, particularly for children. The other knee can usually provide a control against which the injured extremity is compared.

Routine anteroposterior and lateral radiographs of the knee are obtained, to look for osteochondral fractures and physeal fractures. A tunnel view may show bony fragments avulsed from the femoral origins of the cruciate ligament. A hypoplastic intercondylar notch, with a diminished tibial spine, is a sign of congenital absence of the cruciate ligaments (243,244).

MRI is fairly reliable for identifying injuries of the ligaments, menisci, and cancellous bone. Most clinically significant ACL injuries are adequately diagnosed by history and manual examination, so the indications for MRI must be weighed against its cost (245,246 and 247). Imaging studies are most valuable if management decisions will be influenced by the results. MRI is particularly useful if the presence of an associated injury, such as a meniscal tear, is going to influence the decision to operate. If a reconstruction is already decided on, the menisci can be evaluated at the time of arthroscopy.

The natural history of ACL tears in adults depends on patient age, activity level, expectations, degree of instability, ability to rehabilitate muscle strength, and the patient's resolve to modify activities as needed (248,249 and 250). Similarly, the decision to stabilize a young person's knee must be individualized, and the risk of reinjury, leading to subsequent damage of the menisci should be given strong consideration (251). Most should be reconstructed.

Left unstabilized, complete ACL disruption and instability generally have unfavorable results. Of McCarroll et al.'s 16 patients treated without reconstruction, nine gave up their sport because of instability. Each of the remaining seven had episodes of instability; four of them had multiple reinjuries, recurrent effusions, and pain (252).

Young athletes with partial tears (grade II, using the system previously defined for collateral ligament sprains of the knee) of the ACL can be treated without surgery, if there is no significant meniscal pathology. This usually is successful, if the knee does not demonstrate significant instability on examination. The examination is most accurately done under anesthesia with arthroscopy, to document the instability, degree of ACL disruption, and associated meniscal tears. The knee should be soundly rehabilitated before returning to sports. A functional brace is probably indicated. If instability with episodes of subluxation and pain develop, or if there is a subsequent injury, steps need to be taken to prevent further injury, especially to menisci. The activities must be substantially modified or the knee surgically stabilized.

For complete ACL tears, nonoperative treatment is an option, particularly if the physeal plates are open and the patient is relatively inactive. However, children and adolescents tend to be active, rambunctious, and poorly attentive to rehabilitation. Despite the guarded prognosis, nonoperative treatment is occasionally selected in very young patients with substantial growth ahead. Healing of complete midsubstance ACL disruptions is apparently no more favorable in youths than in adults, and primary suturing, as an isolated procedure, is minimally effective (217,253,254 and 255).

Numerous braces have been developed with the intent of protecting the ligaments of the knee. The first were functional braces that had double-upright knee hinges. Although the hinges, strapping, brace fitting, and materials have evolved considerably, the stability imparted by these braces is marginal. Braces may prevent hyperextension injury, but rotational control is poor, and therefore raises doubt about the overall efficacy. A simple upright “prophylactic” brace was developed as a less cumbersome measure to protect uninjured athletes. Most well-designed studies have failed to demonstrate any statistically significant effect of these lateral stabilizing knee braces (256,257).

For the skeletally mature adolescent, the indications for standard reconstructive techniques used for adults apply.

The remaining growth is best evaluated in adolescents by bone age (258,259). Because little growth occurs during the last year that the physes are open, the risk of growth arrest complications are minimal.

Several techniques for reconstruction of the ACL can be considered in patients with open physes. Although extraarticular procedures avoid the physeal plates (252,260,261), they are probably not adequate to prevent a significant pivot shift and thereby protect the menisci (252,260,261 and 262). Intraarticular procedures more accurately reproduce the anatomic and biomechanical properties of the ACL, and prevent subsequent loosening (263). Most intraarticular ACL reconstructions involve crossing the physeal plates. The potential complications of shortening or angular deformity are particularly worrisome in the knee region, because approximately 65% of the leg's growth occurs from the combined distal femoral and proximal tibial physeal plates (264). Complications are uncommon in reported series of intraarticular reconstructions of patients with open physeal plates; however, caution must be used in extrapolating these data to significantly younger patients (252,265).

For the active adolescent with open physeal plates and more than 1 year of growth remaining, the author thinks a semitendinosus and gracilis graft makes the most sense. Drilling a hole across the physis, and filling it with a soft tissue graft is analogous to resecting a physeal bar. If a central bridge does occur in the proximal tibia of an adolescent, it is unlikely to produce an angular deformity or functionally significant shortening. The primary concern rests with the femoral tunnel, because the distal femoral physis has the most rapid growth in the lower limb, and the eccentric location of the resulting physeal bar could lead to a significant angular (valgus) deformity. This is still a controversial area.

Posterior Cruciate Ligament Injuries

Posterior cruciate ligament (PCL) sprains are much less common in children than ACL injuries (266,267). They are significant, because of the serious potential morbidity. The mechanism of injury can be hyperextension or a fall onto a flexed knee. The patient typically has popliteal fossa tenderness, and recurvatum may be present, if the injury was caused by hypertension. The results of the posterior drawer and reverse pivot-shift tests are usually positive, although examination under anesthesia may be necessary to demonstrate this resultant laxity. Although midsubstance injuries may occur, avulsion of the femoral origin of the ligament should be suspected, even if a bony fragment is not seen on radiographs. MRI should be obtained to look for avulsion of the PCL, as well as concomitant injury to the articular and meniscal cartilages.

Primary repair of osteochondral avulsions appears superior to nonoperative treatment. Repair of a femoral end avulsion can be done through an anterior approach, with sutures passed through the epiphysis without crossing the physeal plate (266,267). Tibial end avulsions are better handled through a posterior approach. If a midsubstance PCL tear is encountered in an adolescent, the principles of adult PCL injury treatment should be applied (268,269,270 and 271).

Meniscal Tears

The menisci serve several important functions in the knee, and are no longer considered expendable. The menisci provide stability for the joint, and apparently nourish the articular cartilage by distributing synovial fluid (272). They transmit and distribute load between the articular surfaces (273).

Most tears in young individuals are sports-related, with some injuries resulting from falls and automobile accidents (274). The exact incidence of meniscal tears in youths is unknown. Large series of meniscectomy cases typically include about 5% of cases involving youths younger than 15 years of age. Less than one-third of

these cases are acute traumatic tears. Most meniscal tears in children are related to discoid menisci, or occur with concomitant injury to the cruciate ligaments (275,276). These younger children typically have a more vague history of injury (277).

Adolescent meniscal tears usually result from a significant injury, and typically involve a twisting mechanism. Often a pop is heard or felt. After injury, complaints of popping, intermittent swelling, limping, and giving way are common (276,278,279). Concomitant ligament injuries are common. The diagnosis may be delayed as long as 12 months (274). Rarely, the onset is atraumatic, as is so often the case in the middle-aged patient (276).

Joint line tenderness and effusion are the most common signs (278). The McMurray test, Apley grind test, and quadriceps atrophy may be helpful in the diagnosis of a chronic lesion, but typically, the acutely injured knee is too painful for these maneuvers to be performed effectively (280). With a bucket-handle tear, the knee may become locked. Ligamentous laxity, common in children, results in hypermobility that can produce a false-positive McMurray test (277).

The differential diagnosis includes collateral ligament sprain, synovial contusion, acute plica syndrome, osteochondritis dissecans, chondral fracture, patellar subluxation, discoid meniscus, and popliteus tendinitis (281).

Routine radiographs of the injured knee should be obtained. Further investigation must be tailored to the degree of suspicion for a tear and the perceived urgency for definitive diagnosis and treatment. Imaging is particularly useful in diagnosing the patient with a known medial collateral ligament sprain, for whom joint line pain from the sprain cannot be separated from that potentially caused by a concomitant meniscal tear (220). Imaging can help determine whether early arthroscopy or trial rehabilitation should be recommended (282).

Although arthrography is minimally invasive and relatively inexpensive, it is rarely used for the diagnosis of meniscal injuries, because MRI has become so readily available. MRI scanning for meniscal tears has a reported accuracy as high as 98% (245,247,283).

Several series of total meniscectomy in youths have shown that well over one-half of the patients are symptomatic within 5 to 8 years of surgery. Most of these have significant degenerative changes demonstrated on radiography (274,278,279,284). While patients undergoing arthroscopic partial meniscectomy generally do better than total meniscectomy, the long-term outcome studies are still pending. Meniscal injuries in youths should not be neglected, because of the predictable consequences.

The key issue to meniscal healing appears to be vascularity. Although the embryonic human meniscus has vessels throughout its substance, with age and development, the inner portion becomes completely avascular (285,286). Microangiographic studies have shown that about 30% of the capsular margin of the adult meniscus receives its blood supply from a plexus of circumferential vessels arising from the medial, lateral, and middle geniculate arteries (287) (Fig. 31-13). A proliferation from the interstitial vessels and the adjacent synovium had been experimentally shown in dogs, in response to injury. Mesenchymal cells fill the gap with a cellular fibrovascular scar tissue. With time, the lesion remodels to reflect the contours of the normal meniscus (287,288).

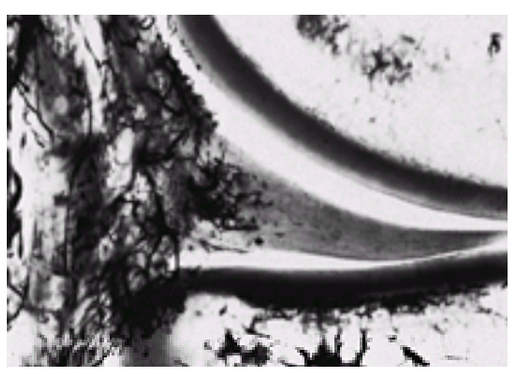

FIGURE 31-13. Vascularity of the human meniscus, as seen in a frontal section of the medial compartment of the knee. Branching vessels from the perimeniscal capillary plexus penetrate the capsular third of the adult meniscus. (From ref. 286, with permission.)

Children and adolescents seem to have a high percentage of peripheral detachments and vertical longitudinal tears near the capsular margin, which are good candidates for repair (277,289). Repair yields an 80 to 90% success rate and minor deterioration over time (254,289). Several open and arthroscopic techniques for meniscal repair have been developed, and each has its merits. There are several key principles. The meniscus should be reduced anatomically and secured by multiple closely placed sutures (291). Since healing is slow, the sutures should be a nonabsorbable or a slowly resorbable material. They must be passed carefully to avoid neurovascular structures, and should be tied down directly on the knee capsule (289,291).

A variety of bioabsorbable fasteners have been developed recently. Most of these offer the advantage of being inserted with arthroscopy alone. The efficacy of these is still being evaluated. Currently, vertical suturing is the standard against which these newer devices are being compared.

Rasping the synovium to stimulate a vascularized tissue response, much like a pannus formation, seems to augment healing (289,291). Puncturing the capsular margin of the meniscus may create channels for vascular ingrowth, and the addition of fibrin clot into the repair may augment healing (287).

Because of the slow healing of the meniscus, the aim of rehabilitation after surgery is to shield the repair from the mechanical stresses of extreme motion and weightbearing. The knee is placed in a brace, to limit motion for 6 weeks, and weight bearing is restricted. Rigorous strengthening is started after 6 weeks. Cycling is started at 3 months postoperatively. Straight-ahead jogging is started at 4 months, with full-speed running and sports at 6 months (292).

Quadriceps Contusion

Blunt trauma to the anterior thigh musculature is a common sports injury, occurring most often in soccer, American football, lacrosse, and rugby (293). Although simple contusions may be a daily event for young athletes, severe quadriceps hematomas can result in marked disability. Because continued participation, despite injury, can significantly worsen the prognosis, players and coaches should be educated to recognize this injury (294).

Bleeding typically occurs in the fascial compartment, and a variable amount of thigh swelling results. Swelling and muscle spasm then limit knee flexion.

The differential diagnosis should include fracture of the femoral shaft, physeal fracture, stress fracture, myositis ossificans, osteomyelitis, and sarcomas of the bone or soft tissues. The keys to the correct diagnosis are a careful history, detailed review of the radiographs, and timely follow-up. The radiographs must be of good quality and checked for subtle evidence of bone resorption and periosteal new bone, which may indicate the problem to be an infection, tumor, or stress fracture that has come to attention because of incidental trauma.

Initial treatment consists of rest, ice, compression, elevation, immobilization, and crutches. After pain and spasm subside, gentle active range of motion exercise is begun. After good motion is achieved, progressive strengthening and conditioning are pursued. Athletes with greater than 90 degrees of knee flexion, within 48 h of injury, have an average of 1 week of disability. Severe contusions of the quadriceps may take several months to resolve (293).

Premature return to activity can result in recurrent hemorrhage. The athlete is returned to sports based on the functional parameters of pain, motion, strength, and agility. A padded guard should be fashioned to protect the area from reinjury. Aspiration of the hematoma and injection of proteolytic enzymes or steroids have not been proved efficacious. These may create complications and are not recommended.

Ossification may be an incidental finding after minor trauma. Myositis ossificans traumatica can occur after severe contusions, particularly if reinjury occurs during the healing phase (295). Ossification of the soft tissue typically appears on radiographs 2 to 4 weeks after injury (294,295). After localized trauma, the course of myositis

ossificans is much more benign than after head trauma. Ossification in the midportion of the muscle belly rarely produces significant limitation of motion (293). The patient is cautiously rehabilitated until normal function is regained. Excision of the lesion is rarely indicated (294,295).

Avulsion Fractures of the Pelvis

Avulsion fractures of the apophysis about the hip and pelvis are most commonly related to athletic injuries during adolescence (296,297 and 298). The usual mechanism is a sudden forceful concentric or eccentric muscle contraction. This occurs with rapid acceleration or deceleration. Excessive passive lengthening or stretch, such as a cheerleading split, and a variety of gymnastic maneuvers may also be responsible. Rarely, a direct blow produces these injuries.

The amount of displacement is related to the degree of injury to the associated soft tissue attachments (Fig. 31-14). The anterior inferior iliac spine is avulsed by the direct head of the rectus femoris, but migration is limited by the reflected head. The iliac crest apophysis is avulsed by the abdominal muscles, and tethered by the attachment of the gluteus medius, iliacus, and tensor fascia lata muscles. The pull of the iliopsoas on the lesser trochanter, the sartorius on the anterior superior iliac spine, and the hamstrings on the ischium are relatively unopposed, resulting in greater potential for displacement.

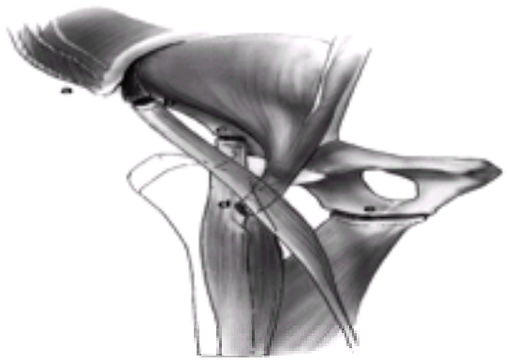

FIGURE 31-14. Avulsion fractures of the growing pelvis result from traction injuries where major muscle groups insert into or originate from apophyses about the pelvis. **A:** The abdominal and trunk muscles insert into the iliac apophysis. **B:** The sartorius originates from the anterior superior iliac apophysis. **C:** The direct head of the rectus femoris originates from the anterior inferior iliac apophysis. **D:** The iliopsoas inserts into the lesser trochanteric apophysis. **E:** The hamstrings originate from the ischial apophysis.

Typically, the athlete experiences an acute onset of pain that may be accompanied by a popping sensation. Tenderness is usually confined to the area of avulsion. The patient is most comfortable in a posture with the attached muscle-tendon unit relaxed. Pain is reproduced by active or passive stretch. Anteroinferior iliac spine avulsions may be particularly hard to localize, because of their location, and the inciting event may not be recalled (296). The avulsed fragment usually is seen on routine radiographs. Occasionally, special views are needed, but for most cases, MRI and radionuclide scans are unnecessary (296).

A history of antecedent apophysitis is common. Persistent tenderness of the anterior iliac crest can result from an apophysitis, which may be associated with radiographic discontinuity of the apophysis. Neoplasm and infection should be considered, especially if the history is atypical (299,300).

Initially, the patient rests, with the injured region in a relaxed position. Generally, crutches are recommended for the first 2 weeks, then a phased rehabilitation program should be guided by functional improvement. The goal should be to restore motion, strength, and sports-specific functioning. Premature return to play may delay recovery or further displace the apophysis. The decision for early or safe return to competition is not easily made and must weigh the clinical findings and radiographic evidence of healing. Complete healing may take 6 weeks to several months.

With time, bone is laid down in response to the injury. Relative shortening of the muscle, prominence of the bony mass, and potential interference of the sciatic nerve have been sighted as causes of residual disability. Limitation of athletic ability rarely occurs, and is apparently only related to severely displaced ischial avulsions (301). In rare cases, troublesome bony fragments should be resected (302). Surgical reduction and fixation are seldom indicated (297,298).

Spinal Injuries

Serious injuries to the head and neck are infrequent, but often devastating. Football, trampoline, ice hockey, rugby, and diving are the most common activities associated with these injuries to younger athletes (303,304 and 305).

American football remains a serious risk to the young athlete, despite improved equipment and changes in tackling techniques; 72% of high school athletes suffering quadriplegia were attempting to make tackles. Defensive backs are the most commonly injured players. Ironically, the improved protective capabilities of the helmet and face mask during the 1960s and 1970s resulted in the use of the head as a primary point of contact in blocking and tackling (305). Fifty-two percent of quadriplegics between 1971 and 1975 were injured by “spearing,” which is the use of the head to ram an opponent. In 1975, the National Collegiate Athletic Association and the National Federation of State High School Associations adopted football rule changes that prohibit spearing. Since then, there has been a downward turn in the incidence of serious cervical spine injuries, and a dramatic decline in quadriplegia (305). Although the incidence of spine injuries is approximately 5 per 100,000 players (1 quadriplegic per 100,000), this remains a serious problem because of the tragic nature of the injury.

In the United States, trampolines and gymnastics are second to football in causing sports-related spinal cord injuries (306). At least 114 cervical spine injuries resulting in quadriplegia are known to have resulted from the trampoline and minitrampoline (307). In 1977, the American Academy of Pediatrics issued a policy statement that prompted most schools to eliminate trampolines. Since then, the estimated frequency of head and neck injuries associated with trampolines has declined by almost two-thirds. The trampoline is a dangerous apparatus, and spine injuries can occur even in experienced athletes taking reasonable precautions (307).

Cineradiography has shown that most cervical spine injuries from sports are caused by axial loading, with the neck in a slightly flexed position (307,308). Improper tackling (American football), checking into the boards (ice hockey), diving into shallow water, and trampolines are clearly causes of spine fractures and paralysis.

Recognizing that these injuries are not just freak accidents provides the opportunity to diminish their occurrence by research, education, rule changes, technique modifications, and equipment improvements. Players should be informed of the hazards, and programs for strengthening neck muscle are essential (308,309). Management of these injuries is beyond the scope of this text, but prevention should be a primary interest of everyone dealing with young athletes.

OTHER COMMON KNEE PROBLEMS

Patellofemoral Disorders

Disorders of the patellofemoral joint include a variety of overuse syndromes, congenital and developmental abnormalities, and instabilities. In adolescents, patellofemoral problems account for almost 10% of all sports injuries (216).

Anatomy and Biomechanics

Evolving in upper-level primates, the patella is a sesamoid bone of the quadriceps mechanism (310). The patella furnishes a site of convergence for the four components of the quadriceps muscle, to provide an extension moment arm through the entire knee range of motion (311,312). Phylogenically, the vastus medialis was the last of the quadriceps group to develop (313). The trochlear shape of the distal femur stabilizes the patella's tracking.

The hyaline cartilage of the patella is the thickest in the body. It provides a low-friction surface that is able to bear high compressive loads, and the patella protects the distal femoral surface from direct blows during a fall (311).

The inferior pole of the patella first contacts the trochlea at 20 degrees of flexion with a relatively low-contact surface area (313). With further flexion, the contact site moves more superiorly, and the surface area increases. The most medial facet or “odd facet” only comes into contact with the trochlea between 90 and 130 degrees of knee flexion.

The patellofemoral articulation is subject to extremely high compressive loads, particularly with progressive knee flexion (314). With the knee flexed 9 degrees during walking, the patellofemoral joint reactive force is approximately one-half of the body weight. This increases to 3.3 times body weight at 60 degrees of flexion, during activities such as stair climbing. The contact forces reach 7.8 times body weight with full knee flexion during a deep knee bend (311).

The alignment of the quadriceps relative to the patellar tendon has a valgus relation, much like that of the tibia and femur. This angle is influenced by the patient's height and pelvis width. The quadriceps vector is approximated by a line from the anterosuperior iliac spine to the center of the patella. The line of pull through the patellar tendon runs from the center of the patella to the tibial tubercle. The relation between these two lines is referred to as the quadriceps angle, or Q angle. As this angle increases, the vector created by the extensor mechanism tends to translate the patella laterally (Fig. 31-15A). As the Q angle increases, so does the degree of that laterally directed force (315). The Q angle increases even further with external rotation of the tibia, which occurs dynamically as the tibia externally rotates during terminal extension. There may be a developmental degree of outward rotation of the tibia (external tibial torsion) as well.

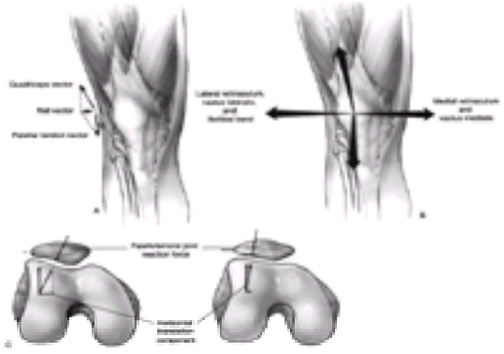

FIGURE 31-15. Patellofemoral biomechanics. **A:** The Q angle relates the direction of pull of the quadriceps mechanism to that of the patellar tendon. These are the two most powerful forces exerted on the patella. Their vector sum is directed laterally. **B:** There are additional soft tissue forces applied to the patella. **C:** The laterally directed net vector is opposed by the patellofemoral articulation. If the groove is shallow, there is less potential resistance to horizontal translation than for knees with a deeper femoral groove. The dysplastic patellofemoral articulation results in less resistance to lateral translation, and therefore greater articular surface sheer forces.

The lateral retinaculum, including the lateral patellofemoral and lateral meniscopatellar ligaments, add to the laterally directed moment of the extensor mechanism (316). The sum of these forces is resisted by the medial parapatellar-stabilizing soft tissues, and the pull of the vastus medialis (Fig. 31-15B). The lateral patellotrochlear articulation is the other key component balancing these forces, and any deficiency of any of these components can exacerbate lateral maltracking or instability of the patellofemoral joint (314,315,317) (Fig. 31-15C).

Anterior Knee Pain

Mechanics and Diagnosis

“Patellofemoral pain syndrome” is a descriptive term applied to patients with nonspecific anterior knee pain. Malalignment or maltracking appears to be a significant predisposing factor. Lateral tracking or subluxation of the patella, demonstrated arthroscopically, is highly correlated with the patellofemoral pain syndrome. In some people, lateral tracking is associated with pain and instability. Other patients complain primarily of instability, and have relatively little pain. For the purpose of this discussion, patellofemoral pain syndrome is separated from patellofemoral instability, although some patients have components of both.

Chondromalacia patella is not typically found in these younger patients. Several hypotheses have been proposed for the mechanism of pain production. Ficat and associates have proposed that excessive pressure from the lateral facet is transmitted to the sensate subchondral bone, leading to the perception of pain (318). Hejgaard and Diemer found increased interosseous pressure of the patella in many patients with patellofemoral pain (319). James proposes that the cause in many patients is an underlying overuse syndrome, resulting in excessive rotational forces in the peripatellar soft tissues (320).

Factors predisposing to patellofemoral pain syndrome include habitual overloading related to overuse, a variety of lower-extremity malalignments, poorly developed quadriceps muscles, and various dysplastic changes about the patellofemoral articulation. One particularly common aggregate of these abnormalities is commonly seen in adolescent girls, and has been called the “miserable malalignment syndrome.” These patients have increased femoral anteversion, external tibial torsion, genu valgum, excessive Q angles, heel cord contracture, and pronated feet (320,321).

The pain in most patellofemoral disorders is generalized to the anterior part of the knee. The pain is typically related to activity, and patients feel more comfortable at rest. Climbing stairs is particularly troublesome, because of the excessive patellofemoral loads. Prolonged sitting may produce discomfort and the need to move the knees. Patients may complain of stiffness after prolonged sitting. Erythema and effusion are uncommon. The patient may experience catching or giving way, but true locking is unusual. Training errors usually related to the change in intensity, duration, or training surface are common factors in patellofemoral disorders (320). The complaints are frequently bilateral, although not necessarily concurrent.

The physical findings include diffuse medial and lateral peripatellar tenderness. The combination of increased femoral anteversion and external tibial torsion causes the patellae to face toward each other to some degree when the feet are directed forward; this has been called “squinting patellae.” Frequently, the lateral retinaculum is contracted; this can be demonstrated by the inability to elevate the lateral margin of the patella during the tilt test. Crepitus may signal significant articular irregularity, although this must be tested in at least 20 degrees of flexion, to ensure that the patella is articulating with the trochlea, rather than with the femoral metaphysis. Perhaps the most important finding is the lack of other specific abnormalities, because patellofemoral pain syndrome is primarily a diagnosis of exclusion.

Because underlying biomechanical abnormalities are common, the evaluation must include a thorough inspection of the entire lower extremities and the athlete's shoes, which may demonstrate asymmetric wear patterns, a finding that can be particularly helpful if the problem is unilateral (320,322). Even if wear is symmetric, breakdown of the medial counter of the shoe indicates excessive pronation. A wedged pattern of heel wear suggests a valgus heel strike, which is typical of runners with excessive pronation. As the foot rolls during pronation, the tibia rotates inward, and the extensor mechanism experiences greater stresses to resist this (113). If the shoes demonstrate wear on the lateral edge of the heel, this suggests a hindfoot varus strike, possibly caused by a cavus foot. The more rigid cavus foot pattern can result in less shock absorption at the foot and relatively greater ground reaction forces being translated to the knee (120).

The Q angle, patellar tilt, and lateral glide should be considered (315,323). Medial and lateral peripatellar tenderness most often is related to inflammation of the soft tissues, rather than a painful articular surface. Thigh circumference and vastus medialis atrophy are signs of long-standing dysfunction, and may even be contributing factors (323). Tightness of the hamstrings and iliotibial band should be checked, because they can lead to increased patellofemoral contact forces (324,325 and 326). Anterolateral or anteromedial joint line tenderness may overlap the symptoms and findings associated with meniscal problems (327,328).

Radiographic evaluation should include anteroposterior, lateral, and tangential views of the patella. The anteroposterior and lateral views may identify bipartite patella, Sinding-Larsen-Johansson disease, osteochondritis dissecans, and dorsal defects of the patella. The lateral view can be used to identify patients with patella alta or patella infera. Insall et al. described a ratio of the maximal patella length to the patellar tendon length; normal was defined as a ratio of 1:1±20% (329).

Lancourt and Cristini have correlated patellar instability and chondromalacia to a decrease in this ratio (330).

Various tangential views have been developed to evaluate the patella's anatomic relation to the trochlear groove and to the femur (318,331,332). Merchant's technique is performed with the knee minimally flexed over the edge of the table and supported by an apparatus (332) (Fig. 31-16). Supine positioning relaxes the quadriceps and avoids direct pressure to the patella. This allows a maltracking patella to rest in a subluxated position, probably making the Merchant's view the most sensitive plain radiographic technique. Patellar views done with the knee simply flexed, often called “sunrise views,” pull the patella into the distal femoral sulcus, and can lead to a false impression that the patella is tracking centrally. CT and MRI can also demonstrate patellar subluxation, but are probably not indicated for the routine case (333,334). A variety of lines, angles, and ratios have been developed to quantitate static patellar tilt and subluxation as an indicator of tracking (332,333,335). However, the usefulness of this information in determining treatment has not been definitively demonstrated (327,336).

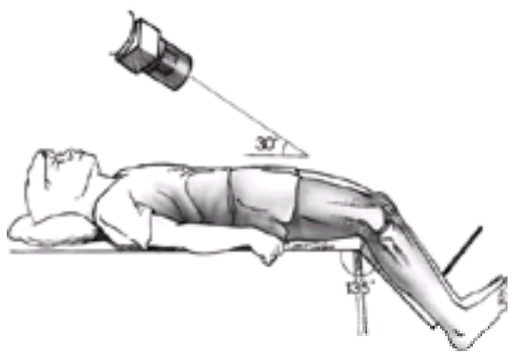

FIGURE 31-16. Tangential x-ray view for evaluating the patellofemoral joint. Merchant's view allows the quadriceps mechanism to relax. The patella is not artificially held reduced in the distal femoral groove.

Bone scans may demonstrate increased radionuclide activity in the patella, suggesting increased metabolic activity of the bone, but for patellofemoral pain, the sensitivity, specificity, and predictive values of bone scans in younger patients have not been proved (337,338,339 and 340).

Treatment

Many patients only need reassurance that the problem is not more serious. The intermittent use of NSAIDs, a knee sleeve, and other isolated modalities may be adequate to control the symptoms. If the symptoms are persistent and troublesome, a more formalized program is helpful. The importance of genuine and concerted efforts at nonoperative management of the patellofemoral pain syndrome should be emphasized. Most patients should be successfully managed without surgery (324,325,341,342).

The treatment program can be divided into four phases, which blend together, rather than being separate steps (343).

Phase 1 concentrates on symptom reduction. The initial management of symptoms includes modification of activities, ranging from elimination of activities, such as stair-climbing or hill-running, to complete cessation of sports. For the serious athlete, modification of training or substitution of an alternative, such as swimming, is critical. NSAIDs may be helpful. Many patients find that use of a knee sleeve with a patella cutout reduces pain, especially when they have pain with daily activities (344). Isometric quadriceps-strengthening exercises and hamstring stretching should be started in this initial phase. Ice is used in conjunction with exercise. Occasionally, the knee may require a brief period of splinting. Crutches are rarely needed. Several bracing and strapping techniques have been advocated to improve patellar tracking. The McConnell taping technique appears to be the most successful of these. An experienced therapist can work with this technique and, if successful, teach it to the patient.

Phase 2 concentrates on reconditioning. When the patient is able to tolerate isometrics comfortably, a quadriceps-strengthening program is advanced. Straight-leg raising and terminal extension quad arc-strengthening exercises are begun. Weights are later added. Isometrically loading the quadriceps, or the use of terminal range of motion strengthening exercises, minimizes the excessive patellofemoral contact forces generated in flexion past 20 degrees (311). DeHaven et al. achieved excellent results with the use of a simple knee extension exercise apparatus or the use of a weight boot (343). Specific instructions are necessary, and most adolescents require some supervision to ensure compliance.

Isokinetic exercise has been shown to be an excellent method of strengthening muscles; however, there can be disadvantages to its use in the early phases of rehabilitation. Isokinetics may result in excessive patellofemoral contact forces being generated by a rigorous contraction. With appropriate precautions, eccentric strengthening can be used effectively, although this is usually unnecessary until the advanced stages of reconditioning (345).

A general lower-extremity strengthening program, including hamstring stretching and strengthening, is included in phase II. Physical therapy modalities, such as high-voltage galvanic stimulation (i.e., Highvolt) or transcutaneous electrical nerve stimulation may be helpful, particularly for the athlete who has limited exercise capacity because of pain. A patellar “stabilizing” sleeve may also be helpful in controlling pain and facilitating weight lifting (346).

In phase 3, activities are gradually resumed. After a patient demonstrates consistent progress in quadriceps strengthening, a graduated running program is instituted. This can commence when the patient is performing quadriceps strengthening at about one-half of projected goal. DeHaven et al. outlined recommendations for this in terms of a young adult male eventually progressing to 60 lbs, using a weight-added isometric technique (343). If using a weight boot or ankle weights, the goal should be 10 pounds for straight-leg raises and terminal extensions, before initiating a running program.

The running program is based on prior training experience and ability, but it should include a period of stretching and warm-up exercises, gradually increased duration and speed, initial avoidance of hills, ice after running, good shoe wear, and a foot orthosis, if there appears to be a significant biomechanical anomaly. Running should initially be done every other day, with the phase 2 weight program on the alternate days.

In phase 4, a maintenance level is reached. Stretching and warm-up exercises before all activities are continued. In addition to the athlete's usual training program, weight training is continued two or three times each week. The athlete is advised that minor setbacks can be expected; the program is backed up to the prior comfortable step and progressed more gradually as symptoms permit.

Although the results of surgical treatment for patellofemoral pain are generally good, failure can result in significant disability. This emphasizes the importance of a sincere effort to have patients persevere with a conservative rehabilitation program, until all reasonable attempts have been made. Patellofemoral pain syndrome typically does not resolve until adequate strength gains are made. Often, the stumbling block is that adequate strength gains cannot be made, because of the pain encountered with each attempt to progress the exercise program. Surgery is not a substitute for exercise therapy; instead, it should be viewed as an aid to improve the patellar tracking, and thereby facilitate strengthening (347).

Lateral Retinacular Release

Contracture of the lateral retinaculum is a common finding in patellofemoral pain syndrome. The contracture may be the underlying cause of the problem or a manifestation of it. The principle is to release the tight structures, and thereby improve tracking. The role of retinacular release in the treatment of the patellofemoral pain in adolescents is controversial. Most patients will respond to conservative means.

The indications for lateral release then include intractable patellofemoral pain, findings such as tenderness over the lateral retinaculum with a tight lateral retinaculum, and no other explanation for the problem (348). The prerequisites include failure of substantial conservative measures, a tight lateral retinaculum with evidence of lateral tracking, and peripatellar pain (349,350). Evidence of lateral tracking or subluxation should be confirmed arthroscopically (328,351,352). The relative contraindications include reflex sympathetic dystrophy, poor cooperation with rehabilitative exercises, psychosomatic illness, and ulterior motives, such as a desire to

establish a compensation-related disability (353,354 and 355).

Arthroscopy should be performed at the time of lateral release to thoroughly assess the knee, identifying concurrent pathologic processes or other problems with symptoms that could lead to misdiagnosis (328). The incidental finding of lateral tracking in an otherwise asymptomatic knee should not be an indication for lateral retinacular release (328,347).

Lateral retinacular release can be performed through an open incision, or percutaneously (326,327 and 328,336,350,356,357,358,359,360,361 and 362). The release should transect the lateral meniscopatellar fibers inferiorly, and extend just above the superior pole of the patella. Adequacy of the release should be demonstrated by an intraoperative manual tilt test. The vastus lateralis should not be detached from the superolateral pole of the patella, because this can be associated with significant atrophy of the vastus lateralis and postoperative medial subluxation of the patella (363).

Hemarthrosis is a relatively common complication, and can be associated with delayed rehabilitation, persistent synovitis, and poor overall results. Specific attention is paid to the superolateral branch of the geniculate artery, which is typically transected. Although cautery is theoretically an advantage of the open technique, the arthroscopic use of electric cautery has also been proven effective (364).

Postoperatively, the use of a sleeve that fills with ice water, such as the Cryocuff (Aircast Corporation, Summit, NJ), seems to greatly reduce pain, swelling, and hemarthrosis. Therapy is begun a few days later, to restore the range of motion and prevent adhesions from forming. Within a short time, strengthening should be better tolerated than before surgery (347).

The overall results of most studies of lateral retinacular release are 75 to 85% favorable (327,328,347,350,359,361,362,365). Complications include persistent pain, painful hemarthrosis, synovitis, reflex sympathetic dystrophy, recurrent medial subluxation, patellofemoral osteoarthritis, saphenous neuritis, and thrombophlebitis. Factors associated with poor results include reflex sympathetic dystrophy, ligamentous instability, and high-grade chondromalacia (331,353,354,362,365).

Chondral Shaving

Cartilaginous debris in a joint produces synovitis. This is the rationale for debriding or shaving articular cartilage in the treatment of patellofemoral pain with advanced grades of chondromalacia patella (152). Ogilvie-Harris and Jackson demonstrated reasonable results from chondral debridement in cases of trauma in which there is no underlying maltracking (365). In these cases, a lateral retinacular release is only indicated if there is demonstrated concurrent maltracking. In cases of patellofemoral pain with concurrent grade II or III chondromalacia, cartilage debridement should be viewed as an adjuvant procedure only.

Other Procedures

Advancement of the vastus medialis and distal realignment procedures may be indicated for specific cases with medial soft tissue defects or excessive Q angles (348). For patellofemoral pain without overt symptoms of instability, lateral retinacular release is usually the first line of treatment. If the lateral retinacular release fails, secondary procedures should be approached cautiously, first confirming that there is no other diagnosis to explain the symptoms.

Chondromalacia

The term “chondromalacia” refers to softening and degeneration of the articular cartilage (313). Adults with maltracking frequently have these cartilage changes, but it is probably incidental in many cases. Significant cartilage fibrillation or fissuring is not typically present in younger patients with signs of patellofemoral pain syndrome. Occasionally, these cartilage changes are seen in larger adolescents, and sometimes result from direct trauma to the patella or occur after patellar dislocations. Symptomatic chondromalacia is much less responsive to rehabilitation efforts than patellofemoral pain. These patients occasionally respond to arthroscopy and chondral shaving, but the physician must beware of other concurrent or underlying processes that have led to the chondromalacia.

Saphenous Nerve Entrapment

Anterior thigh pain extending to the superomedial pole of the patella can be produced by an entrapment syndrome of the saphenous nerve. This branch of the femoral nerve enters the adductor canal alongside the superficial femoral artery. It then penetrates anteriorly through the dense fascia connecting the adductor magnus to the vastus medialis 10 cm proximal to the medial femoral condyle.

Although most reported cases have involved patients past their teens, this condition can be seen in adolescents (366). Medial thigh and knee pain is typically produced with walking or running. It is often aggravated by quadriceps exercises. The most reliable finding is point tenderness, where the nerve exits Hunter's canal. Saphenous nerve entrapment should be considered in the differential diagnosis of anterior knee pain, and not mistaken for patellofemoral maltracking or plica syndrome.

Injection of a local anesthetic into the affected site relieves the pain and produces an area of numbness in the distribution of the saphenous nerve. If the condition is unresponsive to rest and NSAIDs, a steroid can be injected. This may need to be repeated, and the pain may not completely resolve (367).

The results of surgical release and neurolysis are mixed, with failures apparently secondary to scar tissue entrapping the nerve. Neurectomy may be necessary, but the patient must be warned of the resultant numbness (366).

Bipartite Patella

Ossification of the patella begins between 4 and 6 years of age, and is completed by adolescence. Secondary ossification centers often occur, beginning around 12 years of age, and are usually located in the superolateral portion of the patella. In about 2% of the population, the secondary ossification centers failed to fuse completely with the primary ossification center.

Most bipartite patellae are asymptomatic. In some, pain apparently stems from the motion at the interface between the patella and its secondary ossification center. This is analogous to a symptomatic accessory tarsal navicular or a fracture nonunion. In some cases, the articular portion of the bipartite patella is incongruous with the rest of the joint. Typically, these are sloped posterolaterally. The surrounding synovium becomes inflamed, often because of chondromalacia of the surface beneath the secondary ossification center.

Most bipartite patellae are asymptomatic, with the diagnosis being made as a coincidental finding on a radiograph obtained for other reasons. In some youngsters, the secondary ossification center becomes symptomatic after a direct load blow to the patella, typically from a fall. The rigors of training for competition can also precipitate symptoms.

Often, the patient will have localized pain at the superolateral pole of the patella. A prominence and/or cleft may be palpable, along with tenderness of the surrounding joint capsule and synovium. Effusion, instability, or other findings should suggest that the bipartite patella is coincidental, rather than the primary source of the patient's complaint.

Most bipartite patellae can be adequately visualized on plain radiographs of the knee with the Merchant's view demonstrating this the best. Occasionally, CT and MRI aid in evaluation.

The initial treatment includes reassurance, ice, NSAIDs, and a knee sleeve. Occasionally, rest, activity modifications, and a few weeks of immobilization are helpful.

For persistently troublesome symptoms, excision of the smaller bipartite fragments may become necessary. For these, sports can be resumed at 1 to 2 months postoperatively. If the bipartite segment is large, internal fixation may be preferable to excision, depending on the quality and contour of the articular surface.

Dorsal Defects of the Patella

Haswell and associates first described a lesion, now called “dorsal defect of the patella” (368). Radiographically, there is a round radiolucency surrounded by a zone of sclerosis. This is typically located in the superolateral aspect of the patella (Fig. 31-17). It occurs in persons as young as 10 years of age, and rarely persists past 30 years (368,369 and 370). Histologically, it is composed of a vascular fibrous connective tissue surrounded by sclerotic bone without inflammation (371). Some necrotic bone may be present (370,372). The cause is unknown, but the evidence suggests that dorsal defects of the patella result from irregular ossification. This may result from stress exerted by the vastus lateralis insertion. Bipartite patella may have a similar etiology (370).

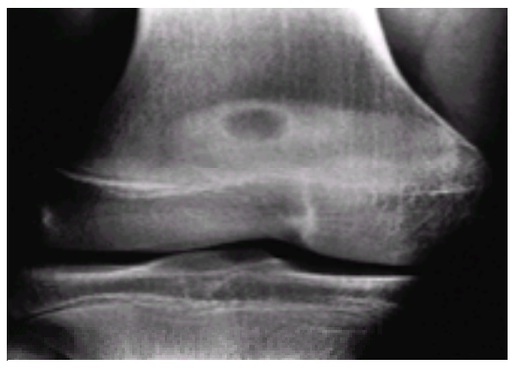

FIGURE 31-17. Dorsal defect of the patella. The typical lesion is a round, radiolucent area in the superolateral pole of the patella. The margins of the lesion are well circumscribed. This is best seen on the anteroposterior radiograph. Typically, the lateral radiograph is normal.

Although a rare occurrence, almost any benign or malignant tumor can appear as a radiolucent lesion in the patella (373). Osteomyelitis, Brodie abscess, and osteochondritis dissecans of the patella should be considered in the differential diagnosis (374,375).

Dorsal defect of the patella is usually an asymptomatic, incidental radiographic finding. It undergoes spontaneous regression in most cases and requires no treatment (368,372). In the adolescent, however, it may become symptomatic, and can be associated with an underlying articular cartilage defect (371,372,376). Most patients with this lesion respond to rest, but surgical excision and grafting occasionally may be necessary (371,372,376).

Fat Pad Impingement

Impingement of the anterior fat pad and its associated synovium was described in 1904 by Hoffa. Most patients are females in their teens and early twenties (377,378).

The cause is unknown, although it is postulated that hypertrophy or trauma initiates repetitive impingement, inflammation, and fibrosis. The fat pad may be hypertrophic. The characteristic histopathologic findings include the presence of mononuclear inflammatory cells and some degree of fibrosis. In chronic cases, the adipose tissue becomes replaced by fibrocartilage (377).

Typically, the pain is related to activity, and is localized to the anterior knee joint. There may be a history of trauma. Prominence of the fat pad on each side of the patellar tendon is by no means diagnostic. Hoffa described a test performed by applying fingertip pressure to the fat pad while the knee is passively extended (377). If pain is elicited near terminal extension, the test result is considered positive.

At times, this condition appears to be a distinct entity, causing anterior knee pain. Other problems, including patellofemoral pain syndrome, chondromalacia, and inflammatory arthritis can inflame the fat pads. Differential diagnosis also includes meniscal cyst, meniscal tear, soft tissue trauma, patellofemoral pain, patellar tendinitis, and patellar instability (378).

Hyperextension injuries to the knee can lead to acute edema of the fat pads, as well as edema and bruising in the bone. For these acute injuries, MRI can detect the edema in the fat pads, and shows the changes in the subcortical bone as well. For chronic or subacute cases, radiographs are typically negative, and the value of the other imaging studies has not been proven.

Nonoperative treatment includes rest, ice, NSAIDs, and a sequential exercise program. Because terminal quadriceps extension often produces impingement, the exercise range of motion is modified to avoid terminal extension. Physical therapy modalities including high-voltage galvanic stimulation and phonophoresis, or conophoresis with hydrocortisone may be helpful.

Nonoperative therapy is usually effective. Occasionally, arthroscopy becomes indicated for recalcitrant cases. The difficulty in differentiating pathologic changes from normal anatomy fuels the controversy in diagnosing this entity. A normal fat pad should not be resected, so a knowledge of the anatomy, including the normal basal prominences of fat and the variability of fat pad size, is essential (377). Generally, the texture and contour of the fibrotic fat pad differs appreciably from the soft texture and yellow color of normal fat. This can be used as a guide during arthroscopic resection, but unfortunately, no proven guidelines are available. Postoperatively, range of motion exercise is resumed early, to minimize scarring. A standard patellofemoral rehabilitation protocol is used, and the patient should demonstrate full return of function before participating in sports activities.

Plica Syndrome

The symptomatic medial patellar plica can be considered “the great imitator” of knee disorders. The challenge is to recognize this disorder without diagnosing plica syndrome for every case of knee pain associated with a tender synovial fold.

Embryologically, the synovial cavity of the knee begins as three separate compartments that fuse during the fourth fetal month. The remaining membranes give rise to the three commonly encountered plicae (Fig. 31-18).

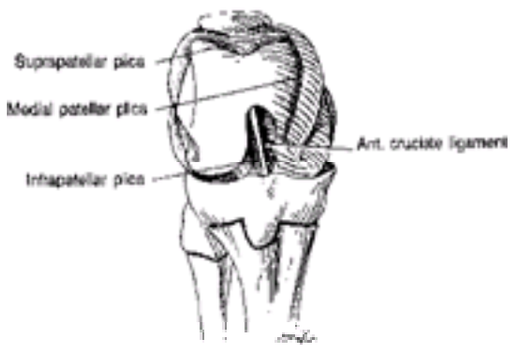

FIGURE 31-18. Plicas of the knee. Superior plica. Medial plica, the one most commonly symptomatic. Inferior plica (ligamentum mucosum) overlying the anterior cruciate ligament.

The suprapatellar plica usually is a crescent-shaped fold originating beneath the quadriceps tendon. It extends to the medial or lateral walls of the joint (379). The suprapatellar plica may result in complete separation of the suprapatellar bursa from the knee. There may be a small opening in the suprapatellar plica, called the “porta.” The suprapatellar plica is also rarely symptomatic.

The medial parapatellar plica lies along the medial wall of the joint, originating near the suprapatellar plica, and coursing obliquely downward to attach near the infrapatellar fat pad (141,380,381). This is the plica that potentially becomes symptomatic.

The incidence of plica varies, depending on the examiner's criteria for how large a fold must be to constitute a plica. The lesions range from a small cord to a large shelf. The plica may completely cover the surface of the medial femoral condyle, and it may be fenestrated (382).

Inflammation or direct trauma can produce thickening and fibrosis of the plica. This can lead to further impingement of the plica in the patellofemoral joint, with the potential for becoming a self-propagating problem. Pain may be secondary to mechanical compression of the plica, or to the plica applying traction to the fat pad (380). In advanced cases, the articular surface may become eroded (379).

The presenting symptoms of plica syndrome include anteromedial knee pain, popping, snapping, and giving way. The pain may be referred to the medial or lateral joint line. Symptoms often begin after repetitive activities, such as running, jumping, and climbing stairs (379,380). Occasionally, the plica becomes acutely inflamed after a twisting injury or direct blow, and the patient may present with pseudolocking of the knee (380,381).

The plica can usually be palpated along the medial surface of the femoral condyle in symptomatic and asymptomatic patients. Tenderness is invariably present, but it is not a pathognomonic finding. Many abnormalities produce localized or generalized synovitis that secondarily affects the plica. To further confuse the examiner, the patient with an inflamed plica may also have a false-positive Apley test, McMurray test, or a patellar compression test. The medial joint line may be tender anteriorly, and rarely, an effusion may be present (380).

Radiographs usually should be normal, and other studies have not proven to be efficacious (379). The diagnosis is based on compilation of all available data and the exclusion of other lesions. Even at arthroscopy, the determination of a pathologic plica from an incidental finding is not always clear, thus the potential for underdiagnosis and overdiagnosis (380).

It is imperative to search for other pathologic processes of the knees, such as a meniscus tear, loose body, chondromalacia, significant patellofemoral maltracking, or instability (379). Initial treatment should include rest, ice, NSAIDs, and a gradual patellofemoral exercise program. Because terminal extension may impinge the plica, exercises are modified to avoid that range. McConnell taping may be helpful. Intraplical steroid injection has been used with mixed results (141).

If persistently symptomatic, the synovial band is easily resected arthroscopically, and the rest of the joint is carefully inspected. Good and excellent results of more than 90% have been achieved, with appropriate patient selection (379,380 and 381). Because scarring may occur from simple division of the plica, complete resection is recommended. The surgeon must keep in mind that the symptomatic plica may be the early signs of patellofemoral maltracking, and this is a common cause of surgical failure.

Acute Patellar Dislocation

Dislocation of the patella is often related to an underlying dysplasia or a malalignment of the patellofemoral articulation (383). The depth of the patellofemoral articular groove, patella alta, excessive Q angle, and ligamentous laxity have been cited as predisposing factors (384). In as many as 75% of patients with patellofemoral instability, at least one element of deficiency can be identified (352). There is a positive family history for one-fourth of these patients (383). A direct blow to the medial aspect of the patella accounts for only 10% of cases (384). Most patellofemoral dislocations are lateral, although medial dislocations are a recognized complication of an overzealous lateral retinacular release (363).

Most patellar dislocations first occur in patients from 14 to 20 years of age (352,383,384 and 385). Although football, baseball, and basketball commonly are involved, significant numbers of patellar dislocations occur from simple falls, gymnastics, dancing, cheerleading, and a wide variety of other activities (386). The mechanism usually involves a twisting event. Although affecting more girls than boys, patellar dislocations must be considered in the differential diagnosis of acute knee injuries in young male athletes (331,352,386,387). A history of prior episodes of subluxation, anterior knee pain, and a family history may help to support the diagnosis.

Most patellar dislocations reduce spontaneously or shortly after they occur, especially if the episodes are recurrent. A patient with an unreduced patellar dislocation presents with the knee flexed and the hamstrings being tight. With the patella displaced laterally, the femoral condyles become prominent medially, often leading the patient or lay observer to report that the dislocation was medial, rather than lateral. A wide array of activities can precipitate the episode.

After reduction, the residual findings include diffuse parapatellar tenderness, and a positive apprehension test. The medial capsule and retinaculum may have been stretched or torn, and the tenderness may extend to the medial femoral epicondyle. Medially, there may be a palpable defect of the patella from avulsion of the vastus medialis insertion.

Hemarthrosis results from a capsular tear or a concurrent osteochondral fracture. The ligaments should be examined carefully, because the mechanism of injury and findings with patellar dislocation are similar to those of a cruciate sprain.

Postreduction radiographs should be inspected for evidence of osteochondral fragments. Bony fragments seen along the medial patellar margin often are not free in the joint, but rather result from avulsion of the vastus medialis insertion. A Merchant's view, showing both patellae, may demonstrate significant residual maltracking.

The natural history of acute patellar dislocation in children is such that approximately 1 of 6 will develop recurrent dislocations, 2 of 6 will have some minor residual symptoms, and 3 of 6 will remain asymptomatic (388). The incidence of redislocation after nonoperative treatment diminishes considerably with advancing age. Cash and Hughston found a 60% incidence among patients between 11 and 14 years of age, 30% incidence among patients between 19 and 28 years of age, and few older than 28 years of age (352).

Acutely, the extensor mechanism holds the patella trapped over the margin of the distal femoral condyles. With the patella posterior to the axis of the knee, and the hamstrings contracted in response to pain, the knee is firmly held in flexion. The reduction is performed without forceful manipulation. Reduction is facilitated by turning the patient into a prone position, so that the hip is extended and the hamstrings become relaxed. The knee is gradually and steadily extended, usually leading to reduction. Afterward, the knee can be aspirated if a tense hemarthrosis develops. The surface of the bloody fluid should be inspected for fat droplets, which would suggest an osteochondral fracture.

Rehabilitation begins as soon as practical, particularly after a repeat dislocation from which there may be little acute damage to the medial stabilizers. The knee is placed in an immobilizer for comfort and support during gait. It is unnecessary to continue immobilization arbitrarily for 6 weeks, as some have suggested (384,388).

Straight-leg–raising exercises are begun immediately, to minimize quadriceps atrophy. The knee is periodically reexamined (for up to 6 weeks), and when comfortable, a formal patellar rehabilitation program is begun. Once range of motion is restored and the extensor mechanism is working adequately to support the knee, the immobilization is discontinued. The patient should be able to do straight-leg raises with 5 lb (2.25 kg) of ankle weights. A flexible knee sleeve, with the patellar cutout, is then used. As strengthening is gained, activities progress, starting with biking and straight-ahead running. Cutting and twisting activities are then reintroduced. The patient is encouraged to continue with quadriceps exercises, particularly emphasizing the vastus medialis.

After an acute patellar dislocation treated with an adequate rehabilitation program, most patients do not require surgical stabilization. Cash and Hughston had acceptable results, after nonoperative care, for 75% of appropriately selected patients. Rather than surgically stabilizing all patients, a group at high risk can be identified (352).

Younger patients are at high risk for recurrent dislocation, with those less than 14 years of age having the highest incidence of recurrent dislocation (352) (Table 31-2). Highly active and competitive athletes may also benefit from immediate stabilization. Those with congenital dysplasia may be at higher risk for recurrence. The

signs of this dysplasia include hypermobility of the patella, radiographic evidence of a shallow intercondylar groove, contralateral subluxation, a positive family history, patella alta, and a mechanism of injury other than a direct blow (352,383,389).

Osteochondral fracture
Child younger than 14 years of age
Highly active or competitive youth
Mechanism other than direct blow
Palpable medial defect
Contralateral evidence of dysplasia
Hypermobility of the patella
Multiple prior dislocations
Positive family history
Patella alta

TABLE 31-2. RISK FACTORS FOR RECURRENT PATELLAR DISLOCATION

If there is an associated osteochondral fracture from the lateral femoral condyle or patellar surface, removal of the fragment or internal fixation is required, depending on the size and location of the injury. Small pieces avulsed from the medial edge of the patella usually are attached, and may not require removal. Small loose bodies can be removed arthroscopically. There are preliminary reports of successful arthroscopic repair of a torn medial retinaculum and capsule (352,390).

Early repair or advancement of the vastus medialis and distal realignment procedures are sometimes indicated. If there is an underlying malalignment or dysplasia accompanying a significant osteochondral fracture, both problems should be addressed. Occasionally, there is significant avulsion of the vastus medialis that requires primary repair (391).

Recurrent Patellar Dislocations

Although the risk of ongoing patellofemoral instability increases with each subsequent dislocation, many patients are successfully managed without surgery. In most cases, even young, active youths with other risk factors deserve a thorough trial of rehabilitation after a first patellar dislocation. Knee sleeves and foot orthoses, for those with severe pronation and tibial torsion, may be helpful. Activity modifications are another option.

The decision to treat recurrent patellar instability surgically must be individualized **[➥5.1–5.2]**. The degree of instability and disability should be weighed against the risks and benefits. Age is another factor to be considered. Compliance with rehabilitation is important, and tibial tubercle transfers are generally contraindicated, if the physes are open.

A lateral retinacular release is routinely combined with medial advancements and distal realignments. The lateral retinacular release procedure is discussed earlier in this chapter. Most studies of lateral retinacular release mix patients with patellofemoral pain among those with patellofemoral instability. Metcalf analyzed the 14 cases of recurrent patellar dislocation in his series of 79 patients, and found that none dislocated subsequent to lateral retinacular release alone (328). Nine were rated good and three rated excellent, and there were no instances of medial instability. Although it appears that lateral retinacular release has a role in the treatment of patellofemoral instability, the degree of instability that responds to this as an isolated procedure is still being defined (334).

Patients with an obvious defect of the vastus medialis insertion are probably best served with advancement of the medial retinaculum and muscle. A variety of techniques have been described, but the fundamental elements include lateral release and plication of the vastus medialis (391,392 and 393). The vastus medialis is advanced one-third to one-half of the width of the patella. The suture repair needs to be protected for at least 4 weeks after surgery.

Patients with an excessive Q angle can benefit from a distal realignment to medialize the pull of the patellar tendon. This can be accomplished by moving part of the patellar tendon itself, by moving the tibial tubercle or by transferring another tendon to the patella.

The Roux-Goldthwait operation involves splitting the patellar tendon, and transferring the lateral half beneath the medial side (Fig. 31-19). For recurrent patellar dislocations, Chrisman et al. reported 93% acceptable results with this procedure, when combined with lateral retinacular release and medial reefing (394). How much of the effect is the result of the distal transfer is unknown.

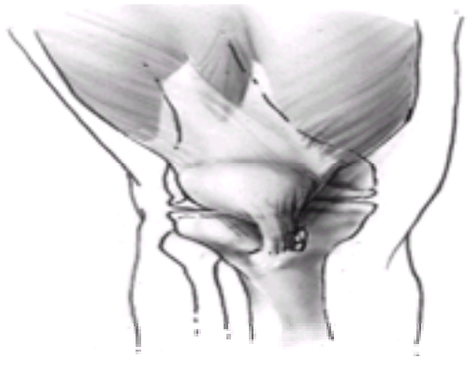

FIGURE 31-19. The Roux-Goldthwait procedure splits the patellar tendon. The lateral half is transferred beneath the medial side and sutured to the periosteum along the metaphysis. This redirects the patellar tendon vector more medially.

The Galleazzi procedure transfers the proximal end of the semitendinosus to the inferomedial pole of the patella, leaving the distal end of the semitendinosus attached to the tibia (395) (Fig. 31-20). This effectively redirects the vector of force of the extensor mechanism. The next most common complication is necrosis of the skin flap, so undermining should be minimized. Baker and colleagues had 81% successful results with this procedure (387). Patients with excessive ligamentous laxity have the highest risk of persistent instability.

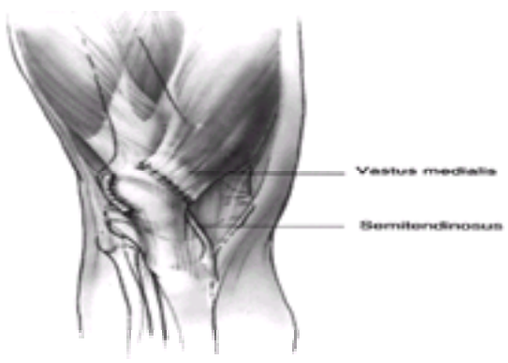

FIGURE 31-20. The Galeazzi procedure transfers the semitendinosus to the inferior pole of the patella. From there, it courses through a drill hole placed obliquely

through the patella, exiting the superior lateral aspect. The tendon is then sutured to the soft tissues. This provides a medial tether and effectively alters the net vector of the patellar tendon toward the medial side. Typically, the vastus medialis is advanced approximately one-third the width of the patella.

For adolescents with closed physeal plates, the tibial tubercle can be transferred medially. This must be done in a manner that does not move the insertion of the tibial tubercle posteriorly along the face of the upper tibia, as did the Hauser procedure (396,397). The Elmslie-Trillat technique avoids this problem by shifting a long segment of bone, including the tubercle (Fig. 31-21A,Fig. 31-21B). If there is significant growth remaining for the patient, tibial tubercle transfers can lead to distal migration of the tubercle or genu recurvatum secondary to growth arrest (337,386).

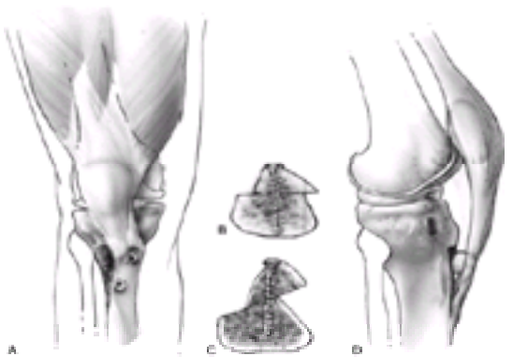

FIGURE 31-21. A, **B:** The Elmslie-Trillat technique shifts the tibial tubercle medially. The tubercle stays in the same plane. **C:** The Fulkerson modification involves an oblique cut that results in anterior translation as the tubercle is moved medially. This reduces the patellofemoral contact forces while shifting the pull of the patella medially. **D:** The Maquet procedure moves the tibial tubercle anteriorly by inserting a block of bone. This diminishes the patellofemoral contact forces but does not medialize the pull of the patellar tendon.

Tibial tubercle transfers are routinely combined with a lateral retinacular release. A vastus medialis obliquus advancement should be added, if the patella drifts laterally when the knee reaches full extension and the quadriceps relaxes (329). For patellofemoral instability, good results can be expected in 80% of cases (398).

If there is a significant component of patellofemoral pain or marked chondral injury of the patella, the Fulkerson modification of the Elmslie-Trillat procedure can reduce patellofemoral contact forces (399). Instead of the osteotomy being in the coronal plane, it is tilted toward the sagittal plane, such that the tubercle migrates anteriorly as it shifts medially (Fig. 31-21C).

The Maquet procedure reduces the patellofemoral contact forces by elevating the tubercle through the use of a bone block (Fig. 31-21D). This does not medialize the pull of the tendon, but it may be useful in cases of isolated patellofemoral chondromalacia.

All of these procedures require adequate rehabilitation to restore knee motion and maximize dynamic stability from the quadriceps.

Popliteal Cyst

Often termed “Baker cysts,” popliteal cysts are common findings in youngsters. Typically, they are located subcutaneously along the medial side of the popliteal fossa. They are simple, synovial-lined ganglion cysts that arise from the semimembranous sheath in youths; they are rarely associated with any other pathologic processes of the knee. Occasionally, they are associated with meniscal tears, inflammatory arthritis, pigmented villonodular synovitis, and others. Popliteal masses deep to the fascia are often sarcomas.

The ordinary popliteal cyst is asymptomatic and is discovered coincidentally. These may wax and wane in size, but should not cause limp or disability. On examination, these are superficial, firm or rubbery, smooth, nontender, mobile and nonpulsatile. Most will transilluminate with a simple handheld light, which should adequately confirm that the mass is fluid-filled, rather than a solid tissue tumor. Most often, history and physical examination are adequate for making this diagnosis. Radiographs are not necessary, unless associated articular pathology is suspected, for other reasons. Aspiration can confirm the diagnosis. However, other tests should be undertaken, if there is a clinical suspicion of sarcoma or vascular anomaly. Ultrasound, CT, or MRI each offer advantages, depending on the situation.

A simple popliteal cyst, arising from the medial hamstring sheath, rarely requires treatment. Typically, they do not interfere with function, cause pain, or produce other problems. They may wax and wane in size for a while, but almost all resolve.

Discoid Lateral Meniscus

The discoid lateral meniscus is a congenital abnormality affecting approximately 1% of all lateral menisci. Occasionally, the medial meniscus is involved (approximately 3% of all discoid menisci), and rarely, both are affected. There may be a familial factor (400). The discoid meniscus was once thought to be an arrest in the resorption of the central portion of the mesenchymal layer between the ends of the tibia and femur. However, a disc-like plate of fibrocartilage is never seen in normal development. This anomaly is apparently caused by the abnormal formation of fibrocartilage in the mesenchyme.

The most widely used classification system for categorizing the varied features of the discoid lateral meniscus is that proposed by Watanabe and coauthors (Watanabe). The Wrisberg ligament-type is the most anomalous. In this variety, the lateral meniscotibial ligaments are absent, so the meniscus is not attached to the tibial plateau. There are meniscofemoral fibers present and the ligament of Wrisberg attaches to the PCL. In addition to the hypermobility of the lateral meniscus, the peripheral portion is quite thickened, and contributes to the symptoms, as well as to the treatment dilemma. The complete-type discoid lateral meniscus covers essentially the entire lateral tibial plateau. The peripheral attachments are intact, so it is stable, although the capsular margin may still be thickened. Finally, the incomplete-type is similar to the complete-type, but covers less of the plateau.

The discoid lateral menisci present in several ways. The Wrisberg ligament-type often presents with the classic picture of a “snapping knee.” Usually, by 8 years of age, the child demonstrates remarkable snap and shift of the tibial plateau, as the knee moves. A visible and palpable mass becomes prominent anterolaterally as the flexed knee extends. Suddenly, the discoid meniscus reduces and disappears, as the knee stutters, then moves freely into full extension. With repetition, the knee may become sore. The repetitive snapping may later be associated with an osteochondritis dissecans lesion of the lateral femoral condyle.

The complete-type and the incomplete-type usually present with signs and symptoms more typical of a meniscal tear. The patient complains of a sudden onset of unilateral joint pain, catching, and swelling. Often, they are younger than typical for meniscal tear (less than 14 to 16 years of age). The onset is often spontaneous or related to a minor injury.

The differential diagnosis includes snapping popliteus tendon, snapping hamstring tendons, loose body, subluxating proximal tibiofibular joint, osteochondritis dissecans, iliotibial band tendinitis, ACL laxity, and a conventional meniscal tear. Routine radiographs are done to rule out a bony anomaly; if the discoid lateral meniscus is particularly thick, there may be some widening of the lateral joint space. MRI is indicated in most cases, because it should be diagnostic, and should delineate the type of anomaly, including any concurrent pathology, such as a tear.

If a partial or complete discoid lateral meniscus is an asymptomatic, incidental finding, excision of the discoid meniscus is not recommended. A study of total meniscectomy for discoid lateral meniscus showed a 75% rate of degenerative articular changes, although 70% of cases were clinically acceptable 20 years after surgery (401). The results of partial discoid meniscectomy, to contour or sculpt the remaining meniscal tissue, are hopeful, but await long-term follow-up data (402). Minor tears of the discoid meniscus may heal or become asymptomatic with nonoperative treatment. Some tears require a combination of partial meniscectomy and

meniscal repair, to optimize the size and shape of the remaining meniscus.

The Wrisberg ligament-type remains the most challenging to convert to a nearly normal cartilage. Although reattachment of a Wrisberg ligament type discoid lateral meniscus has been described (403), the thickness of the remaining rim can lead to recurrent snapping. With time, this can lead to articular cartilage degeneration and osteochondritis dissecans formation. Ideally, the meniscus is contoured and thinned to approximate the anatomy and hopefully, the biomechanics of a normal meniscus. The techniques for doing this are still evolving. Ultimately, meniscal transplantation during adolescence may be the best solution.

Some lesions are amenable to partial meniscectomy, and others can be sutured (404). A symptomatic Wrisberg ligament-type discoid lateral meniscus has been reattached successfully, but long-term success depends on adequate vascularity and collagen healing (403).

CONCLUSION

The care of young athletes presents many challenges. Many of the principles of adult sports medicine and sports orthopaedics apply to youths, but there are many unique problems related to the growing musculoskeletal system. The maturing musculoskeletal systems and psychology of young athletes makes working with them a challenge and a pleasure.

Injuries of all types are the second leading cause of hospitalization among children younger than 15 years (1), and account for 80% of deaths among teenagers and young adults (2). Properly instituted injury prevention programs can be effective in reducing the number and severity of pediatric trauma events (3). Musculoskeletal trauma, although rarely fatal, accounts for 10 to 25% of all childhood injuries (3).

Boys have a 40% risk and girls a 25% risk of incurring a fracture before the age of 16 years (3). The most common sites of fracture are the distal forearm and hand, which account for 50% of pediatric fractures. The fracture rate increases as children grow, with the incidence peaking in early adolescence. Fortunately, most fractures are minor. Only 20% require reduction, whereas greenstick and torus fractures constitute approximately 50% of all fractures in children (3,4 and 5). Thus, the management of pediatric fractures is often straightforward, but one must know when to intervene and when to allow nature to take its course. The skeleton of a young child behaves differently than the skeleton of an older child. There are also musculoskeletal differences in biomechanics, anatomy, and physiology between children and adults. It is the purpose of this chapter to highlight the unique aspects of managing fractures in children, and to delineate age-appropriate treatment guidelines.

GENERAL FEATURES OF FRACTURES IN CHILDREN

Biomechanical Considerations

The bones of children are less mineralized and have more vascular channels than adult bones. This results in a lower modulus of elasticity (6). Thus, for a given stress applied to the same area of pediatric bone, more strain results compared with adult bone. Bending strength is lower than in adult bone, but the low modulus of elasticity allows for greater energy absorption before failure. Pediatric bone also has the capacity for plastic deformation, in which the bone does not return to its original shape. Microscopic mechanical failure, not evident on routine radiographs, occurs through oblique slip lines or microfractures on the compression side of the bone. This produces no fracture hematoma and minimal periosteal reaction during healing. Plastic deformation results from an applied load after the yield point is reached, but before the breaking point is reached. This partly explains why greenstick fractures can occur when a bending load is applied. Much of the strain energy is dissipated through plastic deformation of the concave cortex, while tension failure occurs on the convex side. This prevents larger, more catastrophic failure from occurring.

In addition to greenstick fractures, children can have torus or “buckle” fractures from compression failure. This usually occurs at the metaphyseal–diaphyseal junction, where the more rigid diaphyseal cortex meets the thinner metaphyseal cortex. The less-rigid metaphyseal cortex buckles and deforms without complete failure, creating a relatively stable injury. The rate at which the force is applied also influences the fracture type. Higher load rates more often result in complete fracture (6). Complete fractures display transverse, oblique, or spiral configurations, depending on how the injury force was applied. Comminuted fractures are less common in children than in adults, because pediatric bone can dissipate energy before failure and porosity inhibits fracture line propagation. The smaller diameter of pediatric bone also affects its strength compared with adult bone. The polar moment of inertia of a structure, which measures resistance to torque, is proportional to the fourth power of the radius of the structure. Thus, a relatively small increase in the cortical diameter results in a large increase in a bone's ability to resist torsional load.

The epiphysis also affects the mechanical properties of bone. In young children, the epiphysis is largely cartilaginous, and transmits injury forces to the metaphysis. Increasing ossification in the epiphysis occurs with age and imparts more rigidity to the epiphysis. This increased rigidity partially explains why epiphyseal fractures and separations are more commonly seen in older children.

Anatomic Considerations

Growth plates and their surrounding growth centers are major anatomic features that distinguish children's bones from those of adults. The physis, also called the growth plate or the epiphyseal plate, is the area of growing cartilage that contributes length to the growing bone. The epiphysis is the region at the end of the bone. The epiphysis forms a secondary center of ossification and determines the shape and size of the articular surface. An apophysis is a secondary growth center at a site of tendon attachment. Apophyses are extraarticular and do not contribute to longitudinal growth. Each of these structures ossifies at predictable times during growth and provides information regarding skeletal maturity. Lack of ossification in young children, and variable patterns of ossification during growth, make the diagnosis of injury an even greater challenge in children than in adults.

Another anatomic characteristic of growing bone is the thick, vascular, and highly osteogenic periosteum. The cambium or osteogenic layer lies directly on the cortex of bone. The outer fibrous layer provides attachment for muscles and ligaments. Between these two layers lie elastic fibers that allow the fibrous layer to be stripped from the bone, leaving the osteogenic layer intact (7). Muscle and periosteum are firmly attached to bone in only a few places, such as the linea aspera. The periosteum is also firmly attached to the growth plate at the perichondrial ring of LaCroix, which helps stabilize the physis. The thick periosteum in children is rarely torn circumferentially after a fracture, and often remains intact on the compression side of the injured bone. This intact periosteal sleeve may then be used as a tension band for fracture reduction and stabilization. Intact periosteum may also prevent soft tissue interposition and facilitate reduction. Conversely, the periosteum itself may become interposed between the fracture fragments, and the longitudinally torn periosteum may interfere with reduction, by allowing the bone to “button-hole” through the periosteal defect.

Physiologic Considerations

Children experience considerably more rapid fracture healing than adults. Children also have the potential for bone remodeling and overgrowth after fracture. Nonunion is rare in pediatric fractures. This is explained in part by the osteogenic potential of the periosteum and the magnitude of the vascular response in children (7). The periosteum is vital to fracture healing, and should be preserved as much as possible. Large segments of bone may regenerate and remodel as long as the periosteal tube is intact.

The majority of pediatric fractures unite by secondary fracture healing, which occurs without rigid immobilization, and involves a combination of intramembranous and endochondral ossification. Trauma that results in fracture causes cellular injury and hematoma formation. Blood, marrow, and necrotic cells release cytokines that stimulate inflammation and the proliferation of stem cells (8). The clot gives rise to platelet-derived growth factor and transforming growth factor beta. This leads to general cellular proliferation. Stem cells produce bone morphogenetic proteins, which lead to cellular differentiation. The exact relationship between these factors and other factors involved in the coordination of fracture healing is the subject of ongoing research (9). During the second stage of fracture healing, angiogenesis occurs. This stage of bone healing is facilitated in children by the highly vascular periosteum and preservation of a viable muscle envelope. The periosteum also contributes bone formation by membranous ossification within 10 to 14 days of injury. Angiogenesis is followed by the formation of soft callus. Low oxygen tension and fracture motion promote cartilage formation as the initial stage of endochondral ossification. This cartilage is subsequently removed and replaced by hard callus with woven bone (7,9). Ultimately, the ossification phase gives way to a more prolonged phase of fracture remodeling.

Remodeling of angulated fractures in children is a well-recognized phenomenon (Fig. 32-1). The site of correction and the mechanism by which remodeling occurs are poorly understood. Remodeling at the fracture site occurs by bone resorption on the convexity and deposition on the concavity of the fracture. This phenomenon of “bone drift” is well recognized clinically, and has been quantified in the rabbit model (10). However, the majority of remodeling occurs by reorientation of the growth plates, with improvement in the overall alignment of the limb. Asymmetric and longitudinal growth of the physis contribute to this remodeling. Therefore, measurement of angular remodeling at the fracture site alone gives an inadequate picture of the overall limb alignment as remodeling occurs (10,11). Remodeling capacity depends on the number of years of growth remaining, the proximity of the fracture to a rapidly growing physis, the magnitude of angular deformity, and the plane of angulation relative to adjacent joints. Remodeling may continue for 5 to 6 years after fracture, as long as growth occurs during the period of remodeling (11). The rate of remodeling is minimally influenced by age, but the completeness of remodeling may be limited by the number of years of growth remaining (11,12,13 and 14). Fractures in the plane of joint motion and near a rapidly growing physis have the greatest capacity to remodel. Fractures with smaller degrees of malunion are more likely to remodel completely (15). Remodeling of rotational deformity has also been noted in children, but this is less predictable than angular remodeling (16,17). It has been postulated that torsional remodeling occurs by helical growth of the physis (10).

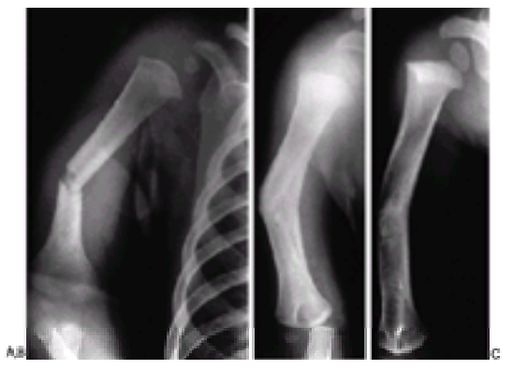

FIGURE 32-1. Periosteal bone formation. **A:** Complete fracture of the humeral diaphysis in a 6-month-old child. The periosteum is presumed to be intact on the compression (concave) side. **B:** Four weeks later, the periosteum has formed a complete column of new bone. **C:** Six months after injury, there has been significant remodeling, with a 50% correction of the angular deformity.

Another distinguishing physiologic response to bone healing in children is the potential for growth stimulation after fracture. The age of the patient and the amount of periosteal stripping influence the amount of growth stimulation (7). This phenomenon is most commonly reported after femoral fractures in children between the ages of 3 and 9 years, but it also occurs after other fractures (18,19,20 and 21). The exact mechanism for growth acceleration is unknown, but increased blood flow to the growth plate and release of periosteal tension after fracture are potential causes. Hyperemia as a cause of overgrowth is supported by the observation that growth acceleration may occur with conditions that cause increased vascularity, such as congenital vascular anomalies, inflammatory conditions, and tumoral disorders (19). Transverse sectioning of the periosteum also produces overgrowth. Periosteal stripping or division close to the growth plate increases the effect of transverse periosteal release, but longitudinal incision of the periosteum does not cause growth acceleration (7,22). Hemicircumferential release of the periosteum causes asymmetric growth and subsequent angular deformity (23). This phenomenon is most often seen clinically after fracture of the proximal tibial metaphysis in children, when the medial periosteum is torn transversely, while the lateral periosteum remains intact. These findings support the observation that the periosteum acts as a mechanical restraint on epiphyseal growth through its attachments to the perichondrial ring (24). In older children, premature physeal closure has been noted after diaphyseal fracture (25,26). Perhaps the variable growth responses after fracture can be partially explained by differences in periosteal damage or asymmetric hyperemic responses after fracture.

INJURY TO THE PHYSIS

Anatomy and Physiology of the Physis

Growth plates are located at the ends of all long bones and contain the cells responsible for bone growth. Longitudinal growth occurs as columns of cartilage form and undergo endochondral ossification. Fracture of the growth plate generally heals within 3 to 4 weeks, because this is a well-vascularized region that is growing rapidly and forming bone at the time of injury.

The development, histology, and physiology of the growth plate are described in greater detail in Chapter 1. Several anatomic features are essential to the understanding of trauma to the growth plate. The germinal zone of cartilage formation is located on the articular side of the physis. This zone consists of resting cells that initiate the process of long-bone growth, by dividing to form the zone of proliferating cartilage. The hypertrophic zone is next. This is a zone of maturation where the chondrocytes begin to enlarge. On the metaphyseal side of this zone, vascular buds grow into the degenerating columns of cartilage and initiate provisional calcification as the chondrocytes degenerate. Remodeling into lamellar bone in the metaphysis rapidly follows provisional calcification.

Fractures through the physis are usually the result of tension or shearing forces. Compressive forces tend to cause fracture through bone. Bright and colleagues (27), using rapid loading techniques to simulate *in vivo* forces, demonstrated that the weakest zone is the zone of provisional calcification. However, fracture failure was rarely limited to one zone, and propagating cracks traversed, at least partially, the upper germinal zones in 85% of the animals tested. In younger animals, the fracture was more likely to traverse only the zone between the hypertrophic cells and metaphyseal bone, avoiding the germinal zones. This is clinically relevant, because injury to the germinal zone may be more likely in older children, and can cause arrest of bone growth.

The perichondrial groove of Ranvier and the perichondrial ring of LaCroix surround each physis circumferentially at the periphery. These structures constitute a separate growth center that provides growth of the physis in width. The groove of Ranvier consists of resting and proliferating cells, whereas the ring of LaCroix consists of cartilage cells that extend toward the metaphysis and become continuous with the metaphyseal periosteum. The groove and ring provide support to the physis and resistance to physeal separation. Additional stability is provided by large and small undulations of the growth plate. The smaller projections are called mamillary processes. Larger contours include the lappet formation, which is the overlapping shape of the physis as it cups the metaphysis. The lappet formation is readily appreciated where the anterior portion of the proximal tibial growth plate extends distally as the tibial tuberosity. Muscular, capsular, and ligamentous attachments to the epiphysis may provide additional stability. However, these structures can also transmit force to the growth plate, resulting in characteristic fracture patterns that vary with the specific anatomy of a joint.

The vascularity of the growth plate is essential to its development. There is strict separation of the epiphyseal and metaphyseal circulation, because blood vessels do not cross the growth plate. There are two patterns of blood supply to epiphyses (28). Some epiphyses are completely intracapsular (e.g., the proximal femur and the proximal radius). Blood vessels for these epiphyses must enter the epiphysis around the periphery of the growth plate, and through a narrow region between the articular cartilage and the physis. This type of blood supply is very susceptible to damage during physeal separation or occlusion of supporting vessels. The second pattern of epiphyseal blood supply is more common, and is seen in epiphyses that are extracapsular (e.g., the proximal tibia and the distal radius). Vessels that supply circulation to the epiphysis and the growth plate penetrate directly through the side of the epiphysis where it is covered with periosteum and capsular attachments. Extracapsular epiphyses are less vulnerable to devascularization when physeal separation occurs.

Physeal Fractures

Physeal fractures constitute 15 to 30% of all childhood fractures (29). The peak age for injury to the growth plate is early adolescence (11 to 12 years), and physeal fracture is uncommon in children younger than 5 years of age. Boys are affected twice as often as girls (29,30). Several classification systems have been proposed since Foucher first described different types of physeal fractures in 1863 (31). The most widely used classification of physeal fractures is that described by Salter and Harris (32). There are five types of fractures in this classification. Rang has added a sixth that is commonly recognized (33) (Fig. 32-2).

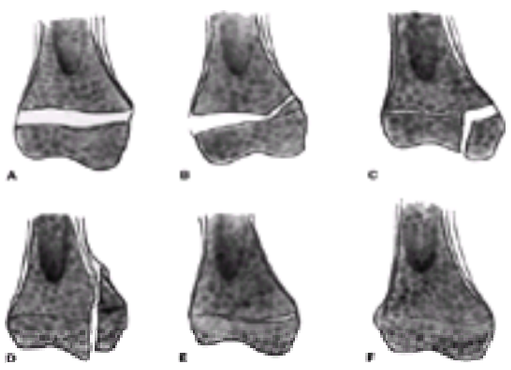

FIGURE 32-2. Salter-Harris classification. **A:** Type I is a transepiphyseal separation without evidence of a metaphyseal fragment. **B:** In type II, the fracture line is through the physis, exiting into the metaphysis, leaving a small triangular portion attached to the physeal plate (i.e., Thurston-Holland fragment). **C:** The type III fracture is an intraarticular fracture, with the fracture traversing the physis and exiting through the epiphysis. **D:** Type IV describes a vertical fracture line that is intraarticular. It passes through the epiphysis, physis, and metaphysis. **E:** Type V fracture describes a crush injury to the physis that usually is not apparent on initial

injury films. **F:** Type VI fracture is a localized injury to a portion of the perichondrial ring. Subsequent healing produces bone formation across the perimeter of the physis, connecting the metaphysis to the epiphysis.

Type I injury involves a transverse fracture through the entire growth plate without evidence of a metaphyseal fragment. This type of fracture is most commonly seen in infants and young children. The epiphyseal fragment may be nondisplaced or minimally displaced, making diagnosis difficult. Localized swelling and point tenderness may confirm the diagnosis. The prognosis for resumption of growth is excellent with a few notable exceptions, such as physeal separation of the proximal or distal femur. Partial growth arrest may occur after severely displaced fractures, when reduction is difficult, or when the growth plate is impaled on the corner of the metaphysis.

Type II fractures represent 75% of all physeal fractures. The fracture line passes through a portion of the growth plate and exits through a triangular segment of the metaphysis that remains attached to the intact portion of the growth plate. The metaphyseal fragment (Thurston-Holland fragment) is on the compression side of the fracture. The prognosis for resumption of growth is good, but growth disturbance occurs in 10 to 30% of patients, depending on the location of the fracture.

Type III injury results when the fracture line traverses a portion of the growth plate, then crosses the epiphysis and the articular surface. The prognosis for resumption of growth is more guarded with this injury, and depends on the vascularity of the physis and damage to the germinal zone. These fractures are more common in older children in whom growth arrest may not be problematic (29). Anatomic reduction is recommended to reduce the risk of growth arrest, and to restore the congruity of the articular surface.

Type IV fractures vertically cross all zones of the physis. These fractures are intraarticular and traverse the epiphysis, physis, and metaphysis. The prognosis for resumption of growth is poor (32). Precise anatomic reduction is recommended to realign the physis and restore the articular surface.

Type V injury results from a crushing force applied to the growth plate. This injury may not be apparent on radiographs, because it does not always involve fracture fragment displacement. Growth arrest is common. Crush injury to the germinal physeal cells can occur in combination with other Salter-Harris fracture patterns.

Type VI injury is a peripheral physeal injury at the level of the perichondrial ring. This may result from ligamentous avulsion, direct trauma, burn, or other forces. Localized growth arrest may occur, and lead to asymmetric growth with angular deformity.

Physeal Arrest

Growth arrest after fracture of the growth plate can result from compromised vascularity of the physis, damage to the germinal cells, and bone bridge formation between epiphyseal and metaphyseal bone (34). Destruction of the epiphyseal vasculature leads to central growth arrest followed by complete epiphysiodesis. In contrast, destruction of the metaphyseal vasculature may temporarily interfere with ossification, but does not result in growth arrest (35). Direct injury to germinal cells of the growth plate can also lead to physeal arrest, but small areas of physeal damage, i.e., less than 7% of the total area, do not usually cause permanent growth disturbance (36,37). Bone bridge formation can also develop after a Salter-Harris type IV fracture when displacement allows the epiphyseal bone to remain in contact with the metaphyseal bone. Peripheral defects result in greater deformities than central defects of the same size, because of their location. Also, small central defects may yield to the force of growth in the remaining viable growth plate (34).

The size and location of physeal arrest determine the kind of deformity that eventually develops. Complete growth arrest may produce limb-length discrepancy without angular deformity. The amount of discrepancy depends on the growth rate of the affected physis and the age of the child. Contralateral epiphysiodesis should be considered as a treatment option, as soon as complete arrest is diagnosed. No treatment is required when there is minimal growth remaining or the resultant lower-extremity discrepancy will be less than 2 cm at maturity. Limb-lengthening is a treatment option, instead of contralateral epiphysiodesis, when the projected discrepancy will be greater than 5 cm.

Partial growth arrest is often a more serious problem than complete arrest, because partial arrest may result in length discrepancy combined with angular deformity and/or joint incongruity. Early recognition is desirable to minimize complications. Partial growth arrest can be recognized as early as a few months after fracture, or may take up to 2 years to become evident. A sclerotic bridge of bone or blurring and narrowing of the growth plate is often visible on plain radiographs if the x-ray beam is tangential to the physis. Another early sign of growth disturbance is the development of an oblique growth arrest line (38) (Fig. 32-3). Magnetic resonance imaging (MRI) may also be useful to detect early physeal arrest (39,40).

FIGURE 32-3. Distal tibial growth arrest. **A:** Distal tibial physeal Salter-Harris type IV injury treated with cast immobilization without reduction. **B:** Two years later, there is varus angulation to the distal tibia from a medial physeal bar. The Harris growth arrest line is not parallel to the distal physis, and does not extend across the entire width of the metaphysis.

Treatment of Partial Growth Arrest

There are many treatment options for partial growth plate damage, depending on the location of the bone bridge, the size of the bar, and the amount of growth remaining. Once identified, partial arrest can be surgically converted to complete arrest to prevent further angulation. This approach may be combined with contralateral epiphysiodesis, when the resulting discrepancy would be greater than 2 cm, but less than 4 to 5 cm. This method can also be combined with osteotomy when angular deformity has already developed. Epiphysiodesis with or without osteotomy is particularly appropriate for growth disturbances of slowly growing physes such as the distal tibia. An alternative treatment plan involves epiphysiodesis with or without angular correction and lengthening (41). This may be appropriate when the predicted discrepancy is greater than 4 to 5 cm, or when osteotomy for deformity correction is necessary. On rare occasions, resection of the physeal bar, with interposition of fat, cranioplast, or other materials, may be appropriate.

Physeal bar resection may be indicated when less than 50% of the physis is damaged, and more than 2 cm of growth remains in the affected growth plate. Corrective osteotomy is often unnecessary if the angular deformity is less than 20 degrees. Before surgical excision, it is necessary to clearly delineate the extent and location of the bar. Plain radiography should be performed with the beam centered on the growth plate and tilted in the same plane as the growth plate. Conventional multiplanar tomography with thin sections has been used in the past to obtain radiographs in the sagittal and coronal planes to detail the bony bar. These radiographs are then used to construct a map of the physis that demonstrates the exact extent and location of the bar (42). Helical computed tomographic scanning and MRI have largely replaced traditional tomography (43,44). Three-dimensional reconstruction using these techniques allows accurate identification of the size and location of the bar.

Three patterns of partial growth arrest have been identified (Fig. 32-4). The most common type is a peripheral bar, which produces an angular deformity. The second type is a central bar, which acts as a central tether, and results in tenting of the physis with eventual articular surface distortion. The third pattern of bar formation is referred to as a “linear bar” and involves portions of the central and peripheral physis. This last type is often the result of a Salter-Harris type IV fracture that has

healed in a displaced position.

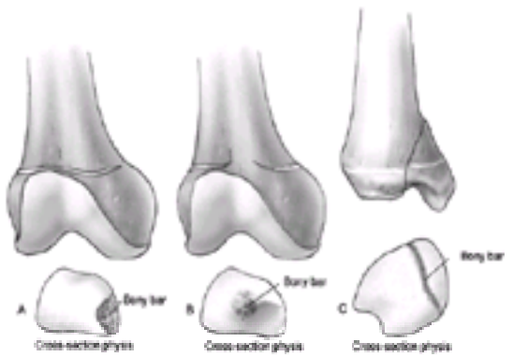

FIGURE 32-4. Growth arrest patterns. **A:** Type I is peripheral growth arrest with a peripheral bony bar. **B:** Type II is central growth arrest with central physeal tethering. The peripheral physis and perichondrial ring are intact. **C:** Type III is combined growth arrest, demonstrating a linear bar involving the peripheral and central portions of the physeal plate. This type of growth arrest is more typical after a Salter-Harris type III or IV fracture.

Peripheral bone bridges are approached directly, with excision of the overlying periosteum and removal of the abnormal bone, until normal physeal cartilage is uncovered. A high-speed bur, small curettes, and a dental pick facilitate the removal of unwanted bone without damaging the normal physis. Loupe magnification, a headlight, and a dental mirror can facilitate visualization of the normal growth plate. Alternatively, an arthroscope can be used to verify complete excision. Interposition material is inserted to prevent the bone bridge from recurring. Fat and cranioplast are the two most commonly used materials for interposition, but cultured chondrocytes or other biologic tissue may be useful in the future (45). The material must remain in contact with the physis during further growth. This is accomplished by securing the interposed substance to the epiphysis. Radio-dense markers are usually inserted in the bone to facilitate the measurement of subsequent growth (Fig. 32-5). Central bars are approached through a metaphyseal window, or through an osteotomy when angular correction is necessary. **[4.22]** An alternative approach is to remove a wedge of metaphyseal bone and replace it after the bar resection has been completed (46). The peripheral margins of the physis are carefully preserved. Intraoperative fluoroscopy may help guide the approach to the bone bridge. A linear bar is approached directly where it contacts the periphery of the growth plate. The bone bridge is then resected from one side to the other, creating a tunnel that follows the original fracture line.

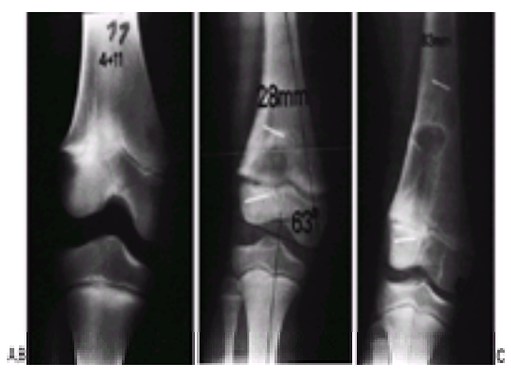

FIGURE 32-5. Physeal bar resection. **A:** A distal physeal bar is depicted in this anteroposterior hypocycloidal tomogram. **B:** This condition was treated with bar excision and insertion of cranioplast. Five months later, the physis remains open, and the two metal markers inserted at the time of surgery are 28 mm apart. There is residual femoral tibial valgus deformity. **C:** Four years later, there has been some improvement in the femoral tibial alignment, and growth of the distal femur has resumed. The markers are 83 mm apart.

Results of excision of partial growth arrest are difficult to evaluate, because long-term results reported in peer-reviewed journals are generally lacking. Some excellent results have been noted, and partial growth has been restored in many cases (47). Williamson and Staheli (48) noted excellent results in 50% of cases with an average follow-up of 2 years. However, others have reported resumption of growth in only 33% of cases (49). Recurrences and additional surgical procedures are common. The resected growth plate may also close prematurely. Therefore, parents should be advised that the results of physeal bar excision are unpredictable.

INITIAL MANAGEMENT CONSIDERATIONS

Multiple Trauma Evaluation and Management

Accidents and injuries are the leading cause of death in children, adolescents, and young adults after the age of 1 year (50). Death from trauma is most often attributable to head injury, but preventable deaths still occur. These are most often caused by airway obstruction, pneumothorax, and hemorrhage (51,52). Children respond differently to trauma than adults. The child's vascular system can maintain systolic blood pressure for a prolonged period of time in the presence of significant hypovolemia. Tachycardia may be the only sign of impending hypovolemic shock, which can occur precipitously. Hypothermia poses a greater problem for children, because they have a higher ratio of surface area to body weight than adults. The child also has greater capacity to recover from neurologic injury and hypoxia. For these reasons, all children should be treated aggressively, with the expectation of survival and recovery of function. Several scoring systems have been developed to predict outcome and assess the need for transport to major trauma centers. The Glasgow Coma Scale is helpful in assessing cortical brain function (53) (Table 32-1). Sequential assessment can help detect worsening or recovery from brain injury. A child with a Glasgow Coma Scale score of less than 8 has a significantly worse prognosis for survival. The score obtained at 72 h after injury is more predictive of permanent impairment (54). The Pediatric Trauma Score is an effective triage tool and a reliable predictor of injury severity (55) (Table 32-2).

Variable	Score
Opening of the eyes	
Spontaneously	4
To speech	3
To pain	2
None	1
Best verbal response	
Oriented	5
Confused	4
Inappropriate words	3
Incomprehensible sounds	2
None	1
Best motor response	
Spontaneous (obedience to commands)	6
Localization of pain	5
Withdrawal	4
Abnormal flexion to pain	3
Abnormal extension to pain	2
None	1

The Glasgow Coma Scale is used to measure level of consciousness. A score of less than 8 carries a worse prognosis for survival. (From ref. 55, with permission.)

TABLE 32-1. GLASGOW COMA SCALE

Variable	+2	+1	−1
Weight (kg)	>20	10–20	<10
Airway patency	Normal	Maintained	Unmaintained
Systolic blood pressure (mm Hg)	>90	50–90	<50
Neurologic	Awake	Obtunded	Comatose
Open wound	None	Minor	Major
Skeletal trauma	None	Closed	Open or multiple

The Pediatric Trauma Score is a reliable predictor of injury severity. Each variable is given one of the three scores. The scores are totaled (range, −6 to +12). A total of 8 or less indicates potentially important trauma.
(From ref. 55, with permission.)

TABLE 32-2. PEDIATRIC TRAUMA SCORE

Initial treatment consists of airway management, fluid resuscitation, and blood replacement. Systematic, multidisciplinary management of all organ systems is essential. Musculoskeletal injuries are common in the severely traumatized child, and may be obscure. Children with multiple injuries should be treated as though they have a cervical spine injury, until this can be ruled out clinically or radiographically. Regional examination of the spine, pelvis, shoulders, and extremities should be complete, especially if the child cannot communicate.

Management of fractures may need to be altered from conventional methods to meet the general needs of the patient. Armstrong and Smith (56) have recommended the following principles for children with major trauma:

1. Make sure that any child with a major long-bone fracture does not have any other significant injuries.
2. Early treatment of the fractures should be compatible with the general care of the patient.
3. Fracture care should consider the need for early mobilization of the child.
4. Care of fractures should facilitate the management of associated soft tissue injuries.
5. The initial method of fracture management should be the definitive method, whenever possible.
6. Fracture care must be carefully individualized.
7. Treat all children as though they are going to survive.

Open Fractures

Open fractures result from high-energy trauma or penetrating wounds. The tibia is the most commonly involved site in children and adults. Open tibial fractures are discussed in the section on tibial fractures. The femur, forearm, humerus, and other bones may also sustain open injuries.

The traditional classification system of Gustillo (modified by Mendoza) (57) is illustrated in Table 32-3. This classification system is appropriate for children as well as adults, and provides a method of assessment for purposes of management and prognosis.

Wound Type	External Wound Size	Fracture Pattern	Soft Tissue Damage
Type I	<2 cm	Simple	Minimal muscle contusion
Type II	2–10 cm	Simple; minimal comminution	Mild muscle damage; no crush
Type IIIA	Extensive or gunshot wound	Comminuted or segmental fracture	Adequate local soft tissue coverage
Type IIIB	Extensive or crush injury	Extensive periosteal stripping; bone loss	Incomplete coverage; exposed bone
Type IIIC	Same as above	Same as above	Neurovascular injury

(From ref. 57, with permission.)

TABLE 32-3. CLASSIFICATION OF OPEN FRACTURES

Management of open fractures requires prompt initiation of antibiotic and tetanus prophylaxis (58). Operative irrigation and debridement should be performed as soon as possible, to minimize the subsequent risk of infection (59). All necrotic or devitalized material is removed. Bone devoid of soft tissue attachments is removed, especially if it is grossly contaminated. However, children frequently have less comminution than adults, and periosteum is often attached to most segments. Avascular segments of bone that are clean may be preserved, if needed, to provide fracture stability. Bone should be stabilized to create optimal conditions for soft tissue recovery. Cultures can be obtained, but their value for subsequent management is questionable. Partial wound closure over a drain is acceptable for clean grade I and grade II injuries (58,60). Early soft tissue coverage is advantageous, and may require local or free-flap reconstruction (61). Patients with open wounds are returned to the operating room in 48 to 72 h for repeat irrigation, debridement, and possible delayed primary closure or flap coverage. Antibiotics are generally used for 72 h. Cephalosporins are used for grade I injury, and an aminoglycoside is added for grade II or grade III injury. Specific antibiotic selection is made after the culture results become available.

Open fractures in children take longer to heal, and have more complications than closed injuries (16,62,63). Open fractures in children share many of the same complications reported in the adult literature. However, the overall complication rates in children are less than in adults with similar injuries (64,65 and 66). This is especially true for children younger than 12 years of age (64,66).

Compartment Syndromes

Compartment syndrome develops when there is an increase of interstitial pressure in a closed osteofascial compartment, resulting in inadequate circulation to the nerves and muscles of that compartment. There is little documentation of the incidence of compartment syndrome, but it has been reported in numerous anatomic regions, including the abdomen. Increased intracompartmental pressure may develop after athletic exertion, relatively minor injuries, and major trauma (67,68 and 69).

Increased tissue pressure in a confined space leads to obstruction of venous outflow from the compartment. This contributes to further swelling and increased pressure. When the pressure increases above the arteriolar circulatory pressure to muscle and nerve, ischemia will occur, leading to irreversible damage to the contents of the compartment. Muscle and nerve damage commences as soon as 4 to 6 h after the onset of abnormal pressures.

Pain out of proportion to the injury should alert the clinician to the possibility of impending or established compartment syndrome. Excessive pain is often the earliest symptom. This is followed rapidly by clinical findings that include sensory changes associated with nerve ischemia within the compartment, excessive pain with passive movement of the muscles within the compartment, and loss of active movement of those muscles. Distal pulses and peripheral capillary refill are unreliable indicators of compartment syndrome. Peripheral circulation may be normal, because major arterial blood flow through the compartment is preserved in the presence of increased pressures, which eliminate microvascular perfusion to the muscles and nerves within the compartment. The injured extremity should not be elevated when compartment syndrome is suspected, because this maneuver reduces mean arterial pressure, causing a reduction in perfusion that leads to further ischemia.

The diagnosis of acute compartment syndrome is based on signs and symptoms. Tissue pressure measurements should be obtained whenever the diagnosis is in doubt (70) (Fig. 32-6). The pressure threshold for fasciotomy is not clearly established. Mubarak and Owen (71) recommend fasciotomy if compartment pressure

exceeds 30 mm Hg. Others recommend fasciotomy if the pressure is greater than 35 to 40 mm Hg or within 30 mm Hg of the patient's diastolic pressure (70).

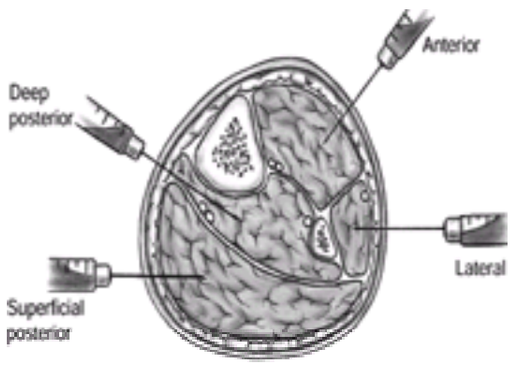

FIGURE 32-6. Orientation and entry points for measurement of compartment pressures. (From ref. 70, with permission.)

Fasciotomy of the forearm can be accomplished by the volar Henry approach or the volar ulnar approach (69). It is essential to decompress the deep flexor compartment, in addition to the superficial flexor compartment muscles (Fig. 32-7 and Fig. 32-8). Fasciotomy of the leg can be performed by single-incision or double-incision technique (70) (Fig. 32-9). The two-incision technique facilitates decompression of the deep posterior compartment. The fibula should be left intact. Devitalized muscle is debrided when necessary, but extensive debridement is usually performed 36 to 72 h later, when muscle viability is more readily determined. Approaches for foot compartment syndromes are discussed in the section on metatarsal fractures.

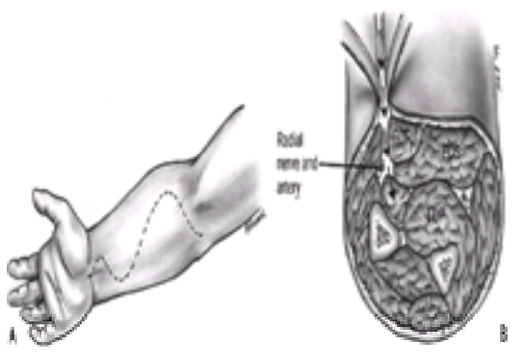

FIGURE 32-7. A: Skin incision crosses the elbow crease and enters the palm along the thenar eminence. **B:** The superficial fascia is divided. The deep compartment is approached by retracting the flexor carpi radialis (*FCR*) to the ulnar side. The superficial radial nerve and brachioradialis are retracted radially. The Henry approach is used for decompression of the volar forearm compartments. *FDP*, flexor digitorum profundus; *FDS*, flexor digitorum sublimus.

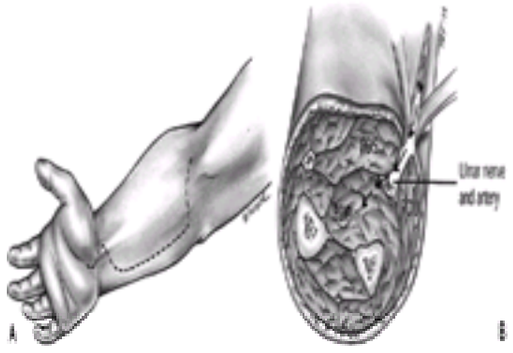

FIGURE 32-8. The volar ulnar approach (modified McConnell exposure) is more direct for decompressing the forearm compartments. **A:** Skin incision extends along the ulnar side of the forearm. **B:** The ulnar nerve and artery are retracted to expose the deep flexor compartment. *FDP*, flexor digitorum profundus; *FDS*, flexor digitorum sublimus; *FCU*, flexor carpi ulnaris.

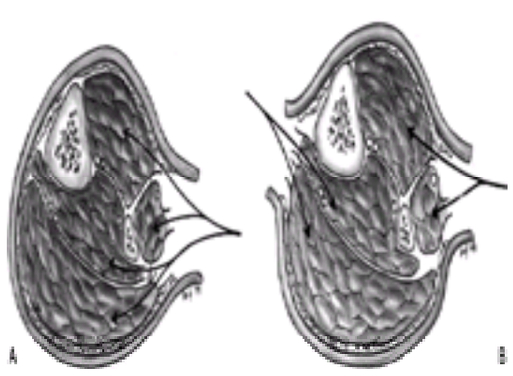

FIGURE 32-9. A: Single-incision fasciotomy may be used to decompress all four compartments of the leg. Excision of the fibula is not necessary. **B:** Double-incision fasciotomy allows a more direct approach to the deep posterior compartment of the leg. (From ref. 70, with permission.)

Anesthesia and Analgesia for Emergency Department Management

Numerous techniques have been used to provide sedation and pain relief for outpatient fracture management (72,73,74,75,76,77 and 78). These can be categorized into three groups: blocks, sedation, and dissociative anesthesia (75). When sedation or dissociative anesthesia is used, it is advisable to follow guidelines for monitoring and management that have been established by the American Academy of Pediatrics (79).

Blocks

Local and regional blocks include hematoma blocks, nerve blocks, and intravenous regional anesthesia. Hematoma block is particularly useful for distal radius fractures. After appropriate skin preparation, a needle is inserted into the fracture hematoma. The hematoma is aspirated, and 3 to 10 mL of 1 or 2% lidocaine (maximum dose is 3 to 5 mg/kg of body weight) is injected into the fracture site. This technique has been shown to be safe and effective in adults, without any reports of infection (72). Excessive volume of injection should be avoided, because hematoma block can increase carpal tunnel pressure and increase the risk of neurologic

complications (80). A randomized prospective study compared hematoma block with intravenous regional block, and found that hematoma block required less time to administer and provided adequate pain relief for reduction (81). The technique of hematoma block may be difficult when the hematoma is small, as in greenstick fractures, or when the fracture hematoma has already coagulated.

Intravenous regional anesthesia, or Bier block, has been reported to be successful by several authors (74,82). The primary site of nerve block is thought to be small, peripheral nerve branches. For this reason, it is suggested that nerve blockade is better achieved with a larger volume of dilute anesthetic (8,74). Intravenous access is obtained in a vein of the dorsum of the hand of the injured extremity. It is not necessary to have additional intravenous access to the opposite extremity. The arm is then exsanguinated by elevation, or by gentle application of an elastic bandage. A single blood pressure cuff is then rapidly inflated above the elbow to 100 mm Hg greater than systolic blood pressure. The cuff may be taped to avoid Velcro failure, and the inflation tube may be cross-clamped to prevent premature cuff deflation. Two cuffs may be used to minimize tourniquet discomfort, but this is not usually necessary for fracture reductions. Lidocaine, diluted with normal saline to a 0.125% solution, is then administered in a dose of 1 to 1.5 mg/kg of body weight (74). The tourniquet should be kept inflated for at least 20 minutes to permit the lidocaine to become fixed to the tissue, thus minimizing the risk of lidocaine toxicity when the cuff is deflated. This method has proven most effective for forearm fractures and less effective for supracondylar, finger, and hand fractures (8).

Ulnar nerve block at the elbow, median nerve block at the wrist, or digital blocks can be useful for reduction of certain hand and finger fractures and dislocations. Axillary block has proved to be a safe technique for a variety of upper-extremity fractures in children (83). In most children, the axillary sheath is superficial, and the pulse is easily identified, compared with adults, who generally have more subcutaneous fat. Intravenous access in the uninjured extremity is recommended, and can be used to administer low-level sedation before axillary block. The arm is abducted and externally rotated to a 90–90 position (i.e., hip and knee flexed 90 degrees); 1% plain lidocaine is used at a dose of 3 to 5 mg/kg of body weight. Cramer et al. (83) recommend the transarterial method of administration. A 23-gauge butterfly needle is inserted through the axillary artery during continuous aspiration. Approximately two-thirds of the lidocaine is slowly injected into the sheath on the opposite side of the artery. Periodic aspiration is performed to minimize the risk of intraarterial injection. The needle is withdrawn just to the superficial side of the sheath, and the remaining lidocaine is injected. This anesthetic technique provides prolonged pain relief for complex manipulations, but requires considerable cooperation from the patient.

Sedation

Conscious sedation is defined as a level of consciousness that maintains protective reflexes and retains the patient's ability to maintain an airway independently. During conscious sedation, the patient can respond appropriately to verbal commands or physical stimulation. Deep sedation is defined as a more profound state of unconsciousness, accompanied by partial or complete loss of protective reflexes and inability to respond purposefully to verbal or physical stimuli. The American Academy of Pediatrics has developed specific guidelines for monitoring and managing pediatric sedation (79). These guidelines state that the risks of deep sedation may be indistinguishable from those of general anesthesia.

Narcotics and benzodiazepines are widely available agents for intravenous sedation. Narcotics provide analgesia, whereas benzodiazepines are primarily sedatives. These drugs act synergistically to induce controlled sedation and analgesia. Intravenous access and continuous monitoring of pulse and oxygen saturation are advised. Respiratory rate and blood pressure should be monitored periodically. An emergency cart with resuscitation equipment should be immediately available. Nasal oxygen and personnel skilled in airway management increase the level of safety.

Numerous medications and combinations of medications have been used (75) (Table 32-4). Varela and associates (77) reported satisfactory pain relief in 98% of patients who were sedated by titrating meperidine (Demerol) and midazolam (Versed). The target doses were 2 and 0.1 mg/kg of body weight for meperidine and midazolam, respectively. Meperidine is less potent than morphine, but it has a slightly faster onset and some euphoric properties (75). Fentanyl, a potent narcotic, is sometimes used as a substitute for meperidine, because it reaches peak analgesia within 2 to 3 minutes, and has a shorter duration of action than meperidine. Hypoxemia and apnea are not uncommon after sedation with midazolam and fentanyl. Monitoring of oxygen saturation is essential, because hypoxemia can occur in the absence of apnea. If respiratory depression occurs, reversal agents should be administered. Naloxone is used to reverse the narcotic effect, and the benzodiazepine is reversed with flumazenil (75).

Medication	Dosage	Comments
Midazolam (Versed)	0.05–0.2 mg/kg IV	Benzodiazepine
Meperidine (Demerol)	1.0–2.0 mg/kg IV	Narcotic
Fentanyl	1.0–5.0 μg/kg IV	Potent, rapid-onset narcotic
Ketamine	1.0–2.0 mg/kg IV, 3.0–4.0 mg/kg IM	Manage emergence reactions with small doses of midazolam
Naloxone (Narcan)	1.0–2.0 μg/kg IV	Narcotic-reversal agent
Flumazenil (Romazicon)	5.0–10.0 μg/kg IV (maximum, 0.2 mg)	Benzodiazepine-reversal agent
Atropine	0.01 mg/kg IV or IM (maximum, 0.5 mg)	Antisialagogue
Glycopyrrolate	4.0–10.0 μg/kg IV or IM (maximum, 0.25 mg)	Antisialagogue

IM, intramuscular; IV, intravenous.
(Adapted from ref. 75, with permission.)

TABLE 32-4. MEDICATIONS MOST COMMONLY USED FOR SEDATION IN PEDIATRIC FRACTURE REDUCTION

Dissociative Anesthesia

Ketamine has gained popularity as a useful drug for emergency department use (84,85). It induces a trance-like state that combines sedation, analgesia, and amnesia, with little cardiovascular depression. It has been suggested that protective orotracheal reflexes are preserved, but respiratory depression is dose-related (84,85). The intramuscular or intravenous route may be used to administer ketamine. The intravenous route permits titration and more rapid onset of action, with quicker recovery. The target intravenous dose is 1 to 2 mg/kg of body weight. The intramuscular dose is 4 mg/kg, and a repeat dose may be given after 10 to 15 minutes, if necessary. Ketamine increases upper-airway secretions, so atropine or glycopyrrolate are recommended before sedation. Emergence hallucinations are more common in children older than 10 years of age. Therefore, ketamine may be a less desirable choice in older children. When ketamine is used in older children, low-dose midazolam (0.05 mg/kg) can reduce the risk of emergence reactions (76).

INJURIES OF THE SHOULDER AND HUMERUS

The clavicle, scapula, and humerus articulate to form the shoulder. The clavicle is flat laterally, triangular medially, and has a double curve that is convex anteriorly in the medial third and convex posteriorly in the lateral third. The scapula is a large, flat, triangular bone that is connected to the trunk by muscles only. The spine arises from the dorsal surface and forms the acromion laterally, and the coracoid process arises from the anterior surface. The clavicle and scapula are attached at the acromioclavicular joint, and held in place by the coracoclavicular ligaments. The clavicle connects the shoulder girdle to the axial skeleton at the sternoclavicular joint. This joint is very mobile and allows the clavicle to move through an arc of 60 degrees and accommodate a wide range of scapular rotation. The shoulder girdle articulates with the humerus through the glenohumeral joint. This joint is a ball-and-socket joint that is supported primarily by the articular capsule and surrounding muscle. Thus, the shoulder mechanism functions as a universal joint, allowing freedom of motion in all planes.

Fractures around the shoulder are generally easy to treat, and rarely require reduction or surgical stabilization. The wide range of motion in this region contributes to rapid remodeling and accommodates modest residual deformity.

Shoulder Injuries in Infants

Difficult birth can result in injury to the infant's shoulder (86). The most common injuries are fracture of the clavicle and brachial plexus palsy. The differential diagnosis should also include proximal humeral physeal separation, septic arthritis of the shoulder, osteomyelitis, and nonaccidental injuries. Lack of arm movement in the neonatal period is the most common clinical finding for each of these problems. Pain, swelling, and crepitus may be noted when fracture has occurred. Often, birth fracture of the clavicle is undetected until swelling subsides and the firm mass of healing callus is noticed in the midshaft of the clavicle. Parental reassurance

and gentle handling are all that are required for managing birth fracture of the clavicle. Clavicle fracture is occasionally confused with congenital pseudarthrosis of the clavicle. Pseudarthrosis can be distinguished from birth fracture of the clavicle by the absence of pain, and by radiographic features of established pseudarthrosis.

Neonatal trauma may also result in Salter-Harris type I physeal separation of the proximal humerus. This injury may be difficult to diagnose radiographically, because the proximal humeral epiphysis does not ossify until 3 to 6 months of age. Ultrasonography, MRI, or joint aspiration may facilitate diagnosis in questionable cases. Closed reduction is not indicated because healing is rapid and remodeling is certain. Immobilization for 2 to 3 weeks provides comfort and allows union to occur.

Clavicle Fractures

Clavicle Diaphysis Fracture

The clavicle is frequently fractured in children, and the most common portion injured is the shaft. The mechanism of injury is usually a fall on the shoulder or excessive lateral compression of the shoulder girdle. The subclavian vessels, brachial plexus, and apex of the lung lie beneath the clavicle, but are rarely injured at the time of fracture.

Treatment of clavicle shaft fractures in children and adolescents is supportive; reduction is not attempted, except for fractures with extreme displacement. Both a figure-eight harness and a sling are used initially to provide comfort. After a few days, the sling may be discontinued. The figure-eight harness is worn for 3 to 4 weeks, and sports are avoided for an additional 2 to 3 weeks. Uneventful, rapid healing is the rule, although many fractures heal in a malunited position with palpable subcutaneous callus. Parents should be advised that, regardless of alignment, healing will produce a bump that will remodel over the course of several months. Operative indications are rare, but include open fractures, severe displacement with the bone end impaled through the trapezius, and irreducible tenting of the skin by the bone fragments. Even in these severe cases, internal fixation is rarely required. Nonunion after clavicle fracture has been reported in adolescents, but it responds to bone grafting and plating (87).

Medial Clavicle Fracture

The medial clavicular ossification center appears at approximately 17 years of age, but the physis does not close until the person is 20 to 25 years of age (88). Thus, fractures of the medial end of the clavicle consist of physeal separations, mimicking sternoclavicular dislocation (89). These are Salter-Harris type I or II injuries, although the epiphyseal fragment is not visualized well on radiographs. The direction of displacement can be anterior or posterior. Posterior displacement can cause dysphagia or respiratory compromise, especially when the child's head and neck are extended. Apical lordotic radiographs are helpful, but computed tomography (CT) scans best visualize the deformity (Fig. 32-10).

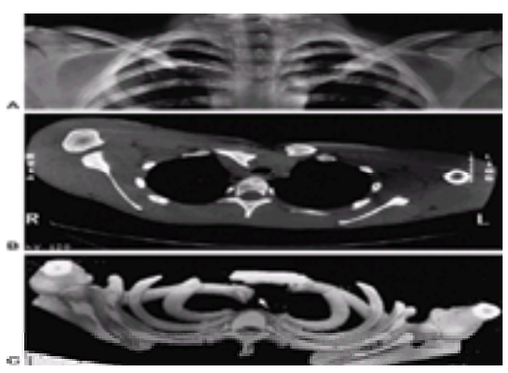

FIGURE 32-10. Sternoclavicular separation. This 14-year-old boy sustained an injury to the right clavicle during a wrestling match when his shoulder was compressed against his chest wall. He complained of shortness of breath, especially when he extended his neck. **A:** The anteroposterior radiograph demonstrates asymmetry of the sternal position of the clavicle. **B:** The computed tomographic scan demonstrates posterior displacement of the medial end of the right clavicle, which is in close proximity to the trachea. **C:** A three-dimensional reconstruction, with a cephalic projection, demonstrates the posterior and midline displacement of the clavicle.

Treatment of posteriorly displaced fractures consists of closed reduction. This is performed under general anesthesia for complete relaxation. The reduction maneuver entails hyperextension of the clavicle combined with longitudinal arm traction. It may also be necessary to capture the medial clavicle with a percutaneous towel clip, and pull in an anterolateral direction. Posteriorly displaced fractures are usually stable after reduction. A shoulder immobilizer or figure-eight harness provides sufficient immobilization. Anteriorly displaced epiphyseal separations are less stable, and partial redisplacement may occur. However, remanipulation or operative treatment is unnecessary, because fracture remodeling will occur.

Lateral Clavicle Fracture

The mechanism of injury to the distal clavicle is similar to adult acromioclavicular separation. A fall onto the point of the shoulder drives the acromion and scapula distally. This results in distal clavicular physeal separation. The distal epiphysis of the clavicle remains a cartilaginous cap into the mid-20s (88), whereas the acromioclavicular and coracoclavicular ligaments are firmly attached to the thick periosteum of the clavicle. Typically, the lateral metaphysis displaces through the injured dorsal periosteum, leaving the ligaments intact and the epiphyseal end of the clavicle reduced in the acromioclavicular joint (90) (Fig. 32-11). Because these injuries represent physeal disruption with herniation of bone from the periosteal tube, tremendous potential for healing and remodeling exists.

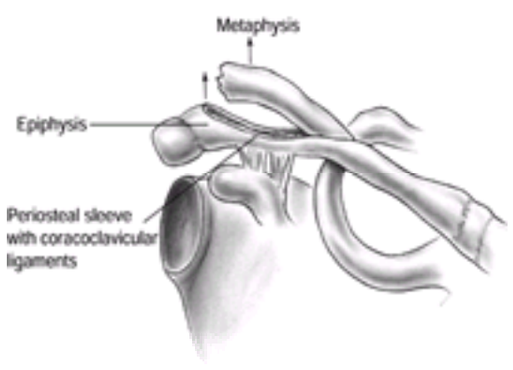

FIGURE 32-11. Lateral clavicle fracture-separation. The swelling and dorsal prominence of the clavicle may suggest an acromioclavicular separation. However, the distal epiphysis of the clavicle and acromioclavicular joint remain reduced. New bone forms from periosteum, with subsequent remodeling of the prominence. (From ref. 90, with permission.)

Treatment of most distal clavicle fractures consists of support with a sling or shoulder immobilizer for 3 weeks. Reduction and fixation are unnecessary, except for the rare instance in which the clavicle is severely displaced in an older adolescent (91).

Acromioclavicular Separation

True acromioclavicular separation is very rare before the age of 16 years. Fracture or physeal separation of the distal clavicle is more common, and has been called “pseudodislocation of the acromioclavicular joint” (92). Tenderness over the acromioclavicular joint and prominence of the lateral end of the clavicle are present with

fracture, physeal separation, and joint separation. Radiographs demonstrate increased distance between the coracoid process and the clavicle, compared with the opposite side. The MRI can distinguish between these three similar injuries, but it is rarely necessary, because the treatments are similar. When true joint separation occurs, the injury may be a sprain, subluxation, or dislocation. These have been classified as grades I to III, depending on the severity of injury to the acromioclavicular and coracoclavicular ligaments (93).

Treatment of all grades of separation is usually conservative without attempting reduction. Therefore, it is unnecessary to determine the degree of separation by stress radiography with handheld weights. A sling or shoulder immobilizer is used for 3 weeks followed by a graduated exercise program. Even in competitive athletes, shoulder strength and range of motion are not impaired after rehabilitation (94,95,96 and 97). In complete separations (type III), the clavicle remains prominent, but is usually asymptomatic. The occasional patient who develops late symptoms of pain and stiffness may be relieved by resection of the distal clavicle (95).

Scapular Fracture

Fracture of the scapula, although rare in children, should be suspected whenever there is shoulder tenderness or swelling after trauma. These fractures are usually the result of a severe, direct blow of high energy. Therefore, initial evaluation should include a diligent search for more serious chest injuries, such as rib fractures, pulmonary or cardiac contusion, and injury to the mediastinum. Fractures of the scapula can involve the body, glenoid, or acromion. Avulsion fractures of the scapula have also been reported, and result from indirect trauma (98). The CT is quite helpful for evaluating scapular fractures and associated injuries.

Treatment for most scapular fractures consists of immobilization with a sling and swathe, followed by early shoulder motion after pain has subsided. The scapular body is encased in thick muscles, so displacement is rare and well tolerated after healing (91). Fractures of the acromion or coracoid require surgery only when severely displaced. Glenoid fractures are the most likely to require reduction and internal fixation. Intraarticular fractures with more than 3 mm of displacement should be restored to anatomic positions. Large glenoid rim fractures can be associated with traumatic dislocations. An anterior approach is recommended for anterior glenoid fractures, and a posterior approach is used for scapular neck and glenoid fossa fractures (99).

Shoulder Dislocation

Less than 2% of glenohumeral dislocations occur in patients younger than 10 years of age (100). These may be traumatic or atraumatic. Atraumatic shoulder dislocations and chronic shoulder instability are discussed in Chapter 4 of this text. Traumatic shoulder dislocation in the adolescent age group is more common. Approximately 20% of all shoulder dislocations occur in persons between the ages of 10 and 20 years. Most displace anteriorly, and produce a detachment of the anteroinferior capsule from the glenoid neck (i.e., Bankart lesion).

Treatment of traumatic shoulder dislocation in children and adolescents is nonoperative, with gentle closed reduction. This is accomplished by providing adequate pain relief, muscle relaxation, and arm traction that is gravity-assisted in the prone position. An alternative method is the modified Hippocratic method, in which traction is applied to the arm, while countertraction is applied using a folded sheet around the torso. After reduction, a shoulder immobilizer or sling is used for 2 to 3 weeks before initiating shoulder muscle strengthening. The most frequent complication is recurrent dislocation, which has an incidence between 60 and 85%, usually within 2 years of the primary dislocation (101,102). Posterior dislocations of the shoulder may also recur, and require surgical stabilization in children (103).

Proximal Humerus Fractures

Proximal humeral growth accounts for 80% of the length of the humerus. The proximal humeral physis is an undulating structure that forms a tent-like peak in the posteromedial humerus quadrant, near the center of the humeral head. The glenohumeral joint capsule extends to the metaphysis medially. Thus, a portion of the metaphysis is intracapsular. The proximal humeral physis remains open in girls until age 14 to 17 years and in boys until age 16 to 18 years.

Mechanisms of injury that would produce a shoulder dislocation in adults usually result in a proximal humeral fracture in children and adolescents. These are usually Salter-Harris type II epiphyseal separations or metaphyseal fractures. Metaphyseal fractures are more common before the age of 10 years, and epiphyseal separations are more common in adolescents. The distal fragment usually displaces in the anterior direction, because the periosteum is thinner and weaker in this region. Posteriorly, the periosteal sleeve is thicker and remains intact. The proximal fragment is flexed and externally rotated, because of the pull of the rotator cuff, whereas the distal fragment is displaced proximally as a result of the pull of the deltoid muscle. Adduction of the distal fragment is caused by the pectoralis major muscle. The long head of the biceps may be interposed between the fracture fragments, and further impede reduction. Remarkably, this is a relatively benign injury, because of the rapid rate of remodeling with growth and the wide range of shoulder motion (104,105).

The majority of these fractures are minimally displaced or minimally angulated. These are managed in a shoulder immobilizer for 3 to 4 weeks, followed by range of motion exercises and gradually increased activity.

Severely displaced fractures pose a greater dilemma for the treating physician. The alarming radiographic appearance invites overtreatment. These fractures are difficult to reduce and almost impossible to maintain in a reduced position by closed methods. Traction and cast immobilization have mostly been abandoned, because these techniques are inconvenient, cumbersome, and have not been shown to improve results. Current options for management include immobilization without attempting reduction and reduction under anesthesia with percutaneous pinning. Authors who have studied these options have concluded that the majority of severely displaced fractures should be treated by sling and swathe immobilization (104,105 and 106). Complete displacement, 3 cm overriding, and 60 degrees of angulation may be accepted in all children and adolescents with open physes (Fig. 32-12). Closed or open reduction under anesthesia with percutaneous pinning may be indicated for fractures with deformity greater than this, or in situations in which tenting could lead to skin breakdown, such as open fractures, vascular injuries, and severe displacement (91) (Fig. 32-13).

FIGURE 32-12. Proximal humeral fracture separation in a 12-year, 3-month-old boy. **A:** The initial fracture displacement was treated with sling and swathe. **B** and **C:** Three months after injury, healing and early remodeling are evident. **D** and **E:** Twelve months after injury, anteroposterior and lateral radiographs demonstrate continued remodeling. **F** and **G:** The patient recovered full range of motion with a 2-cm length discrepancy.

FIGURE 32-13. Salter-Harris type II fracture of the proximal humerus in a 15-year-old adolescent. **A:** Displaced fracture with 70 degrees of angulation. The proximal fragment is abducted and externally rotated, because of the rotator cuff attachments. The shaft is displaced proximally by the pull of the deltoid muscle, and is generally adducted by the action of the pectoralis muscle. The distal fragment is also internally rotated if the arm is placed in a sling. **B** and **C:** Anteroposterior and lateral radiographs after closed reduction and percutaneous pinning. The arm is externally rotated and abducted with longitudinal traction to achieve this position. **D:** Final alignment after removal of the pins 4 weeks later.

Humeral Shaft Fracture

Humeral shaft fractures are less common in children than adults. Birth fractures of the humeral shaft may occur as a result of difficult delivery. Humeral fractures in children younger than 3 years of age are often the result of nonaccidental injury (107). Any time there is a delay in seeking medical attention, inconsistent history of injury, or evidence of concurrent injuries, there is an increased likelihood of inflicted trauma. However, no particular fracture pattern is diagnostic of child abuse. Fractures seen in older children are usually the result of blunt trauma. The radial nerve is susceptible to injury, because it is fixed by the intramuscular septum as it passes lateral to the humerus at the junction of the middle and distal thirds. The prognosis for radial nerve recovery is excellent. Nerve injury with closed fractures of the humerus should be observed for 3 months before considering intervention.

Treatment of humeral shaft fractures consists of closed management. Infants may be treated with gentle positioning, a small coaptation splint, or the arm may be splinted in extension, using a tongue blade and tape. Healing is prompt in infants and young children. It is the authors' opinion that up to 45 degrees of angulation can be accepted before 3 years of age. Older children may be treated with a coaptation splint and a sling to maintain alignment of the arm. A hanging arm cast or collar and cuff may also be used, but a U-slab coaptation splint allows better control of the fracture. Occasionally, an abduction splint or pillow is necessary to control varus alignment. In older children and adolescents, complete displacement and 2 cm of shortening are acceptable. In the proximal shaft, one can accept 25 to 30 degrees of angulation. Fracture deformity closer to the elbow is more visible. Only 20 degrees of angulation is acceptable in the middle third and 15 degrees in the distal third of the humeral shaft (106,108). Greater degrees of deformity are usually unacceptable cosmetically, even though they may remodel without causing functional problems. Operative indications include open fractures, multiple injuries, and ipsilateral forearm fractures in adolescents (i.e., “floating elbow”). Fixation techniques include the use of flexible intramedullary nails **[➥1.9]**, antegrade insertion of a Rush rod, and compression plating. Severe open fractures can be stabilized with an external fixator, until union is complete or until fracture stability and wound healing permit converting to splint immobilization.

FRACTURES AND DISLOCATIONS ABOUT THE ELBOW

It is best to assume the worst when evaluating the child with an elbow injury. Only full range of motion, complete absence of swelling, and normal radiographs warrant the diagnosis of sprain or contusion. Any swelling or restriction of movement necessitates thorough evaluation with comparison radiographs of the opposite elbow, whenever there is doubt regarding normal anatomy. Small fractures that appear to be avulsions should be accurately diagnosed, because they may indicate major pathology. Arthrography, ultrasonography, and MRI have been used to successfully diagnose occult elbow trauma in children (109,110 and 111). These techniques should be considered whenever there is doubt regarding the diagnosis.

The elbow region is injured frequently and accounts for 8 to 12% of all fractures in children and adolescents. The majority of injuries occur in the 5- to 10-year age group. Supracondylar fracture of the distal humerus is the most common, representing 75% of all elbow fractures, followed by lateral condylar (17%) and medial epicondylar injuries. T-condylar, medial condyle, and lateral epicondyle fractures are rare, and have a combined incidence of less than 1%. Delineating exact fracture patterns is a challenge in young children, because of the large cartilage composition of the distal humerus; at birth, the distal epiphysis of the humerus is still completely cartilaginous. There are also multiple ossification centers that appear at different ages (Fig. 32-14). The capitellum is the first to appear, at 6 months of age, followed by the radial head and the medial epicondyle at 5 years of age. The trochlea ossifies at 7 years, and the lateral epicondyle and olecranon appear at 9 and 11 years of age, respectively. The lateral epicondyle, trochlea, and capitellum coalesce to form a single epiphysis by 12 years of age.

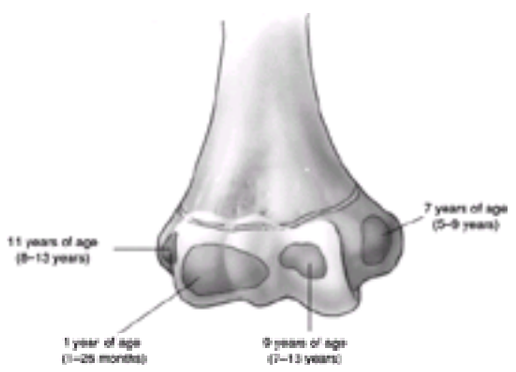

FIGURE 32-14. Ossification of the secondary centers of the distal humerus. The average ages are specified, and the age ranges are indicated. The ossification ranges are earlier for girls than for boys. The lateral epicondyle, capitellum, and trochlea coalesce between 10 and 12 years of age, subsequently fusing to the distal humerus between 13 and 16 years of age. This is about the time that the medial epicondyle fuses to the proximal humerus.

The elbow is a complex joint, and has three major articulations: radiohumeral, ulnohumeral, and radioulnar joints. Except for the medial and lateral epicondyles, the other ossification centers are intraarticular. Other intraarticular structures include the olecranon fossa and the coronoid fossa and process. There are two fat pads: one in the olecranon fossa posteriorly, and the other in the coronoid fossa anteriorly. Displacement of the posterior fat pad may be visible on radiographs after elbow trauma. This is a reliable indication of intraarticular effusion. The anterior fat pad is sometimes seen under normal conditions, and does not necessarily indicate joint effusion. Most of the distal humerus has good collateral circulation, with the majority of the intraosseous blood supply entering posteriorly. Caution should be exercised to avoid disrupting this posterior blood supply during surgical exposure of fractures (112). The trochlea and medial condyle are particularly vulnerable to avascular necrosis, because they are perfused by sets of nonanastomotic nutrient vessels that enter the bone posteriorly and medially (113).

The clinical carrying angle of the normal elbow is a slight valgus alignment, averaging approximately 7 degrees. There are several helpful radiographic lines and angles that can be measured to determine if there is adequate postinjury alignment; a comparison view of the other elbow often is needed as a reference (Fig. 32-15). All measurements are subject to the inaccuracies caused by elbow positioning, and this should be kept in mind when making clinical decisions. The Baumann angle is used to assess the varus attitude of the distal humerus, usually after a supracondylar elbow fracture. It is the angle formed between the capitellar physeal line and a line perpendicular to the long axis of the humerus. This angle normally should be within 5 to 8 degrees of the contralateral elbow. An anteroposterior view of the distal humerus, positioned parallel to the radiographic plate, is necessary to reduce the variation of the Baumann angle that occurs by rotating the arm. Ten degrees of rotation produces a 6-degree change in the angle (114). Another measure of coronal alignment is the medial epicondylar epiphyseal angle. This angle is measured between the long axis of the humerus and a line through the medial epicondylar physis (115). It has the advantage of being reliably measured while the elbow is held

in flexion (i.e., Jones view), such as during the reduction process. The medial epicondylar epiphyseal line ranges from 25 to 46 degrees. This angle is not reliable for children younger than 3 years or older than 10 years of age (115). Sagittal alignment may be determined by the lateral capitellar angle, which indicates the normal forward-flexed position of the capitellum. This angle averages 30 to 40 degrees. The anterior humeral line offers a similar means to assess the position of the capitellum, and is measured on a true lateral radiographic projection. A line along the anterior humeral cortex should pass through the center of the capitellum (Fig. 32-15).

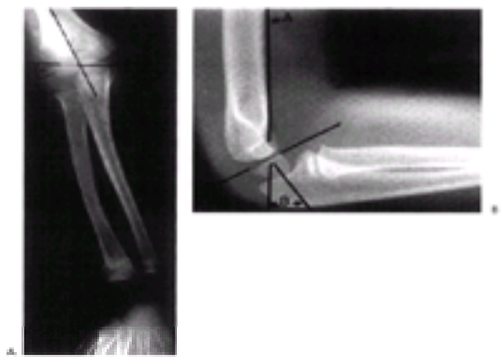

FIGURE 32-15. Radiographic lines of the distal humerus. **A:** The Baumann angle is formed between the capitellar physeal line and a line perpendicular to the long axis of the humerus. As this angle becomes smaller, more elbow varus will occur. This angle should be compared with that of the contralateral, uninjured elbow with a similar anteroposterior view of the distal humerus. **B:** Line *A* is the anterior humeral line, which atypically passes through the middle of the capitellum. Angle *B* demonstrates the anterior angulation of the capitellum relative to the humeral shaft. This is approximately 30 degrees. As angle *B* becomes smaller, the fracture site is moved into extension. Fracture alignment with the capitellum behind the anterior humeral line produces a hyperextension deformity and a loss of elbow flexion.

Supracondylar Fracture

This is the most common elbow fracture. The mechanism of injury is an acute hyperextension load on the elbow from falling on the outstretched arm. The distal fragment displaces posteriorly (i.e., extension) in more than 95% of fractures. The medial and lateral columns of the distal humerus are connected by a very thin area of bone between the olecranon fossa posteriorly and the coronoid fossa anteriorly. The central thinning and the surrounding narrow columns predispose this area to fracture. As the elbow is forced into hyperextension, the olecranon impinges in the fossa, serving as the fulcrum for the fracture. The collateral ligaments and the anterior joint capsule also resist hyperextension, transmitting the stress to the distal humerus and initiating the fracture (116) (Fig. 32-16).

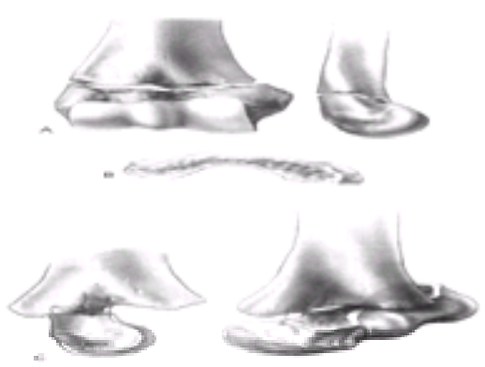

FIGURE 32-16. A: The typical orientation of the fracture line in the supracondylar fracture. Sagittal rotation of the distal fragment generally results in posterior angulation, although, less commonly, it can be flexed. **B:** The cross-sectional area through the fracture demonstrates the thin cross-sectional area of the supracondylar region. **C:** Any horizontal rotation tilts the distal fragment. Typically, medial tilting occurs, producing cubitus varus. The lateral projection readily demonstrates this horizontal rotation, producing a fishtail deformity. In this instance, the distal portion of the proximal fragment is obliquely profiled, although there is a true lateral view of the distal humeral fragment.

The classification system most commonly used is that of Gartland, who described three stages of displacement (117): type I, nondisplaced or minimally displaced; type II, angulated with moderate disruption, but with a portion of the cortex maintaining end-to-end contact; and type III, completely displaced. Supracondylar fractures with medial impaction may appear to be nondisplaced, but may result in cubitus varus attributable to unacceptable angulation (118) (Fig. 32-17). After complete fracture, a small amount of rotational malalignment allows tilting of the fragments, because of the thin cross-sectional area in the supracondylar region. This may also lead to malunion with cubitus varus or, less commonly, cubitus valgus.

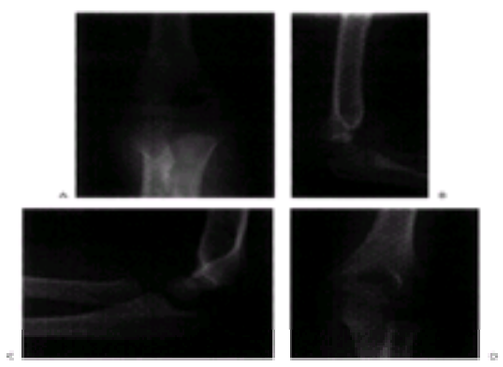

FIGURE 32-17. Impacted type II supracondylar fracture. **A** and **B:** Anteroposterior and lateral projections show medial impaction with hyperextension of the fracture. **C:** The Baumann angle measures 6 degrees. **D:** Comparison radiograph of the opposite elbow demonstrates a Baumann angle of 25 degrees, indicating a 19-degree varus deformity of the fractured humerus.

Associated injuries include nerve injuries, vascular injuries, and other fractures of the upper extremity, including the ipsilateral forearm. The incidence of nerve injury is approximately 15%; most often, nerve injury is a neuropraxia that resolves spontaneously within 4 months. The nerve injured is related to the position of the displaced fragment (119). Median nerve injuries, including injury to the anterior interosseous nerve, are more common with posteromedial displacement of the distal fragment. Radial nerve injuries are seen more often with posterolateral displacement.

Treatment

Nondisplaced or minimally displaced fractures may be treated with an above-elbow cast for 3 weeks. Any medial buckling or impaction of the medial metaphysis may indicate a fracture that requires reduction. This fracture is a diagnostic trap, because the collapse of the medial wall may be very subtle. The Baumann angle, or the medial epicondylar epiphyseal angle, should be carefully measured bilaterally. Greater than 10 degrees of varus impaction warrants closed reduction and

percutaneous pinning. It is difficult to maintain the reduction by cast immobilization alone, and residual deformity will not remodel (118,120).

Type II supracondylar fractures are usually extension injuries, with an intact or nondisplaced posterior cortex. Type II fractures, in which the capitellum is posterior to the anterior humeral line, have an unacceptable amount of extension. Many of these are stable after closed reduction. However, elbow flexion to 120 degrees is often required to hold the reduction (121). This degree of flexion, in the presence of excessive swelling, can result in decreased vascular perfusion to the forearm. This may prevent positioning with adequate flexion to maintain reduction. In such cases, percutaneous pinning is recommended to avoid extreme flexion with possible vascular embarrassment. Follow-up radiographs are made at weekly intervals until there is sufficient healing, usually 3 to 4 weeks.

Type III supracondylar fractures are completely displaced. Treatment begins with a diligent examination for ischemia and nerve palsies. Neurovascular problems are frequent, and management may be altered, if compromise occurred as a result of injury or as a result of treatment. Primary closed reduction and percutaneous pinning is the preferred treatment for type III injuries (122,123 and 124) (Fig. 32-18; see also Fig. 32-42) **[➥1.10]**. Displaced fractures treated with closed reduction and casting have a higher incidence of residual deformity, usually cubitus varus, than those treated with closed or open reduction and percutaneous pinning (123,124,125 and 126). Closed reduction and casting also has a higher risk of Volkmann ischemic contracture than treatment with early pinning (124). This is probably because elbow flexion of more than 90 degrees is often required to maintain reduction without pinning, whereas elbow flexion is not required to maintain reduction when the fracture has been pinned.

FIGURE 32-18. Type III supracondylar elbow fracture. **A:** This type III fracture demonstrates lateral displacement. **B:** The lateral projection also shows flexion of the distal fragment. The treatment of this less common position is the same as that for extension fractures. The posterior periosteum is torn, and hyperflexion of the elbow will excessively forward-flex the distal fragment. The elbow is best pinned at slightly less than 90 degrees of flexion, because it is technically difficult to pin the elbow in extension. **C** and **D:** Anteroposterior and lateral postreduction and pinning films.

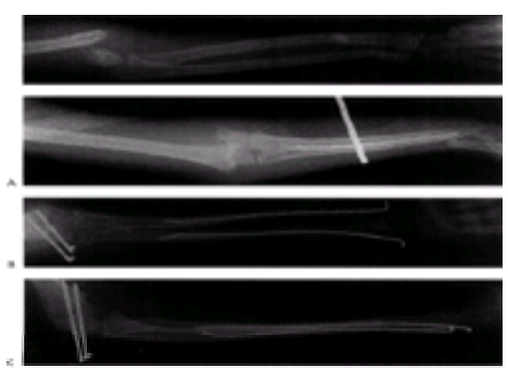

FIGURE 32-42. Displaced fractures of the radius and ulna associated with type III supracondylar fracture. **A:** Radiograph at time of presentation. No neurovascular deficits are noted. **B** and **C:** Flexible intramedullary wires were used to stabilize the forearm, with percutaneous pins to stabilize the humerus. This facilitates postoperative management during cast changes.

Skin or skeletal traction has been used in the management of supracondylar fractures. However, this technique requires longer hospitalization, and may not provide any advantage over immediate reduction (127). The idea that the arm is too swollen for reduction is not valid, because the appropriate bony landmarks are usually palpable. After closed reduction and pinning, the edema lessens.

The technique for closed reduction involves extension of the elbow to 15 to 30 degrees, followed by correction of the medial and lateral translation. Traction is applied, and the elbow is flexed, using digital pressure over the olecranon to bring the distal fragment forward. The elbow is then held in hyperflexion to lock in the position of the distal fragment. If the fracture is medially displaced, the lateral periosteum is torn. For this condition, the forearm is pronated, tightening the reduction against the intact medial periosteum, while helping to maintain closure of the lateral column (128). Pronating the forearm is ineffective in holding some type III fractures, if the periosteal sleeve is completely disrupted. Occasionally, the proximal fragment is in a subcutaneous position, producing the “pucker” sign, and this fracture is unreducible unless the muscles can be manipulated back over the end of the bone. The elbow must be flexed while this is attempted.

After reduction, and with the elbow in maximal flexion, anteroposterior radiographic images are obtained with the arm slightly internally and externally rotated to evaluate the quality of the reduction. The shoulder can be gently externally rotated to yield a true lateral view of the elbow. Percutaneous pinning is performed once reduction has been achieved. Pins should be of adequate diameter to control the fracture. The author prefers 2.5-mm diameter pins, except for in very small children, in whom 1.5-mm diameter pins are used. *In vitro* biomechanical studies have concluded that crossed-pin fixation is more stable than lateral pin configurations (129). However, clinical experience has demonstrated that two laterally placed pins, supplemented with plaster immobilization, are often sufficient for stabilization (130,131). When a medial pin is used, one should be aware that extreme flexion can sublux the ulnar nerve from its groove and increase the risk of damage during pinning. When possible, it is advisable to place the medial pin with the elbow in less than full flexion, so that the ulnar nerve is farther posterior. It is also advisable to make a small incision over the medial epicondyle and dissect with a hemostat, so that the medial pin can be placed directly on bone. Confirmation of satisfactory alignment after pinning is documented with anteroposterior and lateral radiographs of the distal humerus. Anatomic alignment is preferred, but this may be difficult to achieve in some cases. The Baumann angle should be within 10 degrees of the opposite side. It is the author's opinion that one may accept up to one-third translation of the distal fragment, 30 to 45 degrees of malrotation, and 20 degrees of extension after pinning, as long as fixation is secure. Follow-up radiographs of the distal humerus are obtained 7 to 10 days after reduction, to confirm acceptable alignment. Immobilization is maintained for 3 to 5 weeks, after which the pins are removed and active range of motion exercises are instituted.

The rare irreducible fracture can be managed with open reduction through a medial approach, adding a lateral incision, if necessary **[➥1.11]**. An anterior surgical interval (i.e., S-curved incision over the antecubital fossa) can also be used, and is recommended if the neurovascular structures need to be exposed. The posterior approach should be used cautiously, because it disrupts any remaining intact soft tissue, and may disrupt the primary vascular supply to the distal humeral fragment (11).

Complications

In the event of a pulseless extremity, prompt reduction of the supracondylar fracture usually restores arterial flow (132,133) (Fig. 32-19). Complete vascular disruption is uncommon, because the thick local muscle envelope protects the artery. Vascular evaluation after reduction requires differentiation of the pulseless, but pink and viable, extremity from one that is cold and pale with vascular insufficiency. The child who has a well-perfused hand, but an absent radial pulse after satisfactory closed reduction, does not necessarily require routine exploration of the brachial artery (119,122,132,134). The pulse usually returns within 48 h, indicating resolution of arterial spasm. The absence of a Doppler-detected pulse at the wrist is not an absolute indication for arterial exploration. The collateral circulation is vast and often

provides enough distal perfusion, despite brachial artery occlusion. The hand may be warm and normal-colored, with brisk capillary refill and 100% oxygen saturation. There is no clear evidence of a clinical problem with cold intolerance or exercise-induced muscle fatigue for the hand surviving on collateral vascularity, but long-term studies addressing the problem are lacking (134).

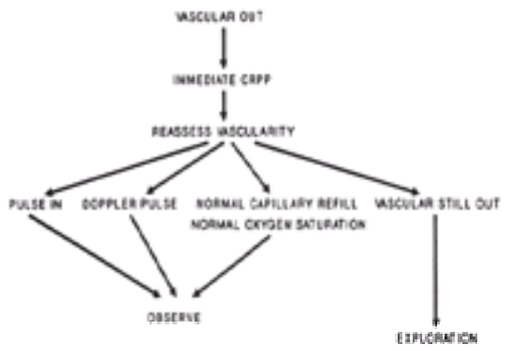

FIGURE 32-19. Vascular compromise flow sheet. *CRPP*, closed reduction percutaneous pinning. (From ref. 119, with permission.)

For persistent true vascular insufficiency (e.g., avascular, cold, pale hand), especially if there is nerve palsy or inadequate reduction, anterior open reduction is recommended. Frequently, the neurovascular bundle is found kinked at the fracture site, and liberation of the artery restores the pulse. There may also be evidence of brachial artery injury. Vascular reconstruction should be performed if the vessel does not respond to local measures (e.g., release of tether, adventitia stripping, lidocaine, papaverine) and the hand remains avascular. The fracture should be stabilized before vascular repair. After reconstruction, there is a significant rate of asymptomatic reocclusion and residual stenosis, even though the hand remains well perfused (134).

Nerve injury associated with supracondylar fracture rarely requires exploration (Fig. 32-20). Patients with preoperative nerve injury should undergo reduction and fixation as described. Exploration of the nerve is not necessary when the reduction is anatomic. However, failure to obtain anatomical reduction may indicate that the nerve is interposed at the fracture site, and exploration may be indicated.

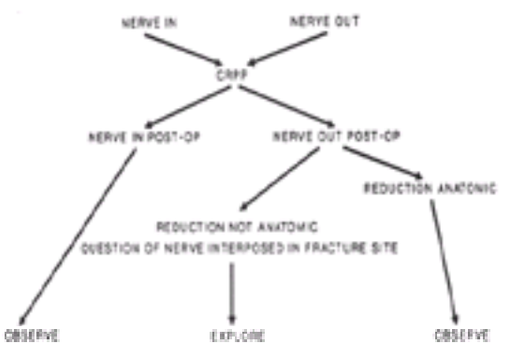

FIGURE 32-20. Nerve compromise flow sheet. *CRPP*, closed reduction percutaneous pinning. (From ref. 119, with permission.)

Postoperative neurologic deficit that was not present preoperatively may represent a preexisting nerve deficit that was undetected at the time of the initial examination, or an iatrogenic injury sustained during reduction. Median and radial nerve injuries are more frequently seen as a result of the initial trauma, and may be observed when the reduction is anatomic. Postoperative ulnar nerve deficits are more often iatrogenic, and result from placement of the medial pin (119,130,135). Recommendations for management of this complication vary from observation to exploration. It is the author's opinion that the medial pin should be removed and the patient should be observed without early exploration of the ulnar nerve. Spontaneous recovery is expected within 2 to 6 months.

Cubitus varus is the most common late complication of supracondylar fracture. This deformity represents fracture malunion and rarely results from partial growth arrest of the medial condylar growth plate (120). Malunion may be avoided by careful attention to the Baumann angle at the time of initial management. Cubitus varus is principally a cosmetic deformity, but increased risk of subsequent lateral condyle fracture and tardy ulnar palsy have also been reported (136,137). Osteotomy to correct deformity may be performed at any age, but complications are not uncommon (138). Full-length radiographs of both arms are recommended preoperatively for accurate planning. Torsional deformity does not require correction. Simple uniplanar closing-wedge osteotomies have the lowest complication rates (139).

T-condylar Fracture

The T-condylar fracture is a variation of the supracondylar fracture. The mechanism of injury is axial impaction with resultant intraarticular fracture. This injury occurs predominantly in adolescents, around the time of physeal closure, but it can also occur in younger children. The capitellum and trochlea usually are separated from each other, and the two are separated from the proximal humerus.

Treatment of displaced fractures usually requires open reduction, with the primary goal of anatomic alignment of the articular surface. A posterior approach is recommended, by splitting the triceps, reflecting a distally based tongue of triceps, or olecranon osteotomy. Re and colleagues (140) observed that the olecranon osteotomy approach resulted in better recovery of extension than the triceps-splitting approach. Extensive dissection of the fragments should be avoided to minimize the risk of avascular necrosis of the trochlea. Transverse fixation of the trochlea to the capitellum is performed first, and this unit is secured to the distal humerus with sufficiently strong crossed pins or cancellous screws. Alternatively, 2.5-mm reconstruction plates are applied to the medial and lateral columns of the distal humerus. Internal fixation should be stable, to allow early motion and preferably continuous passive motion during the early postoperative period (140,141).

Lateral Condyle Fracture

Fracture of the lateral condyle is the second most common elbow fracture in children. This injury is usually the result of a varus force on the supinated forearm, in which the extensor longus and brevis muscles avulse the condylar fragment. The peak age range for this injury is 5 to 10 years, but it is often seen in older or younger children.

This is a complex fracture, because it involves the physis and the articular surface. It is a Salter-Harris type IV injury in the majority of cases, but growth disturbance is rarely seen, because the distal humerus contributes little to the longitudinal growth of the humerus. A significant portion of the fragment is unossified, especially in children younger than 5 years of age. The injury is identified by a thin lateral metaphyseal rim of bone, but the fracture line continues across the physis and into the elbow joint, through unossified cartilage. An internal oblique radiograph of the distal humerus usually provides the best view of this fracture.

The fracture line may take several paths through the unossified cartilage of the distal humerus. Milch suggested two fracture types: the first exits lateral to the capitellar-trochlear groove (Fig. 32-21), and the second exits medial to this groove, with resultant elbow instability (Fig. 32-22). The Milch classification system has been shown to have poor correlation between preoperative radiographs and intraoperative findings (142). However, it is important to have an understanding of the possible fracture configurations before initiating treatment. The fracture may stop before passing completely through the cartilaginous epiphysis. This leaves an intact hinge with inherent stability. The fracture line may pass completely through the cartilaginous epiphysis, including the articular surface, and exit into the elbow joint lateral or medial to the trochlear groove, as described by Milch. When the fracture exits into or medial to the trochlear groove, the ulna may displace laterally with the radius and lateral condylar fragment. In young children, this may be confused with fracture-separation of the entire distal humeral epiphysis. Determining the exact

location and extent of the fracture line is difficult by plain radiography. Arthrography may be helpful intraoperatively, to define the fracture (Fig. 32-23).

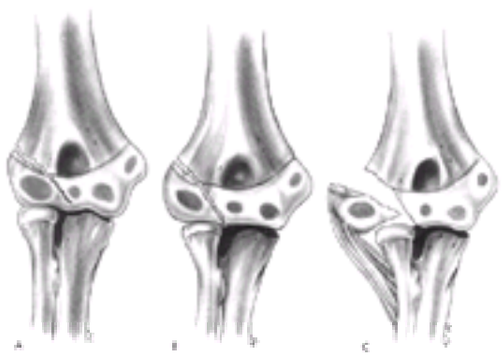

FIGURE 32-21. Milch type I lateral condyle fracture. **A:** The fracture line may stop before passing completely through the cartilaginous epiphysis. **B:** The fracture may pass completely through the articular cartilage lateral to the capitellar trochlear groove. **C:** Displaced Milch type I fracture requires reduction, but does not lead to ulnar instability.

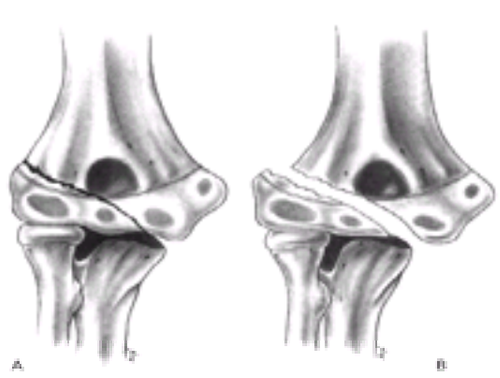

FIGURE 32-22. Milch type II lateral condyle fracture. **A:** The fracture line passes medial to the capitellar trochlear groove. **B:** Displacement leads to lateral displacement of the ulna.

FIGURE 32-23. Fracture separation of the distal humeral epiphysis in a young child may include a small metaphyseal fragment. This can be easily confused with a Milch type II fracture-dislocation of the lateral condyle, when the distal fragment displaces laterally. **A:** A 14-month-old child with apparent lateral condyle fracture-dislocation. **B:** Arthrogram confirms complete distal humeral separation (Salter-Harris type II) with intact joint.

Treatment depends on the degree of displacement and the assessment of fragment stability, rather than the exact classification. Fractures displaced 2 mm or less without obvious rotational deformity can be treated with cast immobilization (143,144) (Fig. 32-24). Follow-up radiographs should be obtained 7 to 10 days later, to detect any additional displacement of the fragment. It is often necessary to remove the cast to obtain adequate anteroposterior and lateral radiographs of the distal humerus. The internal rotation, oblique view is also helpful to determine fracture alignment. Gentle cast removal and radiography will not cause displacement if the fracture is incomplete and inherently stable. Radiographs out of the cast will allow detection of instability that has progressed in spite of immobilization. Healing for minimally displaced fractures is complete when bridging callus is identified, usually by the fourth week of immobilization.

FIGURE 32-24. Lateral condyle fracture. **A:** The anteroposterior projection shows a 3-mm gap. The fracture is wider radially than it is medially, probably representing a stage II fracture, although the articular cartilage could be intact. The stability of this fragment is not easily determined radiographically, and must be closely followed for displacement. **B:** Lateral projection demonstrates minimal sagittal rotation of the lateral condylar fragment. **C:** Six weeks later, there is complete fracture healing after closed treatment in an above-elbow cast.

Operative intervention with pin fixation is indicated when displacement is 3 mm or greater. Some good results have been reported when greater degrees of displacement have been treated nonoperatively (145,146). However, nonunion, delayed union, and further displacement are more frequent complications of fractures displaced 3 mm or more. Closed reduction and percutaneous fixation have been reported for fractures separated 3 to 4 mm (147). An arthrogram may provide confirmation of joint surface congruity. However, many of these fractures display rotation of the condylar fragment, which is difficult to correct accurately by closed reduction. Primary open reduction, with restoration of articular congruity, is preferred in the majority of cases requiring surgery (Fig. 32-25). In severe cases, the condylar fragment may be rotated 180 degrees (Fig. 32-26). A standard lateral approach is used, but excessive soft tissue stripping posteriorly should be avoided, to reduce the risk of avascular necrosis of the capitellum and trochlea. Stabilization is achieved with two smooth pins crossing the fracture site and exiting the opposite

cortex. These pins will traverse the physis, but growth disturbance is rarely a concern.

FIGURE 32-25. Lateral condylar fracture. **A:** The anteroposterior projection shows more than 3 mm of separation, with significant rotation of the condylar fragment. **B:** The lateral projection shows some sagittal rotation of the fragments. **C:** Treatment consisted of open reduction and fixation, with Kirschner wires crossing in the condylar fragment for greater stability.

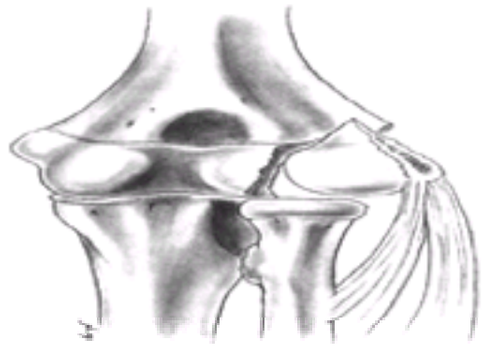

FIGURE 32-26. Lateral condyle fracture may rotate laterally 180 degrees. Reduction requires medial rotation of the displaced fragment.

Complications

Management of the late-presenting lateral condyle malunion is an area of controversy. Displacement greater than 4 to 5 mm can be anatomically reduced and pinned, with good results, for as long as 6 weeks after the injury (148,149). After this time, the ability to reduce the fragment precisely is lessened, because of remodeling of the fracture surfaces and soft tissue contracture. Excessive stripping of the condyle to facilitate reduction may result in avascular necrosis and greater joint stiffness. Two surgical approaches are described in the literature for management of symptomatic patients with malunion. Supracondylar osteotomy, combined with ulnar nerve transposition, has been performed with satisfactory improvement in function (143). Intraarticular osteotomies, with partial reduction, have also achieved satisfactory results in some patients (149).

Nonunion after lateral condyle fracture is seen most often in untreated patients. Long-term sequelae include ulnar neuritis, progressive valgus deformity, and elbow instability with decreased strength. In established nonunions, the lateral condyle fragment should be pinned in a position that preserves the best functional range of motion, realizing that anatomic restoration is not possible. Bone grafting is necessary to achieve union (149,150 and 151) (Fig. 32-27). Any residual valgus deformity can be corrected with a supracondylar osteotomy. Ulnar nerve transposition may be needed, especially if there are preoperative symptoms.

FIGURE 32-27. Nonunion of the lateral condyle. **A:** Anteroposterior view of a child who sustained this fracture 4 months earlier. Symptoms consisted of pain and decreased range of motion. **B:** Anteroposterior projection after stabilization of the condylar fragment with bone screws and bone grafting of the nonunion. **C:** Lateral projection.

Lateral Epicondyle Fracture

Lateral epicondyle fracture is a rare elbow injury that does not involve the articular surface. This ossification center does not appear until the second decade. This injury is often misdiagnosed as an avulsion fracture of the lateral condyle. Treatment is usually immobilization followed by early motion, when comfortable. Displacement greater than 5 mm may lead to joint stiffness. If this occurs, early excision of the displaced epicondyle should be considered.

Medial Epicondyle Fracture

The medial epicondylar apophysis is fractured when a valgus load is applied to the extended elbow. The displacement is encouraged by the pull of the forearm flexor wad, which is attached in this region. The medial collateral ligament also originates from this apophysis, and may play a role in the initial fracture displacement, especially when there is an initial elbow dislocation. This injury typically occurs in children between the ages of 9 and 14 years, later than the peak age for most other elbow fractures. Almost 50% of these fractures occur concomitantly with posterolateral elbow dislocation, and the medial epicondyle may be trapped in the joint after reduction. When this occurs, the ulnar nerve may also be in the joint, and vigorous attempts at closed manipulation should be avoided.

Treatment

There is general agreement that operative intervention is indicated when the epicondyle is trapped in the joint. Otherwise, management is controversial. There are advocates for the closed treatment of this injury, regardless of the magnitude of displacement (152,153). Nonunion is a frequent result of closed management; however, many patients with nonunion are asymptomatic, and those who are symptomatic can be treated with excision of the fragment. Valgus instability to stress testing has been suggested as an indication for operative stabilization (154). However, the majority of medial epicondyle avulsion injuries will demonstrate instability when stressed acutely, so most patients will require surgery if this test is used. The magnitude of displacement probably provides the best indicator for management.

Fractures with less than 5 mm displacement have a lower risk of nonunion and subsequent intervention than fractures with more than 5 mm displacement. Excellent results have been reported after operative stabilization of displaced fractures (155,156). Therefore, the authors recommend consideration of open reduction and fixation for medial epicondyle fractures when displacement is greater than 5 mm (Fig. 32-28) **[➥1.14]**. Surgical intervention should be considered in highly competitive gymnasts or throwing athletes with lesser degrees of displacement. The goal is to restore the integrity of the medial collateral ligament, and to retension the forearm flexors for optimal elbow function (154).

FIGURE 32-28. A: Displaced medial epicondyle fracture in an adolescent. It is difficult to quantitate the amount of displacement based on the anteroposterior projection because the fragment has also moved anteriorly. It also may be malrotated. **B:** Treatment with bone screws and early motion. **C:** Lateral projection. A single screw is sufficient, if it is placed in a posterior-to-anterior direction, capturing the anterior cortex of the distal humerus.

In adolescents, fragment fixation can be accomplished with a cannulated bone screw. It is important to understand that the fragment tends to rotate forward from its posteromedial origin, and fixation should be directed from a posterior position to engage the anterior humeral cortex. Stable fixation allows early postoperative range of motion exercises, as soon as the patient is comfortable. Preadolescents may require fixation with smooth Kirschner wires and cast immobilization for 3 weeks, to minimize the risk of growth arrest of the apophysis.

Medial Condyle Fracture

Fracture of the medial condyle of the humerus is an unusual injury, and may be difficult to diagnose. Before ossification of the trochlea, it is important to examine the radiographs for a chip or flake of bone from the metaphysis (99,157). Medial condyle fracture may be misdiagnosed as medial epicondyle avulsion in children between the ages of 5 and 7 years, because the epicondylar ossification center is visible on radiographs approximately 2 years before the trochlea ossifies. The mechanism of injury is similar to that for medial epicondylar fracture, but medial condyle fracture is a much more serious injury, because it involves the articular surface. Thus, the radiographic appearance of a displaced medial epicondyle fracture in a 5- to 7-year-old child should arouse suspicion of a more serious injury, because the ossified epicondyle may still be attached to the cartilaginous condyle. If the condyle is displaced more than 2 mm, it needs open reduction and internal fixation (158).

Fracture-separation of the Distal Humeral Physis

Fracture-separation of the distal humeral physis is seen primarily in infants and young children. The mechanism of injury involves rotatory shear forces, resulting in a Salter-Harris type I or type II fracture pattern. Abuse should be suspected (159). This injury may present a diagnostic challenge, because of the lack of ossification of the distal humerus in young children (Fig. 32-23). Diagnosis of this fracture should be considered in any young child with significant soft tissue swelling and crepitus on elbow motion. This fracture is most often confused with elbow dislocation and lateral condyle fracture (Fig. 32-29). Elbow dislocation is rare in young children; the forearm is displaced laterally and the long axis of the radius is lateral to the capitellum. A lateral condyle fracture in a 2- to 3-year-old child may be confused with transphyseal separation, especially if there is joint subluxation. However, the subluxation associated with lateral condyle fracture is in the lateral direction, whereas distal humeral physeal separations usually displace in a medial direction. Arthrography, MRI, or ultrasonography can help confirm the diagnosis of separation of the entire distal humeral physis. Arthrography is a helpful adjunct at the time of definitive treatment to confirm the quality of fracture reduction.

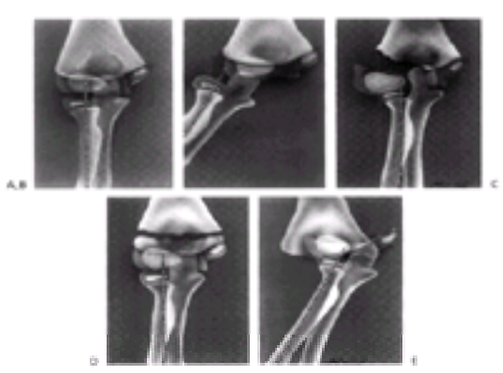

FIGURE 32-29. A: Normal elbow demonstrating the alignment of the radius with the capitellum. **B:** In a dislocation of the elbow, there is disruption of the radiocapitellar alignment. Most dislocations are posterolateral. **C:** In a displaced lateral condyle fracture, there is again disruption of the radial capitellar alignment. **D:** Supracondylar elbow fracture, in which the radius and capitellum remain aligned, despite displacement of the distal humeral fragment. **E:** Fracture-separation of the distal humeral physis. The radiocapitellar relation is preserved, and typically, the distal segment is posteromedially displaced. (Adapted from ref. 159, with permission.)

Treatment and complications are similar to those for supracondylar fractures. Closed reduction and plaster immobilization frequently lead to cubitus varus that does not resolve (159,160 and 161). Therefore, fixation with two small-diameter, laterally placed pins is recommended after reduction. Fractures diagnosed after 7 to 10 days should not be manipulated, because healing is rapid and growth arrest may result from vigorous attempts at reduction. It is better to wait and perform supracondylar osteotomy for residual deformity.

Radial Neck Fracture

Fractures of the proximal radius in children usually involve the radial neck. Associated injuries are found in 50% of cases, and include fractures of the medial epicondyle and olecranon or dislocation of the elbow. Associated injuries should be treated independently, according to accepted guidelines. Radial neck fractures are predominantly Salter-Harris type I or II injuries. The radial head is largely cartilaginous, and is rarely injured. Proximal radius fractures occur most commonly in the 9- to 12-year age group, but may occur at any age. The mechanism of injury is usually valgus stress, with compression of the radial neck from a fall on the extended elbow. Fracture displacement can result in angulation, translation, or both, or complete separation of the radial head from the radius. Angulation after union may remodel, especially in younger children. Translation is more worrisome, and may limit motion as a result of a cam effect, because the congruity of the proximal radioulnar joint is disrupted, and the radial head can no longer rotate in a circle. Approximately one-half of children who sustain fractures of the radial neck will have some permanent limitation of forearm rotation. Results are poorer in children older than 10 years of age, when treatment is delayed, when the elbow has associated injuries, after open reduction, and when the initial angulation was greater than 30 degrees or the displacement was greater than 3 mm (162,163 and 164).

Treatment depends on the age of the child and the amount of angulation and translation (163). When angulation is greater than 30 degrees, or translation is greater than 3 mm, closed reduction usually should be attempted, because anatomic alignment is associated with better outcome (Fig. 32-30). However, closed reduction may fail, and one must decide whether to accept suboptimal alignment or to resort to open reduction, with increased risks in each case. Age is important in this

situation. For a child younger than 10 years of age, the author will accept up to 45 degrees of angulation and 33% translation, before resorting to open reduction. In a child older than 10 years of age, up to 30 degrees of angulation and 3 mm of translation may be accepted.

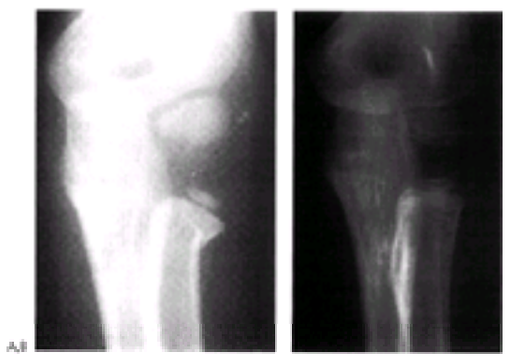

FIGURE 32-30. Impacted radial neck fracture in a 6-year, 5-month-old boy. **A:** Angulation measures 30 degrees. **B:** Nine months later, alignment is normal without treatment. The child regained full range of motion.

The manipulation technique for closed reduction consists of traction and varus stress, combined with digital pressure over the radial head **[➥1.15]**. If this is unsuccessful, the forearm should be pronated and supinated, as pressure over the radial head or metaphysis is maintained. Wrapping the arm firmly in an Esmarch bandage produces compression and elongation forces that may also reduce the fracture. Alternatively, a percutaneous pin proximally, or a flexible intramedullary wire introduced distally, can be used to manipulate and stabilize the proximal fragment (165,166) (Fig. 32-31) **[➥1.15]**. Open reduction is performed when these methods fail to produce an acceptable reduction. Another indication for open reduction is a displaced Salter-Harris type IV fracture involving more than one-third of the articular surface. Fixation is best accomplished with Kirschner wires placed obliquely across the fracture, avoiding the use of a transhumeral pin **[➥1.15]**. These wires are removed in 3 to 4 weeks to begin elbow range of motion. If the metaphyseal fragment is large enough, a minifragment screw can be used instead of the Kirschner wires.

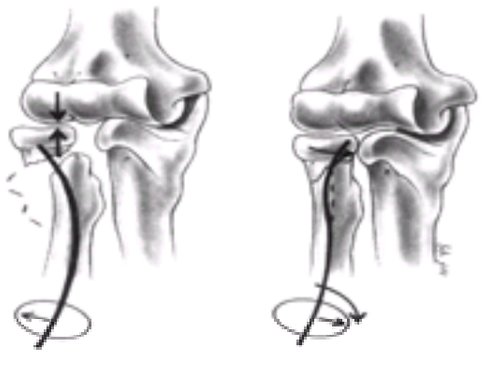

FIGURE 32-31. Radial neck fractures may be reduced by introduction of a percutaneous wire from the distal metaphysis. The wire is rotated after it engages the proximal fragment. (From ref. 166, with permission.)

Complications

Complications of this fracture and its treatment include loss of forearm rotation, radioulnar synostosis, injury to the posterior interosseous nerve, nonunion, premature physeal arrest, and avascular necrosis of the radial head (167). These complications are usually observed, unless they are progressive or disabling. Radial head excision may be performed in growing children when symptoms warrant this procedure (168).

Olecranon Fractures

Olecranon fractures are uncommon in children. In young children, the spongy bone and thick surrounding cartilage often prevent significant displacement. Older children and adolescents are more likely to have displaced fractures and associated injuries. The most common mechanism of injury is an avulsion or flexion injury that disrupts the posterior periosteum and fractures the cortex. Extension injuries leave the posterior periosteum intact, but often result in angulated fractures and associated fractures attributable to varus or valgus forces acting on the extended elbow. Olecranon fractures may also result from a direct blow that causes comminution, but minimal displacement, because the periosteum remains intact (Fig. 32-32).

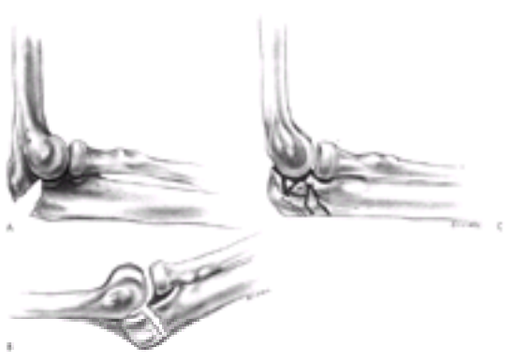

FIGURE 32-32. Olecranon fractures. **A:** Avulsion or flexion injury is most common, and requires reduction in extension. Internal fixation is frequently necessary to maintain reduction. **B:** Extension-type fracture leaves the posterior periosteum intact, and may be reduced by flexing the elbow. **C:** Comminuted fractures result from a direct blow, and may be minimally displaced.

Treatment consists of splint or cast immobilization for 2 to 3 weeks, if displacement is minimal. When displacement is greater than 4 mm in metaphyseal bone, or there is a joint step-off in the coronoid fossa of greater than 2 mm, closed reduction is attempted by reversing the mechanism of injury. Open reduction with internal fixation is recommended when closed reduction fails, or when maintenance of reduction is difficult as a result of fracture instability (169,170). Internal fixation is achieved by standard osteosynthesis, using the AO tension band technique or its modification, which involves placing the distal wire hole anterior to the axis of the intramedullary Kirschner wires (171) (Fig. 32-33). This provides additional compression forces across the articular surface of the olecranon. In younger children, heavy absorbable suture may be used in place of the figure-of-eight wire, because healing is rapid. Angulated metaphyseal fractures that do not align with closed reduction, and which do not involve the articular surface, often can be straightened with insertion of an intramedullary pin.

FIGURE 32-33. Olecranon fracture. **A:** Lateral projection showing displaced intraarticular olecranon fracture. There is also an impacted radial neck fracture. **B:** Treatment with standard tension band technique. The slight variation from standard fixation is to capture the anterior cortex of the ulna with the Kirschner wires (*arrow*). **C:** Standard AO technique, used in a similar case, with parallel intramedullary Kirschner wires with the tension band transverse hole inferior (*arrow*). **D:** Modified AO technique performed by placing the transverse hole anterior to the Kirschner wires (*arrow*). The compressive force is anterior to the pin, which prevents the articular surface of the semilunar notch from gapping. Ideal joint compressive forces are obtained with placement of the Kirschner wires down the middle axis of the ulna and the transverse hole anterior to this axis.

Elbow Dislocation

Elbow dislocation is a relatively uncommon injury in young children; the peak incidence is in the second decade of life. Often, there is an associated fracture, most commonly of the medial epicondyle, but occasionally of the coronoid process or the radial neck. Elbow dislocation is predominantly a male injury (70%) involving the nondominant arm (60%). The most common pattern is posterolateral displacement of the proximal radius and ulna articulation from the humerus, without disruption of the radioulnar articulation (172).

Treatment is accomplished by prompt closed reduction, usually in the emergency department, after establishing pain control and muscle relaxation. The surgeon should be aware of possible interposed fragments, such as from the medial epicondyle, or unsatisfactory postreduction alignment, suggesting soft tissue or cartilaginous interposition. A posterior splint is applied for 2 weeks; thereafter, elbow range of motion is initiated to minimize the risk of fixed contracture.

Complications

The most common complication is loss of motion. This can be minimized for stable reductions by initiating early mobilization 2 weeks after injury (172). Stiffness, in the absence of fracture, usually resolves within 6 to 8 months. The author recommends avoiding the use of passive stretching devices for at least 4 months, because recovery is expected in children. Occult avulsion fractures should be excised if range of motion has not returned by 6 months. Rarely, operative release of contracture may be required in older adolescents, when range of motion is less than functional (30 to 100 degrees) 8 months or more after injury (173,174). Neurapraxia involving the median or ulnar nerves occurs in approximately 10% of dislocations, and usually resolves within 3 months. Arterial injury is rare.

Radial Head Dislocation and Nursemaid's Elbow

Traumatic isolated dislocation of the radial head is a rare injury (Fig. 32-34). The radial head dislocates anteriorly. The majority of these injuries actually represent occult Monteggia injuries, with plastic deformation of the ulna and anterior dislocation of the radial head. Treatment consists of closed reduction and immobilization, with the elbow in flexion and supination.

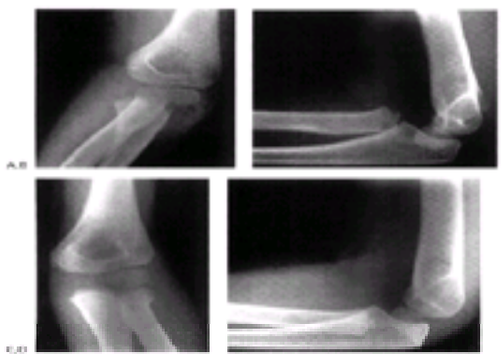

FIGURE 32-34. Anterior radial head dislocation. **A:** Anteroposterior projection demonstrating an overlap of the radial metaphysis with the capitellum, suggesting disruption of this articulation. **B:** Lateral projection indicating anterior dislocation of the radial head. There were no other fractures of the forearm or elbow. **C:** Anteroposterior projection after closed reduction, showing more normal radial capitellar alignment. **D:** Lateral projection showing a reduced radius. A line drawn down the long axis of the radius should bisect the capitellum of the humerus, regardless of the degree of extension of the elbow.

Occasionally, a child with a previously undiagnosed congenital radial head dislocation falls and injures the elbow. Congenital dislocation of the radial head is distinguished from traumatic dislocation by the fact that congenital dislocation is almost always in a posterior direction and the articular surface of the radial head is convex or flat, rather than having the normal concave contour.

Nursemaid's elbow, or pulled elbow, is a very common injury in children between 1 and 4 years of age. Typically, the child is being held by the hand and suddenly falls, or is pulled upward. Pain is variable. The child will not move the arm and will hold it in a slightly flexed and pronated position. Radiographs are not indicated initially, and are normal, because the injury consists of subluxation of the annular ligament, rather than true joint subluxation (175) (Fig. 32-35). When longitudinal traction is applied to the child's pronated arm, the annular ligament slips off the radius and rides up onto the broader radial head, like a rope that has jumped out of the groove in a pulley wheel. The child is unwilling to move the elbow until the stretched annular ligament is reduced.

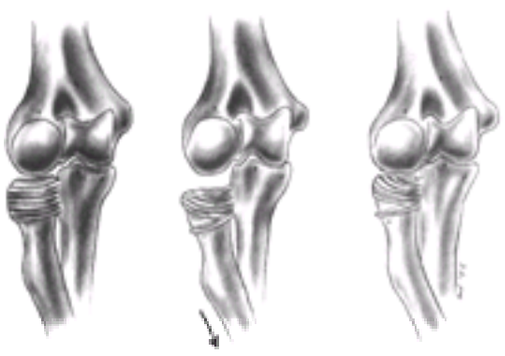

FIGURE 32-35. Pulled elbow, or “nursemaid's elbow,” occurs as the radial head moves distally. The annular ligament is partially torn and displaced onto the radial head. (From ref. 106, with permission.)

Treatment consists of flexing the elbow to 90 degrees, then fully and firmly supinating the forearm. A click or snap is often felt as the ligament snaps back into place. Occasionally, it is necessary to quickly and fully pronate, then supinate the forearm, to achieve reduction. This is especially true for delayed cases. The child should begin to move the arm within a few minutes after reduction. If this is not the case, then radiographs should be obtained to rule out occult fracture, and the arm may be immobilized in a splint for 2 to 3 days, followed by repeat examination. Recurrences are not uncommon, but are treated in the same manner as the initial injury. Eventually, children outgrow this condition, and long-term sequelae have not been reported.

FOREARM AND WRIST FRACTURES

Fractures of the forearm and wrist are common in children, accounting for 30 to 50% of all children's fractures (4,5,176). Most forearm fractures occur in children older than 5 years of age. The location of the fracture advances distally with increasing age of the child, probably because of the anatomic changes in the metaphyseal–diaphyseal junction that occur with maturity (177). The younger child's radius is more elastic, and has a gradual transition of the diameter of the radius from shaft to metaphysis, whereas the transition in diameter is more abrupt at the metaphyseal–diaphyseal junction in the older child (177). The distal forearm is the site of 70 to 80% of fractures of the radius and ulna. Most of these are nonphyseal. Physeal separations are more likely in early adolescence, because of the more adult shape of the radius, which concentrates stress closer to the epiphysis. In 10 to 15% of patients, forearm fractures are associated with elbow fractures. This highlights the importance of a thorough clinical and radiographic examination of the injured extremity.

Anatomically, the forearm is unique. The ulna is a straight bone with a triangular cross section. The radius has a more complex, curved shape, with a cylindrical proximal portion, a triangular middle portion, and a flattened distal third. The radius rotates around the ulna during forearm supination and pronation. There are three areas of soft tissue interconnection between the radius and ulna. Proximally, there is the radioulnar articulation, which is stabilized by the annular ligament. Centrally, the shafts of the two bones are connected by the interosseous membrane, which is wider distally. The fibers run obliquely from the ulna distally to the radius proximally. This helps transmit force to the ulna during load-bearing activities. Distally, the triangular fibrocartilage complex stabilizes the radioulnar joint by means of the ulnar collateral ligament and the volar and dorsal radiocarpal ligaments. The proximal and distal radioulnar joints are most stable in supination, and the interosseous membrane is widest with the forearm in a position of 30 degrees of supination. Because of these interconnections, both bones are usually injured at the time of fracture. When only one bone is broken, there is frequently damage to the proximal or distal radioulnar articulation.

Forearm and wrist fractures are usually classified into three major categories: fracture-dislocations, fractures of the midshaft, and distal fractures.
Fracture-dislocations include the Monteggia and Galeazzi lesions. Midshaft fractures of the radius and ulna tend to follow three injury patterns: plastic deformation, greenstick fracture, and complete fracture. Distal fractures are either metaphyseal fractures or physeal separations. Each type of injury presents unique features with regard to mechanism of injury, recognition, and management.

Forearm Fracture-dislocations

The combination of forearm fracture with joint dislocation is less common than other types of forearm fractures. Misdiagnosis may result if radiographs of forearm fractures fail to clearly demonstrate the elbow and wrist joints. The peak incidence occurs between 4 and 10 years of age. The Monteggia lesion is more common, and involves dislocation of the radial head. The usual mechanism of injury is a fall on the hyperextended arm. The Galeazzi lesion involves dislocation of the distal radioulnar joint, and is usually associated with a distal radius fracture.

Monteggia Fracture-dislocation

The Monteggia lesion should be suspected with any pediatric forearm fracture, including minimally displaced greenstick fractures of the ulna. A true lateral radiograph of the elbow provides the best assessment of the radiocapitellar joint. In the normal elbow, a line drawn down the long axis of the radial shaft will bisect the capitellum, regardless of the position of flexion or extension of the elbow (178) (Fig. 32-36). Congenital dislocation of the radial head is distinguished from traumatic dislocation by the fact that congenital dislocation is usually posterior and the articular surface of the radial head is convex. In contrast, anterior dislocation of the radial head is common with Monteggia fracture-dislocation (179,180).

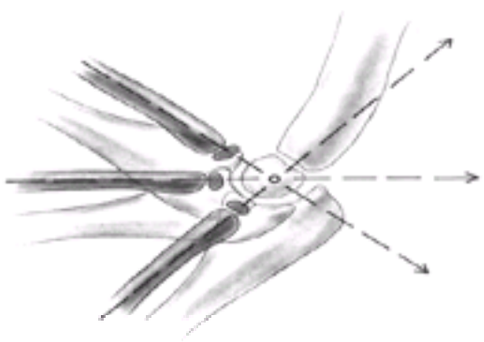

FIGURE 32-36. A true lateral radiograph of the elbow joint allows assessment of the integrity of the radiocapitellar joint. A line drawn down the long axis of the shaft of the radius will bisect the capitellum in all positions of flexion and extension. (From ref. 178, with permission.)

Bado (179) devised a classification system of four basic types of injury and several equivalent lesions. Type I involves anterior radial head dislocation (i.e., ulnar apex deformity anterior), which accounts for the majority of childhood Monteggia injuries (179,180) (Fig. 32-37). Type II fracture is the least common, and entails posterior or posterolateral radial head dislocation. In Type III lesions, the radial head is dislocated laterally, and the ulna fracture is usually in the proximal metaphyseal region. Type III injury accounts for 25 to 30% of pediatric Monteggia injuries. Type IV fracture-dislocations involve anterior dislocation of the radial head, in combination with fracture of the radius and ulna. This may be considered a variant of the type I lesion. There are numerous Monteggia equivalents that represent a multitude of variations. For example, the ulna fracture may be combined with a radial neck fracture, rather than a simple radial head dislocation (Fig. 32-38). Segmental fractures and plastic deformation of the ulna are other forms of Monteggia equivalent injury.

FIGURE 32-37. Type I Monteggia lesion. **A:** The lateral projection shows an ulnar fracture angulated anteriorly, with dislocation of the radial head in the same direction. **B:** The anteroposterior projection shows malalignment of the radiocapitellar joint. **C:** Alignment after closed reduction and correction of the ulnar angulation. A line through the central axis of the radius points to the capitellum. This fracture must be followed closely for recurrent angulation. **D:** The anteroposterior projection shows early healing of the ulna and normal alignment of the radiocapitellar joint.

FIGURE 32-38. Monteggia equivalent lesion. **A:** There is an anteriorly angulated proximal ulnar fracture with an anterior displaced radial shaft. There is also a fracture of the radial neck with malalignment of the radiocapitellar joint. **B:** Anteroposterior projection. **C:** This fracture configuration usually requires open reduction. In this instance, a small plate was used on the ulnar shaft. An alternative would have been an intramedullary rod. The radial neck fracture was treated with a minifragment compression screw. **D:** The anteroposterior projection shows restoration of alignment.

Treatment depends on the character of the ulnar fracture, more than the direction of the radial head dislocation, because stable, anatomic reduction of the ulnar fracture maintains anatomic reduction of the radial head. Most Monteggia injuries in children younger than 12 years of age can be managed successfully by closed reduction and above-elbow casting, with the elbow in full supination and 90 to 110 degrees of flexion. Weekly follow-up is suggested for 2 to 3 weeks, to detect recurrent radial head subluxation. Transient nerve palsies, most commonly of the posterior interosseous nerve, occur in approximately 10% of patients.

Operative intervention is indicated when there is a radial neck fracture, instead of a simple dislocation. Another indication is ulnar angulation that cannot be controlled, which may be the case with oblique or segmental ulnar fracture (181). The percutaneous insertion of an ulnar intramedullary pin is a simple and effective way to manage this problem. Alternatively, the ulnar shaft can be plated. On rare occasions, when the radial head is not reduced after correction of ulnar length and alignment, open examination of the joint is indicated. Interposition of the annular ligament or an intraarticular osteochondral fragment may be found. Transcapitellar pinning of the reduced radial head is usually unnecessary and inadvisable.

Complications. Delayed diagnosis is the most frequent complication associated with Monteggia fracture-dislocations. Patients presenting less than 3 weeks after injury with persistent dislocation should be treated by attempting closed reduction. If the ulna can be reduced and held, the radial head will usually reduce and remain stable. Open reduction, with reconstruction of the annular ligament, is indicated if closed reduction fails, or when the injury is more than 4 weeks old. Ulnar osteotomy to restore length and alignment may be necessary (182,183 and 184).

Galeazzi Fracture-dislocation

The classic Galeazzi lesion is a fracture of the distal third of the radius, without fracture of the ulna, and is associated with dislocation of the distal radioulnar joint. This is an uncommon injury in children. The triangular fibrocartilage complex is disrupted, and the distal ulna is dorsally displaced, as viewed on a lateral radiograph. Injury to the distal radioulnar joint is frequently overlooked, and persistent joint subluxation is responsible for poor long-term results (185). The Galeazzi equivalent injury is represented by physeal separation of the distal ulna, instead of a triangular fibrocartilage tear (186,187). Long-term problems with this injury include premature physeal arrest and loss of supination.

Treatment consists of closed reduction and above-elbow casting with the forearm in full supination. It is rarely necessary to place a smooth Kirschner wire across the joint or the fracture to maintain reduction.

Midshaft Fractures

Plastic Deformation

Plastic deformation or traumatic bowing of the forearm is possible, because of the elastic properties of young children's bones. This injury represents a series of microfractures that are not seen on radiographs. Bowing of both bones may occur, but plastic deformation of one bone is often associated with complete or incomplete fracture of the other forearm bone. Reduction is recommended, if deformity was immediately obvious at the time of injury, or when angulation is greater than 20 degrees (188,189).

Treatment of plastic deformation usually requires general anesthesia, because a prolonged corrective force must be applied to permanently straighten the bone. The position of immobilization follows the principles outlined in the discussion of greenstick fractures.

Greenstick Fractures

A complete fracture of one cortex and plastic deformation of the opposite cortex characterize greenstick fractures. Most greenstick fractures represent a rotational malalignment, in addition to angular deformity. Apex-volar greenstick fracture is the most common type, and results from excessive supination forces applied to the distal segment, combined with axial load. The child presents with the palm facing the apex of the fracture deformity (Fig. 32-39). Apex-dorsal deformity results from excessive pronation force applied to the distal segment; the child presents with the palm facing down, relative to the apex of the fracture deformity (Fig. 32-40). Occasionally, greenstick fractures of the radius and ulna are caused by direct force, producing mostly angular deformity, without much malrotation. Reduction is indicated if deformity was immediately obvious at the time of injury, or when shaft angulation exceeds 20 degrees in a child younger than 8 years or 15 degrees in an older child.

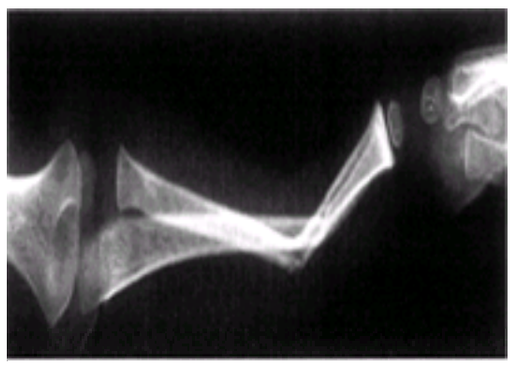

FIGURE 32-39. Coupled relation of rotation and angulation. This fracture demonstrates volar angulation. The mechanism of injury was falling on the outstretched hand. When the fractures of the radius and ulna are at different levels, angulation cannot occur without rotation. Note the anteroposterior appearance of the elbow and the lateral projection of the wrist. This deformity is corrected with pronation of the distal fragment.

FIGURE 32-40. Coupled relation of rotation and angulation. **A:** The radiograph shows deformity with pronation of the distal fragment and dorsal angulation of the radius. The ulna has undergone plastic deformation. When a single bone angulates, it must rotate around the other. **B:** Alignment is restored with supination of the distal fragment. The lateral projections of the elbow and the wrist are now matched.

Treatment of greenstick fractures requires adequate pain relief for one quick reduction attempt that is usually successful. Reduction is accomplished by simply reversing the injury mechanism. Apex-volar deformity (apex of fracture in the direction of the palm of the hand) is reduced by pronating the wrist, while applying pressure to the volar surface of the forearm. Apex-dorsal deformity (apex of fracture in the direction of the dorsum of the hand) is reduced by supinating the wrist, while applying pressure to the dorsal surface of the forearm. Completing the fracture of the opposite cortex is unnecessary, although this occurs frequently during the reduction maneuver. After reduction, the arm is immobilized in a well-molded sugar-tong splint or a bivalved long-arm cast. Three-point pressure is essential for the maintenance of reduction. Weekly follow-up is recommended for 2 to 3 weeks after reduction. It is generally necessary to change the cast for remolding as swelling subsides during this period. Six weeks of immobilization are usually adequate, but refracture is a risk when immobilization is discontinued too soon.

Complications. Refracture is seen more often after greenstick fractures than after complete forearm fractures (190,191). This is possibly attributable to resorption on the fractured side, with the intact cortex preventing gap closure, and leading to delayed union. One method to reduce the risk of refracture is to complete the fracture of the intact cortex at the time of reduction. Another option is to use a longer period of immobilization in a cast or removable splint, until union of both cortices is complete.

Complete Shaft Fractures

Complete fractures of the forearm result from higher-energy trauma than greenstick fractures. The proximal segments usually assume a position dictated by muscle forces, because the muscle actions are unrestrained by an intact cortex. Most proximal fragments are in a position of supination, as a result of the actions of the biceps and supinator muscles. When the fracture is more distal, the pronator teres has a neutralizing effect on the proximal fragment. Evans (192) plotted the rotational position of 50 complete shaft fractures and determined that the proximal radial fragment was in neutral to slight supination, when the fracture was in the distal third. The proximal fragment was more frequently in supination, when the fracture was in the proximal third. None of the shaft fractures reviewed by Evans resulted in pronation of the proximal fragment.

Managing these fractures can be difficult, but nonunions and serious complications are rare after closed treatment. The principal concerns are the possibility of residual deformity and loss of forearm rotation. Guidelines for the management of complete forearm fractures are based on the following observations:

1. Younger children with more distal fractures have the best prognosis (12,13 and 14,193,194).
2. Children within 1 year of skeletal maturity should be treated as adults (195).
3. Residual loss of supination (pronation deformity) is more difficult to accommodate than loss of pronation. When in doubt, immobilize the forearm in neutral or moderate supination (196,197).
4. Cosmetic appearance is principally influenced by the alignment of the ulna. A straight ulna usually produces a straight-appearing forearm (192).
5. Rotational function is determined primarily by the position of the radius (192,198).
6. The interosseous membrane is wider and more accommodating distal to midshaft. Mild loss of radial bow and interosseous encroachment are acceptable distally (198).
7. Bayonet apposition is acceptable for all pediatric shaft fractures, if rotation is correct and there is no angulation (199,200).
8. Consider immobilization with the elbow extended for children younger than 4 years, and for proximal third fractures in all age groups. Incorporate the thumb to avoid cast slippage (201).
9. Improvements in alignment can be made by gentle molding in a new cast, or by remanipulation for 1 to 3 weeks after injury (202,203).
10. In children younger than 8 years of age, 15 degrees of midshaft angulation is acceptable. For a more proximal fracture, less deformity should be the goal (200,204).
11. Children older than 8 years should not be allowed to develop more than 10 degrees of angulation of middle or proximal shaft fractures, and should be held to less than 15 degrees for fractures distal to the midshaft (196,200,205).
12. Malrotation of 20 to 30 degrees is acceptable for a good outcome (200,206).
13. Loss of forearm rotation of less than 30 degrees does not result in significant functional limitations (207,208).

Treatment is usually by closed reduction and plaster immobilization. Adequate pain relief and muscle relaxation are required, because more than one attempt may be necessary. Regional (i.e., Bier or axillary block) or general anesthesia is often preferred. The reduction technique typically involves increasing the angular deformity, applying longitudinal traction to lock in place and straighten the fracture, then correcting any malrotation by supinating or pronating the forearm. If this is unsuccessful, it is often helpful to apply traction, using finger traps for a period of 10 minutes, before another attempt is made. Rotational alignment is assessed by observing the bone widths and matching their contours on radiographs. Comparison radiographs of the opposite extremity, in various degrees of rotation, may be helpful in determining rotational alignment (206). Alternatively, the position of the bicipital tuberosity may serve as a guide to rotation, because it is approximately on the side of the radius opposite the radial styloid and thumb (192). Postreduction casting entails a flat interosseous mold along the volar forearm, creating an oval shape, while keeping a straight lateral border along the ulnar side. An above-elbow cast or splint should be used. Fracture stability is improved with at least 50% bone apposition. If one bone disengages, shortening may occur, followed by increasing angulation. This may respond to remanipulation or require surgical stabilization. Weekly reevaluation is recommended for the first 3 weeks (Fig. 32-41). Union is usually complete in 6 to 8 weeks. Nonunion is rare, and closed treatment produces excellent results in greater than 95% of patients, when the physician is able to observe the management guidelines (196,200,204,209).

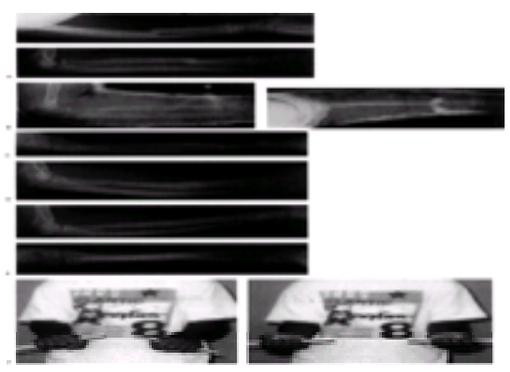

FIGURE 32-41. Forearm with subsequent malunion fracture in a 10-year-old boy. **A:** Radiographs demonstrate displaced fracture of the radius with greenstick fracture of the ulna. **B:** Acceptable reduction is achieved with completion of the ulnar fracture. The cast is poorly molded along the ulnar border. The patient did not return for follow-up as instructed. **C** and **D:** Anteroposterior and lateral radiographs demonstrate midshaft malunion. **E:** Radiographs and clinical photographs 10 months later demonstrate remodeling. **F:** Range of motion and function are normal. The patient is not aware of any cosmetic deformity.

Operative intervention with internal fixation is indicated for 7 to 10% of all complete shaft fractures (210). Indications include open fractures, soft tissue interposition blocking reduction, refracture with displacement, and failed closed management (211,212 and 213). Segmental fractures, multiple trauma, and high-energy injuries constitute relative indications for operative stabilization (Fig. 32-42). Intramedullary fixation is usually preferred for children and adolescents, because healing is rapid and supplemental casting does not lead to loss of motion (210,214,215) **[➥1.16]**. Fixation is usually achieved by insertion of a small, flexible pin of 1.5 mm or 2.5 mm in diameter (211) (Fig. 32-43). The tip is dulled, and a 30-degree bend is made at the very tip, to facilitate passage across the fracture site. The ulnar pin can be inserted proximally just lateral to the tip of the olecranon, or distally in the flare of the ulna. The radial pin is inserted in the distal metaphysis, avoiding penetration of the growth plate. An oblique drill hole is made in the metaphyseal cortex, and the wire is introduced into the medullary canal. It is tapped or gently rotated into the medullary canal, until it passes the fracture site. Occasionally, it is necessary to perform a limited open reduction at the fracture site to facilitate passage of the wire. Both bones are usually stabilized, but one is sufficient in some cases (216). It is usually best to bend the pins and leave them under the skin, because they should be left in place for 3 months to reduce the risk of early refracture. Supplemental casting is used for approximately 6 weeks after fixation.

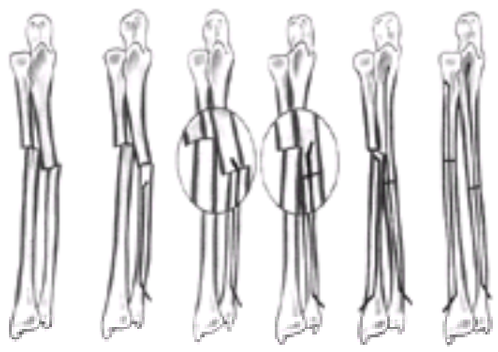

FIGURE 32-43. Surgical nailing procedure for flexible intramedullary nails. The ulnar wire can be introduced digitally, as shown, or through the olecranon. (From ref. 210, with permission.)

Plating is rarely used in younger children, but it is indicated for comminuted fractures, or for adolescents within 1 year of skeletal maturity. This provides anatomic fracture alignment, and allows early unprotected range of motion. Plating requires more dissection, and has the disadvantage of possible later hardware removal, which entails the added risk of neurovascular injury and refracture (217,218).

Complications. Complications of forearm fractures include refracture, malunion, decreased forearm rotation, synostosis, nerve injuries, and, rarely, nonunion or other problems. Malunion is the most common complication, but remodeling may be surprising, and function may return to normal, despite malunion (200,204,205,209,219).

A 3- to 6-month period of observation is recommended when deformity is less than 20 degrees. Shaft deformities greater than 30 degrees should be corrected as soon as some strength and motion have been regained, usually 3 months after the initial injury. Deformities between 20 and 30 degrees may require early correction at 3 months, depending on the clinical appearance, the age of the child, and the location of the malunion. Results are better when deformity is corrected within 1 year of the initial injury (220). Intramedullary fixation is usually sufficient for younger children (221). Older children benefit from plate fixation, to begin early motion after osteotomy to correct malunion (Fig. 32-44).

FIGURE 32-44. Malunion of the forearm in a 14-year-old child. **A:** Anteroposterior view of the alignment after closed reduction and casting. **B:** The lateral projection shows acceptable alignment. **C:** The anteroposterior projection 12 weeks after treatment shows malunion of the radius and ulna. **D:** A lateral projection shows dorsal angulation. Clinical evaluation demonstrated only 15 degrees of rotation of the forearm. **E:** An anteroposterior projection after osteotomy and internal fixation with 3.5-mm compression plates. **F:** The lateral projection shows restoration of anatomic alignment. The range of motion was improved significantly, with full supination but a loss of the last 20 degrees of pronation.

Distal Metaphyseal Fractures of the Radius and Ulna

Distal metaphyseal fractures of the radius and ulna are common, and are usually caused by a fall onto the hand with the wrist in a pronated, extended position. Unicortical fractures (i.e., torus or buckle fractures) are frequently encountered, and are stable injuries. Treatment is directed toward patient comfort and protection of the forearm from further injury. Immobilization with a below-elbow cast or splint for 2 to 3 weeks is sufficient. Torus or unicortical fractures should be differentiated from the minimally displaced bicortical fracture that has a propensity for secondary angulation (222) (Fig. 32-45). A well-molded cast is recommended for complete fracture, and should extend above the elbow, if there is pain with forearm rotation. Follow-up radiographs are recommended 1 week after complete bicortical fractures.

FIGURE 32-45. Bicortical fracture. **A:** This minimally displaced bicortical fracture (*arrow*) of the distal radius can easily be mistaken for a simple dorsal buckle fracture. **B:** Three weeks later, after cast removal, 35 degrees of dorsal angulation is seen. Although this probably will remodel during the next year, there is considerable clinical deformity and loss of rotation until this angulation resolves. This problem can be avoided through the use of a well-molded below-elbow cast or a cast placed above the elbow to control rotation.

Fractures of the distal radial metaphysis have great potential for remodeling, because of their proximity to the distal growth plate. Bayonet apposition may be accepted until early adolescence (223) (Fig. 32-46). Friberg (12,13 and 14) observed that dorsal tilt up to 20 degrees remodels 50% of these fractures in the first 6 months, and the remaining 50% in an additional 18 months, as long as the growth plate remains open. Deformity greater than 20 degrees may also remodel, but this is less predictable, especially in older children. The guidelines for acceptable residual angulation are age-dependent, and serve only as a general indicator of expected results. Dorsal tilt (apex-volar angulation), up to 35 degrees, can be accepted in children younger than 5 years of age. This decreases to 25 degrees for children between 5 and 12 years of age. In older children, the dorsal tilt should be controlled at less than 15 degrees, to ensure a good outcome. Radial deviation remodels less than angulation in the plane of flexion and extension. Therefore, radial deviation should be kept to less than 15 degrees in children younger than 12 years of age and to less than 10 degrees in older children (223,224 and 225).

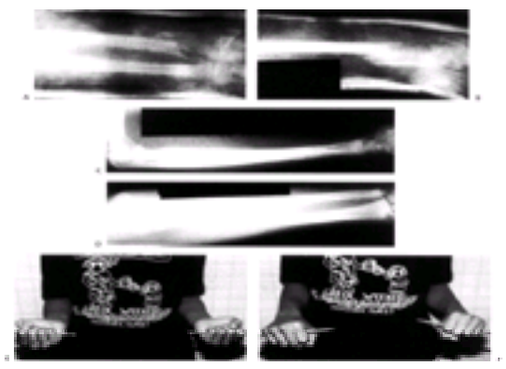

FIGURE 32-46. Distal radius and ulna fractures in a 14-year, 6-month-old boy. **A** and **B:** Bayonet opposition was accepted in cast. **C** and **D:** Eighteen months after injury, radiographs demonstrate satisfactory remodeling. **E** and **F:** Range of motion and function are symmetric.

Treatment of displaced or angulated fractures consists of closed reduction and plaster immobilization. In complete fractures, the distal fragment is usually dorsally displaced, but the dorsal periosteum is intact. Reduction is accomplished by increasing the deformity, which relaxes the intact periosteal hinge. Longitudinal traction is then applied with digital pressure at the fracture site until length is restored. The angular deformity is then corrected (Fig. 32-47). More reduction force is required if the ulna is intact, and pronating the distal segment during the reduction maneuver assists in fragment realignment. After reduction, the wrist should be placed in slight palmar flexion and ulnar deviation. The cast is molded with three-point pressure dorsally over the distal fragment, centrally on the volar surface of the forearm, and proximally on the dorsal surface of the forearm. The cast molding technique is designed to counter the tendency for later radial and dorsal fracture displacement. Most often, an above-elbow cast or splint is used for immobilization, but it has been demonstrated that a well-molded below-elbow cast can also effectively control these fractures (226). Fracture alignment should be monitored closely for the first few weeks after injury, when the potential for redisplacement is greatest.

FIGURE 32-47. Reduction technique for a distal both-bone fracture. **A:** The fracture is 100% translated and shortened. The dorsal periosteum is generally intact. Longitudinal traction alone can tighten the soft tissues, preventing reduction of the fragment. **B:** The dorsal soft tissues need to be completely relaxed, by hyperextending the fracture and providing longitudinal traction, restoring length to the dorsal cortex. Digital pressure on the distal fragment generally helps with this maneuver. **C:** The reduction is completed with volar flexion of the distal fragment. The goal is at least 50% apposition of the bony surfaces with no angulation.

Occasionally, a distal third metaphyseal fracture is irreducible by closed manipulation. This may be accepted, except in patients approaching skeletal maturity, as long as alignment is within the described guidelines. However, redisplacement is more common when bayonet apposition is accepted. The reported incidence of fracture redisplacement varies considerably (226,227). Supination of the forearm has been recommended to reduce the pull of the brachioradialis, and thereby reduce the incidence of delayed dorsal angulation (228). Fractures that do not maintain their positions can be remanipulated. Percutaneous pinning has been recommended to avoid repeated manipulation (228), but physeal closure has been reported with this technique (229).

Complications

Complications are rare. Significant residual deformity can remodel. Dorsal tilt of 35 degrees and radial tilt of 15 degrees should be given a chance to remodel before considering osteotomy. Misdiagnosis of a Galeazzi-type fracture can also occur. Galeazzi-type fracture-dislocation should be suspected when an isolated radius fracture is associated with fracture of the ulnar styloid (186). Distal physeal separation of the ulna is uncommon, but often leads to premature physeal closure (187).

Distal Radius Physeal Fracture

Fracture of the growth plate of the distal radius is the second most common physeal injury, with phalangeal fractures being the most common (29). Distal radius physeal fracture accounts for approximately 15% of all forearm fractures (177). Eighty percent are Salter-Harris type I or II injuries. The germinal cells remain with the distal epiphyseal fragment, and anatomic reduction is unnecessary for continued normal growth. Occasionally, more complex injuries occur, with higher rates of premature growth arrest, and anatomic reduction may be required.

Treatment for the type I and II fractures is similar to the treatment of distal radius metaphyseal fracture described previously. Multiple reduction attempts may lead to growth plate damage. Two or more attempts have produced growth arrest in slightly more than 25% of these patients (230). Repeat manipulation should not be attempted more than 10 days after injury, because physeal healing has already commenced, and further growth plate trauma may result. Cast immobilization can usually be discontinued 4 weeks after injury.

Complications

Growth arrest has been reported after nondisplaced or minimally displaced fracture. If growth arrest occurs, corrective lengthening osteotomy using iliac crest graft has been successful in restoring alignment and function (231,232).

FRACTURES OF THE THORACIC AND LUMBAR SPINE

Clinical Features

Spine fractures in children represent 1 to 2% of all pediatric fractures (3). Most of these injuries involve the cervical spine, and are discussed in Chapter 21. Thoracolumbar spine injuries are less common in children than in adults, but the incidence is difficult to determine. The reported incidence may be artificially low, because some children with injuries severe enough to cause spinal fracture may die from associated injuries (233). Causes of spine injury include falls, athletic activities, battering, and motor vehicle trauma (234,235).

There is a 50% incidence of associated injuries in children who sustain spine trauma from motor vehicle crashes (234). Complete examination is essential when evaluating a child with multiple injuries, because spine fractures are occasionally overlooked (236,237). Examination may reveal tenderness, swelling, ecchymosis, or a palpable defect posteriorly along the spinous processes. A seatbelt mark across the abdomen or injury of an abdominal organ should increase the index of suspicion. Any loss of sensory or motor function should be accurately documented.

Spinal cord injury is less frequent in children than in adults. Perhaps this is attributable to the fact that the pediatric spine is much more flexible than the adult spine, and allows greater deformation without fracture. This increased musculoskeletal elasticity is not shared by the spinal cord, and may lead to the occurrence of spinal cord injury without radiographic abnormality. The disproportionately large head size and other structural features in children place the cervical and upper thoracic region at greatest risk for spinal cord injury. Trauma to the lower thoracic or lumbar spine in children is rarely associated with spinal cord injury. The prognosis for recovery from incomplete neurologic injury is better in children than in adults, but complete lesions rarely improve (234).

Plain radiographs should be obtained when spine trauma is suspected, but these may be difficult to interpret. A CT and/or MRI are indicated for evaluation of the majority of patients, when thoracolumbar injuries are suspected or known to be present (237). A CT is especially helpful to evaluate the bony structures. Sagittal and coronal reconstruction can be used to evaluate alignment and spinal canal encroachment. MRI is more useful than CT to evaluate the spinal cord, intervertebral discs, and other soft tissue structures (237). An MRI is indicated in all cases with neurologic deficit.

Anatomy and Classification

The thoracic and lumbar vertebrae form three main ossification centers, one for the left and right sides of the neural arch and one for the body. The junction of the arches with the body occurs at the neurocentral synchondrosis. This junction is visible radiographically until the age of 3 to 6 years. It lies just anterior to the base of the pedicle, and can be misinterpreted as a congenital anomaly or fracture in younger children. Secondary centers of ossification occur in flattened, disc-shaped epiphyses superior and inferior to each vertebral body. These centers provide longitudinal growth, but do not cover the entire vertebral body (238). Ossification of these growth plates at the age of 7 to 8 years creates the radiographic impression of a groove at the corner of each vertebral body. This groove is circumferential around the upper and lower end plates of each vertebra. The ligaments and discs attach to this groove, which is therefore an apophyseal ring. The ring apophysis develops its own ossification center by the age of 12 to 15 years, and fuses with the remainder of the vertebra at skeletal maturity (239).

Classification systems for thoracolumbar spine fractures in children have not been proposed. The three-column theory of Denis (240) allows classification of adult fractures, and also has relevance for the pediatric population. According to this theory, the thoracolumbar spine consists of anterior, middle, and posterior columns. The anterior column includes the anterior longitudinal ligament, the anterior half of the vertebral body, and the anterior portion of the annular ligament. Middle column structures are the posterior half of the vertebral body, the posterior annulus, and the posterior longitudinal ligament. The posterior column includes the neural arch, the ligamentum flavum, the facet joint capsules, and the interspinous ligament. Spinal stability is primarily dependent on the status of the middle column (241).

Denis (240) applied this three-column theory, to classify minor or major thoracolumbar fractures. Minor injuries include isolated fractures of the posterior elements. Major fractures are subdivided into compression fractures, burst fractures, seatbelt-type injuries, and fracture-dislocations. Compression of the anterior column is usually stable, and results from axial loading in flexion. Lateral compression fractures of the vertebral body may also occur. Further compression results in a burst fracture that is unstable, because the middle column becomes involved. Lapbelt injuries (Chance fractures) are unstable, because they disrupt the posterior and middle columns by flexion and distraction forces. Fracture-dislocations usually involve all three columns, and result from various combinations of forces.

Certain types of thoracolumbar injuries are unique to children. These include most cases of spinal cord injury without radiographic abnormality, posterior limbus or apophyseal fractures, and fractures associated with child abuse.

Treatment of Thoracolumbar Fractures

Older adolescents sustain injuries similar to those seen in adults, and should be managed accordingly (242). The majority of thoracolumbar spine fractures in children and younger adolescents are minor, stable, and without neurologic deficit. Simple bed rest and gradual resumption of activities are generally sufficient for management of these injuries. In the active athlete with an acute fracture of the pars intraarticularis, a thoracolumbar-sacral orthosis (TLSO) is recommended for 6 to 8 weeks in an attempt to obtain union.

Compression Fractures

The majority of compression fractures in children occur in the thoracic spine (Fig. 32-48). Multiple compression injuries are not uncommon. When wedging of the thoracic or lumbar vertebra is less than 10 degrees, treatment consists of bed rest with gradual resumption of activities, as tolerated. When wedging is greater than 10 degrees and the Risser sign is less than 3, immobilization in hyperextension is recommended for a period of 2 months, followed by bracing for 1 year or more (235). Surgical stabilization is recommended when compression is greater than 50%, for lateral compression greater than 15 degrees, or in adolescents near skeletal maturity (235,243).

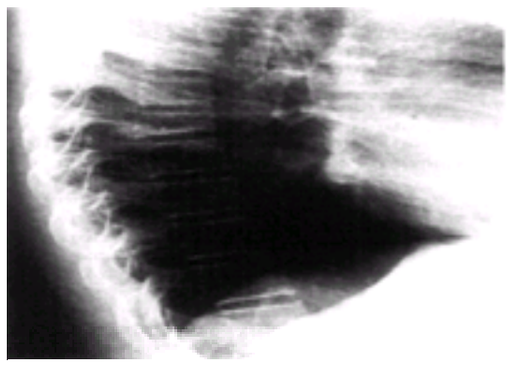

FIGURE 32-48. An 11-year-old girl fell from a horse and sustained a compression fracture at T6, which is seen on this lateral spine radiograph.

Burst Fractures

These injuries can be managed nonoperatively when the posterior column is intact and there is no neurologic injury (235,243,244). Treatment usually consists of hyperextension casting for 2 to 3 months and bracing for an additional 6 to 12 months. Surgical decompression and instrumentation are recommended for patients with neurologic compromise (243,244). Posterior distraction and instrumentation may achieve decompression by ligamentotaxis with reduction of the retropulsed fragments (245). Anterior decompression has been recommended in the presence of multiple nerve root paralysis, but the role of anterior decompression and instrumentation remains controversial (246).

Lapbelt Fractures (Chance-type Fracture)

This flexion-distraction injury has been associated with the use of lapbelt restraints, when the lapbelt slides up the torso and rests over the abdomen, instead of the proximal thighs and hips (246). The incidence of Chance fractures in children has increased since the introduction of mandatory seatbelt laws. Fortunately, this injury has a better prognosis in children than in adults (247). Neurologic deficits are infrequent, but intraabdominal injury is common and obscures the diagnosis of spine trauma (Fig. 32-49).

FIGURE 32-49. Lapbelt fracture (Chance fracture). **A:** Anteroposterior abdominal and chest radiograph of a 10-year-old girl involved in a motor vehicle crash. She was restrained with a lapbelt only. This radiograph was taken after laparotomy for a mesenteric tear. **B:** Several days after laparotomy, the patient complained of back pain. This lateral radiograph shows a flexion/distraction injury through the body of L1, and posteriorly through the cephalad portion of L1 and the spinous process of T12. **C:** Magnetic resonance image. Note the injuries to the body of L1, and to the interspinous and supraspinous ligaments at T12 and L1. The posterior column failed in tension. The patient was managed successfully with an extension cast for 8 weeks.

This is an unstable injury in most cases. Treatment consists of cast immobilization for 8 to 10 weeks, when there is minimal displacement and the fracture line goes through bone. Posterior surgical stabilization is indicated in the presence of displacement or neurologic deficits, or when there is a significant ligamentous component, instead of fracture through bone. One-level posterior fusion is generally sufficient (139,236). This can be achieved by spinous process wiring and cast immobilization, or by hook/rod and pedicle screw fixation in older children.

Limbus Fracture (Apophyseal Fracture)

This fracture is typically seen in the adolescent or young adult, and presents clinically like a herniated nucleus pulposus. It often results from lifting a heavy object, but may occur from falls or twisting injuries. The patient may describe a “pop” at the time of injury, followed by radiculopathy. Delayed diagnosis is common (248). Takata et al. (249) described four types of growth plate injuries to the spine. However, nonoperative management is rarely successful, regardless of the type (243,248). Once the diagnosis is confirmed, MRI and/or CT should be used to determine the exact location and configuration of the lesion. Surgical excision is then performed by piecemeal excision of the limbus fragment.

Complications

Complications of thoracolumbar fractures in children are uncommon, unless there is an accompanying neurologic deficit. Major fractures in children can be unpredictable. They may remodel or develop late deformity with spontaneous progression (234,235). Late deformity is common when there is an associated neurologic deficit, or after wide laminectomy (250). Remodeling is more likely in younger children without spinal cord injury, particularly when the iliac apophysis is incompletely ossified (Risser sign less than 3) (235). However, remodeling can occur in older children. Spontaneous remodeling and redevelopment of the spinal canal has been observed in adults after burst fractures with canal encroachment (251). Long-term back pain is uncommon after spine fractures in children. Perhaps the juvenile discs and facet joints are relatively resistant to permanent damage (234).

PELVIC FRACTURES

Clinical Features

Fractures of the pelvis in children are uncommon. The annual incidence has been estimated to be 1 per 100,000 children per year (3). Avulsion fractures often result from athletic injuries in adolescent athletes. Avulsion injuries are discussed elsewhere in this textbook. Other types of pelvic fractures in children are usually the result of high-energy trauma. However, pediatric pelvic fractures are often stable and minimally displaced. The immature pelvis is more malleable than that of an adult, largely because of a greater component of cartilage and the greater flexibility of adjacent joints. This allows greater energy absorption before fracture. The flexibility of the pediatric pelvis also permits single breaks in the pelvic ring to occur. High-energy, unstable pelvic fractures are rare. The majority of unstable pelvic fractures are caused by a pedestrian being struck by a motor vehicle (252,253).

Approximately 20% of polytraumatized children have pelvic fractures (52), and children with pelvic fractures have associated injuries in approximately 75% of cases (254,255 and 256). These associated injuries include head injuries, intraabdominal trauma, urologic disruptions, and additional fractures. Mortality rates are lower in children than in adults, but death occurs in 3 to 15% of juvenile pelvic trauma cases (51,253,254 and 255,257). Death is most frequently related to head injury, but exsanguination from fractures or visceral injuries can occur. The risks of hemorrhage and associated visceral injuries correlate with fracture patterns (254,258). Patients with bilateral anterior and posterior fractures are at greatest risk, whereas isolated pubic ramus fractures have the lowest risk of hemorrhage and intraabdominal injury.

Evaluation includes a careful physical examination for associated injuries, including neurologic deficits. Any laceration should be inspected to determine whether an open fracture has occurred. Rectal examination is indicated to look for hemorrhage signifying bone penetration into the rectum, and to verify intact perineal sensation (i.e., sacral plexus function). Pelvic stability should be tested with anterior and lateral compression of the pelvis. Peripheral arterial circulation should also be noted. Plain radiographs are useful for screening, but may be difficult to interpret. Pelvic inlet (40 degrees caudal), outlet (40 degrees cephalad), and Judet (45 degrees oblique) views can help define the fracture pattern and the potential involvement of the acetabulum. However, these views have largely been replaced with CT with or without three-dimensional reconstruction.

Anatomy and Classifications of Pelvic Fractures

The pelvis is formed from three ossification centers: the ischium, the pubis, and the ilium. These come together at the acetabulum to form the triradiate cartilage. Secondary ossification centers can be confused with fractures. These appear at the apophyses between 13 and 16 years of age. The apophyses that are principally associated with avulsion injuries are located on the ischial tuberosity, the anterior inferior iliac spine, and the anterior iliac crest. Secondary centers of ossification can also develop along the pubis and the ischial spine. Several other normal variants can also be confused with fractures. An area of particular confusion is at the junction of the inferior pubic ramus and the ischium. Before ossification, this junction can have the appearance of a fracture, especially when ossification is asymmetric. A swelling may also occur in this area, and can simply be observed when asymptomatic.

Several classifications have been proposed for pelvic fractures (253). The author prefers the classification proposed by Watts (259):

1. Avulsions.
2. Fractures of the pelvic ring (stable and unstable).

3. Fractures of the acetabulum.

Fractures of the pelvic ring can be subclassified using the AO/ASIF classification of adult pelvic fractures (257). This classification is based on both the mode of injury and the resulting stability characteristics of the fracture.

Type A: Stable Injury

Stable injuries include isolated fractures of the pubic ramus or iliac wing (Fig. 32-50). It should be noted that diastasis of the pubic symphysis can occur in children, without instability of the sacroiliac joint posteriorly, because of the elasticity of the child's pelvis. In young children, this fracture usually represents separation at the bone–cartilage junction rather than joint disruption.

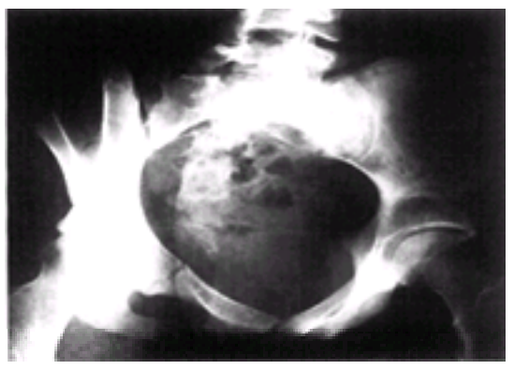

FIGURE 32-50. A 16-year-old girl with an isolated right pubic ramus fracture best visualized on this oblique radiographic view.

Type B: Rotationally Unstable Fractures

This is a pelvic ring disruption that is stable in the vertical plane, but unstable in the transverse plane. Mechanisms include lateral compression causing, for instance, pubic and ischial ramus fractures with contralateral sacral fracture. Alternatively, anterior compression may cause an “open-book” type of injury with pubic diastasis.

Type C: Rotationally and Vertically Unstable Fractures

This group includes bilateral pubic rami fractures (straddle injuries), which rarely displace in children; vertical shear fractures through the ipsilateral anterior and posterior pelvic rings, and anterior ring fractures with acetabular disruption.

Treatment of Pelvic Fractures

Pelvic Ring Fractures

Most pelvic fractures in children have a favorable result with a minimum of treatment. Stable fractures are managed by bed rest followed by gradual resumption of weight bearing, as tolerated. Unstable pelvic fractures that do not involve the acetabulum can be managed with more prolonged bed rest (1 to 2 months), when displacement is minimal (less than 1 cm, in the author's opinion). Careful observation with frequent radiographs is recommended to recognize and treat any additional displacement. Union and remodeling occur reliably, in spite of mild displacement (252,255,260). Unstable pelvic fractures with greater amounts of displacement (more than 1 cm) should be reduced with traction or open reduction. The author recommends reduction of pubic diastasis (open-book) fractures, when the diastasis exceeds 3 cm, or when stability is required for urologic reconstruction. Stabilization after reduction can be achieved with pelvic sling and/or cast immobilization. Usually, external and/or internal fixation are preferred for unstable open-book or other type B fractures (253,257) (Fig. 32-51). Type C fractures may require internal fixation of posterior injury, in addition to anterior stabilization with external fixation or other means. Surgical stabilization is also appropriate to reduce retroperitoneal blood loss, and to facilitate mobilization of the child with multiple injuries.

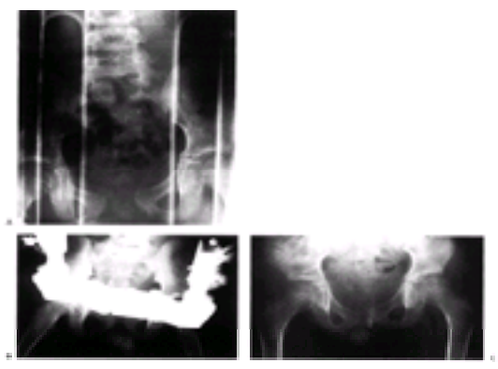

FIGURE 32-51. A 10-year-old boy run over by a bus. **A:** Rotationally unstable pelvic fracture with bilateral acetabular fracture. Note the pubic diastasis. **B:** Open removal of a loose fragment in the left acetabulum and anterior external fixation for pubic diastasis were performed. **C:** Three months after surgery, the pubic diastasis has healed. The patient was fully weight bearing with no pain.

Acetabular Fractures

Acetabular fractures, except for stable posterior fracture-dislocations, require precise restoration of joint congruity. Nondisplaced acetabular fractures are managed closed. When displacement is present, open reduction with stable internal fixation and early motion is recommended (257). Comminution is often less severe in children than in adults, and the results of surgical management are generally satisfactory. Poor results after anatomic reduction may still occur, because of the magnitude of the initial trauma (261).

Premature closure of the triradiate cartilage is a potential complication that is unique to the immature skeleton (262). Fractures that cause premature closure are usually nondisplaced, and do not require open reduction. Children younger than 10 years of age are at the greatest risk for this complication. Disturbance in growth leads to the development of a shallow acetabulum, because the triradiate cartilage is responsible for growth in the height and width of the acetabulum. Hip subluxation may follow, necessitating redirectional pelvic osteotomy.

Complications

Acute management of pelvic fractures and associated injuries can be challenging, but long-term complications are rarely attributable to the bony structures. Untreated, severely displaced fractures can result in a limp, rotational deformity, or limb-length discrepancy. Acetabular injuries are at risk for developing traumatic arthritis, in spite of anatomic reduction. Premature closure of the triradiate cartilage can be problematic in younger children. However, residual morbidity is usually attributed to associated injuries, especially traumatic brain injury.

FRACTURES AND DISLOCATIONS OF THE HIP

Hip Dislocation

Dislocation of the hip in children is uncommon, representing only 5% of all pediatric dislocations. Most hip dislocations are posterior, but anterior and obturator dislocations can occur (263,264). This injury may result from minor trauma, such as tripping or falling; from moderate force, as in football or soccer; or from high-energy impact, as in motor vehicle crashes. The mechanism of injury depends somewhat on the age of the child. Hip dislocations in children younger than 10 years of age are frequently the result of mild trauma, because joint laxity is common, and the acetabulum is largely cartilaginous (263,264). Dislocations in children older than 10 years of age are likely the result of moderate or severe trauma. Dislocation from moderate trauma may result in spontaneous incongruous reduction and capsular interposition (265). This is rare, but easily misdiagnosed in children and adolescents. Any suggestion of joint space widening after reduction should be investigated with CT (Fig. 32-52).

FIGURE 32-52. Traumatic hip dislocation. **A:** Anteroposterior projection of a 3-year, 6-month-old child with a low-energy injury producing a posterior hip dislocation. **B:** An anteroposterior view of the pelvis after closed reduction of the hip, taken in an emergency department. Clinically, a stable reduction was obtained, but there is significant joint space widening, suggesting an intraarticular obstruction. **C:** The computed tomography scan confirms incomplete reduction. There is some radiodense material in the posterior acetabulum. **D:** Posterior open reduction of the hip was performed, and the interposed soft tissue was removed. There was no osteochondral fracture. An anteroposterior radiograph of the pelvis confirms the concentric symmetric reduction of the hip. A spica cast was applied for 4 weeks.

Treatment

Treatment consists of closed reduction with adequate muscle relaxation and analgesia. Early closed reduction within 6 h of injury is recommended. Reduction is rarely difficult in children, but gentle reduction is especially important in the adolescent age group. Occult epiphyseal injury may be present in this older age group, and epiphyseal separation can occur during attempted reduction. The reduction technique for posterior dislocation requires hip and knee flexion, usually with adduction of the hip. Longitudinal traction is then applied, while an assistant stabilizes the pelvis. The limb is then extended, internally rotated, and abducted. After the hip is reduced, the stable arc or motion should be assessed. Postreduction radiographs should include the opposite hip to confirm a concentric reduction with symmetric joint spaces. A CT is recommended for any joint space widening, when instability is noted, and after reduction in older children. A CT is not necessary in younger children with stable concentric reduction and no evidence of acetabular fracture on plain radiographs. The child younger than 8 years should be immobilized in a spica cast or abduction pillow, with strict bed rest for 4 to 6 weeks, to reduce the risk of recurrent dislocation. Stable closed reductions in older children can be managed with activity restriction and decreased weight bearing for 6 weeks, to allow capsular healing and reduction of posttraumatic inflammatory response.

The indications for open reduction include unstable closed reduction, nonconcentric reduction, or a large acetabular rim fragment with displacement of more than 2 mm. Open reduction is approached in the direction of the dislocation, such as the posterior interval (i.e., Kocher-Langenbeck approach) for posterior dislocations. Postoperative management after open reduction is the same as that after closed reduction.

Complications

The reported incidence of avascular necrosis in children is 3 to 10%, approximately one-half that of adults. The risk of avascular necrosis is diminished when reduction is achieved within 12 h, and preferably within 6 h, of injury (263,264). Traumatic arthritis is infrequent. The long-term prognosis for arthritis is related to the severity of the trauma, associated fractures, and treatment delays beyond 24 h. Coxa magna in the absence of avascular necrosis has been observed in many children after traumatic hip dislocation. The cause is probably reactive hyperemia secondary to extensive soft tissue injury. Coxa magna does not seem to influence clinical outcome.

Proximal Femur Fractures

Proximal femur fractures represent approximately 1% of all pediatric fractures, and are usually the result of high-energy trauma, typically a motor vehicle crash or a fall from a substantial height. In 30% of cases, there is another significant associated injury to the chest, head, or abdomen. The exceptions to this mechanism of injury are children younger than 2 years of age who have been subjected to child abuse and fracture through a pathologic lesion of the femoral neck (e.g., bone cyst). Fortunately, proximal femur fractures are rare. The consequences of this injury are significant, including femoral head avascular necrosis, physeal damage with growth arrest, malunion, and nonunion. Long-term studies indicate an overall 47% avascular necrosis rate for proximal femur fractures, with a 30% malunion rate (266,267). Most patients who develop avascular necrosis need later reconstructive hip surgery, with almost one-half requiring total hip arthroplasty (267).

Anatomy and Classification

In the infant, the proximal femur is composed of a single, large cartilaginous growth plate (268) (Fig. 32-53). The medial portion becomes the epiphyseal center of the femoral head (ossifying around 4 months of age), forming the proximal femoral physis. The lateral portion of the proximal femur forms the greater trochanter physis, and this epiphysis ossifies by 4 years of age. Injury to the proximal femur can affect one or both centers of growth. The proximal femoral physis is responsible for the metaphyseal growth of the femoral neck, and provides 13% of the total length of the femur. The greater trochanter helps shape the proximal femur, and damage to this apophysis, in children younger than 10 to 12 years of age, produces an elongated, valgus femoral neck (269).

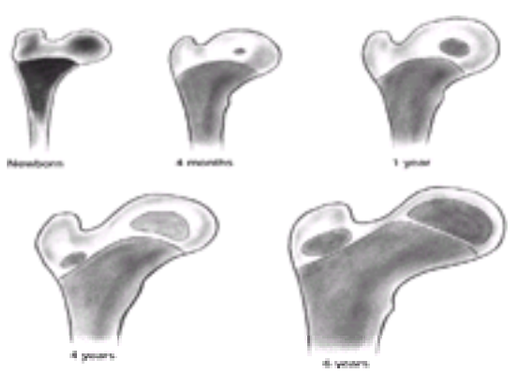

FIGURE 32-53. Development of the growth centers in the proximal femur. (From ref. 268, with permission.)

The vascular supply of the growing child's proximal femur is jeopardized by these fractures, and the extent of damage greatly affects the final outcome. The dominant arterial source for the femoral head is the lateral epiphyseal vessels, which are the terminal extension of the medial femoral circumflex artery. These posterosuperior and posteroinferior vessels are found at the level of the intertrochanteric groove, where they penetrate the capsule and course along the femoral neck toward the head, supported by the retinacular and periosteal tissue in the region (270,271) (Fig. 32-54). The lateral circumflex system can supply a portion of the anterior femoral head until 2 to 3 years of age, after which it primarily supplies the metaphysis. In children older than 14 to 18 months of age, the proximal femoral physeal plate becomes an absolute barrier to the metaphyseal blood supply, preventing direct vascular penetration of the femoral head (270,271). Subsequently, the metaphyseal and epiphyseal vascular networks remain separate in children, until complete physeal closure occurs. This may account in part for the higher incidence of avascular necrosis among children than adults. The vessels of the ligamentum teres do not contribute a significant portion of the blood supply to the femoral head, especially in children younger than 8 years of age.

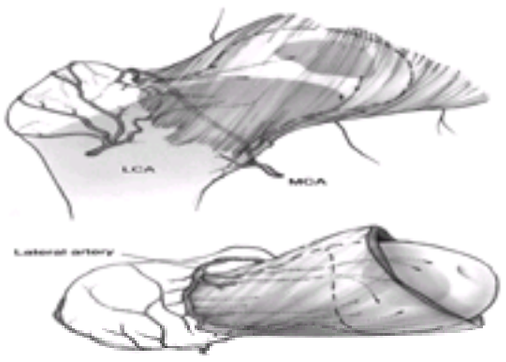

FIGURE 32-54. Arterial supply of the developing proximal femur. **A:** The anterior view demonstrates the lateral circumflex artery (*LCA*), which supplies the metaphysis and greater trochanter. The medial circumflex femoral artery (*MCA*) is the dominant vessel to the femoral head. **B:** The superior view shows the lateral ascending artery, which sends numerous epiphyseal and metaphyseal branches (*arrows*) that supply the greatest volume to the femoral head and neck. These ascending cervical branches traverse the articular capsule as the retinacular arteries. The interval between the greater trochanter and the hip capsule is extremely narrow, and is the area where the lateral ascending cervical artery passes. This may be a site of vascular compression or injury.

It is postulated that displaced fractures may leave the vascular leash intact, but occluded until realignment is established (272). Nondisplaced fractures do not have the same incidence of avascular necrosis as displaced fractures. This fact further supports the concept that the magnitude of initial fragment separation is a major determinant of vascular damage (273). It has also been suggested that prompt decompression of the intracapsular hematoma contributes to the restoration of normal vascular flow, and reduces the incidence of femoral head avascular necrosis (272,274,275).

Delbet's classification (Fig. 32-55) offers a simple yet useful system for the treatment and prognosis of proximal femur fractures (277). Type I fractures are transphyseal separations. Although this physeal separation is occasionally seen as a birth fracture, it is usually the result of high-energy trauma, and it may also be the result of intentionally inflicted injury. Obstetric fracture-separations uniformly have excellent clinical results without avascular necrosis, despite frequent delayed diagnosis and no apparent treatment (276). Children who are younger than 2 years of age, with type I fractures, have a better prognosis than older children. Older children experience an 80% avascular necrosis rate, and the rate of osteonecrosis is much lower in younger children. This difference is mainly the result of the mechanism of injury, which involves less force in younger children. More rapid healing and the reestablishment of transphyseal vascularity are unique to children younger than 18 months of age, and may help to prevent clinical avascular necrosis. Transphyseal fracture is associated with dislocation of the epiphyseal fragment from the acetabulum in 50% of cases involving high-energy trauma (277). This combined injury has an especially poor prognosis, with certain avascular necrosis and frequent proximal femoral growth arrest.

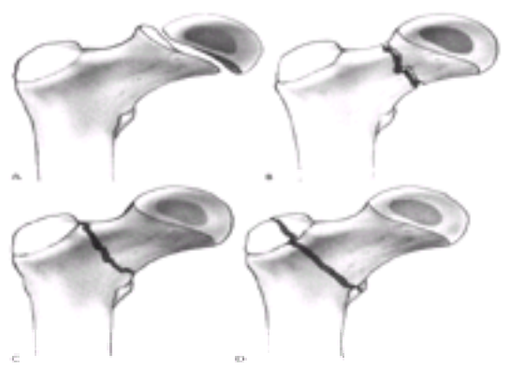

FIGURE 32-55. Delbet's classification for proximal femur fractures. **A:** Type I is a transepiphyseal fracture. **B:** Type II is a transcervical fracture. **C:** Type III is a cervicotrochanteric fracture (basicervical). **D:** Type IV is an intertrochanteric fracture.

Type II fractures occur in the neck of the femur, between the epiphyseal plate and the base of the neck, and are called “transcervical fractures.” They constitute approximately one-half of all fractures of the proximal femur (267). Complications are frequent with type II fractures. The incidence of avascular necrosis and physeal growth arrest approaches 50 to 60%. The nonunion rate is 15%. The proximal femoral physis is responsible for 0.125 inch (0.3 cm) of femoral length per year, and a significant limb-length discrepancy is only a potential problem for the preadolescent.

Type III fractures occur in the cervicotrochanteric or basal neck region of the femoral neck. This is the second most common location of proximal femoral fractures in children. Avascular necrosis occurs in 30% of displaced fractures, and the malunion (i.e., varus) rate is 20%. Because the fracture line is vertically oriented, shear forces can inhibit bone union. Nonunion occurs in 10% of these patients. This problem may be lessened by precise fracture reduction, combined with compression across the fracture site by means of cancellous bone screws (i.e., lag technique) (278,279).

Type IV fractures occur in the intertrochanteric region. This proximal femur fracture has the least risk of damage to the femoral head vascular supply. The incidence of avascular necrosis is between 0 and 10%. Varus deformity is the most likely complication, but this often corrects with growth in younger children (280). The malunion rate is approximately 30%, and malunion is more common in fractures treated with closed methods (267,277).

Treatment

Proximal femur fractures should be treated as urgent cases, preferably within 12 h of injury. Delay in treatment may be necessary because of associated life-threatening injuries. The author recommends joint aspiration for delayed cases, to potentially reduce intracapsular tamponade of femoral head circulation. Initial fragment displacement and delay in fracture reduction may be the most significant factors affecting the incidence of avascular necrosis.

Type I Fractures. Treatment with closed reduction and casting is appropriate for minimally displaced fractures, and for children younger than 2 years of age (281). In children 2 to 12 years of age, stabilization of the reduced fracture may be accomplished with two smooth pins supplemented with spica casting. In older children, the author prefers to place the screws across the physis, when better stability is required. Open reduction is often necessary if the epiphysis is dislocated.

Type II Fractures. Nondisplaced fractures in patients younger than 6 years of age can be treated with spica cast alone with good results (267). Displaced fractures can usually be reduced by closed methods, but a small incision to open the hip capsule is recommended, because it might reduce the risk of avascular necrosis

(274,275). Fixation is achieved by the percutaneous insertion of two or three cannulated bone screws into the metaphyseal portion of the proximal fragment (Fig. 32-56). If the proximal metaphyseal fragment is too small for secure fixation, smooth pins can be placed across the physis, to allow subsequent growth. Stable fixation of the fracture should be given priority over preservation of the proximal femoral physis (279). After the age of 12 years, threaded screws may be placed across the physis for better fixation. Spica casting is used to augment fixation in children, especially when smooth pins have been used. Open reduction is occasionally required if suitable alignment is not obtained by closed means. An anterolateral (Watson-Jones) approach is recommended, with opening of the anterior capsule to avoid damaging the posterior vascular network.

FIGURE 32-56. Femoral neck fracture in an 11-year-old child. **A:** Anteroposterior radiograph demonstrates a type II transcervical fracture. **B:** Stability was achieved with two screws and a spica cast. The capsule was opened for decompression. A smooth pin across the growth plate may be substituted for the second screw. **C** and **D:** Twelve months after injury, there is no evidence of osteonecrosis.

Type III Fractures. Nondisplaced fractures in young children can be treated with a spica cast, if there is anatomic alignment, especially of the medial cortex. Serial radiographs are necessary to monitor possible fracture migration that would lead to varus malalignment. Nondisplaced fractures in the older child or adolescent should be treated with internal fixation to prevent late displacement. Displaced fractures are reduced by gently flexing the hip while traction is applied. The limb is then internally rotated and abducted. Biplanar radiographs are obtained to confirm reduction. Two cannulated bone screws provide compression across the fracture site, and are sufficient fixation if supplemented with a spica cast. Larger-diameter compression hip screws may be used in larger children or for comminuted fractures. Caution is advised when using compression hip screws in children, because dense bone may generate heat necrosis of the femoral neck during reaming. An additional smooth pin is recommended to improve rotational stability (Fig. 32-57). Open reduction through an anterolateral approach is indicated when reduction cannot be achieved by closed means.

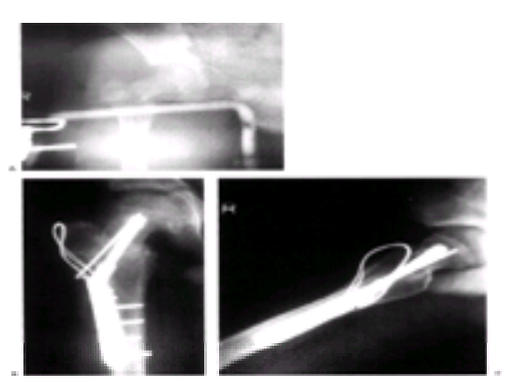

FIGURE 32-57. Comminuted type III femoral neck fracture. **A:** The anteroposterior projection shows a cervicotrochanteric fracture with an associated fracture of the greater trochanter. **B** and **C:** Open reduction with internal fixation was necessary. Adolescent-sized lag screw fixation was supplemented with a smooth pin for rotational stability. The trochanter may be stabilized with Kirschner wires instead of a tension band. Spica cast immobilization is indicated when fixation does not cross the growth plate.

Type IV Fractures. This fracture does not demand the urgency of the types I, II, and III fractures, but in polytrauma, the prompt stabilization of this injury improves general management. Nondisplaced fractures in this region are uncommon, but can be managed by spica cast immobilization and close follow-up in younger children. Displaced fractures in infants and toddlers may be treated with early closed reduction and casting, as long as the neck–shaft angle does not decrease to less than 115 degrees. Displaced fractures in older children can be managed by skeletal traction, followed by casting, but hospitalization is often lengthy. After the age of 6 years, the author prefers open reduction with internal fixation. Interfragmentary screws may provide sufficient stability when combined with cast immobilization, but a pediatric-size hip screw with side plate, or an angled blade plate, is recommended. The physis should be avoided. The femoral neck should be stabilized before reaming, and reaming should be performed slowly to avoid heat necrosis of the femoral neck. Adolescents are treated in the same manner as adults, with stable fixation across the physis, if necessary, using a sliding hip screw or angled blade plate. This avoids the need for a supplemental body cast for older adolescent patients.

Complications

The most frequent complications after fracture of the proximal femur in children are osteonecrosis of the femoral head, malunion, and nonunion. Other complications include infections, premature closure of the proximal femoral growth plate, and chondrolysis. Exact complication rates are difficult to determine, because of changing patterns of treatment. Prompt, accurate reduction, joint decompression, and appropriate internal fixation and immobilization reduce all of these complications (275,278).

Avascular necrosis in children may involve a portion of the femoral head, just the portion of the femoral neck between the fracture and the physis, or the entire femoral neck and physis. Recovery is expected when only the neck is involved, but delayed physeal instability can result in subsequent slipped capital femoral epiphysis. Necrosis of the femoral head occurs in approximately 30% of all hip fractures in children, and often leads to poor results (279). Early recognition is helpful, and can be obtained by MRI or isotope bone scanning. Children with osteonecrosis who are younger than 12 years of age can be treated with containment and/or prolonged non weight bearing. These patients have a possibility of recovering satisfactory function (266,282). The outcome for older children with osteonecrosis of the femoral head is poor. The author recommends treating these adolescents in a manner similar to adults, because the consequences of femoral head collapse are much more severe than the consequences of premature closure of the proximal femoral physis.

Nonunion occurs in 6 to 10% of pediatric fractures of the proximal femur (279). Treatment is recommended as soon as the diagnosis is established. Subtrochanteric valgus osteotomy is preferred, with bone grafting, internal fixation, and application of a spica cast for 3 months (279,283). Supplemental vascularized bone grafting, with a vascular-pedicle graft from the iliac crest, should be considered when there is a large defect in the femoral head or neck (284).

Malunion and coxa vara occur in approximately 20% of reported patients, but this complication has a lower incidence when internal fixation is used (279). Remodeling may occur in younger patients (280). Subtrochanteric osteotomy is recommended for persistent deformity.

FEMORAL SHAFT FRACTURES

Femoral shaft fractures account for 1 to 2% of all childhood fractures (3,5,285). Boys sustain this injury 2.5 times more often than girls. There is a bimodal age distribution, with a peak incidence at 2 to 3 years of age and another peak in adolescence. The cortical thickness of the femur increases rapidly after the age of 5

years, and this may explain the decreasing incidence of femur fracture in late childhood. When obvious causes of fracture, such as motor vehicle crashes are excluded, 65% of femur fractures in infants younger than 1 year old may be attributable to abuse (286). In children 1 to 5 years of age, the incidence of abuse decreases. Children in this toddler age group may sustain fractures with relatively minor trauma, such as falling from a low height or tripping while running. Intentional abuse should always be considered in young children, but there are no distinguishing clinical parameters or fracture patterns to help determine which injuries are inflicted and which are accidental (286). Approximately one-half of femoral shaft fractures caused by bicycle crashes occur in the 4- to 7-year age group. In the adolescent age group, motor vehicle crashes account for the large majority of femur fractures.

As stated by Mercer Rang (106), “It does not require a physician to diagnose a fractured femur.” However, the physician must carefully evaluate the entire patient. Children and adolescents with femur fracture have a 35 to 40% incidence of associated injuries. Some of these injuries are occult, and include femoral neck fracture, hip dislocation, ligamentous instability of the knee, and visceral injuries (287,288). Hemodynamic instability or steadily declining hematocrit does not occur as a result of isolated closed femur fracture. Other sources of blood loss must be evaluated in these patients (288).

Treatment of Femoral Shaft Fractures

Principles of Management

The age of the child and the severity of the trauma are the principal determinants of management. Younger children are less likely to require prolonged traction or surgical stabilization. Higher-energy trauma is more likely to benefit from operative intervention. At one end of the spectrum, there are low-energy injuries in young children, which are managed with closed reduction and immediate spica casting. At the other end of the spectrum, high-velocity injuries in adolescents are managed with early operative stabilization. Occasionally, however, infants with life-threatening trauma require surgical stabilization of femoral fractures to facilitate life support. There are many treatment methods, and fortunately, they all work well when applied properly.

Proximal fractures in all age groups are more difficult to control, but residual deformity is better-tolerated, because of multidirectional hip motion. Deformity is also less obvious proximally, because thick thigh muscles hide residual angulation. Proximal fragments tend to flex, abduct, and externally rotate as a result of the unopposed action of the hip abductor, external rotator, and iliopsoas muscles. The proximal fragment of a midshaft fracture also tends to flex, abduct, and externally rotate, but the deformity is less extreme, because of adductor and hamstring attachments proximal to the fracture. Fractures closer to the knee are easier to control, and produce little proximal fragment angulation, except for supracondylar fractures, which tend to hyperextend as a result of the posterior pull of the gastrocnemius muscle on the short distal fragment. Fractures of the distal femur require more precise alignment, because deformity is more visible closer to the knee, and remodeling in the coronal plane is limited.

The potential for remodeling determines the guidelines for acceptable alignment. Children younger than 1 year of age have considerable remodeling potential, because their femurs will more than double in size before skeletal maturity. Remodeling potential between 2 and 12 years of age is also excellent. Long-term studies have demonstrated that up to 20 degrees of midshaft angulation in any plane can be expected to correct satisfactorily (11,289,290) (Fig. 32-58). Slightly greater deformity may correct in the sagittal plane. Remodeling continues for up to 5 years, and results from fracture site remodeling, as well as reorientation of the growth plate. Rotational remodeling may also occur, but the precise amount is unpredictable (17,291). Clinically significant rotational deformity is uncommon, even when failure of remodeling has been documented (16,292).

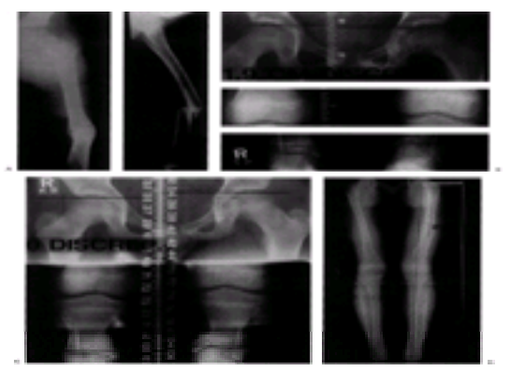

FIGURE 32-58. A: Femoral shaft fracture in a 10-year, 7-month-old boy, healed with 15 degrees of varus and 19 degrees of anterior angulation. **B:** Discrepancy measures 1.9 cm. **C:** Eighteen months later, the discrepancy has resolved, and there is no significant anterior bowing. **D:** The varus deformity has corrected to 8 degrees with reorientation of the growth plate to produce a normal mechanical axis.

Stimulation of growth after femoral fracture occurs routinely in the 3- to 9-year age group (18,20). Unfortunately, most authors reporting the overgrowth phenomenon do not distinguish between “catch-up growth,” which compensates for fracture overriding, and true overgrowth, which results in the fractured femur being longer than normal. Growth stimulation is greater when overriding is greater, and may continue for 5 years after fracture. Average growth stimulation is approximately 1 cm, and ranges from 0.5 to 2.5 cm. Therefore, any femoral fracture that heals in a shortened position should be observed for several years to determine the final outcome (Fig. 32-59). Overgrowth has also been reported after rigid internal fixation, but the risk of overgrowth in this circumstance has not been clearly defined (293,294). Parents are usually more forgiving when the injured femur grows longer than when the femur is allowed to heal in a markedly shortened position.

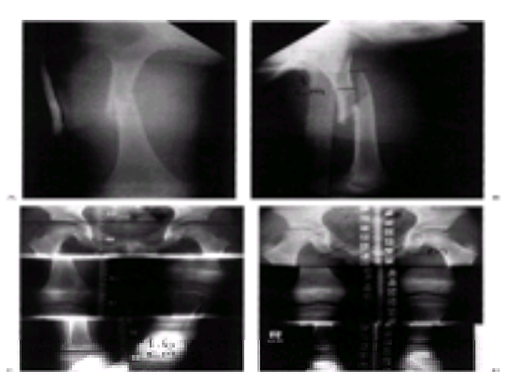

FIGURE 32-59. A 5-year-old boy with a femur fracture. **A** and **B:** Early spica cast application. Alignment is good, but overriding is 3 cm in the initial cast. **C:** Four weeks after cast removal, the leg-length discrepancy measures 4.6 cm. **D:** Two years later, the discrepancy measures 2.6 cm. Equalization of length may continue for 3 more years.

Special circumstances, such as open fractures, subtrochanteric fractures, floating knee, and multiple trauma, are discussed at the end of this section.

Management Guidelines by Age

Age or weight is the first determinant of treatment choices. Age is used here with the understanding that age reflects children of average weight and maturity.

Infants. Infants younger than 1 year of age often sustain femur fractures as a result of birth trauma or abuse. Osteogenesis imperfecta and other metabolic disorders should also be suspected. Thick periosteum and rapid hematoma consolidation usually prevent worrisome shortening or angulation. Healing is rapid, and remodeling potential is great. One can accept 2 to 3 cm of shortening and 30 degrees of angulation in both the coronal and sagittal planes. Immobilization may not be necessary

for infants with stable fractures, such as nondisplaced spiral fractures or impacted metaphyseal fractures. Unstable fractures in infants may be treated with immediate application of a conventional plaster spica cast, a Webril spica cast, or a Pavlik harness (295). Modified Bryant skin traction, which consists of straight-leg traction at an angle of 45 to 60 degrees, can also be used as definitive treatment (296). Immobilization for 2 to 3 weeks is usually sufficient.

Age 1 to 6 Years. Children between the ages of 1 and 6 years are usually treated with early spica cast application. All aspects of spica cast treatment are easier for preschool children than for older children (297). Children in this age group also heal rapidly, so immobilization time is brief. Closed reduction and casting may be performed under sedation in the emergency department, but overnight observation is recommended in most cases. More frequently, the child is placed in skin traction for 1 or 2 days, to allow swelling and pain to subside before applying the cast under general anesthesia. Alignment should be as close to normal as possible, but full functional recovery can be expected in this age group if shortening at the time of union is no greater than 3 cm and angulation is less than 20 degrees in any plane. Fractures in the distal third should be angulated no more than 15 degrees.

Age 6 to 10 Years. Children between the ages of 6 and 10 years may be managed by a wide variety of methods, depending on the severity of the fracture and social circumstances. Low-velocity injuries without severe displacement or shortening may be managed by early spica cast immobilization (298,299). However, children in the 6- to 10-year age group require a longer period of immobilization than younger children. This immobilization and dependency may pose a problem if both parents are working, or when the child lives with a single working parent. Operative stabilization may be beneficial in these and similar social circumstances. High-energy fractures, with severe displacement, comminution, or shortening greater than 3 cm require maintenance of length in addition to alignment. This may be achieved by skeletal traction for 2 to 3 weeks, before cast immobilization, or by incorporating a traction pin in the spica cast (300). Alternatively, surgical stabilization with internal or external fixation achieves the same objectives and allows early mobilization. Guidelines for acceptable alignment in this age group are the same as for the 1- to 6-year age group, although remodeling and recovery may be more prolonged in this older age group.

Age 10 Years to Maturity. Children older than 10 years of age are frequently best managed by operative stabilization with internal or external fixation (138,301). Accurate restoration of length and alignment is desirable in older children, because of limited remodeling potential. Operative stabilization permits early mobilization and return to school and social activities. Various techniques for stabilization are discussed below. It is generally agreed that rigid reamed intramedullary nailing through a piriformis fossa entry point should be avoided, because of the risk of iatrogenic avascular necrosis of the femoral head (302). The risk of this complication is present as long as the proximal femoral physis remains open.

Management Techniques

Techniques for management are selected according to the principles and guidelines discussed in the preceding paragraphs.

Early-fit Spica Cast. The typical candidate for early cast immobilization is a child younger than age 10 years with a low-energy closed femur fracture that has less than 2 cm overriding at rest (298,299,303). The spica cast may be applied in the emergency department under conscious sedation. More commonly, 1 or 2 days of traction are followed by closed reduction and casting under general anesthesia. Four to 5 lb of skin traction is sufficient for most children younger than 7 years old. Skeletal traction is preferred for older, heavier children, or when delay in cast application may exceed 72 h. Several methods of cast application have been reported (298,299,304) **[➥4.12]**. The author's prefcerence is to use the image intensifier to assess alignment and overriding. If the fracture fragments shorten more than 3 cm with gentle longitudinal compression, then traction, pins and plaster, or surgical stabilization may be more appropriate than early spica casting (telescope test) (298). After fracture alignment is obtained, a bent-knee, long-leg cast is applied and molded anteriorly and laterally, to prevent the tendency for later angulation into flexion or varus. The foot may be left free. The popliteal area and all bony prominences should be well padded. The hip is held at 70 to 90 degrees of flexion, 30 to 45 degrees of abduction, and slight external rotation (sitting position), while the remainder of the cast is applied (304) (Fig. 32-60). Slight traction may be applied to the cylinder cast, while the cast is being completed, but this should not be excessive to prevent skin breakdown, calf compartment syndrome, or peroneal nerve palsy (305). After casting, patients are usually discharged within 24 h. Two or three weekly follow-up visits are necessary to monitor alignment (Fig. 32-61). It is often helpful to tape a paper clip or other small metallic object to the outside of the cast before radiographic examination. This can be used to identify the fracture site, if wedging of the cast is required.

FIGURE 32-60. Early-fit spica cast. In children younger than 6 years of age, the usual position of reduction is 70 to 90 degrees of hip flexion, 30 to 45 degrees of abduction, and slight external rotation. Anterior and lateral molding of the cast helps prevent varus deformity and anterior angulation.

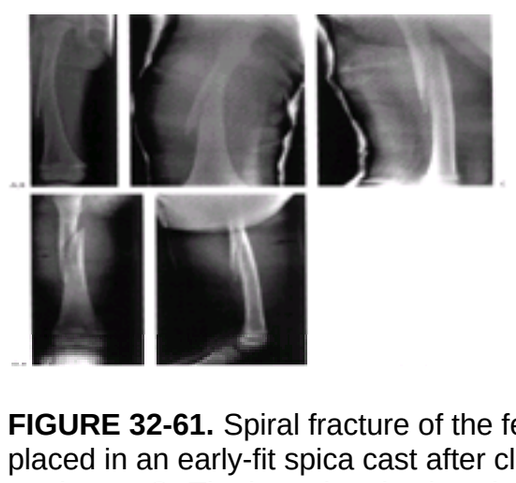

FIGURE 32-61. Spiral fracture of the femoral shaft. **A:** The anteroposterior projection shows some initial varus angulation. This child was 4 years of age, and was placed in an early-fit spica cast after closed reduction. **B:** One week later, the fracture has drifted into varus alignment. The cast is not molded correctly to prevent this tendency. **C:** The lateral projection shows adequate alignment and an acceptable amount of shortening. **D:** Anteroposterior projection after application of a new cast. The lateral aspect of the cast is molded to correct the varus alignment (*arrow*). **E:** The lateral projection shows the flat anterior mold. There is a tendency for these fractures to angulate anteriorly, and it is important to have a flat anterior mold proximal to the fracture (*arrow*).

Skeletal Traction. Skeletal traction is a safe, reliable, and easily instituted form of management for almost any femur fracture in any age group. There are several ways in which balanced traction can be constructed (306,307 and 308). The simplest is the 90–90 position for preadolescents, and for proximal femur fractures. Adolescents are usually placed in balanced traction with a thigh sling and adjustable knee support to allow 45 degrees of knee flexion (Fig. 32-62). The technique entails insertion of a smooth or threaded traction pin in a lateral to medial direction, into the metaphyseal region of the distal femur, under local anesthesia and intravenous sedation. Proximal tibial pins are avoided, although they may not be responsible for some cases of growth arrest (26,309,310). The pin should be approximately 2 cm proximal to the distal femoral growth plate and aligned parallel to the knee joint to reduce the risk of malalignment (311). A traction bow is attached to the pin, and traction is applied. Periodic radiographs are obtained to guide the weight and direction of traction vectors needed to restore alignment. After relative fracture stability has been obtained (17 to 21 days) and callus formation is confirmed on radiographs, a cast is applied for an additional 4 to 8 weeks.

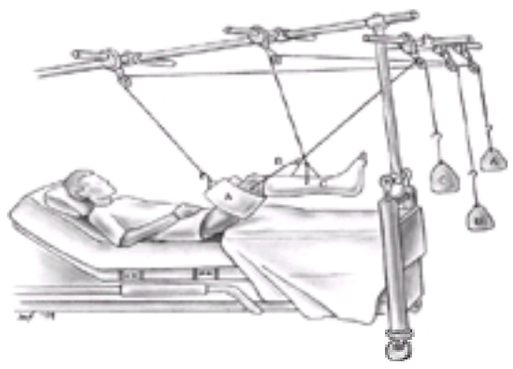

FIGURE 32-62. Balanced traction with a distal femoral pin, a thigh sling, and cast suspension of the leg. This is easily converted to 90–90 traction for more proximal fractures. Weight *A* supports the thigh, weight *B* provides traction, and weight *C* supports the leg in a cast.

Cast Brace and Home Traction. Cast brace management of femoral shaft fractures in children has been reported by several authors (312,313 and 314). A functional cast is applied from groin to toe, using a quadrilateral mold or socket for the proximal thigh. Polypropylene or metal hinges cross the knee, to allow knee movement. Cast application usually follows a period of traction, to allow early healing and increased stability. A distal femoral traction pin may be used in the cast to help control alignment and permit earlier cast brace application (312,313). Cast brace management of pediatric femur fractures requires experience and close follow-up. Potential problems include poor control of proximal fractures and patient discomfort attributable to increased levels of activity in the cast, compared with bed rest activities in a spica cast (314,315).

Skeletal traction at home has been used successfully to decrease length of hospitalization (316,317). These methods require special beds or frames and close attention by trained nursing staff (318). Readers are referred to the original articles for technical details.

External Fixation. The prime indication for external fixation is a fracture with significant comminution or soft tissue damage, as in open fractures or burns (319). Other relative indications include polytrauma, in which multiple fractures and the child's general medical condition favor the rapid and bloodless stabilization that is possible with this technique (Fig. 32-63). It may be considered as a form of ambulatory traction, enabling the child to be partially weight bearing and independent several days after sustaining the injury.

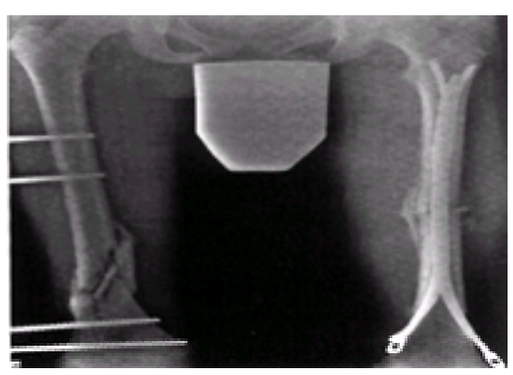

FIGURE 32-63. Bilateral femur fractures. The distal location, proximity to the growth plate, and marked comminution of the right femur fracture are best managed through the application of an external fixator. Although external fixation could have been applied to the contralateral fracture, intramedullary fixation was chosen because of the transverse pattern of the fracture.

The technique involves the sequential insertion of two pins above and below the fracture site and attaching them to a unilateral frame **[➥4.14]**. Preferred pin location should be far enough away from the fracture site that pins avoid the fracture hematoma. However, pins should avoid penetrating the femoral neck calcar or the distal femoral physis. Under fluoroscopic guidance, final alignment can be adjusted as the pins are secured to the body of the fixator (Fig. 32-64).

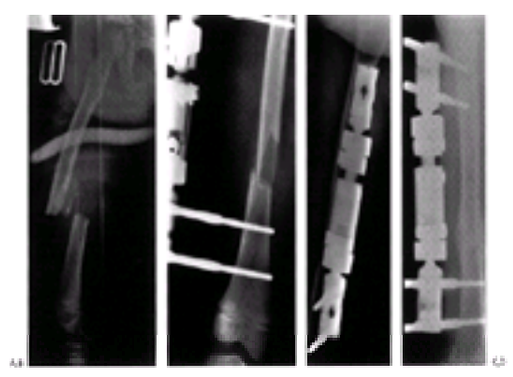

FIGURE 32-64. External fixation for open fracture. **A:** Injury film of grade III open femur fracture in a 7-year-old child. **B:** Alignment and stabilization with external fixation after irrigation of the wound and removal of the devitalized segment of the femoral shaft. **C:** The lateral projection shows anatomic alignment. **D:** Twelve weeks later there is good callus formation and new bone formation in the area of segmental bone loss. The child was ambulatory with full weightbearing without assistance. The fixator was removed at this time.

The most frequent problems encountered with the use of external fixation are pin-track infections, delayed union, and refracture after device removal. Pin-track inflammation and superficial infection requiring oral antibiotics are common (320,321). Rarely, deep infection may require intravenous antibiotics or pin removal. In this instance, fixator removal before complete union can be managed by application of a cast. Delayed union and refracture are more frequent with transverse and short oblique midshaft fractures that are anatomically reduced (322). Delayed healing has also been associated with excessively rigid constructs and lack of dynamization (321,323). Careful attention must be paid to operative technique and postoperative management to reduce the risk of complications.

Intramedullary Fixation. Two devices used for intramedullary fixation are rigid nails and flexible unreamed nails (293,315,324). Rigid nails are ideally suited for adults, because they can be locked proximally and distally, to control shortening and rotation. However, the use of reamed rigid nails introduced through the piriformis fossa has been associated with avascular necrosis of the femoral head in children and adolescents (302). Rigid nails in children younger than 13 years of age have also been associated with a high incidence of growth disturbance with femoral neck deformity, including coxa valga and thinning of the femoral neck (325,326). For these reasons, it is recommended that rigid reamed nails should be reserved for adolescents who are closer to skeletal maturity. The technique of insertion should be modified, so that entry is through the tip of the greater trochanter, carefully avoiding the piriformis fossa.

Flexible or elastic intramedullary nails have the advantage of being applicable to the smaller and younger child, without risking damage to the trochanter, the femoral neck, or the vascular supply to the femoral head. Flexible rods are commonly inserted from the distal femoral metaphysis, retrograde, toward the proximal end of the

femur, avoiding the physes. Two C-shaped nails, one inserted medially and one laterally, usually provide sufficient stability, if three-point intramedullary contact is obtained (327,328) (Fig. 32-65) **[➥4.13]**. Another option is to use a unilateral approach distally, and insert one C-shaped nail and one S-shaped nail. Alternatively, nails may be introduced proximally in the region of the greater trochanter when the fracture is very distal. Additional nails may be added, if needed. A transverse or stable fracture pattern is best for this method of internal fixation. Comminuted, spiral, or segmental fractures are unstable, and are not well suited for this kind of fixation. The addition of a cast can supplement unstable internal fixation, but this partially defeats the advantages of operative stabilization.

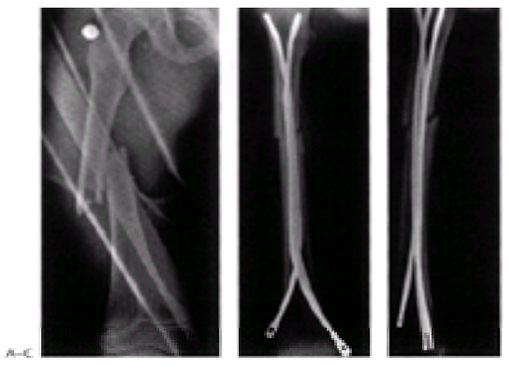

FIGURE 32-65. Flexible intramedullary fixation. **A:** Short, oblique midshaft femur fracture in a skeletally immature child. **B:** Flexible nails placed distal to proximal. The starting point is in the metaphyseal flare of the distal femur, and three-point fixation is obtained by using curved nails. **C:** The lateral projection shows that three nails were used to stack the femoral canal. A cast is unnecessary.

Plate Fixation. Femoral plate fixation has not been widely used for pediatric femur fractures (329). Ziv and Rang (330) reported a high rate of deep infection when this method was used in children with head injury, but Ward et al. (329) reported satisfactory results without any infections in 25 cases. This method of fixation may be suitable for fractures that are located in an area difficult to secure with an intramedullary nail or external fixation (Fig. 32-66). The advantages of plate fixation of femoral fractures are anatomic reduction and early mobilization. Disadvantages include extensive dissection with additional blood loss, possible plate breakage or delayed union, and the risks of plate removal, in some cases.

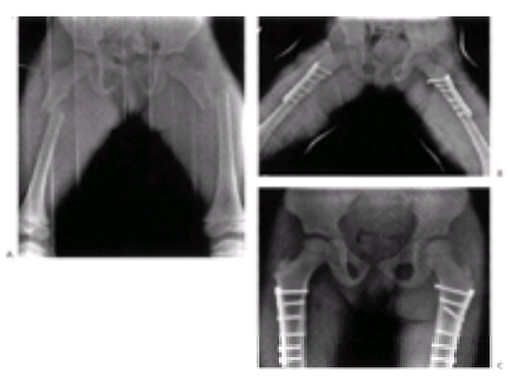

FIGURE 32-66. Compression plates and screws. **A:** Bilateral subtrochanteric femur fractures in a 4-year-old child with a closed head injury. **B:** Open reduction and application of 3.5-mm compression plates and cortical screws. Supplemental stabilization was provided with a spica cast, which was removed 4 weeks later. **C:** The anteroposterior view of the pelvis 3 months after injury shows complete healing.

Complex Femoral Fractures

Femur fracture management may be altered in complex circumstances, as seen in children with head injuries, multiple trauma, open fractures, floating knee, or high subtrochanteric fractures. Children with head injuries or multiple trauma benefit from more aggressive fracture stabilization so that they can be transported and mobilized (52). The general management of open fractures is discussed earlier in this chapter. External fixation is recommended for open fractures with severe soft tissue injury, but grade I and many grade II open femur fractures can be managed in standard fashion after appropriate wound care.

Floating Knee

Simultaneous ipsilateral fracture of the femur and tibia has been termed the “floating knee” (331,332). This injury pattern has been classified by Letts and colleagues (332) (Fig. 32-67). The fracture usually is the result of high-energy trauma, such as a pedestrian–motor vehicle collision. Knee ligament damage occurs in approximately 10% of these patients, and is better assessed after fractures are stabilized. The juxtaarticular fracture pattern, and fractures in children older than 10 years of age, have worse prognoses for early and late problems (331). Operative stabilization of at least one bone is recommended in most cases, especially in older children (331,332).

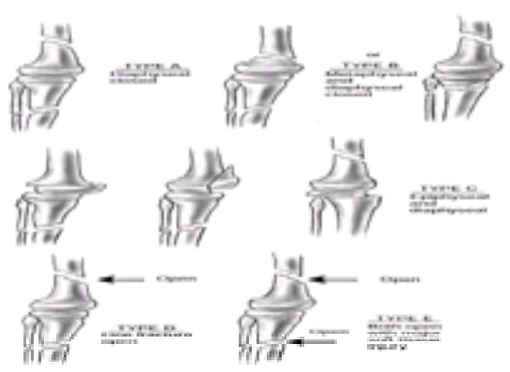

FIGURE 32-67. Classification of the “floating knee” in children. (From ref. 332, with permission.)

Subtrochanteric Fractures

Subtrochanteric fractures usually result from high-energy trauma and are difficult to treat closed, because of flexion, abduction, and external rotation of the proximal fragment. Union in the anatomic position is rarely achieved with closed treatment, but remodeling potential is great in this anatomic region. Fractures that are closer to the greater trochanter, and fractures in children older than 8 years, have poorer prognoses for malunion (333,334). Early spica cast application in the “sitting” position may suffice in very young children, but traction in the 90–90 position is frequently necessary until callus formation has occurred (334,335). Alternatively, children older than 8 years of age, or younger children with very unstable fractures, may be considered for surgical stabilization.

Complications of Femur Fractures

Malunion with or without limb-length discrepancy is the most frequent complication of pediatric femur fractures. Compartment syndrome, neurovascular injuries, nonunion, and infections may also occur. These latter complications are more frequent after open injuries, and are discussed elsewhere. Management principles are similar to those in adults. Malunion and limb-length discrepancy may resolve with remodeling, as long as the deformities are within management guidelines. Osteotomy is performed to correct persistent deformity in older children, or when remodeling is incomplete in younger children after a period of observation. Persistent limb-length discrepancy is rarely severe, and is usually managed by epiphysiodesis of the contralateral extremity at an appropriate age.

FRACTURES AND DISLOCATIONS ABOUT THE KNEE

Significant trauma to the knee in children usually results in a fracture, instead of a ligamentous injury. The attachments of the joint capsule and the surrounding ligaments expose the pediatric knee to certain characteristic avulsions and physeal injuries. However, isolated ligamentous damage can occur, especially in the maturing adolescent (336). Soft tissue injuries of the juvenile knee and acute patellar dislocations are discussed in Chapter 31. The child presenting with an acute hemarthrosis of the knee may have a soft tissue injury, a fracture, or both. Physical examination may determine the site of the injury; the clinician should note the precise location of tenderness, and test for ligamentous integrity. Plain radiographs can usually confirm the diagnosis of a fracture. Stress views are sometimes useful, if there is any remaining question about the nature of the injury. The MRI has been used to provide additional information, but this modality is much less accurate in children than in adults (337,338). Arthroscopic evaluation is warranted when the cause of hemarthrosis remains obscure. Radiographically silent osteochondral fractures have been noted in 7 to 67% of juvenile patients undergoing arthroscopy for acute hemarthrosis (339,340).

Distal Femoral Physeal Separations

Distal femoral physeal fractures constitute approximately 5% of all long-bone physeal fractures and 1 to 2% of all fractures (29,176). The distal femoral growth plate has a complex geometric configuration, and is securely anchored to the metaphysis. Any fracture, whether displaced or not, represents considerable trauma. The diagnosis is easily made, except in cases of nondisplaced fractures. These injuries may mimic ligamentous instability on clinical examination. However, careful inspection will reveal that the area of tenderness and swelling is proximal to the joint line. Stress radiographs, with the patient sedated, can be used to reveal the fracture. When the epiphysis is displaced, the direction of displacement reflects the direction of the injuring force. Hyperextension of the knee produces anterior epiphyseal displacement, and valgus or varus stress produces medial or lateral displacement. Direct impact in the knee-flexed position causes posterior displacement of the femoral epiphysis.

The Salter-Harris type III fracture of the medial femoral condyle usually results from valgus force on the knee. The medial collateral ligament and joint capsule transmit this force to the condyle producing the fracture. Spontaneous reduction is frequent, and may obscure the diagnosis. The Salter-Harris type III injury to the medial condyle may appear innocuous, but is often associated with cruciate ligament damage and intraarticular osteochondral fragments (341).

Salter-Harris type I and II fractures account for the majority of distal femoral epiphyseal separations, but there is poor correlation between the type of fracture and the likelihood of growth arrest (342,343). It has been observed that growth arrest is more closely related to the severity of displacement (343,344). Fractures in the 2- to 11-year age group are frequently caused by severe trauma, and have the poorest prognosis for physeal arrest (80%) (344). Fractures in the adolescent age group are often the result of less-severe trauma, but still, they have a 50% risk of growth disturbance. Close follow-up is recommended to detect partial or complete growth arrest during the early stages of deformity development. In contrast to these fractures in the juvenile and adolescent age groups, distal femoral separations in infants and toddlers rarely lead to growth problems, and have excellent remodeling potential.

Treatment

Nondisplaced fractures can be immobilized in a long-leg or cylinder cast for 3 to 4 weeks, until the fracture site is nontender. Close follow-up is warranted to detect any tendency toward displacement. Displaced distal femoral physeal separations are probably best treated with prompt, gentle, closed reduction under general anesthesia (343). After reduction, fixation is recommended, using crossed percutaneous pins to avoid redisplacement while in a cast. Pins may be placed from proximal to distal, to avoid traversing the synovium of the knee joint (Fig. 32-68). If the metaphyseal portion of the Salter-Harris type II metaphyseal fragment is large enough, fixation can be accomplished with percutaneous insertion of one or two cancellous bone screws through this fragment (Fig. 32-69).

FIGURE 32-68. Distal femoral physeal fracture. **A:** An anteroposterior radiograph shows a widening of the distal femoral physis. **B:** The lateral view shows an anteriorly displaced Salter-Harris type II fracture. **C:** Intraoperative anteroposterior view after closed reduction and crossed Kirschner wire fixation. The pins are placed from a proximal to a distal direction. Smooth pins are used when crossing the physis. **D:** The lateral projection shows the pins in the midaxis of the femur.

FIGURE 32-69. Distal femoral physeal fracture. **A:** An anteroposterior radiograph shows a displaced Salter-Harris type II fracture of the distal femur. **B:** Incomplete closed reduction and casting. **C:** The intraoperative view shows cancellous compression screw placement over a percutaneous Kirschner wire after closed reduction. The Thurston-Holland fragment was large enough for placement of the threaded portion of the screw into it. When a single screw is used, fixation should be supplemented with a cylinder cast. **D:** At 6 weeks, reduction and fracture healing are maintained. **E:** Lateral projection.

Open reduction is indicated when periosteum or muscle blocks closed reduction, for Salter-Harris type III and IV injuries, for open injuries, and for fractures associated with neurovascular disruption. Salter-Harris type III and IV injuries require precise alignment to restore the articular surface and reduce the risk of growth arrest. At least two cannulated 6.5-mm-diameter screws are recommended to ensure stability (Fig. 32-70).

FIGURE 32-70. Distal femoral physeal fracture. **A:** Salter-Harris type IV fracture involving the lateral condyle of the distal femur. Although the injury film does not show significant displacement, fragment stabilization is recommended to maintain this alignment. **B:** Anteroposterior projection after placement of cancellous bone screws. **C:** Lateral projection.

After reduction and fixation, the patient is immobilized in a long-leg or cylinder cast for 3 to 6 weeks. Pins can be removed in the clinic, and gentle range of motion is initiated. Progressive weightbearing and strengthening are permitted as tolerated. Follow-up consists of repeat evaluation for ligamentous laxity and observation for early growth disturbances.

Complications

Growth arrest is frequent after distal femoral epiphyseal separations. Early diagnosis is helpful, and can be determined by plain radiography or MRI 3 to 6 months after injury (39,40). Management of physeal arrest has been discussed in a previous section of this chapter.

Tibial Spine Fracture

The terms “tibial eminence fracture” and “tibial spine fracture” have been used interchangeably to describe avulsion of the tibial attachment of the anterior cruciate ligament. The tibial eminence consists of two bony spines, and is located between the medial and lateral plateaus of the tibia. The anterior cruciate ligament attaches to the medial spine, but nothing attaches to the apex of the lateral spine. Between these spines are the attachments of the menisci. Avulsion of the tibial eminence in children is usually caused by a fall from a bicycle, a sporting injury, or some other indirect trauma to the knee. The typical age range for this injury is 6 to 15 years.

Myers and McKeever (345) classified this avulsion fracture by degree of displacement:

type I: minimally displaced, with only slight elevation of the anterior margin;
type II: hinged posteriorly, producing a beak-like appearance on the lateral radiograph;
type III: completely displaced and elevated from its bed.

With displacement, the meniscus may become trapped underneath the fragment and interfere with reduction. Long-term studies have reported some residual knee laxity, regardless of anatomic reduction with internal fixation (346,347). This would suggest that the fibers of the anterior cruciate ligament are stretched before bone failure. After closed treatment of type I and II fractures, any residual instability is mild, with a firm end point, and has not led to functional deficits or subjective feelings of knee instability. A more troublesome problem has been failure to regain full knee extension. Wiley and Baxter (347) carefully evaluated knee range of motion, and determined that 60% of all patients lost more than 10 degrees of extension. This loss of motion was noted in all type III injuries that were treated closed, and in approximately one-half of the type III injuries treated with open reduction. Long-term functional results are generally excellent, except for those for displaced type III fractures (346,347 and 348).

Treatment

Type I injuries do not require reduction, and can be immobilized in a cylinder cast for 4 to 6 weeks. This is followed by range of motion exercises, strengthening, and gradual resumption of activities.

Type II fractures may be difficult to distinguish from completely displaced fractures. Aspiration of the joint and injection of local anesthetic facilitate reduction. Reduction is then attempted by fully extending the knee and applying a cylinder cast (Fig. 32-71). If radiographs after reduction are inconclusive or demonstrate inadequate reduction, MRI or arthroscopic evaluation may be necessary to determine whether the posterior attachment is disrupted, and whether there is meniscal entrapment. The preferred position of immobilization after reduction is controversial. Some authors recommend immobilization in extension (349), whereas others recommend immobilization with 20 to 30 degrees of knee flexion to relieve tension on the anterior cruciate ligament (349). The authors recommend immobilization in extension, because loss of extension after union is more problematic than joint instability when adequate reduction has been achieved. Hyperextension should be avoided, because this position becomes uncomfortable.

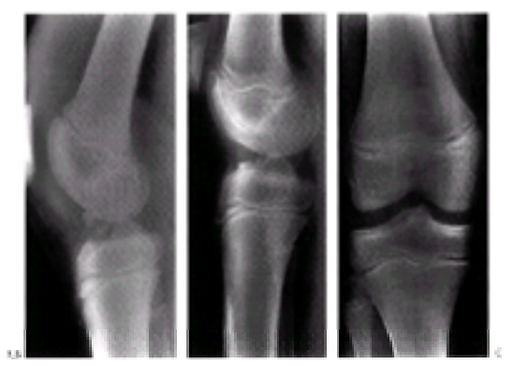

FIGURE 32-71. Tibial eminence fracture. **A:** Lateral projection of a type II avulsion fracture. This fracture is probably in transition between type II and type III displacement. However, when the knee was placed in full extension, the fragments were reduced to an acceptable degree. Treatment was in a cylinder cast. **B:** Six weeks after injury reduction has been maintained, and there is evidence of healing. **C:** The anteroposterior projection shows no significant elevation of the tibial spine.

Type III fractures are best treated with open or arthroscopic reduction and stable internal fixation (350). This can be achieved by using a small intraepiphyseal cancellous screw. Alternatively, sutures or wires can be passed that enter the osteochondral fragment and exit through the periphery of the epiphysis (351). Consideration should be given to countersinking the fragment to achieve retention of the anterior cruciate ligament. When fixation is secure, early mobilization can be initiated to avoid loss of motion.

Complications

Some loss of motion and ligamentous instability are common after tibial eminence fracture, even when management has been appropriate. These problems are usually mild and rarely interfere with function. Occasionally, patients will present late with malunion that limits knee extension. This can be treated with anterior

closing-wedge osteotomy with internal fixation (349).

Tibial Tubercle Fracture

The tibial tubercle is the anterior and distal extension of the proximal tibial epiphysis. It develops a secondary ossification center and serves as the insertion site of the patellar tendon. Fracture of the tibial tubercle is an injury of the adolescent knee joint, usually occurring in boys between 13 and 16 years of age. During this period of growth, the proximal tibial physis is usually in the process of physiologic closure. Tibial growth plate closure begins centrally, proceeds centrifugally, and finally proceeds distally to include the tubercle. The mechanism of injury for avulsion of the tubercle is forceful quadriceps contraction against resistance (e.g., jumping). There may be a preceding history of Osgood-Schlatter disease (352,353).

Examination reveals swelling, deformity, and tenderness. The ability to perform a straight-leg raise should also be tested. The diagnosis is confirmed on a lateral radiograph by identifying the displaced fragment and a high-riding patella. A classification was proposed by Watson-Jones, and modified by Ogden and colleagues (353) (Fig. 32-72). Type I fracture is through the distal ossification center; type II is at the junction of the tubercle and the tibial ossification centers; and type III involves the articular surface of the tibia.

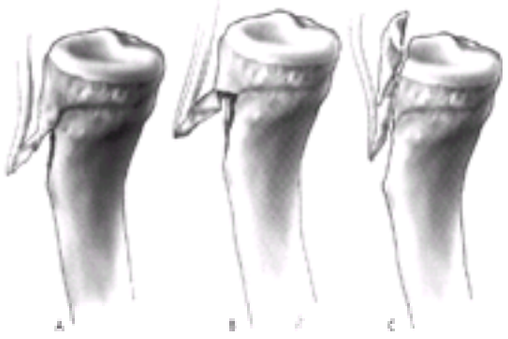

FIGURE 32-72. Classification of tibial tuberosity fractures. **A:** Type I fracture through the secondary ossification center. **B:** Type II fracture located at the junction of the primary and secondary ossification centers. Sometimes this fragment is in two pieces. **C:** Type III fracture, which is an intraarticular fracture (Salter-Harris type III). This can also be a two-part fracture.

Treatment

Treatment for all but minimally displaced type I fractures consists of anatomic reduction and internal fixation. This can be accomplished by open reduction and insertion of cancellous bone screws (Fig. 32-73). In younger children with significant growth remaining, smooth pins, placed obliquely across the fracture, can be substituted for screws. This can be supplemented with a tension band suture or wire to the tibial metaphysis, if pin fixation is insecure. Knee immobilization is used for 3 to 4 weeks, before beginning active range of motion.

FIGURE 32-73. Tibial tubercle fracture. **A:** The lateral radiograph shows a type III tibial tubercle avulsion. This is a Salter-Harris type III fracture. Open reduction and internal fixation are indicated. **B:** The postoperative lateral radiograph demonstrates reduction of the fracture with intraepiphyseal cancellous screw placement. This type of fixation was chosen, because the patient was a 13-year-old boy who had significant growth remaining. In the older adolescent with less than 2 years of growth remaining, the screws can cross the physis.

Complications

Avulsion fractures of the tibial tubercle have few associated long-term problems. However, several authors have reported acute compartment syndrome of the leg after this injury (354). This may be attributable to the fact that the tubercle is in close proximity to the anterior compartment fascia, and bleeding from the fracture enters this compartment. Pape and colleagues (354) observed that compartment syndrome may be more frequent in patients who are managed closed or by percutaneous methods. Bolesta and Fitch (352) recognized this potential complication, and performed prophylactic fasciotomy on selected patients.

Posttraumatic genu recurvatum can occur in younger patients after tibial tubercle avulsion fracture. This is caused by premature arrest of the anterior aspect of the growth plate. Patients with more than 1 year of growth remaining should be observed for development of this deformity. Bilateral proximal tibial epiphysiodesis is generally the preferred procedure when deformity is mild. Greater degrees of deformity may necessitate proximal tibial flexion osteotomy to restore normal alignment.

Patellar Fractures

Patellar fractures are much less common in children than in adults. This may be attributable to the fact that the patella is largely cartilaginous until adolescence. The child's patella is also more mobile than the adult's, and is subjected to less tensile force during quadriceps contraction. In adolescents, the patellar anatomy approaches that of the adult, and is more likely to be damaged by direct trauma. Osteochondral fractures have also been reported in 40% of children and adolescents sustaining acute patellar dislocations (355). The patellar sleeve fracture is a type of patellar fracture that is unique to younger children. The age range for patellar sleeve fracture is 8 to 12 years. This injury consists of an avulsion of the cartilaginous portion of the distal patella from the ossification center (356,357) (Fig. 32-74).

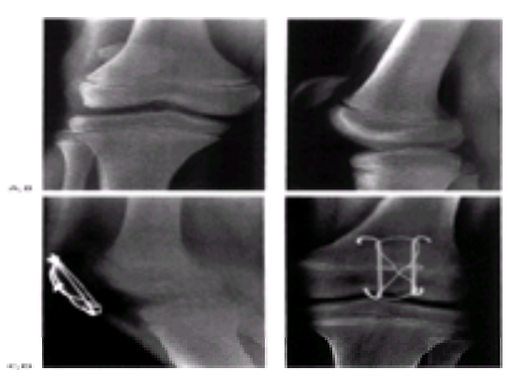

FIGURE 32-74. Patella injury. **A:** An anteroposterior radiograph of the knee suggests proximal displacement of the patella. **B:** The lateral view demonstrates patella alta, and a faint calcification is seen 1 cm distal to the inferior pole of the patella. These findings are consistent with patellar sleeve fracture. **C:** Lateral view after open reduction and fixation with AO tension band technique. The patella has returned to its normal position. **D:** The anteroposterior projection shows the configuration of the internal fixation devices.

The diagnosis of patellar fracture may be more difficult in children than in adults. Palpation may reveal a defect, but can be difficult to perform, because of pain and tense hemarthrosis. Lack of function and abnormal movement of the extensor mechanism on physical examination are generally useful indicators of patellar injury. Radiographs can be difficult to interpret. Bipartite patella (i.e., secondary ossification center) may be painful, and can be confused with nondisplaced fracture. A fractured patella may be difficult to diagnose accurately, as a result of incomplete ossification. This is particularly true for patellar sleeve fractures, in which the lateral radiographs may demonstrate only patella alta and a very small fragment of bone attached to the distal unossified cartilage. The MRI can be diagnostic when there is doubt regarding the nature of the injury.

Treatment

Treatment of patellar fractures in children is generally the same as for adults (358). The patella is a sesamoid bone that grows by apposition, so growth disturbances are uncommon. Nondisplaced fractures with intact extensor mechanisms may be treated by immobilization in extension for 4 to 6 weeks. Open reduction with internal fixation is indicated for displaced fractures. Stability may be achieved by means of the AO tension band technique or by cerclage wiring.

TIBIAL FRACTURES

Tibial fractures are the most common lower extremity fracture in children, and make up 10 to 15% of all pediatric fractures (5,176). Many of these are toddler fractures or low-energy nondisplaced fractures occurring from minor falls, twisting injuries, or sports. Motor vehicle crashes and high-energy injuries are more common in older children, resulting in displaced tibia and fibula fractures. Soft tissue injury is more severe in displaced fractures, and adds to the complexity of fracture management. The location of the fracture, its severity, and the child's age influence treatment.

Proximal Tibial Epiphyseal Fracture

Separation of the proximal tibial epiphysis is uncommon (Fig. 32-75). This is probably attributable to the supporting ligamentous structures and the shape of the physis. The fibula buttresses the tibia laterally, and the physis slopes downward anteriorly in the region of the tibial tubercle. The medial collateral ligament inserts on the metaphysis, in addition to the epiphysis. Many of the musculotendinous units that span the knee do not insert on the proximal tibial epiphysis. Thus, varus and valgus stresses are not propagated to the tibial epiphysis.

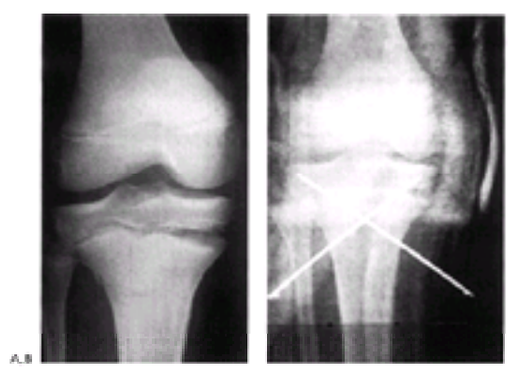

FIGURE 32-75. A: Salter-Harris type II fracture of the proximal tibia. Compartment syndrome accompanied this injury. **B:** Fasciotomies were performed for compartment syndrome, and the fracture was treated with closed reduction and percutaneous pin fixation.

The mechanism of injury to this epiphysis is usually direct force to the knee, as in a fall from a height, lawn mower injuries, or motor vehicle crashes. Hyperextension injuries from sports may also injure this region. Lawn mower injuries are seen in younger children, but the majority of patients are older than 12 years at the time of injury (359,360). Most proximal epiphyseal injuries are Salter-Harris type II fractures, demonstrating posterolateral or posteromedial displacement. These are followed in frequency by type I separations, which tend to displace posteriorly. This threatens the popliteal artery, because the artery is tethered to the posterior aspect of the tibia by its branches. The posterior branch passes under the arch of the fibers of the soleus muscle, whereas the anterior branch passes into the anterior compartment just distal to the growth plate (Fig. 32-76).

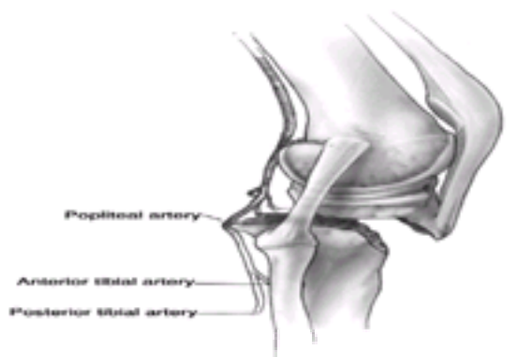

FIGURE 32-76. Proximal epiphyseal fracture. The distal tibial segment is displaced posteriorly, producing vascular occlusion of the popliteal artery.

Treatment

Management consists of closed reduction in most cases, but percutaneous pinning or cannulated screw fixation is performed if the fracture is unstable, if vascular repair is necessary, or if early motion is required. Precise reduction is recommended, because future growth may be impaired or insufficient to spontaneously correct residual deformity. Displaced type III and IV fractures are intraarticular injuries, and require precise reduction and internal fixation to preserve joint function and reduce the risk of premature physeal closure. These fractures should be followed closely for growth arrest, which occurs in 25 to 33% of patients, regardless of the type of physeal separation (359,360).

Complications

Vascular compromise requires prompt reduction and stable fixation. After reduction, blood pressures by Doppler pulse are compared with those in the opposite limb. Any significant difference is an indication for arteriography. It is recommended that this be performed in the operating room to avoid delay in vascular exploration and

repair. If vascular repair is necessary or if ischemia has exceeded 4 h, prophylactic fasciotomy is recommended (68). This prevents reperfusion compartment syndrome from developing.

Proximal Tibial Metaphyseal Fracture (Cozen Fracture)

Metaphyseal fractures of the proximal tibia occur most commonly in children between the ages of 2 and 8 years. The usual mechanism of injury is a valgus force applied to the extended knee, producing an incomplete fracture of the tibia, with or without fracture of the fibula. The lateral cortex of the tibia may be buckled or impacted, or may undergo plastic deformation. Pronounced displacement is uncommon, except in instances of high-energy trauma. This innocuous-appearing fracture is often in more valgus than one readily appreciates from the initial radiographs. A comparison radiograph of the opposite tibia is helpful to determine the true deformity of the injured leg.

Treatment

Management consists of closed reduction with the knee in extension. This position allows effective three-point cast molding to generate a varus force. The extension position also facilitates subsequent radiographic interpretation. After reduction, the author recommends that an angle formed by a line through the physis and a line down the tibial shaft should be within 5 degrees of the opposite intact tibia. The cast is maintained until healing is complete, usually 6 weeks. Displaced proximal tibial fractures in adolescents sometimes require operative stabilization to control alignment and expedite mobilization. During the 48 h after closed reduction and casting, the extremity should be closely monitored for signs of excessive compartment swelling.

Complications

Progressive valgus deformity of the leg frequently develops in children younger than 10 years of age who sustain this fracture (361,362 and 363) (Fig. 32-77). Close review of the initial postreduction radiographs occasionally reveals that an imprecise reduction was responsible for at least part of the deformity. However, nondisplaced and anatomically aligned fractures can also develop progressive valgus deformity (362). Angulation increase begins several weeks after fracture and usually ceases by 12 months after fracture. The cause of this problem remains somewhat obscure, but it probably results from selective overgrowth of the medial tibial physis, in response to asymmetric vascular stimulation (361,362). Overgrowth of the tibia, with tethering by the intact fibula, has also been postulated as a possible cause, but progressive valgus deformity can develop, even when the fibula is fractured. Treatment of this deformity consists of observation, because it usually resolves spontaneously with the development of a slightly S-shaped tibia (364,365). Tibial osteotomy and hemiepiphyseal stapling have been reported for correction of more severe deformities (358,366). However, McCarthy et al. (364) observed similar results at follow-up, when surgically treated patients were compared with untreated patients. In the authors' opinion, osteotomy should be avoided, because of the high risk of recurrent deformity. Although rarely indicated, hemiepiphyseal stapling in children younger than 10 years can be performed with resumption of normal growth after staple removal.

FIGURE 32-77. A: Radiograph of a proximal metaphyseal fracture of the tibia with valgus deformity. Closed reduction was performed. **B:** Radiographic appearance at the time of union demonstrates satisfactory alignment. **C:** Radiographs 8 months later demonstrate valgus alignment attributable to asymmetrical growth stimulation.

Tibial Diaphysis

Fractures of the shaft of the tibia and/or fibula account for approximately 4 to 5% of all pediatric fractures (5,176). These fractures generally fall into three categories: (i) nondisplaced, (ii) oblique or spiral, and (iii) transverse and comminuted displaced fractures (367,368). In infants and young children, the tibial shaft is relatively porous, and is more likely to bend or buckle than to comminute. The surrounding periosteum is strong and imparts stability to the fracture site, limiting displacement and shortening. In contrast, the adolescent tibial shaft is composed of more dense cortical bone and a thinner, weaker periosteum. Fractures in the adolescent age group are more often the result of high-energy trauma, and are associated with greater fracture displacement, comminution, and slower healing rates than in younger children.

The remodeling potential of the tibia is limited. Rotational deformity does not remodel, although external rotation deformity is better tolerated than internal rotation deformity (368). Final alignment should be within 10 degrees of angulation in any direction (367,368,369 and 370). Infants and young children can correct approximately 50% of residual angulation with growth. In children older than 10 years of age, only 25% of the axial malalignment improves. Hansen and Grieff (367) reported only 13.5% correction of angular deformity with subsequent growth, but Shannak (368) demonstrated that one-third of children with more than 10 degrees of angulation at healing had persistence of the malunion at final follow-up assessment. In general, varus malalignment seems to remodel more completely than valgus deformity.

The ability to compensate for shortening decreases with age. Children younger than 5 years of age show the greatest capacity. Unlike the fractured femur, this increase in tibial growth rate is less dramatic, and growth acceleration greater than 5 to 7 mm is unusual (371). In a review of 142 tibial fractures, Shannak (368) reported an average of only 4.35 mm of growth acceleration. Comminuted and long spiral fractures displayed the greatest amount of overgrowth, including those that were treated with anatomic reduction and internal or external fixation. Overgrowth is not routinely seen in girls older than 8 years or boys older than 10 years of age.

Nondisplaced Fractures of the Tibial Shaft

Nondisplaced tibial fractures are more common in younger children. So-called “toddler's fracture” is seen in the 1- to 4-year age group. A mildly traumatic event may have been observed, but often the child presents with an acute limp of unknown cause. Approximately 20% of these acutely limping toddlers have sustained occult fractures, and one-half of these fractures are in the tibia (372). Low-energy torsional forces, as when the child twists a leg, usually cause these fractures. The child limps or refuses to walk on the affected lower limb. Examination may reveal a point of tenderness or subtle swelling in the distal third of the leg, but often the examination is unremarkable. Radiographs may show a fracture, but frequently the fracture line is not initially evident. Toddler's fracture is differentiated from pathology of the hip and femur by the child's ability to crawl and a normal range of motion of the hip joint. Infectious processes need to be considered in the differential diagnosis, but these can usually be diagnosed by the presence of fever and laboratory studies demonstrating increased sedimentation rate, C-reactive protein, and leukocyte count. A triphase bone scan may help establish the diagnosis when pain and limp are severe and the workup remains equivocal (373). Treatment is initiated when fracture is suspected, and the diagnosis is usually confirmed 10 to 14 days later, when periosteal new bone has formed.

Treatment for nondisplaced fractures of the tibial shaft in all age groups consists of immobilization in a cast until union has occurred, usually 3 to 4 weeks for toddlers and 6 to 10 weeks for older children.

Oblique or Spiral Fractures of the Tibial Shaft

Isolated fracture of the tibia, with an intact fibula, is the most common tibial shaft fracture in the pediatric age group (370,374). A rotational or twisting force, resulting in a spiral or oblique fracture at the junction of the middle and distal thirds of the tibial shaft (Fig. 32-78), usually causes these fractures. The most common mechanism of injury is indirect trauma, such as sports accidents or falls. The intact fibula imparts stability, but may interfere with reduction of displaced fractures and

contribute to the development of varus angulation.

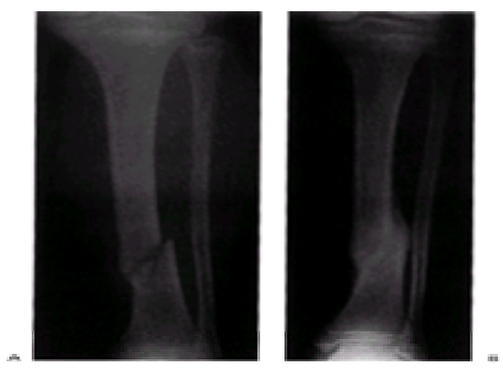

FIGURE 32-78. A: Spiral or oblique fracture of the tibia, without fibula fracture, is common in children. **B:** Radiograph at the time of union demonstrates satisfactory alignment with acceptable varus deformity.

Treatment consists of reduction and immobilization in an above-knee cast, with the knee flexed to 30 degrees and the ankle in 15 degrees of plantar flexion, to minimize varus muscle forces (370,374). Unstable displaced fractures may require fibular osteotomy and surgical stabilization (Fig. 32-79). Angulation greater than 10 degrees in any direction should be corrected, except in very young children, in whom 15 degrees may be accepted (367,368,369 and 370).

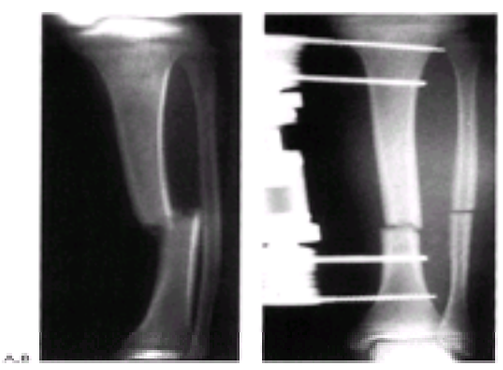

FIGURE 32-79. A: Transverse fracture of the tibia, with an intact fibula. **B:** Osteotomy of the fibula was necessary to obtain reduction. After this, the fracture was very unstable and required fixation. Flexible intramedullary nails, introduced through the metaphysis, also would have provided stabilization.

Transverse and Comminuted Displaced Fractures of the Tibia and Fibula

Complete fractures of the tibia and fibula are more common in older children. These fractures result from high-energy trauma, and are frequently unstable. Open fractures of the tibia are not uncommon, and account for 4% of all tibial fractures in children and adolescents (375). Soft tissue damage and periosteal stripping predispose to more severe complications, such as compartment syndrome, delayed union, and infection. Inherent fracture stability after reduction is variable.

Treatment of closed injuries is similar to that for oblique and spiral fractures. Closed reduction may be easier to achieve than when the fibula is fractured, but there is a tendency for the fracture to drift into valgus and procurvatum, because of the greater muscle bulk posterolaterally in the leg. An above-knee cast is used for 4 to 8 weeks, until initial stability has been achieved. Immobilization may then be continued with a patella-tendon–bearing cast, until healing is complete. Final axial alignment should be within 10 degrees in any direction.

Unstable fractures may require surgical stabilization to maintain alignment or facilitate rehabilitation. The techniques for surgical stabilization are similar to the techniques discussed with regard to femur fractures, and include the use of pins and plaster, flexible intramedullary nails introduced through the metaphysis, plates and screws, and external fixation. Additional indications for surgical stabilization of tibial fractures include associated head injuries, multiple trauma, floating knee, vascular injury, and open fractures requiring wound access.

Open Fractures of the Tibia

The general management of open fractures has been discussed earlier in this chapter. Open fractures of the tibia in children are the result of high-energy trauma, and are associated with other injuries in 25 to 50% of cases (59,375).

Treatment. Initial management consists of administration of intravenous antibiotics and tetanus prophylaxis, followed by aggressive wound irrigation and debridement (59,60,66,375). Clean, grade I open wounds may be loosely closed over a drain after adequate debridement, but the majority of wounds should be left open, with repeated debridement, before soft tissue coverage (60). Surgical stabilization facilitates wound management. External fixation is generally preferred, but satisfactory results have been reported with pins and plaster, plates and screws, and flexible intramedullary fixation (59,60,66,375).

Complications. Open fractures in children share many of the same complications reported in the adult literature (62,63). Kreder and Armstrong (59) noted that a delay of more than 6 h correlated with a 25% infection rate, compared with a 12% rate for patients operated on within 6 h. Others have noted that age is the most significant prognostic indicator (64,66). Children younger than 12 years of age require less aggressive surgical management, heal faster, have lower infection rates, and have fewer complications than older children. Children older than 12 years of age have fracture patterns and complications that are similar to those in the adult population.

FRACTURES OF THE ANKLE

Ankle fractures in children constitute approximately 5% of all pediatric fractures and one of six physeal fractures (17%) (3,29). The same mechanisms that produce spiral fractures of the tibial shaft in younger children may produce epiphyseal fractures of the ankle in older children. Tillaux and triplane fractures, referred to as transitional fractures because they occur in adolescents during the transition to skeletal maturity, are specific injuries that occur as the distal tibial growth plate is beginning to close (376).

The ossification centers of the distal tibial and fibular epiphyses appear between the ages of 6 months and 2 years. The medial malleolar extension forms around 7 to 8 years of age, and is complete by age 10 years. Closure of the distal tibial growth plate begins centrally, proceeds medially, and ends on the lateral side. This sequence of closure is responsible for transitional fracture patterns. The fibular physis lies at the level of the talar dome, and closes 1 to 2 years later than the distal tibia.

Ankle motion consists essentially of plantar flexion and dorsiflexion only, rendering this region susceptible to injury with twisting or bending forces. Medial stability is provided by the deep fibers of the deltoid ligament that attach the medial malleolus to the body of the talus. The lateral ligament complex consists of anterior and posterior talofibular ligaments and the calcaneofibular ligament. Strong ligamentous structures also bind the distal tibia to the fibula at the level of the joint. The anterior tibiofibular ligament is important in the pathomechanics of transitional fractures. All of these ligaments, and others around the ankle, principally attach to the

epiphyses distal to the level of the growth plate. This anatomic arrangement transmits injury forces to bone, and results in physeal fractures in older children and adolescents.

Diagnosis can be difficult in patients with nondisplaced or minimally displaced fractures. This is particularly true for distal fibular physeal separations and Tillaux fractures. Swelling may be minimal. Careful palpation usually reveals that the most tender area is the growth plate rather than the joint or ligaments. Displaced fractures are painful, with visible deformity attributable to the subcutaneous nature of the ankle joint. The position of the foot relative to the tibia provides evidence of the mechanism of injury, and indicates the direction of manipulation required for reduction. Motor, sensory, and vascular assessments should be performed before reduction. Plain radiographs usually confirm the diagnosis and define the fracture pattern. Ultrasound assessment has been used to diagnose nondisplaced Salter-Harris type I separations of the distal fibula, but this has not altered treatment (377). CT scanning, with or without three-dimensional reconstruction, is invaluable for the evaluation and management of transitional fractures. An MRI does not offer great advantage over plain radiography, except to evaluate complications such as growth arrest (378).

Malleolar avulsion fractures are more common in younger children, whereas a variety of epiphyseal injuries may be seen in older children. Fractures with syndesmosis disruption are uncommon in children until late adolescence. The most common injury is avulsion of the tip of the lateral malleolus, followed by separation of the distal fibular physis (376,377,379).

Classifications

Ankle injuries in children have been classified by mechanism of injury, by type of growth plate injury, and by combinations of both systems (380,381). Classifications based on mechanism of injury have been proposed to help guide reduction, but these classifications have been formulated independent of the clinical examination. Also, children rarely have comminution or syndesmosis disruption, which have poor prognoses in adult classification schemes. In children, the steps necessary for reduction are usually evident when the clinical examination of foot position is combined with the radiographic appearance. Classifications have also been proposed that combine mechanism of injury with the type of growth plate injury, but these classifications can be confusing and difficult to remember. The authors agree with Vahvanen and Aalto (379), who stated: “The simultaneous use of the classifications based on both type of trauma and type of epiphyseal lesion for classifying ankle fractures in children has led to unsatisfactory and unnecessarily complex groupings. In children the mechanism of trauma can often not be identified, and experimental work, such as what Lauge-Hansen did to support the mechanism-of-trauma classification in adults, is lacking in children.” Those authors subsequently proposed a simple classification to guide management and predict outcome. According to their system, ankle fractures in children can be classified into two categories (379):

group I: low-risk, including avulsion fractures and epiphyseal separations (Salter-Harris types I and II); and
group II: high-risk, including fractures through the epiphyseal plate (Salter-Harris types III, IV, and V) and transitional fractures.

In this classification scheme, transitional fractures would be considered high risk. The authors prefer to consider transitional fractures as a separate category, because of the distinct pathoanatomy of these injuries. Spiegel et al. (382) used a slightly different classification of high-risk and low-risk pediatric ankle fractures, with a third category for transitional fractures.

Treatment

Low-risk Fractures

This category includes avulsion fractures that do not involve the growth plate, and all Salter-Harris type I and II physeal separations. Nondisplaced fractures are treated with cast immobilization for 3 to 6 weeks. Close follow-up with frequent early radiographs is recommended to detect any displacement in the cast.

Displaced low-risk fractures are usually managed by closed reduction (Fig. 32-80). This can be attempted in the emergency room, but complete muscle relaxation may be required for successful manipulation. Interposed soft tissue may interfere with reduction and necessitate surgical exploration. A flap of periosteum is usually found, but tendons or neurovascular structures can also become interposed. Internal fixation with smooth pins or metaphyseal screws can be used after open reduction, but this is not required if the fracture is stable clinically. Minor amounts of displacement and angulation can be accepted, especially in younger children, because these injuries are usually extraarticular and have good prognoses for resumption of growth. Immobilization in an above-knee cast is recommended for the first 3 weeks after closed reduction. A below-knee cast, for an additional 2 to 3 weeks, follows this.

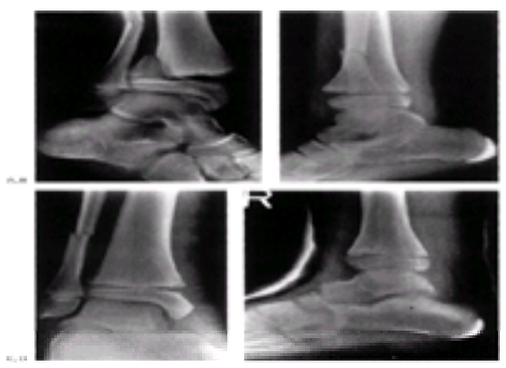

FIGURE 32-80. Pronation and external rotation ankle fracture. **A:** The anteroposterior radiograph demonstrates a Salter-Harris type II fracture of the distal tibia. The Thurston-Holland fragment is lateral. The fibular fracture is transverse and located well above the fibular physis. **B:** Lateral projection of the same injury. **C:** This fracture was treated with closed reduction and application of an above-knee cast. **D:** A lateral radiograph demonstrates acceptable alignment. This fracture was managed successfully with closed reduction.

High-risk Fractures

These fractures include Salter-Harris type III and IV fractures. They are usually intraarticular, with joint instability. Hairline fractures, in which the fracture line is 1 mm or less on all views, can be managed by immobilization in a long-leg cast (Fig. 32-81). Greater degrees of displacement require accurate reduction. Salter and others (383,384 and 385) have noted that reduction of these fractures must be “perfect,” to restore the articular surface and minimize the risk of growth arrest. Closed reduction may be attempted for displaced fractures, but is rarely successful. Open reduction is usually performed with fixation, using intraepiphyseal smooth Kirschner wires or small, cannulated screws (Fig. 32-82). Lintecum and Blasier (386) described a technique of direct visualization and reduction through an anterior arthrotomy incision. This was accompanied by percutaneous fixation with cannulated screws inserted medially or laterally. Every effort should be made to avoid crossing the growth plate with internal fixation devices. However, restoration of articular integrity is more important than preserving growth at the ankle. The distal tibia and fibular epiphyses contribute only 3 to 4 mm of longitudinal growth per year. In older patients with unstable fractures, it is occasionally advisable to place internal fixation devices across the physis and perform epiphysiodesis to avoid subsequent angular deformity.

FIGURE 32-81. A: A 9-year-old girl sustained an undisplaced Salter-Harris type III fracture of the distal tibial epiphysis, as seen in this anteroposterior radiograph. **B:** Management in a cast resulted in healing by 6 weeks. This anteroposterior radiograph shows the result at 3 months. There is symmetrical growth of the physis at the tibia and fibula.

FIGURE 32-82. Supination-inversion ankle fracture. **A:** The anteroposterior radiograph demonstrates a bimalleolar ankle fracture with ankle dislocation. There is a Salter-Harris type I fracture of the distal fibula and a Salter-Harris type III fracture of the medial tibial epiphysis. **B:** Lateral projection. **C:** Anteroposterior radiograph after open reduction and internal fixation. Transepiphyseal screws are used to avoid fixation crossing the growth plate. The joint surface is restored to anatomical alignment. No fixation was required for the fibula fracture. A smooth Kirschner wire can be placed across this physis, if needed, for ankle stability.

Transitional Fractures

These fractures are also high-risk, and include the Tillaux and triplane injuries. These fractures occur as the growth plate is in the process of closing, so growth disturbance in not a concern. Restoration of articular congruity is the objective of treatment.

Tillaux fracture results from an external rotational force, and consists of avulsion of the anterolateral portion of the distal tibial epiphysis by the anterior tibiofibular ligament. This is a biplane Salter-Harris type III injury that can be difficult to detect on plain radiographs. Closed reduction is performed, followed by internal rotation and immobilization in an above-knee cast. The quality of reduction should be accurately documented. CT scans are helpful if plain radiographs are inconclusive. Open reduction with internal fixation is indicated when displacement after closed reduction is greater than 2 mm (376,387) (Fig. 32-83). An anterolateral approach is used, and the fracture is repaired with cancellous screws crossing the physis.

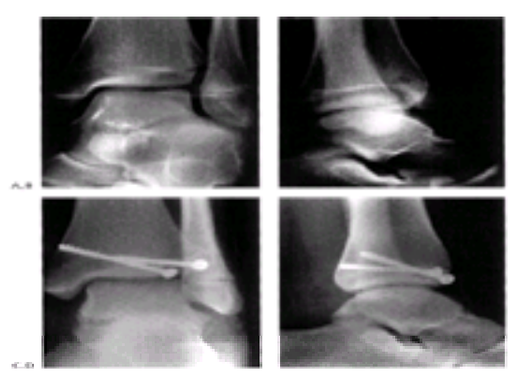

FIGURE 32-83. Transitional fracture. **A:** The anteroposterior radiograph shows displacement of the anterolateral distal epiphysis (Tillaux fracture). **B:** The lateral radiograph demonstrates anterior displacement and rotation of the fragment. **C:** Postoperative radiograph after open reduction and internal fixation with cancellous bone screws. **D:** Lateral radiograph. In this instance, the screws can cross the physeal line, because this injury occurred in an adolescent after the growth plate had begun physiological closure.

Triplane fracture is also caused by external rotation of the foot (Fig. 32-84). On anteroposterior radiographs, it appears as a Salter-Harris type III fracture, but on the lateral projection, it appears to be a type II fracture (Fig. 32-85). The triplane fracture may be a two-part fracture or a three-part fracture, but greater comminution can occur. The CT scans of two-part fractures reveal a single fracture line on the horizontal section through the epiphysis. Three-part fractures demonstrate three radiating fracture lines (“Mercedes sign”) on the transverse section through the epiphysis. An extraarticular type of triplane fracture can also occur when the fracture line exits through the medial malleolus, past the articular surface (376) (Fig. 32-86). Initial management consists of closed reduction with internal rotation and application of a long-leg cast. CT is recommended to confirm reduction. Open reduction with internal fixation is indicated when displacement exceeds 2 mm after attempted closed reduction (376,387,388). The anterolateral approach is satisfactory for reduction and fixation of two-part fractures. Three- and four-part fractures generally require anterolateral and posteromedial exposures. Arthroscopic assisted reduction can also be performed.

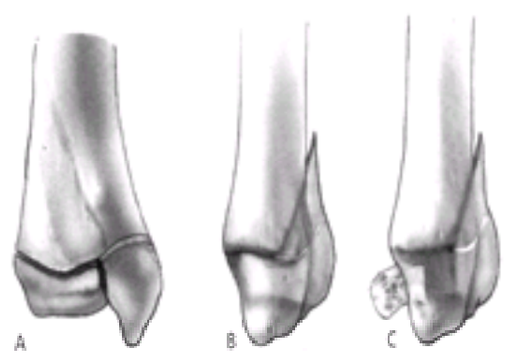

FIGURE 32-84. Triplane fracture. **A:** On the anteroposterior radiograph, the fracture appears as a Salter-Harris type III fracture of the distal tibial epiphysis. **B:** On the lateral view, the fracture appears as a Salter-Harris type II fracture of the distal tibia. **C:** In the three-part triplane fracture, the anterolateral epiphyseal fragment is

displaced as a separate fragment.

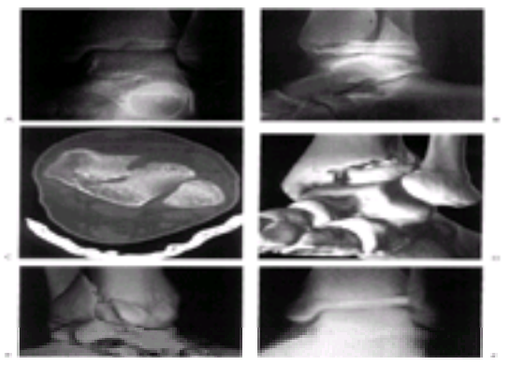

FIGURE 32-85. Triplane fracture of the distal tibia in a 12-year-old girl. **A:** The anteroposterior radiograph shows a Salter-Harris type III fracture. **B:** The lateral radiograph shows an apparent Salter-Harris type II fracture. This indicates a triplane injury. **C:** Computed tomography through the epiphysis confirms a two-part fracture. **D** and **E:** Three-dimensional reconstruction demonstrates the fracture from the anterolateral and posteromedial views. **F:** Closed reduction was unsuccessful. Arthroscopically assisted open reduction was performed. The fracture was stabilized with a single anterolateral cannulated screw inserted percutaneously.

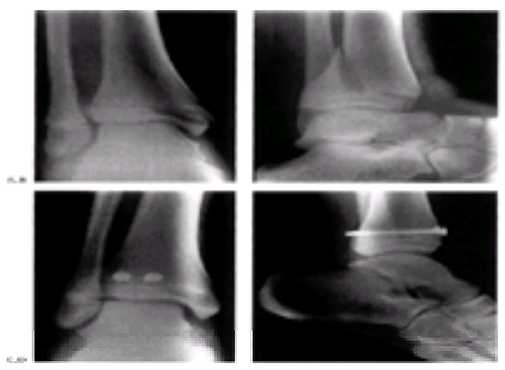

FIGURE 32-86. Two-part triplane fracture. **A:** The anteroposterior radiograph shows a Salter-Harris type III fracture. In this instance, the fracture line does not come out in the intraarticular portion, but exits in the medial distal epiphysis. **B:** The lateral radiograph shows what appears to be a Salter-Harris type II fracture of the distal tibia. Despite closed manipulation, improvement in alignment could not be obtained, and open reduction and internal fixation were performed. **C:** The anteroposterior radiograph shows anatomical alignment and the placement of distal metaphyseal screws. **D:** The lateral view shows reduction of the displaced fracture.

Complications

Complications of pediatric ankle fractures are related to joint incongruity and growth disturbance. Both of these are influenced by the adequacy of reduction. Kling et al. (384) reported that 19 of 20 Salter-Harris type III and IV fractures, which were treated with accurate open reduction and internal fixation, healed without growth disturbance. In contrast, 5 of 9 similar fractures, which were treated by closed means, developed bone bridges. Growth arrest leads to angular deformity. The distal tibia and fibula grow 3 to 4 mm in length per year. Therefore, leg-length discrepancy is rarely a major problem, except in younger children. Complete epiphysiodesis, with or without contralateral epiphysiodesis, should be considered as soon as growth disturbance is recognized. Other alternatives for management of growth arrest are discussed in the physeal injuries section of this chapter.

Restoration of joint congruity is essential to prevent long-term disability (387,388). More than 2 mm of displacement at the articular surface is poorly tolerated. Every attempt should be made to restore articular surfaces without interfering with growth. However, it is the authors' opinion that maintenance of articular integrity is a higher priority than preservation of growth around the ankle.

FRACTURES OF THE FOOT

Fractures of the metatarsals and phalanges of the toes are common, accounting for 7 to 9% of all pediatric fractures (3,5,29). However, fractures of the tarsal bones are uncommon in children, and account for less than 1% of all childhood fractures. The majority of these are nondisplaced, and may be an underreported cause of limping in toddlers (389,390). The rarity of midfoot and hindfoot fractures is attributable to the fact that the juvenile foot is very flexible, with a large component of cartilage until late adolescence. The ossification center of the medial cuneiform does not appear until 4 years of age. Some of the secondary ossification centers do not appear until 10 years of age or later. Thus, there are numerous ossification centers in various stages of development. This can make radiographic interpretation difficult. Comparison radiographs of the opposite foot should be obtained when the diagnosis of a fracture is in question. A CT is often helpful to evaluate complex fractures.

Anatomy

The calcaneus functions posteriorly with the distal first and fifth metatarsals to form a tripod for weight bearing and shock absorption. Ligamentous structures, joint capsules, bone geometry, and dynamic muscular forces maintain longitudinal and transverse arches. The talus is a complex bone that links the tibia to the foot, and bears all the forces of body weight. It is composed of three parts: head, neck, and body. The talus is supported by the calcaneus, and the head of the talus articulates with the tarsal navicular bone. The cuboid laterally and the three cuneiforms medially constitute the distal row of tarsal bones.

The talus allows plantar flexion and dorsiflexion through the ankle joint, and accommodates pronation-supination motion through the obliquely oriented subtalar joint. This articular function determines the fact that the talus is largely covered with articular cartilage, leaving few avenues of entry for nutrient vessels. Thus, the talus is particularly susceptible to osteonecrosis after fracture. The navicular is also susceptible to osteonecrosis, and lies between the head of the talus and the cuneiforms. Idiopathic or posttraumatic necrosis of the navicular is a self-limited condition without long-term sequelae. However, this condition, also known as Kohler disease, can cause pain and have the radiographic appearance of a fracture.

The calcaneus supports the talus with a bony architecture that is much more cancellous, and has a thin cortical wall with less articular covering. It has a direct weight-bearing function through the complex subcutaneous septae and the thick skin of the heel pad. Anteriorly, transmission of longitudinal forces is achieved at the calcaneocuboid joint. The calcaneus is susceptible to compression failure and collapse of the outer cortical shell when subjected to direct impact, such as the force sustained in a fall from a height. In addition, the wedge-like lateral process of the talus may be driven into the superior region of the calcaneus between the posterior and middle or anterior surfaces of the subtalar joint. This intraarticular mechanism of injury is seen more often in adults and older adolescents. It results in division of the calcaneus into anterior and posterior fracture fragments.

Talus Fractures and Dislocations

Talar Neck Fractures

Fractures of the talar neck are thought to result from forced dorsiflexion. However, there is a 25 to 30% incidence of associated medial malleolar fractures, which

suggests a supination component to the deforming force (391). Most talar neck fractures in children are nondisplaced. The majority of displaced fractures are from high-energy trauma. Displacement jeopardizes the tenuous blood supply of the talus, because the neck region is the primary site of vascular penetration into the talus. Fortunately, there are numerous vascular anastomoses within the body of the talus. The principal blood supply penetrates the neck from within the tarsal canal that is formed by the sulcus of the calcaneus and the sulcus of the talus at the base of the neck. The other major blood supply is a deltoid branch from the posterior tibial artery that enters the medial body of the talus along the deltoid ligament (392).

Letts and Gibeault (393) proposed a classification for pediatric fractures of the talus, which is helpful to determine prognosis:

type I: minimally displaced fracture of the distal talar neck (the incidence of osteonecrosis is low);
type II: minimally displaced fracture of the proximal neck or body (the risk of osteonecrosis is also low with this type);
type III: displaced talar neck or body fracture (osteonecrosis is more likely);
type IV: talar neck fracture with dislocation of the body fragment (osteonecrosis is expected in all of these fracture-dislocations).

Treatment. Fractures that are minimally angulated (less than 5 degrees on the anteroposterior view), and displaced less than 2 mm, can be managed closed (394). The foot is placed in slight plantar flexion to reverse the mechanism of injury. Immobilization in a non-weight-bearing below-knee cast is continued until union is evident, usually 6 weeks. Then a full-weight-bearing cast is used for an additional 4 to 6 weeks. Displaced fractures require open reduction with internal fixation. The anteromedial approach is preferred for fragment reduction. Kirschner wires or cannulated screws can be placed anterior to posterior or retrograde, depending on the location of the fracture (Fig. 32-87). Lag screws are recommended, because they may eliminate displacement better than smooth wires (391). Cast immobilization with non–weight bearing is maintained until union is achieved.

FIGURE 32-87. Talus fracture. **A:** Anteroposterior radiograph of the ankle of a 13-year-old gymnast who injured her foot during a dismount. It appears that the head and neck of the talus are displaced laterally toward the fibula. **B:** The lateral projection shows a type III talus fracture with subluxation of the talonavicular joint. **C:** The intraoperative film shows provisional fixation with Kirschner wires. The fracture is reduced with plantar flexion of the foot. **D:** Another intraoperative anteroposterior view shows anatomical alignment of the talar neck with the body. The entry sites for the screws are in the nonarticular portion of the talar neck. **E:** The postoperative film shows cancellous screw placement. **F:** An anteroposterior radiograph shows restoration of the normal alignment of the ankle. Compared with the injury radiograph, there is no longer a prominence of the talar neck laterally.

Osteonecrosis in children does not usually prevent healing of the fracture, and the long-term outcome may be satisfactory. Prolonged non–weight bearing in a cast yields the best results when osteonecrosis has developed (394). Subchondral lucency may become visible in the body of the talus 6 to 8 weeks after fracture (Hawkins sign). This sign results from disuse osteopenia, and indicates that the body of the talus is vascularized.

Osteochondral Fractures of the Talar Dome

Forced supination of the foot, as in a sprained ankle, may produce osteochondral fracture of the medial or lateral margin of the talar body. This lesion should be suspected when a “sprained ankle” does not improve as expected. Medial lesions tend to be posteromedial, and result from inversion, plantar flexion, and external rotation. Lateral lesions tend to be anterolateral, and result from inversion and dorsiflexion. Plain radiographs of the ankle mortis in plantar flexion and dorsiflexion may be necessary to visualize the fracture. A CT is useful in problematic cases.

Initial treatment after diagnosis is non-weight-bearing immobilization for 6 to 8 weeks. Many patients become asymptomatic in spite of persistent defects (395). Drilling and pinning, or removal of the loose fragment, is indicated, if symptoms persist after a period of immobilization. This frequently can be accomplished arthroscopically.

Lateral Process Fracture

Lateral process fractures of the talus may occur in an inversion or twisting injury to the foot. The initial symptoms are similar to those of an ankle sprain, but these fractures are easily missed, unless there is a high index of suspicion and good-quality anteroposterior radiographs of the talus are obtained. More commonly, the patient presents with persistent symptoms after an “ankle sprain” (396). The diagnosis can be made with stress radiographs or CT scanning. Displaced fractures are often associated with other fractures.

Treatment consists of cast immobilization for nondisplaced injuries. When the patient presents late or an acute fracture is displaced, small fragments can be excised, but large fragments should be treated with reduction and internal fixation.

Calcaneus Fracture

Fractures of the calcaneus may be extraarticular, sparing the subtalar joint, or intraarticular. Extraarticular fractures are more frequent in younger children (75% of cases), whereas intraarticular fractures account for the majority of calcaneus fractures in adolescents and adults. Fracture of the calcaneus may be minimally displaced, and can be easily overlooked in children. Delay in diagnosis occurs in 30 to 50% of cases (397,398 and 399). Swelling, pain, or localized tenderness after a fall should alert the clinician to the possibility of calcaneus fracture. Multiple radiographic views are recommended for diagnosis. However, CT has evolved as the best method for imaging calcaneal fractures for the complete assessment of displaced fractures.

Schmidt and Weiner (399) classified calcaneal fractures in children as extraarticular, intraarticular, or those with loss of the insertion of the Achilles tendon and significant soft tissue injury (e.g., lawnmower injury). Intraarticular fractures in adults have been further classified by Sanders et al. (400), to help plan operative management and predict outcome.

Treatment

Nondisplaced and extraarticular fractures have good prognoses. Closed injuries are usually treated with 4 to 6 weeks of cast immobilization and progressive ambulation as tolerated. Displaced avulsion fracture of the tuberosity of the calcaneus is an extraarticular fracture that requires reduction (401). This may be accomplished by closed reduction, using direct pressure over the Achilles insertion, while the knee is flexed and the ankle is plantar-flexed to relax the posterior calf muscles. Open reduction with internal fixation is recommended, if closed reduction is unsuccessful.

Open reduction and internal fixation are recommended for displaced intraarticular fractures. The preferred approach is lateral, through a long, L-shaped incision, lifting the peroneal tendons within their sheath, and protecting the sural nerve. The lateral wall of the calcaneus is folded down to reveal the medial side, allowing elevation of depressed central fragments. Internal fixation of the posterior facet is achieved by placing subchondral cancellous screws into the medial sustentaculum, then buttressing the lateral wall with an H-shaped or Y-shaped plate (Fig. 32-88). Excessive comminution of the articular surface precludes this type of surgery (400). Long-term results in children are usually good. Satisfactory long-term results have also been reported after closed management of intraarticular calcaneal fractures in

children (402).

FIGURE 32-88. Calcaneus fracture. This 12-year-old boy injured both feet after jumping off a second-story deck. **A:** The lateral radiograph of his left foot reveals a minimal fracture of the body of the calcaneus. The Bohler angle is subtended by a line connecting the anterior process of the calcaneus to the highest part of the posterior articular surface, intersecting a line along the most superior point of the calcaneal tuberosity. This angle normally is 25 to 40 degrees, and usually is compared with the contralateral side. The crucial angle (*c*) is directly related to the shape of the overlying lateral process of the talus. In axial compression fractures, the lateral process is driven into the calcaneus, and the crucial angle is distorted. **B:** The radiograph of the more significantly injured right calcaneus shows flattening of the calcaneus, reduction in the Bohler angle, and flattening of the crucial angle. **C:** The computed tomography scan demonstrates displacement of the posterior facet of the calcaneus, with impaction of the lateral fragment and widening of the body of the calcaneus. The lateral wall is fractured. This injury should be treated with open reduction and internal fixation. **D:** After reduction of the posterior facet, a cancellous bone screw is placed through the lateral joint fragment into the sustentacular fragment, securing the subtalar reduction. The lateral wall can be buttressed with a contoured Y-shaped plate or a small H-shaped plate. The Bohler angle and the height of the calcaneus are restored.

Midfoot Fractures and Tarsometatarsal Injuries

Injuries to the tarsometatarsal joints and fractures of the cuboid or cuneiform bones are rare in children, but can have long-term sequelae (403,404). Fracture of the base of the second metatarsal is usually an indication of associated tarsometatarsal joint injury. These injuries are often misdiagnosed and easily overlooked, and may occur more commonly than recognized. The mechanism of injury may be direct impact, but is more commonly forced plantar flexion of the forefoot, combined with a rotational force (405). Heel-to-toe compression of the foot can also produce these injuries. Dislocations or displaced fractures require closed reduction. Percutaneous pinning and cast immobilization are usually necessary to maintain reduction (Fig. 32-89).

FIGURE 32-89. Tarsometatarsal joint injury. This 4-year-old girl had a file cabinet land on the dorsum of her foot. **A:** There is widening between the first and second metatarsals, and a small fragment of bone is seen in the space. This suggests a partial incongruity, with lateral subluxation of the metatarsals. **B:** The contralateral foot shows a normal relation of the tarsometatarsal joint.

Fractures of the Metatarsals

Metatarsal fractures are common in children, accounting for 5 to 7% of all pediatric fractures (3,5). The second through fourth metatarsals are most commonly injured. The mechanism of injury producing metatarsal fracture is usually direct trauma or crush to the foot. Associated swelling can be significant, and may cause compartment syndrome.

Fractures of the base of the fifth metatarsal are usually avulsion injuries, and can cause diagnostic confusion. Transverse fracture at the junction of the metaphysis and diaphysis is called a “Jones” fracture. This fracture has a high incidence of nonunion. An oblique avulsion fracture through the tuberosity of the fifth metatarsal may be confused with the normal secondary ossification center of the apophysis or avulsion of the apophysis. The apophysis does not extend into the joint. Stress fractures may also occur at this location. Prolonged casting is frequently required for fractures at the base of the fifth metatarsal, and healing should be verified before resumption of activities.

Nondisplaced and minimally displaced metatarsal fractures can be immobilized in a below-knee cast for 4 to 6 weeks, with weight bearing as tolerated. Operative treatment is indicated for open fractures, displaced fractures of the metatarsal heads, and displaced intraarticular fractures (Fig. 32-90). Kirschner wire fixation is usually adequate, but the pinning technique requires securing the metatarsophalangeal joint in a reduced position. If this is not done, extension contracture of the metatarsophalangeal joint can result, with development of a prominent and painful metatarsal head. The wires are left in place for 3 to 4 weeks, with non-weight-bearing immobilization, followed by weight bearing in a cast until union is complete.

FIGURE 32-90. Tarsometatarsal displacement. **A:** Anteroposterior projection of the foot of a 14-year-old boy who sustained a plantar flexion injury in a motor vehicle crash. There is complete dislocation of the first metatarsal-cuneiform joint and medial displacement. There are fractures of the second, third, and fourth metatarsal shafts. The ipsilateral tibial fracture was treated with intramedullary fixation. The swelling in the foot was attributed to the tibial shaft injury, and diagnosis of the foot injury was delayed. **B:** The postoperative anteroposterior radiograph demonstrates reduction and pinning of the fracture-dislocation.

Significant swelling, associated with unusually severe pain, should be evaluated to exclude compartment syndrome. Fasciotomy is indicated if compartment syndrome is confirmed. Compartment syndrome of the foot can involve any of the four compartments: medial (i.e., abductor hallucis), central (i.e., flexor brevis, lumbricals, quadratus), lateral, and interosseous (406). Fasciotomy may be performed through a medial approach, with incision from the medial malleolus to the first metatarsal head. The neurovascular bundle is identified and released, including the tarsal tunnel. This releases the medial compartment, and allows retraction for exposure of the central, lateral, and interosseous compartments from the plantar side. Alternatively, two longitudinal dorsal incisions are centered over the second and fourth metatarsals. Blunt and sharp dissection is performed through each interspace to release all compartments. The dorsal approach can also be combined with a medial incision to release the medial compartment.

Fractures of the Phalanges

A direct blow usually causes these common injuries. Fractures of the phalanges can be treated with closed management, such as buddy taping and use of a hard-soled shoe. The exception to this is an open fracture, which most often occurs to the proximal phalanx of the great toe, and may require open debridement and stabilization with Kirschner wires. The physis of the great toe's proximal phalanx underlies the nail bed, and may be injured in the same fashion as a nail bed avulsion of the hand. Antibiotics should be prescribed, if there is concern about a communicating skin breach, and obvious contamination requires debridement.

CHAPTER 33

THE ROLE OF THE ORTHOPAEDIC SURGEON IN CHILD ABUSE

BEHROOZ A. AKBARNIA
ROBERT M. CAMPBELL, JR.

B. A. Akbarnia: Department of Orthopaedics, University of California—San Diego, La Jolla, California 92093; San Diego Center for Spinal Disorders, San Diego, California 92123.
R. M. Campbell, Jr.: Department of Orthopaedics, University of Texas Health Sciences Center at San Antonio, San Antonio, Texas 78229; Department of Pediatric Orthopaedics, Christus Santa Rosa Children's Hospital, San Antonio, Texas 78207.

Few of us can tolerate with equanimity the concept of small and defenseless children, the weakest members of our species, deliberately and cruelly being harmed by those who care for them. Inflicted trauma is not a new occurrence. Over the centuries, parents have reacted to the stress and frustration of everyday life by striking out at their children, causing soft tissue and bone injuries. As for children, there never has been a golden age. Throughout the history of various societies, children have been killed, abandoned, beaten, and sexually abused. However, only for the past three decades has the attention of the medical community been focused on child abuse and neglect.

In 1946, Dr. John Caffey (1), a pediatrician and pediatric radiologist in New York City, reported, for the first time in the United States, the association of multiple fractures in long bones with chronic subdural hematoma in six infants who had no recorded history of trauma. He recommended investigation for subdural hematoma in infants with long-bone fractures as well as investigation for long-bone fractures in patients with subdural hematoma. In 1953, Silverman (2) clearly implicated parents and guardians as the cause of these traumatic lesions, and described, as part of the syndrome, irregular fragmentation of one or more metaphyses in the tubular bones associated with new bone formation external to the shaft. In 1960, Altman and Smith (3) became the first authors to report cases of unrecognized trauma in infants and children in the orthopaedic literature, and concluded that removing the child from the home environment could be lifesaving.

Although many physicians contributed to the recognition and understanding of child abuse, medicine as a profession did not officially acknowledge child abuse until a paper describing the battered-child syndrome was published by C. Henry Kempe and associates (4) in 1962. The introduction of the term “battered-child syndrome” was helpful in attracting attention to this neglected medical and social problem. Within a few years of the publication of this article, reporting laws were passed in all states, mandating that health professionals report suspected cases of abuse. Increased public awareness finally resulted in the passage of the Child Abuse Prevention Act of 1974. The first large study of patients with orthopaedic manifestations of this syndrome was published in 1974 (5). In 1990, Schmitt and Clemmens (6) reported that 35% of abused children will be reinjured and 5% will die if they return to the original environment without any intervention. Great strides have been made, not only in the passage of child abuse legislation, but also in the diagnosis, management, and understanding of the social, psychologic, and epidemiologic aspects of this problem. Unfortunately, the syndrome remains a major cause of death and physical and mental disability among our children.

DEFINITION

In 1968, Helfer and Kempe (7) defined child abuse as physical injury inflicted on children by persons caring for them. Since then, the concept of child abuse has been broadened to include physical and emotional neglect, physical abuse, and psychologic and sexual abuse. In addition, the list of professionals required to report such abuse has been increased to include virtually all those who are responsible for the care of children. Thus, the definition can vary, depending on the professionals involved. This chapter deals mainly with the diagnosis and management of physical abuse.

PREVALENCE

The prevalence of child abuse is difficult to determine. It has been estimated that 1 to 1.5% of all children are abused each year. The number ranges from 70,000 to 3 million (8,9). In 1997, 45 states reported that nearly 3 million children were alleged victims of maltreatment (for a national rate of 42 children per 1,000 children in the population). One-third of investigations resulted in a disposition of either substantiated or indicated child maltreatment (the rate of victimization was 13.9 per 1,000 children). More than one-half of all victims suffered neglect, and almost one-fourth suffered physical abuse. The number of childhood deaths attributable to abuse is difficult to estimate. This is particularly true in infancy, when many cases of homicide are likely to remain undetected (4). In 1997, 41 states reported 967 child maltreatment fatalities, which were extrapolated to a national estimate of 1,197 (for a rate of 1.7 per 100,000 children, or 123 child fatalities per 100,000 victims of maltreatment). However, many states have indicated that the actual number may be significantly higher. The number of children who were victims of maltreatment peaked in 1993, and has since decreased from 15.3 victims per 1,000 children to 13.9 per 1,000, and it is now only slightly higher than the rate in 1990 (8). For every case that is reported, many others are not. The case reports and statistics are heavily biased toward poor and minority children. Children of the affluent may receive different diagnostic labels for their problems (i.e., “accidents” rather than “abuse”), and practitioners may feel an obligation to protect more affluent families from the stigma of reporting to public agencies (5). About 30% of fractures in children younger than 3 years of age are nonaccidental (10,11). In a study of children younger than 1 year of age, 56% of fractures were found to be nonaccidental (12,13). The gender ratio is about equal, but premature babies and stepchildren are at greater risk. Besides parents, who are the perpetrators in three-fourths of cases, boyfriends and stepparents are also frequent abusers. Younger children, in general, are at greater risk, because they are demanding, defenseless, and nonverbal. In a study of 231 abused children, 50% were younger than 1 year of age, and 78% were younger than 3 years of age (5). Although a larger percentage of maltreated children are between birth and 4 years of age, the number of victims is distributed across most age ranges between birth and 16 years. However, fatalities from physical abuse are seen most often in children younger than 3 years of age (75%) (8).

DIAGNOSIS

In the spectrum of child abuse and maltreatment, orthopaedic surgeons are involved more often in cases of physical injury, and less often in cases of physical and

emotional neglect. Physical abuse and chronic neglect of young children tend to be recurrent, and often result in permanent sequelae, such as skeletal deformities, brain injury, and even death. The orthopaedic surgeon must be satisfied that each injury seen in a child is adequately explained, and that the injury is consistent with the history provided. The role of the orthopaedic surgeon extends beyond simple treatment of the child's fracture.

To differentiate those lesions resulting from inflicted trauma from those caused by accidents, physicians should have a high index of suspicion, as well as diagnostic skill. Furthermore, they should be knowledgeable regarding the patterns of normal growth and development, and the common injuries of children (14,15). The diagnosis of child abuse seldom is made without difficulty. A combination of the history given, the age of the child, the behavior of the parent, and certain clinical manifestations serves as a practical guideline for differentiating nonaccidental injury from injury associated with pathologic conditions. Child abuse should be viewed in the same manner as any other medical condition in which facts are gathered and evaluated and a medical judgment, based on knowledge and expertise, is formulated (16).

Because all cases of suspected inflicted injuries are possible forensic cases, the diagnosis should include an expression regarding the level of certainty to which the physician is willing to commit. This might be a phrase such as “reasonable degree of medical certainty,” “more likely than not,” or “suspicious.” All interventions other than voluntary ones in child abuse cases require that the existence of the abuse be proven at some specific level of certainty (17).

THE INVESTIGATIVE INTERVIEW

The child abuse interview is usually taken in the chaotic environment of a busy emergency room, and it is important to find a quiet area for the interaction, where tempers can cool and distractions can be minimized. The interview goes beyond the usual history in many ways. Documenting the symptoms (or the absence of symptoms) of the injury is only the beginning; what is equally important is to discover enough details about the child's life, so that plausible scenarios can be created to explain the injury. The orthopaedist must become both social worker and detective in the interview, calmly and methodically establishing how the child lives, seeking information about everyone, friends and family, with access to the child, and determining how likely it is that they might have contributed to the injuries.

At-risk Profiles

The Parents

Although any parent could be capable of child abuse, during the interview specific “at-risk” profiles are developed for the parents or other caregivers, to determine if they are more likely to abuse a child. Substance abuse, whether by alcohol or other drugs, makes a parent more likely to abuse a child. With maternal cocaine use, the risk of physical abuse of a child is increased fivefold (18). Households in crisis from job loss, marital separation, divorce, a family death, housing difficulties, or money problems are more prone to abuse situations (19). Boyfriends and stepparents are frequent abusers, as are relatives, baby-sitters, and even older siblings (20,21). Young, unmarried mothers are more likely to have their infants die from intentional injury, with one Colorado study (22) showing a peak incidence of 10.5 intentional deaths per 10,000 live births for mothers 16 years of age. Parents of abused children often, themselves, were abused in childhood (23). Typically, the adult who abuses a child is young, poor, and socially isolated (24), but any adult from any social or economic level may be guilty of abusing a child (13).

The Children

Certain groups of children are more likely to experience abuse. Age is an important risk factor, because most abuse involves children younger than 3 years of age, with infants 1 year or younger especially at risk. Stepchildren, premature infants, and first-born children are at greater risk for abuse (13). Children of families with two unplanned births have a threefold higher risk of abuse than children from families with no unplanned births (25). Handicapped children have a 4.6% incidence of abuse, with severely disabled children somewhat less likely to be abused, and marginally functioning children at greatest risk (26). The incidence of sexual abuse in handicapped children has been estimated between 25% and 83%, with boys more likely to be abused (27). Children who are repeatedly brought in for medical assessment by their parents for vague illness, with a history of multiple diagnostic or therapeutic procedures without definitive diagnosis, may be at risk for Munchausen syndrome by proxy (28). In this condition, the parents, through a misguided sense of purpose, invent symptoms of illness for the child, and induce signs of disease, provoking needless workup and treatment, which can lead to an 8% risk of long-term sequelae from induced illness and a 9% risk of death. Acute signs and symptoms cease only when the child is separated from the parent.

A careful, detailed history of each adult family member should be obtained individually in a quiet, private setting. If the patient and siblings can communicate, they should be interviewed separately from the parents. The crucial questions to be answered are not only whether the history of trauma given is sufficient to explain the severity of injury, but also what possible scenarios could explain the injury if the volunteered explanation is not plausible. This involves establishing a working knowledge of how the family operates: Who has access to the child? Which of those individuals are unsupervised by family members when they are with the child? What are the living conditions for the family? Which adult is working and which is not? Who is the primary caregiver for the child? Who is responsible for feeding the child, as well as for toilet training and discipline? What are the sleeping arrangements for members of the household? What is the marital status of the parents? Does the single parent have a boyfriend or a girlfriend? Is there any history of substance abuse in the adults who have contact with the child? Is there any past history of child abuse in the family?

The interview is begun by asking the primary caregiver in a nonjudgmental manner how the presentation injury occurred. If the answer is vague or implausible, or if risk factors are present for child abuse, other undocumented injuries must first be searched for by careful physical examination and radiographic skeletal survey, before proceeding with the full interview. Once a full injury assessment of the child is complete, then the full interview can resume. To avoid provoking emotions, any additional soft tissue or skeletal trauma discovered should be brought up *at the end of the interview* for explanation, once the presentation injury has been thoroughly discussed. Each investigative interview should follow a systematic review of symptoms: What happened? Who was there? When was the injury recognized? How long before medical treatment was sought? Inconsistencies between accounts are not contested, and the orthopaedist should avoid volunteering more plausible explanations for the injury. The location where the incident occurred and the individuals who were actually present are determined. Leading questions are to be avoided. Do not ask *who* caused the injury; rather, ask each person *what* he or she saw or *what* he or she thinks happened. Establish who discovered the injury, how soon the child received medical attention, and where the child was taken for care (19). Delays in treatment should raise the index of suspicion for an abuse situation. Be as gentle as possible in questioning the injured child, asking *how* he or she got hurt, rather than *who* hurt him or her. Ask the child what he or she was doing at the time of the injury, and compare that account with what the adult witnesses state. If possible, also interview the siblings of the injured child, because they too are at risk for child abuse.

Nonvisual clues during the interview may help to define an abuse situation. Parents who are abusive can be evasive, and may not readily volunteer information. They may be self-contradictory, and may display irritation at inquiries regarding their children's symptoms. They may show overreaction, such as hostility, or underreaction, such as casualness or little evident concern. They may be unavailable or refuse to give information or to consent to different tests. Often, they have inappropriately delayed seeking medical care. When they interact with their children, they may seldom touch or look at them, seeming indifferent to the child's distress, or they may be critical and angry with the child, and not mention any positive or good qualities. The abused child may be sobbing hysterically or may be quiet and withdrawn. These children may not look to the parents for reassurance, may avoid physical contact with adults, may be overly compliant, and may appear wary of danger (13,23).

Careful documentation is critical. Chart notes may be needed later in court as evidence in custodial hearings. Record each account as faithfully as possible, using *italics* for exact quotes, and specify who is giving the history. Not infrequently, the family will wish later to change their story. No changes should be made to the earlier record, but an addendum should be added detailing the new account. The record should be as detailed as possible, noting all accounts of the mechanism of injury, family social history, past medical history, any family history of diseases such as osteogenesis imperfecta, physical examination findings, and radiographic and laboratory results. Photographs of soft tissue injuries should also be added to the record. The results from any consultations are also placed in the chart note. Along with the diagnosis of any injuries, the orthopaedist must specifically include the diagnosis of *probable* or *possible* child abuse, if the evidence supports such a conclusion. Treatment recommendations should include a care plan for the acute injuries, and a status report for child protective services involvement in the case. If child protective services recommends emergency transfer of the child to a foster home or shelter, the orthopaedist should summarize all chart documentation in a separate notarized narrative, which is preferred by the court system.

CLINICAL MANIFESTATIONS

When confronted with a traumatic lesion, the physician must examine the whole child and look for other possible clues. If there is any question regarding the general medical examination, help should be sought from medical colleagues. Often, it is the nonorthopaedic manifestations of child abuse that lead to the diagnosis.

Failure to thrive, or growth retardation secondary to physical and emotional deprivation, is common in children who have been subjected to repeated abuse. This should be differentiated from the usual causes of growth retardation.

Soft Tissue Injuries

Soft tissue injuries are strong indications of abuse. Soft tissue injuries were found in up to 92% of children suspected of being victims of child abuse (29). A variety of skin lesions, including ecchymosis, abrasions, burns, welts, lacerations, and scars, are by far the most common finding in cases of child abuse (30). Typical toddlers have bruises over the shins, knees, elbows, and brow. They may have a few old cuts or scars around the eyes or cheekbones as a result of normal collisions. However, bruising of the buttocks, perineum, trunk, back of the legs, and especially the head or neck, suggests inflicted trauma. These lesions may have the same shapes or configurations as the implements used to create them (Fig. 33-1). Loop marks or scars on the skin are inflicted by a doubled-over cord or rope. Human bite marks are distinctive, paired, crescent-shaped bruises that face each other. McMahon et al. (29), however, found that these pathologic patterns occurred in only 8% of their patients. The skin lesions may be in various stages of healing (Fig. 33-2). Wilson (31) has suggested some guidelines for estimating the age of a bruise from its color. From 0 to 3 days after injury, a bruise usually is red, blue, or purple; from 3 to 7 days, it is green or green-yellow; and from 8 to 28 days, it is yellow or yellow-brown. These guidelines can be helpful in determining whether bruises are the result of one or more traumatic episodes. When bruises are present, diseases such as leukemia, idiopathic thrombocytopenia purpura, and hemophilia should be ruled out. Other cutaneous manifestations of child abuse include bruises in the shape of a hand print, alopecia or subgaleal hematoma from pulling of the hair, and areas of abraded skin from bindings or restraints. Impetigo in its various forms can be confused with burns or inflicted injuries.

FIGURE 33-1. Rope marks on an infant who was a victim of repeated physical abuse.

FIGURE 33-2. Bruising of the back and buttocks, typical of physical abuse. Bruises may be found in different stages of healing.

It is essential that photographs of skin lesions be taken for the purpose of documentation and possible future use in the courts. Informed consent should be obtained, and the photographs can be taken by a member of the child abuse team or by a social worker.

Cao-gio, or “scratch the wind,” is a Vietnamese folk medicine practice. It consists of using a boiled egg covered with hair, a coin, or a similar object to scratch skin previously massaged with hot oil. This leaves broad bruises or ecchymosis. It is believed that these scratching maneuvers help rid the body of “bad wind.” These lesions should not be confused with nonaccidental lesions (32).

Burn injuries are common and are seen in 10% of abused children (13). These lesions can be scalding injuries, cigarette burns, or burns caused by flames. Burns are most common among children between birth and 2 years of age (29). The pattern of deliberate immersion burns often is symmetric, with sharp lines between the burned and unburned skin. Accidental scald burns usually are distributed asymmetrically (30).

Head Injuries

The head is a convenient and vulnerable target. Because “the face represents the person,” it is logical to strike the face to assail the person. The most convenient weapon for striking a child is the human hand. An open palm, the knuckles, or a closed fist is sufficient to produce severe damage to the brain, skull, or scalp, when used forcefully. Of 110 physically abused children seen by O'Neill and associates (21), 32 had evidence of cerebral trauma. More than 50% of all cases of permanent disability occur among children younger than 2 years of age, and result, in large part, from inflicted head injuries. The scalp may be swollen. Extension of the swelling and ecchymosis to the eyelids and face is a telltale sign of cranial trauma. Head injuries may be severe and result in immediate death, or they may be less severe and cause various subtle neurologic impairments. Subdural hematoma can occur with or without skull fractures. Many children with brain injuries have no external evidence of trauma. Caffey (33) suggested that violent shaking may cause stretching and tearing of the veins, creating subdural hematoma. If the insult is repeated, causing minor brain injury each time, it may result in additional brain damage manifested by mental retardation, seizure disorders, and other motor and learning disabilities, some of which do not become apparent for months or years after the abusive behavior has ended.

Careful neurologic assessment of all suspected victims of abuse or neglect is essential. Conversely, the unexplained appearance of central nervous system symptoms in an infant should trigger suspicion of abuse. Fractures of the skull are not easy to produce in infants, because of the yielding elasticity of the thin cranial bones, which are not yet fixed at the sutures. When present, they may be indicative of a forceful nonaccidental impact to the skull. Several cases have been reported of children with inappropriate widening of the cranial sutures, which is believed to result from increased intracranial pressure secondary to cerebral edema or subdural hematoma (5). Computed tomography (CT) has greatly improved the precision in differentiating accidental and nonaccidental head injuries, and this test should be performed in any child with unexplained acute or chronic neurologic signs. A child with acute and unexplained unconsciousness should undergo head CT immediately after stabilization, often followed by abdominal CT and skeletal survey radiography. Magnetic resonance imaging (MRI) is not recommended as the primary imaging study, because it can fail to reveal subarachnoid hemorrhage in the early stages. After a few days, MRI can be helpful in detecting cerebral abnormalities. MRI also is useful in patients with chronic neurologic findings.

Internal Injuries

Child abuse can produce injuries to the internal organs, such as rupture of the pancreas and pseudocyst formation, laceration of the liver and spleen, intramural hematoma of the bowel, hemorrhage behind the peritoneum, laceration or contusion of the kidneys, perforation of the intestine, and rupture of the ureter or bladder (34). Of the deaths that result from child abuse, many are caused by internal hemorrhage from the rupture of abdominal organs after punches or kicks. Most such deaths occur in children 3 years of age or younger. The high death rate from these injuries is attributable not only to the severity of the trauma, but also to the delay of

the abuser in seeking medical attention. Unfortunately, the lack of a history of trauma and the failure of the physician to notice other signs of abuse often result in a delay of diagnosis as well.

ORTHOPAEDIC MANIFESTATIONS

About one-third of all physically abused children require orthopaedic treatment (5). The incidence of fractures in child abuse cases varies from 11 to 55%. Skeletal injuries are significantly more common in the younger age groups. Factors that influence the reported incidence of fractures relate to the age of the patient, the type of abuse, and the type and quality of the imaging techniques used to detect skeletal injuries. Fractures can occur in almost any bone of the body. However, the long bones, ribs, and skull are common locations. Fractures can be categorized as epiphyseal, metaphyseal, diaphyseal, or miscellaneous (5).

Physeal Fractures

Physeal fractures, although rare, are seen most often in the femur, tibia, and humerus, and are being recognized in more cases of child abuse (35,36 and 37). A fracture through a growth plate, especially when the epiphysis is not visible, can cause difficulty in diagnosis. Metaphyseal lucency or irregularity and soft tissue swelling may be the only findings on radiographic examination. Arthrographic examination of the joint, as well as MRI, can be helpful in certain cases, such as fractures around the elbow (35) (Fig. 33-3).

FIGURE 33-3. A 15-month-old infant was seen in the emergency department because she was not able to move her right elbow. **A:** The exact location and severity of the fracture of the distal humerus cannot be identified. **B:** An arthrogram of the elbow shows the outline of the distal humeral epiphysis, which is separated.

Fractures of the proximal femur involving the epiphyseal–metaphyseal region are much less common than those involving the shaft and distal femur. They are identical to fractures caused by birth trauma. These fractures not only are difficult to detect, especially before the ossific nucleus has appeared, but they may result in the most severe deformities of the lower extremities caused by child abuse.

Metaphyseal Fractures

Metaphyseal fractures are classified as corner fractures, impaction injuries, buckle fractures, or irregular metaphyseal deformities. Corner fractures are caused by forceful downward pulling on the extremity, and often are bilateral. They may not be visible on the initial radiograph, but they can result in periosteal separation and subperiosteal hemorrhage, with subsequent new bone formation external to the cortex. The periosteal new bone formation becomes visible in about 7 to 10 days. These patients often have swollen and painful extremities that cannot be moved. If the lesion is already 7 to 10 days old, the swollen and warm extremity with periosteal new bone formation, often associated with fever, can be confused with osteomyelitis.

Metaphyseal injuries, especially corner fractures as opposed to shaft fractures, are highly specific. However, detection of these lesions often requires high-quality radiographic images. Kleinman and colleagues (38) believe that these lesions are the most diagnostic fractures indicating nonaccidental trauma. They presented an extensive radiologic–histopathologic study, and indicated that the fundamental histologic lesion is a series of microfractures occurring in a planar fashion through the most immature portion of the metaphyseal primary spongiosa. The most subtle indication of injury is a transverse lucency within the subepiphyseal region of the metaphysis. These lucent lines occasionally are indistinguishable from those found in patients with chronic diseases, such as leukemia. The fracture fragment is made up of epiphysis, physis, and a thin portion of metaphysis (Fig. 33-4). In the peripheral margin, the disc-like fragment is relatively thick, and can show evidence of different degrees of density. It is this peripheral margin that has been called a “metaphyseal corner fracture.” A similar fragment often is seen in the lateral and anteroposterior projections, indicating that these apparently separate triangular fragments actually are portions of the same larger disc-like fragment (Fig. 33-5 and Fig. 33-6).

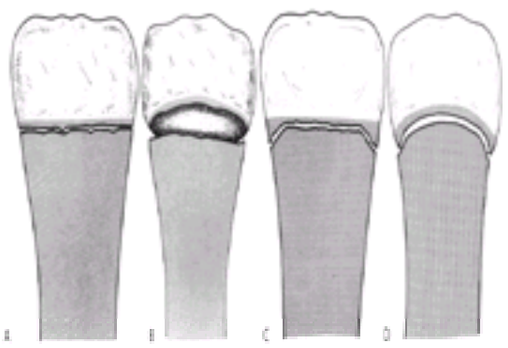

FIGURE 33-4. Metaphyseal lesions. **A:** A planar fracture through the primary spongiosa produces metaphyseal lucency. **B:** If the metaphysis is tipped, or simply projected at an obliquity to the x-ray beam, the margin of the resultant fragment is projected with a bucket-handle appearance. **C:** If the peripheral fragment is substantially thicker than the central fragment, and the plane of injury is viewed tangentially, a corner fracture appearance will result. **D:** If the metaphysis is displaced or projected at an obliquity, as in **B**, a thicker bucket handle will be apparent. (From ref. 16, with permission.)

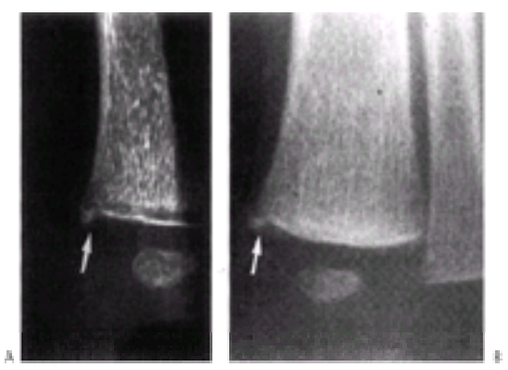

FIGURE 33-5. Distal tibia of a 3-month-old abused infant. **A:** Specimen radiograph reveals a corner fracture medially (*arrow*), in addition to a conspicuous metaphyseal radiolucency. **B:** Antemortem radiograph tangential to the metaphyseal margin also demonstrates the corner fracture (*arrow*), with the suggestion of a

radiolucent band. (From ref. 16, with permission.)

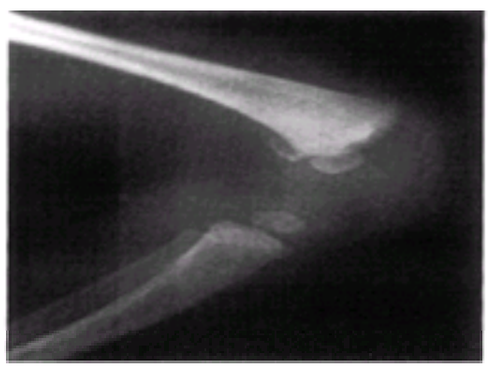

FIGURE 33-6. Metaphyseal corner fracture or bucket-handle fracture in the lateral view.

In an impaction injury that is severe, the epiphysis is impacted into an expanded metaphysis, and exuberant periosteal new bone formation occurs subsequently (Fig. 33-7). Simple buckle fractures are common in the metaphysis, and often are multiple. Unlike other metaphyseal lesions, they do not produce a significant amount of callus (Fig. 33-8). Gross irregularity of the metaphysis is seen after repeated injuries, and frequently is associated with deformity of the joint and limitation of motion (39).

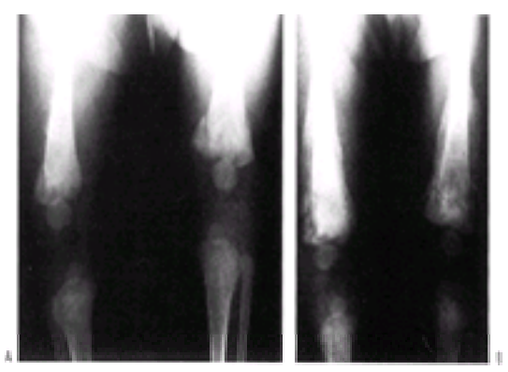

FIGURE 33-7. Bilateral impaction fracture of the distal end of the femur (**A**), with subsequent exuberant periosteal new bone formation (**B**). (From ref. 5, with permission.)

FIGURE 33-8. Metaphyseal buckle fractures involving the distal end of the femur. These fractures often are bilateral.

Diaphyseal Fractures

Diaphyseal lesions are grouped into three categories:

1. Transverse, spiral, or oblique fractures of the shaft, sometimes associated with exuberant callus, because of delay in seeking medical help and lack of proper immobilization.
2. Multiple lesions in various stages of healing.
3. Gross bony deformities.

The femur and humerus are the two long bones most frequently fractured in abused children. The overall incidence of femoral fractures is 20% (5,21,37). In a series of 80 femoral fractures in children younger than 4 years of age, 30% were caused by child abuse (40). Anderson (41) described 117 patients with 122 femoral fractures. Of 24 children younger than 2 years of age, 19 (79%) were abused. Of 18 children younger than 13 months of age, 15 (83%) were abused. In older children, there are more accidental injuries causing femoral fractures.

Some authors have emphasized the frequency of spiral and oblique fractures of the long bones caused by physical abuse (42). However, it is increasingly evident that the usual types of diaphyseal fractures (e.g., transverse fractures) are common in cases of nonaccidental trauma. Therefore, in long-bone fractures, especially in the femur, no specific type of fracture (e.g., transverse, oblique) should be considered pathognomonic of child abuse. Other criteria, such as history and patient age, are more helpful in making the diagnosis (43) (Fig. 33-9).

FIGURE 33-9. A 2-month-old boy reportedly fell from a sofa. **A:** Femur fracture was not very specific. **B:** Because of the patient's age and vague history, a bone scan was obtained. The bone scan showed increased uptake in the rib that was not seen on the plain radiographs.

In a review of 429 fractures in 189 abused children, King and associates (34) found the humerus to be the long bone most often affected, and transverse fractures to be the most common type. About 50% of their patients had only a single long-bone fracture, 35% in the femur and 29% in the humerus (Fig. 33-10).

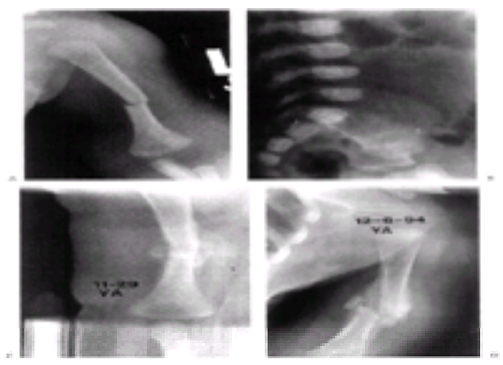

FIGURE 33-10. A 2-month-old infant with a nonaccidental transverse humeral fracture, a spinal fracture, and cerebral hemorrhage. **A:** Transverse humeral fracture. **B:** L4 compression fracture and anterior wedging. **C** and **D:** Humeral fracture at 2 and 3 weeks after injury, showing progressive healing and new bone formation.

Long-bone fractures caused by child abuse can be similar to those resulting from accidental trauma. Careful attention to the history and the age of the child could reveal the nonaccidental nature of the injury. Because the risk for accidents begins with mobility, especially walking, when these injuries occur in young, nonambulatory infants, they almost always are inflicted in the absence of bone disease.

Miscellaneous Fractures

Rib fractures account for 5 to 27% of all fractures occurring in abused children (16). Fractures involving the ribs usually are posterior or posterolateral, and can be in various stages of healing (Fig. 33-11). They rarely are caused by cardiopulmonary resuscitation. In the absence of radiographic evidence of intrinsic bone disease or obvious major trauma, unexplained rib fractures are specific for abuse. Rib fractures usually are not suspected clinically. Radionuclide bone scanning has been shown to be extremely useful in the detection of rib fractures in abused infants and children, and should be used if nonaccidental injury is suspected and the skeletal survey is negative.

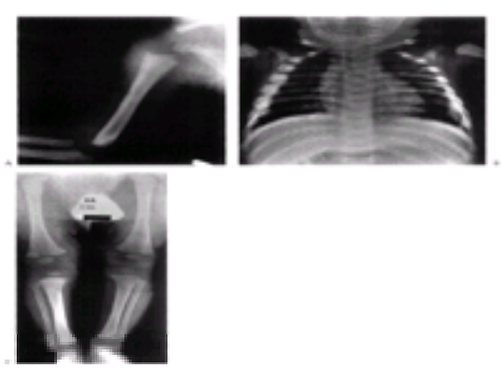

FIGURE 33-11. A 3-month-old infant with a history of a fall. The infant was discharged, but returned dead. **A:** Unusual proximal humerus fracture. **B:** Lateral and posterior rib fractures. **C:** Metaphyseal fracture of the proximal right tibia.

Other miscellaneous fractures include spinal, clavicular, scapular, and sternal fractures. Spinal and sternal fractures are more specific than clavicular fractures. Although the clavicle is one of the most common bones to be fractured accidentally in children, it accounts for only 2 to 6% of fractures associated with child abuse (5,20,44). Therefore, it is not specific for child abuse. Spinal fractures are described separately.

Spinal Injuries

The true incidence of spinal injuries is difficult to determine. The reported incidence has varied from 0 to 3% in large series (5,37,41). Abused children with spinal injuries occasionally show mild kyphosis, but most do not have significant clinical symptoms referable to the spine. Therefore, many of these injuries go unrecognized. Because spinal injuries are likely to be silent, but associated with extremely violent assaults, routine evaluation of the spine in cases of suspected child abuse is mandatory. Spinal radiographs, especially a lateral projection of the entire spine, should be part of the routine skeletal survey.

In a report of 85 spinal fractures in 41 children, Kleinman (16) found the average patient age to be 22 months. Most of the fractures involved the vertebral bodies. Occasionally, fractures of the posterior arch, without involvement of the vertebral bodies, are described. Vertebral bodies can show varying degrees of anterior compression. There can be anterior notching, which usually is superior (45). In cases of disc herniation, intervertebral disc narrowing can be present (Fig. 33-10 and Fig. 33-12). Fracture dislocations, with or without neurologic deficits, have been reported. Spinal cord injuries or hematomas also can be seen without bony involvement. Significant fracture-dislocations, especially those that are not associated with neurologic deficits, may go unrecognized, and can result in significant spinal deformity later in life.

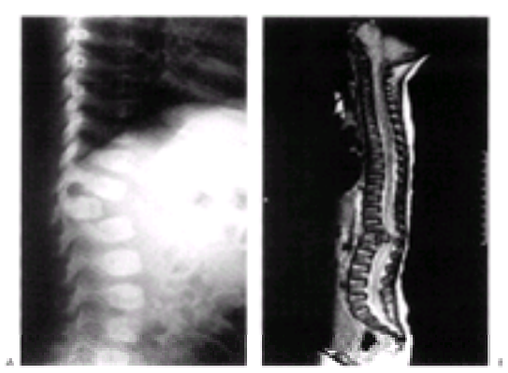

FIGURE 33-12. Fracture-dislocation of the spine in a 10-month-old infant, a victim of abuse, who had incomplete paraplegia. **A:** Lateral radiograph of the spine. **B:** Magnetic resonance image showing cord compression. (Courtesy of Keith Gabriel, M.D., Cardinal Glennan Children's Hospital, St. Louis, Missouri.)

The mechanism of injury in most cases is hyperflexion, extension, or both. Therefore, multiple compression fractures in a single patient are common. Occasionally, fractures of the upper extremities are associated with these compression fractures, when the child is held above a table or kitchen counter and the buttocks are slammed against the surface. The child uses outstretched arms to break the impact, causing fractures of the upper extremities. Most compression fractures are in the region of the thoracolumbar and lumbar spine. However, fractures and fracture dislocations of the cervical and sacral regions also are seen.

The changes in vertebral bodies and discs that accompany normal development or infection can cause confusion. Notching of traumatic origin generally involves a large portion of the anterior margin. Disc space narrowing caused by infection usually is more severe than that caused by trauma and disc herniation. The value of bone scanning in detecting spinal injuries is not clear. Standard radiography generally is regarded as the primary method of investigation. In the presence of any neurologic findings, MRI is useful for evaluation of the spinal canal.

DECISION-MAKING

Orthopaedic surgeons often are asked to give an opinion regarding the cause of certain fractures (i.e., accidental versus nonaccidental). The presence of fractures alone may not provide a sufficient basis for making such a determination. However, a major part of the recognition of child abuse still depends on radiologic diagnosis. Certain fractures are more specific than others in these cases. Again, the history and the age of the patient should be considered in making the determination.

In a study of 89 fractures in 36 children with documented histories of child abuse, the pattern of fractures was found to be more helpful than the presence of multiple fractures in various stages of healing in making the diagnosis of child abuse (37). Suspicious fracture patterns included metaphyseal corner fractures; lower-extremity fractures in nonambulatory children; bilateral acute fractures; fractures in special locations, such as the ribs and spine; and physeal fractures in young children (46). As infants begin walking, they may sustain a classic fracture known as the toddler's fracture (47,48), which appears as an oblique lucent line in the tibia (Fig. 33-13). Although there can be a good explanation for this fracture, the history and any other available clues should be evaluated carefully before the diagnosis is made. In a very young patient of the right age without a convincing history, even a fracture of the clavicle should be considered suspicious.

FIGURE 33-13. Undisplaced oblique fracture of the tibia (toddler's fracture).

Kleinman (16) suggests that relative specificities can be applied to these fractures, based on their nature, location, and chronicity (Table 33-1).

High Specificity
Metaphyseal lesions
Posterior rib fractures
Scapular fractures
Spinous process fractures
Sternal fractures
Moderate Specificity*
Multiple fractures, especially bilateral
Fractures of different ages
Epiphyseal separations
Vertebral body fractures and subluxations
Digital fractures
Complex skull fractures
Common but Low Specificity*
Clavicular fractures
Long-bone shaft fractures
Linear skull fractures

* Moderate- and low-specificity lesions become high-specificity lesions when a history of trauma is absent or inconsistent with injuries.
(From ref. 16, with permission.)

TABLE 33-1. SPECIFICITY OF RADIOLOGIC FINDINGS

Dating Fractures

The relation between the alleged cause and the timing of an injury is one of the critical elements in the decision-making process. The literature contains little information regarding the dating of fractures based on their radiographic appearance (49,50). Obliteration of soft tissue planes is the earliest sign of injury. Edema of the soft tissues is associated clinically with pain and swelling that are accentuated by any attempt to move the extremity. When fractures are not displaced, the duration of acute inflammation can be only a few days. Infants and children can be free of pain as early as 1 to 2 days after the original injury. Generally, new bone formation occurs between 10 and 14 days after injury. In young infants, this interval is shorter, probably between 7 and 14 days (50). In addition, solidification and remodeling are more rapid in infants than in older children (Fig. 33-14). The age of the child should be considered in dating a fracture, along with the history, the presence of repetitive injuries, and the degree of immobilization.

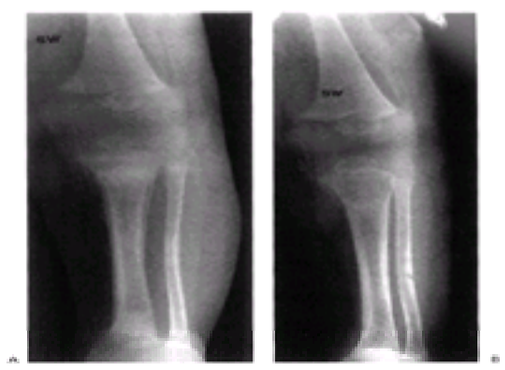

FIGURE 33-14. A 6-month-old infant abused by his baby-sitter. **A:** Ten-day-old proximal tibial fracture and periosteal new bone formation. **B:** Significant remodeling has occurred 2 months later.

Although the actual date of a fracture can only be approximated, a few guidelines have been developed. A fracture without periosteal new bone formation usually is

less than 7 to 10 days old, and seldom is 20 days old. Slight but definite periosteal new bone formation can be as recent as 4 to 7 days old. A 20-day-old fracture almost always has well-defined periosteal new bone and typically has early (soft) callus. A large amount of callus always indicates a fracture more than 14 days old (Fig. 33-10). Loss of marginal sharpness of the fracture line can be delayed for 7 to 14 days. Corner fractures may not cause significant periosteal new bone formation, and can only be dated based on their loss of marginal definition. Chronic repetitive trauma and lack of immobilization can lead to loss of fracture line definition as the earliest finding.

The results of radionuclide bone scanning become positive a few hours after injury, and remain positive for a long time (1 to 2 years). They are not helpful in establishing the age of fractures. The role of MRI in the dating of fractures has not been established. O'Connor and Cohen (50) have outlined a timetable of radiographic changes in children's fractures (Table 33-2).

Category	Early	Peak	Late
1. Resolution of soft tissues	2 to 5 d	4 to 10 d	10 to 21 d
2. Periosteal new bone	4 to 10 d	10 to 14 d	14 to 21 d
3. Loss of fracture line definition	10 to 14 d	14 to 21 d	—
4. Soft callus[a]	10 to 14 d	14 to 21 d	—
5. Hard callus	14 to 21 d	21 to 42 d	42 to 90 d
6. Remodeling[b]	3 mo	1 yr	2 yr to epiphyseal closure

Repetitive injuries may prolong categories 1, 2, 5, and 6.
[a] The stage of soft callus usually lasts 3 to 4 weeks, or until the bony fragments are bridged by lamellar bone, and ends clinically when fragments no longer can be easily moved.
[b] In this stage, both periosteal and endosteal bone begin to be converted to lamellar bone and remodeling of the callus begins.
(From ref. 50, with permission.)

TABLE 33-2. TIMETABLE OF RADIOGRAPHIC CHANGES IN CHILDREN'S FRACTURES

MANAGEMENT

The management of child abuse is divided into two phases: diagnosis and documentation, and treatment. When physical abuse is suspected, documentation is the first step. Skeletal radiography, bone scanning, and CT are the usual imaging modalities. However, the indiscriminate use of these tests in all cases of suspected child abuse contributes to unnecessary radiation exposure and increasing health care costs. Radiographic skeletal surveys are more helpful in children younger than 5 years of age who have clinical evidence of physical abuse (51). The yield from skeletal surveys in neglected and sexually abused children is extremely low, and does not justify the investigation. The skeletal survey should include anteroposterior and lateral views of the skull and thoracolumbar spine, as well as anteroposterior views of the thoracic cage and extremities. The radiographs of the extremities should include the shoulders, pelvis, hands, and feet. Other imaging studies can add more information to that gained by the full skeletal survey, but the orthopaedist should be knowledgeable in the limitations of each technique.

Limitations of Imaging Techniques

A single film of the entire infant (i.e., the so-called babygram) usually is not helpful, because it lacks detail, is a single anteroposterior view without an accompanying lateral view, and subtle findings, such as metaphyseal corner fractures, may be obscured by the oblique projection of the x-ray beam at the margins of the film. A full skeletal survey is much more accurate, and a follow-up survey 2 weeks later will detect additional fractures and aid in dating the fractures in a majority of cases (52).

The use of radionuclide bone scanning as a screening procedure for skeletal trauma is controversial. Some authors have suggested that this is a more sensitive screening test in cases of physical abuse, and are using it as part of the initial evaluation (53,54). In a study of 261 cases of suspected child abuse, radiographic skeletal surveys and bone scanning were performed, with meticulous attention paid to technique (54). Abnormalities were found at one or more sites on bone scans in 120 patients and on radiographs in 105 patients. False-negative results were obtained in 32 patients with radiography, but in only 2 patients with bone scanning. This report demonstrates the superior sensitivity of bone scanning to radiography under the conditions described by those authors. However, this view is not shared by most pediatric radiologists, who still prefer the skeletal survey as the primary radiologic screening test in cases of suspected child abuse. Bone scanning is more sensitive in assessing rib fractures, particularly those involving the costovertebral junction (55); acute, undisplaced long-bone fractures; and subperiosteal hemorrhage (38). Skeletal surveys are more sensitive in detecting spinal fractures, bilateral metaphyseal injuries, skull fractures, and scapular fractures.

Other factors also influence the use of these methods in the initial evaluation. Bone-seeking radionuclides concentrate in areas of increased blood flow and bone formation, so that fractures appear as hot spots. However, these findings are not specific for fractures, and can be seen in other conditions of rapid bone turnover, such as osteomyelitis and neoplasia. In addition, radionuclide uptake and activity normally are increased near the growth plate, making it more difficult to identify epiphyseal–metaphyseal fractures, especially when they are bilateral.

Other disadvantages of bone scanning as the initial skeletal imaging procedure include the limited availability of nuclear medicine services at all hours in many hospitals, the inexperience of many general radiology departments in taking and interpreting pediatric bone scans, and the relatively high radiation dose delivered to the patient's growth plates (51). In addition, bone scans not only are more costly, but they lack the ability to identify the age and mechanism of the injury, often necessitating additional radiologic examination of suspicious areas for confirmation. Skeletal surveys, on the other hand, are more specific, rarely require patient sedation, and are less subject to interpretive error. Thus, radiographic skeletal surveys should be used first in the evaluation of suspected child abuse cases. If these radiographs do not show any evidence of trauma, despite clinical suspicion, a bone scan may prove valuable in identifying subtle or occult injuries to the ribs, the diaphyses, and, occasionally, the epiphyses. Some of these occult fractures are not visible on plain radiographs until 7 to 10 days after injury. In these situations, a second radiograph 1 to 2 weeks later usually is helpful. Bone scanning should be performed as well, if the results of plain radiography are negative or questionable (Fig. 33-9). Children older than 5 years of age usually can provide a more reliable history. Radiographic studies, in these cases, are selected based on the clinical findings and the index of suspicion. CT often is helpful when head or abdominal trauma is suspected, especially if liver function test results show elevation of aspartate aminotransferase, alanine aminotransferase, and lactate dehydrogenase.

Differential Diagnosis

Coagulation disorders, both hereditary and acquired, can produce bruises that can be confused with bruises caused by physical abuse. Hereditary coagulation disorders include hemophilia and von Willebrand disease. Acquired coagulation disorders, such as idiopathic thrombocytopenia purpura and leukemia, also have been confused with physical abuse (56). In cases of suspicious or unexplained bruising, blood tests, such as complete blood count, partial thromboplastin time, prothrombin time, platelet count, and bleeding time, should be performed. A prolonged partial thromboplastin time is seen in both hemophilia and von Willebrand disease.

Many conditions can cause fractures, periosteal new bone formation, and bone irregularities, and these should be considered in the differential diagnosis of physical abuse. Errors in diagnosis can result from suboptimal radiographic techniques or errors in interpretation.

The most common difficulty in diagnosis involves the differentiation of accidental from nonaccidental trauma, especially in isolated, nonspecific fractures. An example of this was discussed in the section on diaphyseal femur fractures. Normal variants, such as periosteal new bone formation and cupping of the metaphysis, can be seen in healthy infants. These findings are observed first at 1 to 3 months of age, and usually resolve by 8 months of age (57).

Conditions to be considered in the differential diagnosis are syphilis, osteogenesis imperfecta, scurvy, Caffey disease, osteomyelitis, septic arthritis, fatigue fractures, osteoid osteoma and other tumors, rickets, hypophosphatasia, leukemia, metastatic neuroblastoma, fractures in neurogenic disorders, congenital indifference to pain, and osteopetrosis and the so-called “temporary brittle-bone disease” (58). These conditions usually have additional signs of the primary disorder and a history of previous disease, to distinguish them from nonaccidental trauma.

Osteogenesis imperfecta (OI) may be easy to diagnose when there is easy bruising, the presence of family history of the disease, blue sclerae, thin cortices, osteopenia, and the tendency to bowing and angulation, but some forms of OI are difficult to identify and could lead to a mistaken diagnosis of child abuse. Easy

bruising is not unique to OI, and could be caused by any condition associated with coagulopathy or capillary fragility. There is no family history when OI is caused by spontaneous mutation.

OI has been classified into types based on inheritance and clinical features (52,59). Type I patients have blue sclerae and normal stature, and most have hearing loss, little extremity deformity, and autosomal dominant inheritance. Type II patients have severe disease with marked deformity, and may die soon after birth; their inheritance is usually autosomal dominant, although, rarely it may be autosomal recessive. Type III patients have gradual progression of deformity and blue sclerae that may lighten with time; dentinogenesis imperfecta, a central core darkening of the teeth, is often present; stature is short, hearing loss is common, and inheritance is autosomal dominant, although it is autosomal recessive in some cases. Type IV patients have mild deformity and dentinogenesis imperfecta, some have short stature, and inheritance is autosomal dominant.

Intensely blue sclerae is consistently present only in patients with type I OI; it may be present at birth in type II or III patients, but the sclerae may become normal by adolescence; and blue sclerae may be completely absent in type IV patients (52,58,60). On the other hand, blue sclerae can be found in normal children. Long bones may have normal density in types I and IV OI, whereas type II patients frequently have osteopenic long bones. Type III OI, which is usually associated with early death, has both long-bone bowing and osteopenia. Wormian bones of the skull are usually seen only in type III disease, whereas they are often absent in types I and IV. In cases in which the diagnosis of OI cannot be made clinically, fibroblasts obtained by skin biopsy can be assayed for the abnormal procollagen found in OI (59,61,62). Although the presence of OI could explain the fractures and bruising of a child with a history of minimal trauma, the orthopaedist should always remember that children with OI can also be victims of child abuse (63).

A controversial temporary brittle-bone disease was described by Patterson and co-workers (58) in 1993, as a variant of OI. They reported 39 patients with fractures observed only within the first year of life with later spontaneous improvement. Clinically, these children also had vomiting, diarrhea, anemia, hepatomegaly, episodes of apnea, edema, and neutropenia. On radiographs, there were metaphyseal corner fractures, diaphyseal fractures, rib fractures, periosteal reaction of the long bones, lucency at the costochondral junction, and delayed bone age. Osteopenia was seen in only 31% of patients. A transient period of copper deficiency was suggested as the cause of the disease, but copper levels in selected patients were inconclusive. Other medical authors (64,65) doubt the existence of temporary brittle-bone disease, because of the rarity of fractures associated with proven copper deficiency. Judicial authorities (66,67) have commented that, although one patient in the series by Patterson et al. had injuries attributable to child abuse, this fact was not included in the study. They had concerns that assumptions by medical experts that injuries are caused solely by disease may inhibit full investigation of such injuries by civil authorities and place abused children at risk.

Congenital indifference to pain has an autosomal recessive inheritance. These children have normal intelligence, and the only abnormal neurologic finding is insensitivity to painful stimuli. Repeated trauma to the growing skeleton can go unrecognized and result in major changes and deformities of the metaphysis, as well as the epiphysis. A careful sensory neurologic examination and history helps in making the diagnosis.

Congenital syphilis involves multiple bones of the body, most commonly the tibia, femur, and humerus. Destructive changes are seen in the metaphysis and diaphysis between the first and sixth months of life. Pathologic fractures of the metaphysis and periosteal new bone formation can mimic the skeletal findings of child abuse. The serologic test for syphilis is most helpful in making the diagnosis.

In most conditions, radiologic features are helpful in differentiating the injuries of child abuse. In other conditions, clinical findings of the disease provide diagnostic clues.

Fractures in the neonatal period often involve the humerus, clavicle, and femur. In these injuries, callus usually appears on radiographs within 2 weeks of life. In this age group, an unusual site or the absence of callus after 2 weeks should alert the physician to the possibility of nonaccidental trauma (42). Pathologic fractures caused by rickets also are seen in neonates, especially premature infants.

Falling out of bed is a common history frequently related when parents bring the child to the care of a physician. Helfer and associates (68) studied 246 children younger than 5 years of age who fell out of bed. There were only three cranial fractures, three clavicular fractures, and one humeral fracture. None of the children had neurologic impairment from skull fractures. In another prospective study of 436 infants from birth to 1 year of age, 101 (30%) sustained falls (69). There were no limb fractures, and only two skull fractures. Based on these statistics, falling out of bed is rarely the cause of fractures in young infants. A large body of literature exists on the incidence of fractures in children after accidents such as falls (68,69,70,71 and 72). The orthopaedic surgeon must be familiar with this literature to interpret properly the history of the accident.

If child abuse is suspected, every effort should be made to protect the child. Although the statistics regarding the incidence of child abuse and the resulting mortality are admittedly inaccurate, it is recognized that many children may eventually die of these or subsequent injuries. The home environment in which child abuse occurs is unquestionably pathologic. Returning the child to this home in most cases poses the risk of repeated abuse, additional complications, and possible death.

The Team Approach

Because child abuse is believed to be a symptom of family distress, and a problem with multiple complex origins, it should be managed by an interdisciplinary team that can include a pediatrician, a social worker, a nurse, a psychiatrist, and an attorney. When such a diagnostic unit is not available, the physician must work with a social worker and the protective agencies to which mandated reports are sent in the management of these cases. A social worker should be contacted at the time of the family's presentation, to facilitate the social assessment and to form a helping relationship. It is helpful to avoid confrontation. The parents should be informed of the physician's responsibility, and the fact that other professionals, such as a social worker, will be talking to them. The child should be admitted to the hospital only for medical reasons. In view of the cost of hospitalization, most of the workup and referral should be accomplished in the emergency department or an outpatient facility. If this is not possible, the child should be admitted to the hospital (73). In most cases, this is acceptable to the parents, if the need is clearly explained to them. If the parents refuse admission of the child, the law in most states allows the hospital or the physician to assume custody of the child for a limited period until a court order can be obtained. A report should be made to the local protective services agency immediately. This usually is an oral report followed by a written report within 24 h. Under the Child Abuse Prevention and Treatment Act, a central registry of child abuse is required in all states. Laws mandate reporting in all states.

Abuse and neglect must be identified before child protective agencies can deal with them. An increase in public awareness has led to an increase in the number of reported incidents of abuse and neglect. Professionals who work with children are in a unique position to observe child abuse and neglect, and are required by law to report suspected cases to the authorities. Among these individuals are nurses, social workers, physicians, daycare providers, teachers, and school personnel. A reporter does not have to be certain that abuse or neglect has occurred. All that is required is a reasonable suspicion of maltreatment (74). However, some professionals are hesitant to report suspected cases, for a variety of reasons. Some of the reasons they hesitate to file reports are lack of knowledge of the responsibility to report; lack of knowledge regarding the type of cases to report, and to whom to report them; concern about confidentiality conflicts; pressure by others not to report, and the threat of lawsuits or other reprisals by parents; reluctance to get involved; and the belief that reporting would not really help and may aggravate the situation.

The amount of time and effort required in these cases also can make orthopaedic surgeons reluctant to get involved. Each case can place a significant demand on a physician's schedule for depositions, testimony, and court appearances. To avoid such involvement, the responsibility can be delegated to a child abuse team in the hospital. In most hospitals, procedures are in place for reporting and subsequent follow-up. All that may be required is that the physician start the process when suspicion of maltreatment exists. When formal teams or other professionals are not available, the orthopaedic surgeon may have no choice but to get involved. However, the legal system is cooperative and understanding. Physicians' schedules usually are accommodated, and compensation for their time is provided. Physicians should submit their hourly fees as they do for any other legal work.

Education is the most effective way to overcome the problem of underreporting. Since the creation of a nationwide toll-free telephone hotline for 24-h reporting, the number of reported cases has increased sharply. A physician or any other reporter has immunity against any civil or criminal liability (30). This means that a parent or caretaker cannot bring a successful lawsuit against a physician for defamation or for invasion of the family's right to privacy. However, in many states, failure to report subjects the physician to civil or criminal liability.

The most important phase in the management of child abuse cases is the follow-up and rehabilitation of the child and the family. In many cases, failure to provide such follow-up, because of lack of funding or personnel, has resulted in a higher rate of reinjury or death.

The following seven axioms of child abuse management appear in the literature on child abuse (75).

1. Once diagnosed, an abused child (especially an infant younger than 1 year of age) is at great risk of reinjury or continued neglect.
2. In the event that the child is reinjured, it is likely that the parents will seek care at a different medical facility.
3. There rarely is any need to establish precisely who injured the child and whether the injury was intentional. The symptoms themselves should open the door to a helping alliance and the development of a comprehensive service plan for the child and the family.
4. If there is evidence that the child is at significant risk, hospitalization may be appropriate to allow time for interdisciplinary assessment. The complex origins of the child's injuries seldom are revealed in the crisis atmosphere at the time of presentation.
5. Protection of the child must be the principal goal of intervention, but protection must go hand in hand with the development of a family-oriented service plan.
6. Traditional social casework alone may not adequately protect the abused child in the environment in which the injuries were received. Multidisciplinary follow-up is necessary, and frequent contact by all those involved in the service plan may be needed to encourage the child's healthy development.
7. Problems of public social service agencies in both urban and rural areas, especially in the number of adequately trained personnel and the quality of administrative and supervisory functions, mitigate against their effective operation in isolation from other care-providing agencies. Simply reporting a case to the public agency mandated to receive child abuse case reports may not be sufficient to protect an abused child or to help the family.

There is no doubt that prevention is the primary goal. This goal can be achieved by identifying high-risk children and helping families in distress. Orthopaedic surgeons can play an important role in breaking the cycle of child abuse and neglect by remaining aware, facilitating early detection, and helping to initiate therapeutic and rehabilitative measures for both the child and the family.

Medical Neglect

During the usual course of therapy for an orthopaedic condition, parents or caregivers may not follow the instructions provided by their treating physicians, and may not adhere to the treatment protocols. For example, the family of a child with developmental dysplasia of the hip who is being treated in a Pavlik harness may fail to bring the child for follow-up appointments, or the family of a child with a positive Ortolani sign who is being treated with a harness may remove the device after returning home, and fail to keep follow-up appointments. The family of a child with idiopathic scoliosis may refuse to use a brace, when orthotic treatment is likely to be effective. They may allow the curve to progress to 55 to 60 degrees, then refuse surgical intervention. Situations such as these are considered instances of medical neglect.

If the treatment is clearly advantageous, and the child is harmed by the lack of treatment, intervention through the proper authorities is indicated. There are situations in which a chronic condition requires more complex treatment, and the type and length of the treatment clearly present a hardship for the family. In these cases, help should be provided to the family through appropriate social workers and social service agencies. In some cases, the presence of medical neglect is uncertain. In these instances, the amount of harm caused by the lack of treatment should be compared with the benefits of treatment and an appropriate decision should be made. In more complex cases, it often is helpful for both a physician and a social worker to explain fully the nature of the treatment and the responsibility of the family before treatment is initiated. In this way, any necessary arrangements can be made before treatment is begun, to maximize compliance.

THE ORTHOPAEDIC SURGEON, CHILD ABUSE, AND THE LAW

Orthopaedic surgeons should be familiar with the law regarding child abuse. Questions about obtaining informed consent for testing, maintaining medical confidentiality, filing mandated child abuse reports, understanding court actions, and testifying in a courtroom are common. Although the law varies from state to state, the principal issues are the same. Orthopaedic surgeons should obtain appropriate legal counsel whenever necessary. The sensitive management of cases of family violence requires both medical and legal expertise (76). In many hospitals, this is facilitated by the use of a team approach, and by the maintenance of continuous contact between the department of social services, protective agencies, and the police department.

Legal consent is required for any action taken to treat an abused child. Parents or legal guardians can give this consent. A minor child cannot give consent except in an emergency or other exceptional situation. When there is a conflict with the parent or guardian, it is advisable to consult a hospital lawyer. Consent also is necessary for the release of any information from the medical record, and for testifying in court, unless a court-ordered subpoena has been issued.

The physician's findings should be recorded as soon as the patient is seen. The record in the chart should be legible, and any errors should be corrected by adding follow-up entries rather than removing previous statements.

For the purpose of identifying and protecting abused children, all 50 states have mandatory reporting statutes. The basis of notification is “reasonable suspicion or belief.” Legally, it always is better for a mandated reporter to file an abuse or neglect report, even if the allegation later proves erroneous, than to fail to file. All states have immunity provisions protecting mandated reporters. The question of privacy statutes often arises, but abuse reporting requirements override this privilege (76). After the child is examined, the report should be filed by the professional who knows the child best. This usually is the family physician, the pediatrician, or a social worker; however, the orthopaedic surgeon is responsible for reporting if he or she is suspicious, and no other report has been filed. Reports should be filed, based on the reasonable cause of the injury, and not on the characteristics of the family. Many people complain that even if a case is reported, the state does not provide appropriate protection. Again, a report should be filed, regardless of whether the state's response is helpful.

Preparation for Court Testimony in Child Abuse Cases

The number of physicians who are being required to testify in court is increasing because of the rapid increase in the volume of child abuse reports, as well as a continuing trend toward the use of litigation (77). The orthopaedist should be well prepared before appearing as a witness, and should determine the degree of certainty to which he or she is willing to testify. Although most child abuse reporting laws require reporting at the level of suspicion, actions of any sort require proof at some higher level of certainty. The process of substantiation or verification is always a medical one in cases of physical abuse.

If a physician is not willing to carry out these examinations and to testify in court as an expert witness, no legal action of any kind is possible in most child abuse cases (77). In court, the burden of proof is on the plaintiff. In the courtroom, for better or worse, it is evidence or proof that matters, not reality or fact. Most judges feel that children should remain with their parents whenever possible. The testimony of the physician as an expert witness is an important part of the process. Often, court action is the result of a “war between experts.” Of greatest concern is what the orthopaedic surgeon does not say on the witness stand or in a deposition that he or she should say, and most physicians are reluctant to become actively involved in such cases. Brent (78) has called attention to the problem of irresponsible medical experts, and has provided guidelines for responsible conduct in court. These have been adopted by the Committee on Medical Liability of the American Academy of Pediatrics in a policy statement (79) (see Appendix).

The orthopaedist will usually serve as a material witness in the courtroom. Testimony will be confined to his or her personal involvement in the care of the child, although it may include clarification of the information in progress notes or other past documentation. The expertise of the orthopaedist is also defined by the attorneys before testimony, and if this includes special knowledge of or experience with child abuse, then he or she may be sworn in as an expert witness who can render opinions about certain facts in the courtroom (80).

Preparation is of paramount importance before a deposition or trial (A. Brodeur, personal communication, July 1988). The American law system is adversarial, and the courtroom is an unfamiliar, hostile environment for most orthopaedists, where the perception of truth is just as important as the truth itself. The testimony of a witness is a response to a series of questions asked to develop a logical and progressive line of thought leading to a conclusion. In child abuse cases, the testimony concentrates on the fact that abuse has occurred, and that it has been appropriately diagnosed. Questions about medical findings may be prefaced by the legal term “is there reasonable medical certainty,” which is a concept that is poorly understood by most physicians. Reasonable medical certainty is defined by Chadwick (77) as “certain as a physician should be in order to recommend and carry out treatment for a given medical condition.” Cross-examination will search for inconsistencies in the testimony or unfamiliarity with the record to discredit the orthopaedist's testimony. To avoid being a poor witness, the orthopaedist should thoroughly review the child's medical records and the recent literature on child abuse (80).

Physicians should dress appropriately for the courtroom, appear attentive, poised, and competent, and be at ease with the testimony given (77). If they want to show radiographs, they should make sure that the necessary equipment is available.

Physicians should be objective and act as neutral experts. When a question is asked, they should pause before answering to consider the form and content of their response and to give their attorneys a chance to object. Physicians should listen carefully to each question, and answer only the question asked. They should not expand on the question or open up new issues. Answers should be framed in clear terms, understandable by anyone in the courtroom. It also is a mistake for physicians to assume that they are credible and effective just because they have a medical degree. If they do not know the answer to a question, they should say so.

Physicians should be prepared for their testimony; however, they may review a patient chart to refresh their memory on the witness stand, if necessary. Physicians should not argue with the attorney, because invariably they will appear foolish; rather, they should look to the judge for help. Attorneys may ask confusing yes-or-no questions that could place misleading words in the mouth of the orthopaedist; when neither answer is appropriate, these may be answered in a full sentence with the permission of the judge.

Another tactic in the courtroom is for the attorney to frame a complex question that contains both elements that the physician agrees with and others that the physician cannot agree with, then ending the question with the statement, “Isn't that so, doctor?” This is a way for the opposing attorney to insert facts supportive of his or her case into the testimony of the orthopaedist in a misleading manner. The orthopaedist should clearly split such questions into parts that can be agreed with and parts that cannot be agreed with (77). Attorneys may also offer hypotheses in their questions that are extremely unlikely; in their answers, physicians should point out the improbability of such theories. In making conclusions, physicians should provide supportive facts, and ensure that the link between the facts and the conclusion is clear.

Orthopaedists should become accustomed to dating fractures based on the amount of bone repair and the criteria described above. More than anyone else, orthopaedists are in a position to testify when children sustain broken bones. This type of evidence is helpful in cases in which the evidence is cumulative, rather than direct and explicit. Chadwick (77) has published an excellent article regarding preparation for court testimony (D. L. Chadwick, personal communication, March 1999).

Finally, if physicians have any doubt or uncertainty, they should consult with colleagues before testifying to formulate clear and reasonable opinions regarding the degree of certainty to which they are willing to testify. Even when the evidence is almost overwhelming, defense attorneys will attempt to prove that injuries resulted from diseases or accidents rather than abuse, and physicians must be prepared to defend their diagnoses. Although physicians should never present opinions that are not justified by the data, they should not exercise excessive caution when a child has characteristic patterns of abusive injury, and abuse is the only reasonable explanation.

APPENDIX: GUIDELINES FOR EXPERT WITNESSES

1. The physician should have current experience and ongoing knowledge about the areas of clinical medicine in which he or she is testifying and familiarity with practices during the time and place of the episode being considered as well as the circumstances surrounding the occurrence.
2. The physician's review of medical facts should be thorough, fair, and impartial and should not exclude any relevant information to create a view favoring either the plaintiff or the defendant. The ultimate test for accuracy and impartiality is a willingness to prepare testimony that could be presented unchanged for use by either the plaintiff or the defendant.
3. The physician's testimony should reflect an evaluation of performance in light of generally accepted standards, neither condemning performance that clearly falls within generally accepted practice standards nor endorsing or condoning performance that clearly falls outside accepted practice standards.
4. The physician should make a clear distinction between medical malpractice and medical maloccurrence when analyzing any case. The practice of medicine remains a mixture of art and science; the scientific component is a dynamic and changing one based to a large extent on concepts of probability rather than absolute certainty.
5. The physician should make every effort to assess the relationship of the alleged substandard practice to the patient's outcome, because deviation from a practice standard is not always causally related to a less-than-ideal outcome.
6. The physician should be willing to submit transcripts of depositions and/or courtroom testimony for peer review.
7. The physician expert should cooperate with any reasonable efforts undertaken by the courts or by the plaintiffs' or defendants' carriers and attorneys to provide a better understanding of the expert witness issue.

These principles have been adopted as guidelines by the American Academy of Pediatrics for its members who assume the role of expert witness. (From ref. 79, with permission.)
