Preface to the Fourth Edition

Obstetrics: Normal and Problem Pregnancies was published for the first time in 1986. With this fourth edition, our book thus enters its third decade. During these years, remarkable advances have occurred in some areas of obstetrics, whereas in others progress has been less marked. To provide our readers with the most important and most up-to-date information in our specialty, significant and extensive changes have been made throughout this fourth edition. Three new chapters have been added: Fetal Therapeutic Interventions, Surgical Procedures in Pregnancy, and Endocrine Diseases in Pregnancy. The chapter on Fetal Therapeutic Interventions describes especially exciting advances, both surgical and medical, emphasizing that the fetus as well as the mother is our patient. Other changes in this edition have been made for ease of reading and lucidity. With the exception of cesarean delivery, all surgical procedures in pregnancy were combined in a single chapter, emphasizing common principles of care. A separate chapter on diabetes mellitus complicating pregnancy has been developed, encompassing new information on the pathophysiology, diagnosis, and treatment of this important medical complication. We have replaced the chapter on anatomy with an appendix; readers can quickly access the excellent illustrations provided by Mikki Senkarik.

This fourth edition includes 28 authors who are making their first contributions to our textbook. They represent the vanguard of our specialty; readers will appreciate their expertise in presenting the most recent information in obstetrics. In addition to these new contributors, we want to recognize Drs. George J. Annas, Thomas J. Benedetti, Richard L. Berkowitz, Watson A. Bowes, Jr., D. Ware Branch, John E. Buster, Sherman Elias, Timothy R.B. Johnson, Mark B. Landon, Adam A. Rosenberg, Philip Samuels, John W. Seeds, Baha M. Sibai and Phillip G. Stubblefield. These luminaries have written chapters in every edition of our textbook. We thank them immensely and recognize them as leaders in our specialty.

With the acquisition of Churchill Livingstone by Harcourt Health Sciences Publishing Company, our book has benefited from the energies of a new publishing team, including Judith Fletcher and Ann Ruzycka. Readers will appreciate the more extensive use of color in headings, tables, and other key areas. In addition to the assistance provided by the staff at Harcourt Health Sciences, the editors have had the invaluable editorial and secretarial support of Susan Blewett, Nancy Schaapveld, and Belinda Felder.

This fourth edition of *Obstetrics: Normal and Problem Pregnancies*, like the three preceding it, has been a labor of love. We deliver it to you, our readers, with hopes that you will enjoy it and will find it a valuable resource.

Steven G. Gabbe M.D.
Jennifer R. Niebyl M.D.

Gabbe: Obstetrics - Normal and Problem Pregnancies, 4th ed. , Copyright © 2002 Churchill Livingstone, Inc.

Preface to the First Edition

This book is written for a new generation of obstetricians and gynecologists. Today's obstetrician must not only be able to plot and interpret a labor curve and deliver a breech presentation but also must assess fetal heart rate tracings and scalp pH data. While doing so, he or she must also consider the legal and ethical ramifications for these actions. In the past decade, the practice of obstetrics has been altered by a technologic explosion. Antepartum and intrapartum fetal monitoring, diagnostic ultrasound, and a host of advances in prenatal genetic diagnosis have enabled obstetricians to identify and understand some of the most important disease processes. This information has already led to significant improvements in maternal and perinatal outcome. Yet, the practice of obstetrics and the applications of this technology must be built on a firm base of knowledge in anatomy, embryology, physiology, pathology, genetics, and teratology.

Obstetrics: Normal and Problem Pregnancies has been written to meet these needs. The first sections of the book provide the essential foundation for the practice of obstetrics. The reader can then proceed to discussions of the problems encountered in clinical practice and finally progress to the chapters devoted to high-risk obstetrics. Where does the information necessary to be a specialist end and that needed to be a subspecialist begin? This boundary is difficult to define. It is hoped that *Obstetrics: Normal and Problem Pregnancies* will serve as a reference source for the general practice of obstetrics and provide the necessary base of information for those in fellowship programs in maternalfetal medicine.

The contributors to this book represent the vanguard in their areas of expertise. Each chapter has been written to stand on its own and, in general, can be read in one evening. As editors, we are most indebted to our collaborators for their excellent contributions and their willingness to create a new book with a new approach.

Our book could not have been written without the help of many special people. Toni M. Tracy, Editor-in-Chief at Churchill Livingstone, and Linda Panzarella, Sponsoring Editor, successfully guided us through this enormous but rewarding project. Lynne Herndon got us off to a good start. Mikki Senkarik prepared all of the original artwork for the book and, in doing so, showed her unique artistic skills and understanding. Dr. Gerald Lazarus, Chairman of the Department of Dermatology, Dr. Marshall Mintz of the Department of Radiology, and Dr. James Wheeler of the Department of Pathology, all at the Hospital of the University of Pennsylvania, provided guidance in the selection of illustrations for the chapters on infectious diseases, placental development, and antepartum fetal evaluation. Also, all of us owe so much to the secretarial support provided by Michele Simons and C. Winston Wisehart.

This is the first edition of *Obstetrics: Normal and Problem Pregnancies*. Now a neonate, it has completed its months and years of gestation. Hopefully, it will help those embarking on careers in obstetrics to enjoy the specialty as much as we have. We look forward to hearing comments, both positive and negative, from our readers.

Steven G. Gabbe M.D.
Jennifer R. Niebyl M.D.
Joe Leigh Simpson M.D.

XIV

NOTICE

Obstetrics is an ever-changing field. Standard safety precautions must be followed, but as new research and clinical experience broaden our knowledge, changes in treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current product information provided by the manufacturer of each drug to be administered to verify the recommended dose, the method and duration of administration, and contraindications. It is the responsibility of the treating physician, relying on experience and knowledge of the patient, to determine dosages and the best treatment for each individual patient. Neither the Publisher nor the editor assumes any liability for any injury and/or damage to persons or property arising from this publication.

THE PUBLISHER

Section 1 - Physiology

3

Chapter 1 - Endocrinology and Diagnosis of Pregnancy

John E. Buster
Sandra A. Carson

The evolutionary advent of viviparity necessitated changes in the maternal metabolic, hormonal, and immunologic systems. To compensate for the increased and altered demands of an intracorporeal pregnancy, a new organ the placenta and a series of proteins specific for and secreted only during pregnancy evolved. These proteins, aided by alterations in the already stimulated steroids, allow invasion of a half-foreign tissue into the maternal system that not only tolerates but actively nourishes and protects the growing fetus. The changes in the hormonal milieu also help to diagnose and monitor pregnancy, and they are the focus of this chapter.

Gabbe: Obstetrics - Normal and Problem Pregnancies, 4th ed. , Copyright © 2002 Churchill Livingstone, Inc.

PREGNANCY PROTEINS

Ontogeny of Pregnancy Protein Production

From the moment of conception, proteins are released into the maternal system by the newly formed conceptus, presumably to alter the maternal immune metabolic and hormonal responses to the advancing gestation. The production and secretion of these proteins mirror the demands that each developmental stage of gestation brings.

The Preimplantation Conceptus

Pregnancy proteins are present in the maternal circulation almost at the time of conception. Presumably released from the fertilized ovum after sperm penetration, a platelet-activating factor (PAF)-like substance is evident almost immediately.^[1]^[2]^[3]^[4] The conceptus remains in the tubal ampulla for approximately 80 hours after follicular rupture, travels through the isthmus for approximately 10 hours, and then enters the uterus as a two- to eight-cell embryo.^[5]^[6] The embryo develops into a blastocyst while freely floating in the endometrial cavity 90 to 150 hours after conception.^[6] Although human chorionic gonadotropin (hCG) mRNA is detectable in the blastomeres of six- to eight-cell embryos at 2 days, the hormone is not detectable until 6 days (blastocyst) in culture media.^[7]^[8]^[9] Secretion into the maternal serum is limited by the absence of vascular communication.^[10] Successful implantation results from a precise orchestration of cytokines and growth factors that bind the foreign embryo to the maternal interface^[11] (Fig. 1-1) (Figure Not Available) . Only after implantation is completed is hCG detectable in maternal serum, 8 to 11 days after conception.^[12]^[13]

The Implanted Conceptus

Blastomeres destined to form the placenta can be identified as trophoblasts lining the periphery of the blastocyst 5 days after conception (Fig. 1-2) . By the tenth day, invading trophoblasts have formed two distinct layers: an inner layer composed of individual, well-defined, and rapidly proliferating cells, the *cytotrophoblasts*; and an outer and thicker layer comprising a continuous mass of cell plasma containing multiple nuclei with indistinct cell borders, the *syncytiotrophoblast* (Fig. 1-3) and (Fig. 1-4) . The syncytiotrophoblasts line the fetal side of the intervillous space opposite the decidualized endometrium on the maternal side (Fig. 1-4) .

Cytotrophoblasts stain immunohistochemically for hypothalamic-like peptides: corticotropin-releasing hormone (CRH), gonadotropin-releasing hormone (GnRH), and thyrotropin-releasing hormone (TRH).^[14]^[15]^[16]^[17]^[18]^[19]^[20]^[21]^[22]^[23]^[24]^[25]^[26] The juxtaposed cytotrophoblasts stain immunohistochemically for corresponding pituitary-like peptides: adrenocorticotropic hormone (ACTH), hCG (analogous to

4

Figure 1-1 (Figure Not Available) Interface between trophoblasts and endometrium at implantation. At approximately day 7 of embryonic life, the blastocyst attaches to the uterine wall. Endometrium clamps around the blastocyst. The uterus is not receptive until the "windows of implantation" are open. Maternal estrogens are believed to induce the endometrial permissiveness needed for blastocyst attachment. Estrogens induce the release of cytokines such as leukemia inhibitory factor (LIF), interleukin-1 (IL-1), epidermal growth factor (EGF), and others. The adhesive mechanisms that regulate embryonic attachment are not well understood but likely involve the interactions of carbohydrates and phospholipids: Cho-lectin, integrin-integrin, and integrin-extracellular matrix (ECM) linkages. (Adapted from Cross JC, Werb Z, Fisher SJ: *Implantation and the placenta: key pieces of the development puzzle. Science* 266:1508, 1994, with permission.)

pituitary luteinizing hormone [LH]), and human chorionic thyrotropin (hCT). This anatomic arrangement suggests that these two layers mirror the paracrine relationship of the hypothalamic-pituitary axis^[14]^[15]^[16]^[17]^[18]^[19]^[20]^[21]^[22]^[23]^[24]^[25]^[26] (Table 1-1) .

Syncytiotrophoblasts are the principal site of placental steroid and protein hormone biosynthesis. The cells have a large surface area and line the intervillous space, which exposes them directly to the maternal bloodstream without the blood vessel endothelium and basement membrane, which separates them from the fetal circulation. Thus, both cell types are ideal for both hormone secretion and nutrient exchange.^[27] This anatomic arrangement also explains why placental proteins are secreted almost exclusively into the maternal circulation in concentrations much higher than those in the fetus.^[27]

The syncytiotrophoblast cell layer contains abundant rough endoplasmic reticulum, Golgi complexes, and mitochondria, the subcellular machinery that characterizes hormone syntheses (Fig. 1-4) . Prohormones are assembled from amino acids of maternal origin within the rough endoplasmic reticulum of the syncytiotrophoblast. Assembled into early secretory granules in the Golgi complex, these prohormones are transferred across trophoblastic cell membranes as mature granules. The mature granules then become soluble as circulating hormones in maternal blood passing through the intervillous space^[27] (Fig. 1-4) .

Decidualized endometrium is a site of maternal steroid and protein biosynthesis that is related directly to the maintenance and protection of the pregnancy from immunologic rejection.

The Mature Placenta

Throughout the second and third trimesters, the placenta adapts its structure to reflect its function. As fetomaternal exchange dominates hormone secretory functions, the relative numbers of trophoblasts decrease.^[19] The villi near term (Fig. 1-4) and (Fig. 1-5) consist largely of fetal capillaries with little or no stroma beyond that required for anatomic integrity. Cytotrophoblasts are sparse, and the remaining syncytium is thin, scarcely visible by light microscopy. In contrast to the early villus, in which the trophoblasts are present in abundance with a continuous basal cytotrophoblast layer and an overlying surface syncytium, the placenta's membranous interface between fetal and maternal circulation is extremely thin.^[27] This villous structure facilitates specialized transport of compounds across the fetomaternal interface.^[27]

5

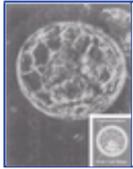

Figure 1-2 The human preimplantation blastocyst. The inner cell mass, the cells destined to form embryonic structure, are seen between 3 and 6 o'clock. Trophoblast, comprising the remainder, evolves into placenta and membranes. (Adapted from Buster JE, Bustillo M, Rodi LA, et al: *Biological and morphologic development of donated human ova recovered by nonsurgical uterine lavage. Am J Obstet Gynecol* 153:211, 1985.)

Physiology of Pregnancy Proteins

The sequential appearance is characteristic for each protein, reflecting their various functions unique to pregnancy (Table 1-1).

Early Pregnancy Factor

MOLECULAR STRUCTURE.

Early pregnancy factor (EPF) has been purified from human platelets and found to be closely homologous to chaperonin 10 (cpn10), a member of the heat-shock family of proteins.^[2] Cpn10 is an intracellular protein that is believed to act together with chaperonin 60 (cpn60) within mitochondria to mediate protein folding.^{[1], [2]} EPF, a product of platelet activation and cell proliferation, is secreted into the circulation from cytoplasm by unknown mechanisms. Chaperonin proteins are believed to be highly potent immunosuppressants that assemble immunoglobulins, direct lymphocyte homing, and suppress some autoimmune diseases.^{[1], [2]} Although they act intracellularly, they are also expressed on the cell surface.^{[1], [2]} One group of investigators reports having purified EPF from human platelets.^{[29], [30]} This cpn10 homologue has a molecular mass of 10,843.5 Da.^[28] The only assay for EPF is a bioassay, the rosette inhibition test. The rosette inhibition test assesses ability of lymphocytes to bind in vitro and is quantitated by the degree to which rosette formation between lymphocytes and heterologous (sheep) red blood cells is inhibited.^{[1], [2]} This bioassay is lengthy, tedious, and imprecise. No radioimmunoassay has been described.

ORIGIN.

That EPF is a single molecular substance is not accepted by all investigators.^{[31] [32] [33] [34] [35]} EPF is believed to be produced within activated platelets, the maternal ovaries, and other maternal tissues.^{[1] [2] [3] [4]} Its release is stimulated by a PAF that is released from the conceptus at fertilization (Fig. 1-6).^{[3], [4]} It is believed that sperm entry into the ovum releases PAF, which circulates to other maternal tissues.^{[3], [4]} PAF also acts upon the ovum itself to stimulate local EPF release. By blastocyst stage, this local EPF may have endometrial immunosuppressive function.^{[1], [2]} Because embryonic EPF probably does not reach the circulation until implantation, removal of the ovaries in experimental animals shortly after conception, but before implantation, produces immediate disappearance of EPF from the circulation.^{[3], [4]}

NORMAL VARIATION.

Serum EPF is the earliest known marker of fertilization. It is detectable in the circulation within 6 to 24 hours after conception, with maximum levels reached in the early first trimester, diminishing to almost undetectable levels at term^{[1], [2]} (Fig. 1-7). In early human studies, EPF was detected after intercourse in 18 of 28 ovulatory cycles, suggesting a fertilization rate of 67 percent. Embryonic loss was high (78 percent), because EPF disappeared from the circulation before the onset of menstruation in 14 of 18 cases.^[36] In the remaining four cases, EPF remained detectable beyond 14

Figure 1-3 Postimplantation embryo and early placental structures. Trophoblasts are seen to invade maternal decidua, which contains blood-filled lacunar spaces. The embryo has evolved as a simple embryonic disk in association with a very large yolk sac and developing amniotic cavity.

6

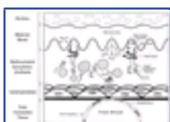

Figure 1-4 The human placenta at term in a cross-sectional electron microscopic view. Syncytiotrophoblasts line the fetal surface of the intervillous space and interact with the maternal blood supply to secrete placental proteins directly into the circulation. Decidua lines maternal surfaces of the intervillous space and secretes its own unique protein hormones into the maternal circulation. (Adapted from Osathanondh R, Tulchinsky D: *Placental polypeptide hormones. In Tulchinsky D, Ryan KJ [eds]: Maternal-Fetal Endocrinology. Philadelphia, WB Saunders Company, 1980, p 18.*)

days with presence of a viable embryo.^[36] EPF appears within 48 hours after successful in vitro fertilization and embryo transfer.^{[1], [2]} It disappears within 24 hours after reduced abortion and is undetectable in many spontaneous abortions, ectopic pregnancies, and following a complete removal of gestational trophoblastic diseases.^{[36] [37] [38] [39] [40] [41] [42] [43]} EPF is detectable in cases of latent trophoblastic disease and disappears when the disease resolves completely.^[43]

Inability to detect EPF during pregnancy portends a poor prognosis. Clinical application of EPF measurements is promising but elusive because of difficulties in isolating the molecule and developing practical assays for it.^{[1] [2] [3] [4]}

FUNCTION.

EPF is believed to prevent rejection of an antigenically alien embryo. Binding to a specific lymphocyte population, it recruits suppressor cells that in turn release soluble suppressor factors that are believed to protect the pregnancy.^{[1], [2], [44], [45]} In its association with dividing cells, EPF also has properties of a growth factor that regulates cell proliferation.^{[1], [2], [44], [45]}

The coding sequence for EPF has a high degree of homology with a sequence for human cpn10.^[46] Sequences have been identified in nine locations on eight different chromosomes, suggesting that EPF is a member of a large gene family.^[46] EPF-like molecules have also been obtained in culture supernatants from stimulated lymphocytes of pregnant women.^{[29], [30]} EPF activity has been confirmed in these supernatants by the rosette inhibition test.^{[29], [30]}

Placental Proteins

Placental protein hormone synthesis may be a direct reflection of both trophoblastic mass and intervillous maternal blood flow.^[27] Control of their release is poorly understood; one hypothesis suggests that placental hormone production is regulated by negative feedback to maintain a fixed intervillous hormone concentration. An alternative hypothesis suggests the hypothalamic-like placental peptides (CRH, GnRH, TRH, and somatostatin [SRIF]), located in the cytotrophoblasts, stimulate the pituitary-like placental hormones (ACTH, hCG, and hCT) located in the adjacent syncytiotrophoblasts.^{[14] [15] [16] [17] [18] [19] [20] [21] [22] [23] [24] [25] [26] [27]} The former hypothesis is only speculative, but does prove a convenient grouping of hormones which, for heuristic reasons, is used in this discussion (Table 1-1).

PITUITARY-LIKE HORMONES

Human Chorionic Gonadotropin

Molecular Structure.

HCG is a glycoprotein with structural similarity to follicle-stimulating hormone (FSH), LH, and thyroid-stimulating hormone (TSH). As are the other glycoprotein hormones, hCG is composed of two nonidentical subunits associated noncovalently [14], [47] (Fig. 1-8) (Figure Not Available). The subunit consists of a 92-amino-acid sequence essentially identical and shared in common with the pituitary glycoprotein hormones (Fig. 1-8) (Figure Not Available). The subunit, although structurally similar, differs just enough to confer specific biologic activity on the intact (dimer) hormones. The subunits differ primarily at the COOH terminus, where the subunit of hCG has a 30-amino-acid tailpiece that is not present in the human luteinizing hormone (hLH) subunit. Assuming an average carbohydrate content of 30 percent, the molecular weight of dimer hCG is approximately 36.7 kDa; the subunit contributes 14.5 kDa and the subunit 22.2 kDa. [47] Biologic activity of the hCG molecule is profoundly affected by its carbohydrate content and its resulting tertiary structure (Fig. 1-9). [48] [49] [50] Desialation of pregnancy hCG renders the molecule biologically inactive. [48]

Origin.

HCG mRNA is detectable in blastomeres of six-to eight-cell embryos. [7] After implantation, hormonal hCG is present in the outer syncytial layer. [12], [22] [23] [24] -HCG subunits are localized to the cytotrophoblasts with none in the syncytial layer. [19], [22]

HCG secretion is related to the mass of the hCG-secreting trophoblastic tissues. Thus, the release of hCG in vivo has been correlated with the respective trophoblast layer widths from weeks 4 through 20 and with placental weights from 20 to 38 weeks. [19] Between 3 and 9 weeks' gestation, rapidly rising hCG coincides with proliferation of immature trophoblastic villi and an extensive syncytial layer. [19] Between 10 and 18 weeks' gestation, declining hCG is associated with a relative reduction in syncytiotrophoblasts and cytotrophoblasts (Fig. 1-5). From 20 weeks to term, a gradual increase in dimer hCG corresponds with a gradual increase in placental weight and villus volume. [19] In summary, rising hCG reflects the histology of a rapidly proliferating and invasive placenta. Falling hCG is associated with a relative reduction in trophoblasts

Figure 1-5 A, Gross morphology of the human placenta. The effects of advancing gestation on placental morphology evolve from left to right. Placental mass increases and hormonally active and invasive trophoblasts compose a lesser percentage of the total mass as the placenta evolves as an organ of transfer. *B*, Anatomic structure of early and late terminal villi. These transverse sections through terminal villi are from early (*left*) and term (*right*) pregnancy. Cytotrophoblastic cells become infrequent with placental maturity. Increasing fibrin deposits occur by term gestation as placental function adapts more to maternal fetal transfer and relatively less to hormone production. Fetal capillary endothelium is the only structure separating the maternal circulation from the fetal circulation in the mature placenta. (Modified from Williams L, Warwick L: *Gray's Anatomy*, 36th ed. Philadelphia, WB Saunders Company, 1980, p 125.)

and reflects a morphologic transformation of the placenta into an organ of transfer. [19]

HCG secretion is linked to placental GnRH. [51] In an in vitro trophoblast perfusion system, hCG is released in 11- to 22-minute pulses, where the pulse frequency and amplitude are believed entrained to the release of placental GnRH. [51] HCG production is stimulated by glucocorticoids and suppressed by dehydroepiandrosterone sulfate (DHEA-S). [52] Cyclic adenosine monophosphate (cAMP) analogues augment secretion of hCG and -hCG in vitro. [51], [52] Decidual inhibin and prolactin inhibit hCG production by term human trophoblasts, whereas decidual activin augments it. [47], [53]

In a countermechanism, follistatin binds activin and therefore inhibits the stimulatory activity of activin. Other growth factors (insulin-like growth factor 1 [IGF-1], IGF-2, transforming growth factor- [TGF-] and epidermal growth factor [EGF]) also impact on gene regulation of the hCG system in the placenta. ^[54], ^[55]

Although nonpregnancy tissues make hCG, the placenta uniquely glycosylates it (Fig. 1-9). ^[48] ^[49] ^[50], ^[56] ^[57] ^[58] Glycosylation substantially reduces hCG clearance; consequently, the half-life of pregnancy hCG is extended (Fig. 1-9). ^[49] Thus, nonpregnancy hCG has a very short half-life, as does hLH. ^[48], ^[59] The DNA sequences of the -hCG gene and the -LH gene are close to identical; however, different promoter and transcriptional sites uniquely located upstream in the -hCG subunit gene, as opposed to -LH subunit gene, confirm structure as well as regulation. ^[60] It has been suggested that hCG secretion escapes feedback regulation by the sex steroids, because the -hCG subunit promoter does not contain steroid hormonal response elements, a phenomenon in contradistinction to FSH and LH. ^[60] ^[61] ^[62] ^[63] The genes that encode for the subunits of LH, hCG, and TSH are located on chromosome 19q13.3. There are reportedly six genes for the subunit of hCG as opposed to only one for -LH. There appears to be a single human gene for the expression of the subunit. That gene, which also codes for subunits of FSH, LH, and TSH, is located on chromosome 6p21.1 ^[60] Whereas the subunit gene is expressed in many different cell types, the subunit genes are restricted in cell type (i.e., -TSH in thyrotropes, -FSH in gonadotropes,

9

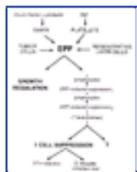

Figure 1-6 Flow chart demonstrating multiple sources of EPF. It is believed to be produced within activated platelets, maternal ovaries, and other maternal tissues. Ovum factor, a form of platelet activating factor, is thought to be released from the conceptus at fertilization, which leads to the above immunologic cascade. DTH, delayed tissue hypersensitivity (Modified from Morton H: Early pregnancy factor: an extracellular chaperonin 10 homologue. *Immunol Cell Biol* 76:483, 1998, with permission.)

and -hCG in the placenta). ^[60] ^[61] ^[62] ^[63] HCG may be secreted by maternal tissues including kidneys and pituitary. ^[56] ^[57] ^[58] Pituitary secretion of hCG in very small amounts is probably a normal event in healthy postmenopausal women. ^[59] There are rare case reports of larger amounts being secreted from this source. ^[56]

Normal Variation.

Figure 1-10 depicts maternal levels of dimer hCG, -hCG subunits, and -hCG subunits from 3 to 40 weeks gestational age. ^[19] At 4 weeks' gestation, mean doubling times of dimer hCG are 2.2 (SD ± 0.8) days, falling to 3.5 (SD ± 1.2) days at 9 weeks. ^[19] The peak median level is 108,800 mIU/ml at 10 weeks. ^[19] Between 12 and 16 weeks, median dimer hCG decreases rapidly, with a mean halving time of 2.5 (SD ± 1.1) days to 25 percent of first-trimester peak values. Levels continue to fall, from 16 to 22 weeks, at a slower mean halving rate of 4.1 (SD ± 1.8) days to become 10.7 percent of peak first-trimester median hCG. ^[19] During the third trimester, mean hCG rises gradually but significantly from 22 weeks until term. ^[19]

-hCG subunit levels parallel dimer hCG (Fig. 1-10B). -hCG, not detectable until about 6 weeks, rises in a sigmoid curve to reach peak levels in 36 weeks (Fig. 1-10C). Levels of subunit are very low relative to dimer hCG, approximately 2,000-fold to 150-fold less at 6 and 35 weeks, respectively ^[19] (Fig. 1-10C).

"Nicked hCG," hCG molecules missing a peptide linkage on the subunit, increase with advancing gestation in parallel with free subunits into which it disassociates. ^[64] A final reduced fragment, the core fragment, is a product of renal metabolism and is cleared through the kidneys. These are over 30 known hCG isoforms present in maternal blood, with calculating concentrations similar and parallel to the increases observed in hCG in early pregnancy and the decreasing levels seen as pregnancy advances to term. ^[64]

HCG secretion may be increased in cases of fetal Down syndrome, where up-regulation of hCG occurs as an effect of the extra chromosome 21. ^[65]

Function.

HCG is believed to be the major factor in maintaining the corpus luteum. ^[66] It stimulates both adrenal and placental steroidogenesis, ^[67] and it stimulates the fetal testes to secrete increasing amounts of testosterone to induce internal virilization. ^[68] HCG is immunosuppressive and may be involved in maternal lymphocyte function. ^[69] Finally, HCG possesses thyrotrophic activity. ^[70]

Adrenocorticotropin

Molecular Structure and Origin.

Placental ACTH is structurally similar to pituitary ACTH. Under paracrine influence of placental CRH from the juxtaposed cytotrophoblasts,

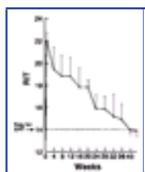

Figure 1-7 Early pregnancy factor (EPF) activity in serum tested before and at various times throughout pregnancy and after parturition. EPF activity is expressed as rosette inhibition titre (RIT; mean ± SEM). Broken lines indicate the RIT obtained with nonpregnant serum. (From Morton H, Rolfe BE, Cavanagh AC: Ovum factor and early pregnancy factor. *Curr Top Dev Biol* 23:73, 1987.)

10

Figure 1-8 (Figure Not Available) HCG and LH amino acid cores. They are structurally similar to one another except for a "tailpiece" at the terminus of the side chain of hCG, which makes the latter structurally distinct. Disulfide bonds are marked with dark lines. Structural homology (inset) is shown for hCGs and three other pituitary glycoprotein hormones, LH, FSH, and TSH. The -chain of hCG is biochemically and immunologically similar to the -chain of the three pituitary glycoproteins. (Modified from Ren SG, Braunstein GD: Human chorionic gonadotropin. *Semin Reprod Endocrinol* 10:95, 1992; and Walker WH, Fitzpatrick SL, Barrera-Saldana HA, et al: The human placental lactogen genes: structure function, evolution and transcriptional regulation. *Endocr Soc* 4:316, 1991. © The Endocrine Society, with permission.)

placental ACTH is produced by the syncytiotrophoblasts and secreted into the maternal circulation. ^[71] ^[72] ^[73]

Normal Variation and Function.

Circulating maternal ACTH is increased above nonpregnancy levels, but remains within the upper normal range. ^[72], ^[74] Placental ACTH stimulates an increase in circulating maternal free cortisol resistant to dexamethasone suppression. ^[71], ^[74] Thus, the relative hypercortisolism of pregnancy occurs despite a high normal ACTH concentration. This regulation is made possible by two differences in endocrine relationships during pregnancy. First, maternal ACTH response to exogenous CRH is blunted. ^[74] Second, a paradoxical relationship exists between placental ACTH and CRH and their end-organ product, cortisol: glucocorticoids augment placental CRH and ACTH secretion. ^[74] ^[75] ^[76] Teleologically, this positive feedback mechanism allows an increase in glucocorticoid secretion in times of stress over and above the amount necessary if the mother was not pregnant. ^[76]

Human Somatomammotropin

Molecular Structure and Origin.

Human chorionic somatomammotropin (hCS), or human placental lactogen (hPL), is a single-chain polypeptide with two intramolecular disulfide bridges and a molecular weight of 22.3 kDa. Of the 191 amino acids, 167 (85 percent) are identical to human pituitary growth hormone and human pituitary prolactin.^[77],^[78] Accordingly, hCS shares biologic properties with both growth hormone and prolactin.^[77],^[78] The hCS gene belongs to a superfamily of five closely related genes localized contiguously on chromosome 17.^[79] HCS is produced in the syncytiotrophoblast.

Normal Variation.

First detectable during the fifth week, hCS rises throughout pregnancy but maintains a constant

11

Figure 1-9 Tertiary structure of homodimer hCG by crystallography. This model represents two mature subunits joined through the C-terminal peptide of the first subunit. These homodimer molecules can recombine with two free subunits. The two subunits are believed to fold upon each other as a globular structure. This model also illustrates the configurational impact of glycosylation. Desialylation of intact pregnancy hCG reduces the molecule to its amino acid backbone and renders the hormone biologically inactive. Subunits are represented by the dark shaded areas and subunits by the lighter shaded areas. (From Lustbader JW, Pollak S, Lobel L, et al: *Three-dimensional structures of gonadotropins*. *Mol Cell Endocrinol* 125:21, 1996; and Lustbader JW, Lobel L, Wu H, et al: *Structural and molecular studies of human chorionic gonadotropin and its receptor*. *Recent Prog Horm Res* 53:395, 1998, with permission.)

hormone weight/placental weight relationship.^[80] Concentrations reach their highest during the third trimester, from 3.3 µg/ml to 25 µg/ml at term^[80] (Fig. 1-11). HCS levels rise and fall in response to fasting and glucose loading.^[81]

Function.

HCS antagonizes insulin action, inducing glucose intolerance, lipolysis, and proteolysis in the maternal system (see Chapter 32). The hormone is thought to promote transfer of glucose and amino acids to the fetus.^[78] HCS is believed responsible for marked increases in maternal plasma IGF-1 concentrations as pregnancies approach term.^[80]^[81]^[82] It enhances insulin secretion, impairs glucose tolerance, and promotes nitrogen retention in pregnant and nonpregnant women^[79]^[80]^[81]^[82]^[83] (Fig. 1-12). Surprisingly, women without the hCS gene have no detectable hCS but experience normal pregnancy outcome.^[84]

Human Chorionic Thyrotropin.

HCT is structurally similar to pituitary TSH but does not have the common subunit.^[85] Placental content of hCT is very small.^[20] HCG also has thyrotropic activity and probably has more significant effects on maternal thyroid function than does hCT.^[86]

HYPOTHALAMIC-LIKE HORMONES

Gonadotropin-Releasing Hormone

Molecular Structure and Origin.

Placental GnRH is biologically and immunologically similar to the hypothalamic decapeptide GnRH.^[16]

Origin.

GnRH activity has been localized to the cytotrophoblastic cells along the outer surface layer of the syncytiotrophoblast.^[16] HCG is localized to adjacent syncytiotrophoblast.

Normal Variation.

GnRH histochemical activity peaks at 8 weeks and then decreases with advancing gestational age.^[16]^[17]^[18]^[19] These changes parallel hCG concentration in both the placenta and maternal circulation.^[19]

Function.

Placental GnRH stimulates hCG release through a dose-dependent paracrine mechanism.^[51] In first-trimester placental tissue culture, there is little hCG augmentation by GnRH because hCG production is already close to maximum.^[51] In the second trimester, however, there is marked dose-dependent hCG augmentation of hCG release in vitro. This effect diminishes in the term placenta. In a superfusion system, 1-minute infusions of GnRH analog significantly increased pulse amplitude and frequency of hCG secretion.^[51] GnRH administered intravenously during pregnancy does not increase serum hCG, presumably because placental GnRH receptors have low affinity and the GnRH is diluted in the maternal circulation. It is more likely that locally produced GnRH is the mechanism for stimulation of placental hCG.^[51]

Corticotropin-Releasing Hormone

Molecular Structure.

Placental CRH appears to be structurally similar to the 41-amino-acid hypothalamic CRH peptide,^[87]^[88] and is therefore readily measured by radioimmunoassay in amniotic fluid, fetal plasma, and maternal plasma. Both hypothalamic and placental CRH are products of the same gene, which is located on the long arm of chromosome 8.^[89]

Origin.

Pro-CRH messenger RNA is present in the cytotrophoblast.^[89] CRH activity is most intense in cytotrophoblasts during the first trimester and diminishes toward term.^[19] Also, there is intense CRH immunoreactivity in the decidua.^[15]

Normal Variation.

CRH immunoreactivity has been measured in maternal plasma, fetal plasma, and amniotic fluid.^[90]^[91] Maternal CRH increases sharply at 20 weeks' gestation, reaching highest concentrations at term^[90] (Fig. 1-13) (Figure Not Available). Although concentrations in umbilical plasma are lower than in maternal plasma, there is a highly significant correlation between maternal and umbilical plasma CRH.^[90] In amniotic fluid, there is an

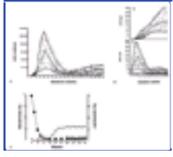

Figure 1-10 A, Dimeric hCG levels (mIU/ml) in 500 serum samples collected between 3 and 40 weeks' gestation (LMP) from 55 patients. The 5, 50, and 95 centiles are shown. B, Subunits of serum -hCG (a) and -hCG (b) measured directly without correcting for hCG cross-reaction; centiles 5, 50, and 95 are shown. C, The mean percentage -hCG/dimer () -hCG/dimer () -hCG/dimer ratios between 3 and 40 weeks' gestational age. (From Hay DL, Lopata A: *Chorionic gonadotropin secretion by human embryos in vitro*. *J Clin Endocrinol Metab* 67:1322, 1988, with permission.)

approximately threefold rise between the second and third trimesters. ^[90], ^[91]

Function.

Placental CRH stimulates placental ACTH release in vitro in a dose-dependent relationship. ^[52], ^[76] Both CRH and ACTH are released into the fetal and maternal circulations, although their activity is moderated by a maternal CRH-binding protein. ^[92] Placental CRH participates in the surge of fetal glucocorticoids associated with late third-trimester fetal maturation. ^[52], ^[90], ^[92] Secretion of both CRH and ACTH increases when uterine blood flow is restricted. CRH is a potent uteroplacental vasodilator. ^[93], ^[94] CRH is released into the fetal circulation in response to fetal stress and in conditions leading to growth restriction. ^[95] ^[96] ^[97] High circulating maternal CRH is believed responsible for the elevated plasma ACTH and cortisol in pregnant women, which renders them unresponsive to feedback suppression of plasma cortisol. ^[52], ^[90] ^[91] ^[92] ^[93] CRH stimulates prostaglandin synthesis in fetal membranes and placenta. Finally, CRH is frequently elevated in preeclampsia, fetal asphyxia and premature labor, and various conditions causing growth restriction. ^[95] ^[96] ^[97]

Somatostatin.

A substance similar to SRIF is identifiable in cytotrophoblasts and decidual stroma. Although it is logical to suggest that somatostatin is an hCS inhibiting factor, this cannot be confirmed in vitro. ^[99]

Thyrotropin-Releasing Hormone.

TRH has been detected in the cytotrophoblast; however, the molecule is chromatographically different from the hypothalamic TRH tripeptide. ^[85] Because the principal placental thyroid-stimulator is believed to be hCG, a significant role for placental TRH is tenuous. ^[86]

GROWTH FACTORS

Inhibin and Activin

Molecular Structure.

Inhibin and activin are heterodimeric glycoproteins each with two subunits.

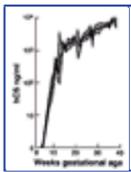

Figure 1-11 Weekly concentrations of hCS (ng/ml) in maternal plasma throughout pregnancy. Solid lines represents the geometric mean; shaded area represents predicted 95% confidence interval widths. (Modified from Braunstein GD, Rasor JL, Wade ME: *Interrelationships of human chorionic gonadotropin, human placental lactogen, and pregnancy specific beta-1 glycoprotein throughout normal human gestation*. *Am J Obstet Gynecol* 138:1205, 1980.)

Origin.

Inhibin and activin dimers have been localized to syncytiotrophoblast, with their subunits detected in both cytotrophoblasts and syncytiotrophoblasts. ^[100] Inhibin is secreted by the corpus luteum and has been detected in decidua. ^[101], ^[102]

Normal Variation.

Dimeric inhibin () in the maternal circulation begins to increase above nonpregnant levels by 12 days after conception, dramatically increasing at 5 gestational weeks to peak at 8 to 10 weeks. A subsequent decrease is observed at 13 weeks, stabilizes until 30 weeks, and then rises again with the approach of term ^[103] (Fig. 1-14). The early fluctuations in inhibin concentration probably reflect corpus luteum release, whereas the third-trimester increase probably reflects inhibin originating from the placenta and decidua. Inhibin disappears to nondetectable levels after delivery. Inhibin dimer has a similar pattern throughout pregnancy. ^[103]

Function.

Placental inhibin, functioning through a paracrine mechanism, is believed to inhibit the release of chorionic GnRH and hCG. ^[53], ^[104] Activin stimulates release of GnRH and hCG. Decidual activin and inhibin probably have the same effects and appear to serve a role whereby maternal tissues modulate chorionic GnRH and hCG production. Potential immunosuppressive and mitogenic roles have been suggested. ^[104]

Insulin-like Growth Factor.

The placenta is an important site of intrauterine IGF-1 and IGF-2 synthesis. ^[105] Syncytiotrophoblasts from second-trimester placentas transcribe IGF-1 mRNA; IGF-2 mRNA is found in placental

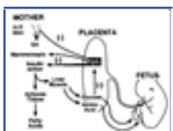

Figure 1-12 Physiologic role of hCS during pregnancy. The current model of the functional role of hCS in maternal metabolism is that hCS preferentially increases glucose availability for the fetus by its lipolytic and insulin antagonist activity. (Modified from Yen SCC: *Endocrinology or pregnancy*. In Creasy RK, Resnick R. [eds]: *Maternal-Fetal Medicine: Principles and Practice*. Philadelphia, WB Saunders Company, 1989, p 382.)

fibroblasts. Human placental tissues are rich in IGF receptors. ^[106], ^[107] IGF-1 stimulates prolactin synthesis in human decidual cells and may affect steroidogenesis. ^[78]

Transforming Growth Factor-

TGF- has been purified from placenta and is thought to be a paracrine regulator of mesenchyme-epithelium interactions. ^[55], ^[108]

Epidermal Growth Factor.

EGF is synthesized by the syncytiotrophoblast, and EGF receptors are observed

Figure 1-13 (Figure Not Available) Maternal serum concentrations of immunoreactive CRH in 256 individual pregnant women in relation to gestational age and postpartum (mean \pm SD). Clin Endocrinol* 38:101, 1993.)

on these same cells. EGF has been shown to increase release of hCG and hCS. ^[55], ^[109]

OTHER PREGNANCY-RELATED PEPTIDES

Besides the chorionic glycoproteins, which are analogous to pituitary glycoproteins present in the nonpregnant state, the placenta secretes a host of proteins with no known analog in the nonpregnant state. One group of these proteins was first identified by producing an antiserum to serum drawn in term pregnancy. Antiserum was then used to isolate and identify the pregnancy associated plasma proteins (PAPP) A through D. A second group was isolated by extraction of proteins from placental tissue that was later purified and characterized as pregnancy-specific 1-glycoprotein (Schwanger-schaftsspezifische protein 1 [SP-1]).

Pregnancy Specific 1-Glycoprotein.

This glycoprotein has a molecular weight of about 100 kDa. Secreted from trophoblastic cells, it is detected 18 to 23 days after ovulation. ^[110], ^[111] Rising initially with an approximate 2- to 3-day doubling time, it reaches peak concentrations of 100 to 200 ng/ml at term. SP-1 is a potent immunosuppressor of lymphocyte proliferation and may help to prevent rejection of the conceptus. ^[112]

Pregnancy Associated Plasma Protein-A.

PAPP-A, the largest of the pregnancy-related glycoproteins, has a molecular weight of 750 kDa. It originates principally from placental syncytiotrophoblasts. ^[113], ^[114] It is first detected at a mean time of 33 days after ovulation. It then rises initially with a 3-day doubling time and continues to rise until term. ^[113] PAPP-A may serve an immunosuppressive role during pregnancy. ^[114]

Placental Protein-5.

A glycoprotein with a molecular weight of 36 kDa, placental protein 5 (PP5) is believed to be produced in the syncytiotrophoblasts. It is detected about 42 days after ovulation, with a continuous rise until term. ^[115] Because PP5 has anti-thrombin and anti-plasmin activities, it is believed to be a natural blood coagulation inhibitor active at the implantation site. ^[116]

Decidual Proteins

PROLACTIN

Molecular Structure.

Decidual prolactin is a 197- to 199-amino-acid peptide with chemical and biologic properties identical to pituitary prolactin. ^[78]

Origin.

Prolactin, produced by decidualized endometrium, is first detectable in the endometrium on cycle day 23, a time corresponding to implantation. Decidual prolactin secretion is thought to be induced by progesterone or a combination of estrogen and progesterone ^[117] with growth factors (e.g., IGF-1) and other poly-peptide hormones (-hCG) as co-regulators. Decidual prolactin is transported across intact amnion and chorion from adherent decidua and released into the amniotic fluid with little entering the fetal or maternal circulation. ^[118] Production, independent of dopaminergic control, is not affected by bromocriptine. ^[78] Circulating fetal prolactin is secreted by the fetal pituitary, while circulating maternal prolactin is secreted by the maternal pituitary under the influence of estrogens. Both are suppressed by maternal ingestion of bromocriptine.

Normal Variation.

Decidual prolactin parallels the rapid rise in maternal serum prolactin until 10 weeks' gestation, rises rapidly until 20 weeks, and then falls as term approaches ^[119] (Fig. 1-15).

Function.

Decidual prolactin regulates fluid and electrolyte flux through fetal membranes. Decidual prolactin reduces permeability of the amnion in the fetal to maternal direction. ^[78], ^[117], ^[118], ^[120] ^[121] ^[122] ^[123] ^[124]

RELAXIN

Relaxin is a 6-kDa peptide hormone, structurally related to insulin, comprised of two short peptide chains that are linked by disulfide bridges. ^[125] ^[126] ^[127] It is believed that the corpus luteum is the major source of this hormone;

15

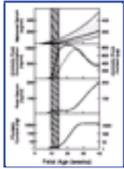

Figure 1-15 Amniotic fluid prolactin peaks in the second trimester and declines toward term. In contrast, maternal and fetal prolactin increase to maximum level during the third trimester. Solid line = amniotic fluid concentration; dotted line = amniotic fluid content. (From Clements JA, Reyes FI, Winter JS, et al: *Studies on human sexual development, IV: fetal pituitary and serum, and amniotic fluid concentrations of prolactin.* *J Clin Endocrinol Metab* 44:408, 1977, with permission.)

however, relaxin has been identified in the placenta and decidua. Relaxin is undetectable in women without ovaries and appears nonessential in normal pregnancy outcome.^{[125] [126] [127]}

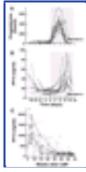

Figure 1-17 A, Serum progesterone and (B) PP14 concentrations in serum of normally ovulating women. PP14 rises approximately 8 days after the luteal phase rise of progesterone and remains elevated well into the next cycle. C, PP14 concentrations in maternal serum throughout pregnancy. (A and B from Seppala M, Riittinen L, Kamarainen M, et al: *Placental protein 14/progesterone-associated endometrial protein revisited.* *Semin Reprod Endocrinol* 10:164, 1992; C from Julkunen M, Rutanen EM, Koskimies A, et al: *Distribution of placental protein 14 in tissues and body fluids during pregnancy.* *Br J Obstet Gynaecol* 92:1145, 1985, with permission.)

IGF-1 BINDING PROTEIN (IGF-1BP OR PP12)

IGF-1 binding protein (IGF-1BP) contains 234 amino acids, with a molecular mass of approximately 25 kDa.^[128] IGF-1BP is believed to originate from decidual stromal cells. In nonpregnant women, circulating IGF-1BP does not change with the cyclicity of the endometrium. However, during pregnancy, there is a severalfold increase in serum IGF-1BP levels that begins

16

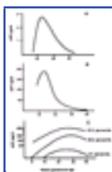

Figure 1-18 Normal median concentrations of AFP in fetal serum (A), amniotic fluid (B), and maternal serum (C). Maternal serum is shown with 2.5 and 97.5 percentile limits. (From Habib ZA: *Maternal serum alpha-feto-protein: its value in antenatal diagnosis of genetic disease and in obstetrical-gynaecological care.* *Acta Obstet Gynecol Scand* 61:1, 1977, with permission.)

during the first trimester, peaks during second trimester, falls, and then peaks a second time before term^[129] (Fig. 1-16) (Figure Not Available). IGF-1BP inhibits the binding of IGF-1 to receptors in the decidua.^[129]

PLACENTAL PROTEIN

Placental protein (PP14) is a glycoprotein with 162 amino acids and a molecular weight of 28 kDa. It is synthesized in secretory and decidualized endometrium and is detectable on menstrual cycle day 24.^[130] PP14 in serum rises sharply on days 22 to 24 of the cycle, reaches peak values at the onset of menstruation, and is maintained at high levels if pregnancy occurs.^{[131] [132]} In pregnant women, PP14 rises in parallel with hCG^[130] (Fig. 1-17). PP14 levels are very low in patients with ectopic pregnancy, in which there is minimal decidual reaction. PP14 is thought to be an immunosuppressant.^[130]

Fetal Proteins

-Fetoprotein (AFP) is a glycoprotein with a molecular weight of about 69 kDa.^[133] AFP is believed to be synthesized sequentially in the yolk sac, gastrointestinal tract, and fetal liver.^[129] It enters the fetal urine in abundance and is readily detected in the amniotic fluid. Concentrations of fetal plasma AFP, amniotic fluid AFP (AFAP), and maternal serum AFP (MSAFP) are shown in Figure 1-18.^[135] MSAFP peaks between 10 and 13 weeks' gestational age and then declines from 14 to 32 weeks. The rapid fall in fetal plasma AFP is believed due to increasing fetal blood volume and a decline in fetal production. AFP peaks at 12 and 14 weeks' gestation and then steadily declines to term.^[135] The concentration gradient between fetal plasma AFP and MSAFP is about 150- to 200-fold. Detectable as early as 7 weeks' gestation, MSAFP reaches peak concentrations between 28 and 32 weeks.^[135] The apparent paradoxical rise in MSAFP in association with decreasing AFAP and fetal serum levels can be accounted for by increasing placental permeability to fetal plasma proteins that occurs with advancing gestation.^[135]

Function.

AFP regulates fetal intravascular volume as an osmoregulator^[135] and may also be involved in immunoregulation.^[135] AFAP and MSAFP measurements are clinically important because they are elevated in association with neural tube defects.^[137] MSAFP is decreased when the fetus has Down syndrome.^[138]

PREGNANCY STEROIDS

The novel pregnancy peptides described above are in part responsible for the altered steroid milieu in pregnancy. In addition to stimulation of maternal hormones, the fetus and placenta produce and secrete steroids into the maternal circulation. The changes in maternal hormone concentrations are integrally related to metabolic and immunologic changes vital to intracorporeal gestation.

Ontogeny of Fetoplacental Steroid Production

Origins and amounts of fetoplacental steroid shift dramatically during gestation.

The Preimplantation Conceptus

Estradiol and progesterone secretion by the conceptus and its cumulus is detectable in vitro well before implantation. ^[139], ^[140] There

17

is little information on the regulation of conceptus steroid production. Mechanical removal of the corona cells is associated with cessation of secretion, whereas return of corona cells in co-culture restores steroid secretion. ^[139] Steroid production, therefore, is likely negligible by the time the conceptus reaches the endometrial cavity, since it has been mechanically denuded of cumulus during transport through the oviduct. Once implantation occurs and secretion of trophoblastic hCG and other pregnancy-related peptides is established, steroid production by the conceptus resumes. ^[139] ^[140] ^[141]

Progesterone production by the preimplantation conceptus is believed important in tubal and uterine transport, because receptor sites for progesterone are highest in concentration in the mucosal layer of the distal one third of the fallopian tube. The ova and sperm are most likely to meet at this location. ^[142]

The Decidua

Cortisol is secreted by decidual tissues. ^[143], ^[144] In concert with hCG and progesterone secreted by the conceptus, decidual cortisol probably suppresses the maternal immune rejection response, helping to confer immunologic "privilege" to the implanted conceptus. ^[143], ^[144]

The Corpus Luteum

Progesterone, 17-hydroxyprogesterone, estradiol, and androstenedione are the principal steroid products of the corpus luteum. Progesterone is considered the steroid of greatest importance because progesterone alone given to a lutectomized woman in early pregnancy will maintain a pregnancy that would otherwise abort. ^[145] Likewise, exogenous progesterone given to an agonadal woman pregnant with donated embryos sustains viability through the early first trimester until the pregnancy can be maintained with its own placental progesterone production. ^[146] Although the human corpus luteum secretes up to 40 mg of progesterone a day during the midluteal phase of the ovarian cycle and into early pregnancy, surprisingly small amounts of progesterone are required to maintain donor embryo pregnancies when no corpus luteum is present. ^[147] ^[148] ^[149]

Low-density lipoprotein (LDL) cholesterol is the principal regulatory precursor of corpus luteum progesterone production. ^[150]

The Fetus and Placenta

The fetal adrenal cortex and placenta serve as incomplete but complementary steroidogenic organs, functioning in concert to become the principal sites of steroid production as gestation advances. After 7 weeks' gestational age, the placenta dominates steroid production. At this point, pregnancy continues even if the corpus luteum is excised, for in its stead is the beginning of the fetoplacental unit. ^[151] At this time of gestation, pituitary basophilic cells are producing significant amounts of fetal ACTH and stimulate the fetal adrenal cortex, whose cells have been amassed for 4 weeks, awaiting trophic stimulation to synthesize steroids. ^[152] This corresponds to the time in gestation when estriol is first detectable in the maternal circulation. The intricate interdependence of the fetal and adrenal cortex and the placenta allow these two relatively small organs to exchange, metabolize, and secrete more steroids than any other human endocrine tissue.

Because the fetal adrenal and placenta contain incomplete but complementary steroidogenic enzyme systems, they constantly exchange circulating steroid precursors, which produces the steroid profile that characterizes normal pregnancy. As one might expect, nature has also evolved an organ that exists only in pregnancy to handle this unique function: the fetal zone of the adrenal cortex (Fig. 1-19). ^[143], ^[153] Between 32 and 36 weeks (Fig. 1-19B), a marked increase in fetal adrenal cortex growth velocity reflects the acceleration of fetal maturation processes just before parturition. ^[143], ^[157] This fetal zone then rapidly involutes postpartum. ^[155], ^[156]

The anatomic distribution of key steroidogenic enzymes involved in the production of circulating intrauterine steroids is diagrammed in Figure 1-20. ^[157], ^[158] The fetal adrenal cortex is functionally deficient in 3-hydroxysteroid dehydrogenase, the enzyme that converts pregnenolone and DHEA to progesterone and androstenedione, respectively. ^[159] Therefore, the fetus cannot make progesterone or androstenedione, the immediate precursor to the sex steroids. The placenta, however, has an abundance of 3-hydroxysteroid dehydrogenase. Therefore, the fetal adrenal cortex extracts LDL from the fetal circulation and converts it to pregnenolone sulfate and DHEA-S. ^[157], ^[160] Pregnenolone sulfate is delivered through the umbilical artery to the placenta. The placenta converts pregnenolone to progesterone and returns the latter to the fetus for synthesis into mineralocorticoids and glucocorticoids. Interestingly, the placenta contains a relative lack of 17-hydroxylase. ^[159] Teleologically, this deficiency may exist to prevent placental metabolism of progesterone, which is the precursor of fetal adrenal cortex corticosteroids. ^[159] The placenta also has the enzymatic capability to extract LDL cholesterol and to convert it into progesterone without relying on the fetal adrenal cortex.

The other fetal steroid precursor, DHEA-S, is first delivered to the fetal liver, where it is converted into 16-hydroxydehydroepiandrosterone sulfate (16-OHDHEAS) before being converted in the placenta first to 16-hydroxyandrostenedione and then further aromatized

18

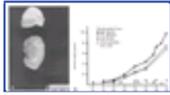

Figure 1-19 A, Fetal adrenal gland and kidney at 18 weeks. The adrenal cortex in fetal life is much larger relative to other organs in children and adults. (Courtesy of Dr. Steven Gabbe.) **E**, Growth of the fetal adrenal cortex. Total fetal adrenal mass is shown as a function of gestational age. Rapid increase in growth velocity occurs between 32 and 36 weeks' gestation. In anencephalic pregnancies, adrenal mass does not increase after the second trimester. (Data from Jost,^[154] Kondo,^[155] and Buster^[157])

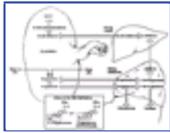

Figure 1-20 Exchange of circulating steroid intermediates between fetal zone and placenta. Steroidogenic enzyme deficiencies of the fetal zone are offset by enzyme activities of placenta enabling the two organs to work cooperatively to produce a massive and extensive profile of intrauterine steroids. The bulk of fetal zone steroids are secreted as sulfoconjugates.

into estriol.^[158] The estrogens are subsequently secreted into the maternal and fetal circulations.^[158]

Besides the obvious functional interdependence of these two organs, the placenta also acts as a structural stimulator of the fetal adrenal cortex. In the first 20 weeks of gestation, placental hCG and progesterone play important roles in fetal adrenal cortex maintenance and regulation.^[161] HCG stimulates fetal adrenal cortex production of DHEA-S in vivo. Atrophy of the fetal zone after delivery may be in part due to removal of the trophic effect of hCG, although hCG appears to be less important after week 20 of gestation.^[161], ^[162] Indeed, the fetal adrenal cortex acquires increasing sensitivity to circulating ACTH, with advancing gestational age during the second half of gestation being primarily influenced by ACTH.^[163], ^[164] In addition, prolactin receptors have also been demonstrated in the adrenal cortex, and prolactin may therefore act in association with ACTH and hCG to regulate fetal adrenal cortex steroid production.^[165] ^[166] ^[167] ^[168]

Regulation of Fetoplacental Steroidogenesis

Steroidogenic regulation has been investigated extensively in vitro by study of fetal placental tissue explants. In vivo, regulation has been investigated in catheterized primate models, particularly the rhesus monkey and baboon. Factors emerging as major regulators of fetoplacental steroidogenesis include (1) LDL cholesterol, (2) pituitary regulatory hormones, (3) intraplacental regulators, and (4) intra-adrenal regulators.^[167] ^[168] ^[169]

LDL CHOLESTEROL

LDL cholesterol, the principal lipoprotein utilized in fetal adrenal steroidogenesis, limits or augments steroid output by its availability. Between 50 and 70 percent of the cholesterol used for fetal adrenal steroidogenesis is extracted from circulating fetal LDL.^[151], ^[160], ^[170] Fetal adrenal tissues contain high-affinity, low-capacity binding sites for LDL. In the presence of ACTH, adrenal-binding capacity for LDL is increased.^[151], ^[159], ^[163] Cholesterol liberated from intra-adrenal hydrolysis of LDL is converted to steroids.

Simpson et al. proposed that fetal LDL cholesterol and the steroidogenic systems of the fetal adrenal and placenta may interact in a self-perpetuating positive feedback loop that becomes increasingly active with advancing gestation.^[171] Most LDL cholesterol arises de novo from synthesis in the fetal liver^[171] (Fig. 1-21). Fetal adrenal cortisol and placental estradiol (derived from fetal DHEA-S) augment de novo fetal liver biosynthesis of LDL.^[96] All of these interacting elements increase with advancing fetal maturity in a chain-like sequence of self-perpetuating loops that increase steroid production to meet the needs of a growing fetus.^[171]

PITUITARY REGULATORY HORMONES

Fetal pituitary ACTH is detectable by 9 weeks' gestation.^[162], ^[172] ^[173] ^[174] Plasma immunoreactive ACTH levels increase steadily until about 20 weeks. Levels remain relatively stable until approximately 34 weeks, when a significant decrement appears and persists until term.^[163] Concentrations of ACTH over time therefore do not correlate with the increasing fetal adrenal mass or the increasing steroidogenic activities that characterize the third trimester.^[163]

Fetal ACTH regulates steroidogenesis in both adrenal zones. ACTH receptor activity, present in both zones, is diminished somewhat in the fetal zone early in the second

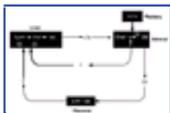

Figure 1-21 Proposed scheme for the regulation of steroidogenesis in the human fetal placental unit. Fetal adrenal cortisol (F) and estradiol (E) are produced in the placenta from dehydroepiandrosterone sulfate (DS) of fetal adrenal origin, which regulates de novo fetal hepatic synthesis of cholesterol (Chol). Cholesterol bound to LDL is then provided to the fetal adrenal for F and DS production, which is enhanced by ACTH of fetal pituitary origin. (From Simpson ER, Parker CR, Carr BR: *Role of lipoproteins in the regulation of steroidogenesis by the human fetal adrenal*. In Jaffe RB, Dell Acqua S [eds]: *The Endocrine Physiology of Pregnancy and the Peripartal Period*, Vol. 21. Serono Symposia Publications. New York, Raven Press, 1985, with permission.)

trimester when other trophic factors, such as hCG, are probably more important in the maintenance of this structure.^[171] In vitro superfusion system studies of human fetal adrenal tissue show that ACTH stimulates the release of 5 pregnenolone sulfate and DHEA-S, whereas isolated definitive zones secrete only cortisol when stimulated by ACTH.^[171] ACTH, in addition to its effect on LDL binding, acts on its own adrenal cell membrane receptor subunit and then adenyl cyclase to express its direct stimulatory effect on steroidogenic enzymes.^[171]

ACTH 119 and ACTH 138 have been extracted from human fetal pituitaries and have been shown in vitro to stimulate the production of DHEA-S and cortisol.^[162], ^[173] Although fetal ACTH is clearly a major fetal adrenotropic principle, its activity is modulated by other trophic factors such as CRH and prolactin.

Fetal pituitary prolactin is detectable at 10 weeks.^[174] Cord prolactin concentrations increase with advancing gestation in parallel with increased adrenal mass.^[166] With prolactin receptors demonstrated in the adrenal cortex, prolactin may act as a co-regulator with ACTH, hCG, and growth factors in fetal adrenal steroid production.^[165], ^[175] In fetal baboon experiments, both in vivo and in vitro, prolactin augments ACTH-stimulated adrenal androgen production.^[167], ^[169]

INTRAPLACENTAL REGULATORS

As the secretor of *hCG*, *placental CRH*, *progesterone*, and *estradiol*, the placenta is an important fetal zone co-regulator.^[153]

HCG receptor activity is present in the fetal zone, and hCG stimulates fetal adrenal production of DHEA-S both in vitro and in vivo.^[67], ^[164] HCG appears to be less important after the 20th week, when the fetal zone is primarily influenced by the ACTH. Fetal zone atrophy observed after delivery may be attributable to removal of placental hCG, but loss of other trophic factors is probably of similar importance.^[162], ^[171], ^[175] Placental CRH, in a paracrine relationship with placental ACTH, probably participates with the fetal hypothalamus and pituitary in the surge of fetal glucocorticoids associated with the late third trimester.^[91], ^[176] This relationship is highlighted earlier in the chapter.

Placental progesterone inhibits the 5 to 4 steroid transformation in the fetal zone.^[161], ^[177] This effect is another explanation for the functional fetal adrenal 3HSD deficiency.

Placental estradiol modifies metabolism and production of corticoids and progesterone. In chronically catheterized baboons, the placenta regulates maternal cortisol-cortisone interconversion, and fetal pituitary production of ACTH. [177], [178] This effect occurs by modulation of maternal cortisol across the placenta into the fetus.

INTRA-ADRENAL REGULATORS

The fetal adrenal becomes more sensitive to circulating ACTH with advancing gestational age. [169] At least three factors are involved.

Fetal adrenal mass increases with advancing gestation [154], [155] (Fig. 1-19B). At 8 weeks' gestation, a rudimentary but distinct adrenal cortex appears composed of two zones: the fetal zone, which comprises approximately 80% of fetal adrenal mass, and a surrounding definitive zone, a narrow capsular band of highly proliferative cells that corresponds to the adult zona glomerulosa. [178], [179], [180], [181], [182] Rapid growth that begins at approximately the 10th week of gestation consists almost entirely of enlargement of the fetal zone [178], [179] (Fig. 1-22) (Figure Not Available). By the 13th week of gestation, a third zone, the transitional zone, a layer residing between the above two zones, emerges and takes on the appearance of the zona fasciculata, the source of adult cortisol. [183] Between 32 and 36 weeks' gestation, the fetal zone increases its mass sharply (Fig. 1-19B). [178], [179] This growth is thought to occur principally from hyperplasia in the definitive and transitional zones and from hypertrophy in the fetal zone (Fig. 1-22) (Figure Not Available). The adrenal gland after birth shrinks abruptly by apoptosis occurring in the principally fetal zone. [178], [179] During growth phases, an overall increase in cell numbers is thought to produce an increase in the number of ACTH receptors. The adrenal as a whole thus becomes more responsive to

Figure 1-22 (Figure Not Available) Zonation of the human fetal adrenal cortex at mid trimester. This schematic structure illustrates the three zones of the fetal cortex and their putative modes of growth in each zone. Hyperplasia is believed to be a predominant form of growth in the definitive zone; hypertrophy is believed to occur mainly in the fetal zone; apoptosis occurs mainly in the central areas of the fetal zone. Cells are believed to migrate from the periphery to the center of the gland. (From Mesiano S, Jaffe RB: *Developmental and functional biology of the primate fetal adrenal cortex. Endocr Rev 18:378, 1997, with permission.*)

21

circulating ACTH with resulting augmentation of steroid production. In late gestation, the definitive and transitional zones, with their 3HSD steroidogenic activity, begin to produce Cortisol from cholesterol, as in the adult [183] (Fig. 1-23) (Figure Not Available). After birth, these three zones survive: the definitive zone is transformed into the zona glomerulosa, the transitional zone evolves into the cortisol-secreting zona fasciculata, and the fetal zone evolves into the androgen-secreting zona reticularis [179] (Fig. 1-22) (Figure Not Available) and (Fig. 1-23) (Figure Not Available).

Fetal adrenal blood flow, modulated by arterial oxygen tension, tropic hormones, and intra-adrenal vascular proliferation, exposes fetal adrenal receptors to increases in circulating tropic hormones. Beginning at 9 weeks' gestation, an extensive network of capillary sinuses forms between the cords of the fetal zone. The

Figure 1-23 (Figure Not Available) Expression of steroidogenic enzymes in the three zones of the fetal adrenal cortex. Relative amounts of steroidogenic enzyme activity are represented as line thickness and shown to change from mid gestation to late gestation for P450_{scc}, P450_{c21}, 3HSD, and P450_{c11}. Dashed line indicates lack of expression. Note the lack of P450_{c17} expression in the definitive zone at all stages of gestation and the ontogenic expression of 3HSD only in the definitive and transitional zones in late pregnancy. (From Mesiano S, Jaffe RB: *Developmental and functional biology of the primate fetal adrenal cortex. Endocr Rev 18:378, 1997, with permission.*)

fetal cortex becomes one of the most highly vascularized fetal organs. [181]

Growth factors regulate the adrenal steroidogenic pathway by differential stimulation of zone growth. Basic fibroblastic growth factor (-FGF) induces proliferation of cells in the definitive zone in preference to the fetal zone. [184], [185] ACTH increases mRNA encoding for -FGF by two- to three-fold. [186] Similarly, EGF, IGF-1 and IGF-2, activin/inhibin, and TGF- induce total adrenal growth as well a preferential growth of specific zones. [187], [192] These substances function as paracrine modulators to circulating fetal pituitary and placental ACTH. [178], [179]

Physiology of Fetoplacental Steroids and Pregnancy

Fetoplacental estrogens, progestogens, and adrenocorticoids are secreted abundantly into both fetal and maternal circulations during pregnancy.

Estrogens

The origins and impact of estrogens in the maternal circulation vary with time in gestation and needs of the pregnancy.

VARIATION DURING PREGNANCY

Estradiol originates almost exclusively from the maternal ovaries for the first 5 to 6 weeks' gestation. [141] Later, the placenta secretes increasing quantities of estradiol, which it synthesizes from conversion of circulating maternal and fetal DHEA-S. After the first trimester, the placenta is the major source of circulating estradiol. [141] At term, approximately equal amounts of placental estradiol are converted from circulating maternal DHEA-S and fetal DHEA-S. [193], [194] Estradiol concentrations are less than 0.1 ng/ml during the follicular phase and reach 0.4 ng/ml during the luteal phase of normal menstrual cycles. [195] Following conception, estradiol increases gradually to range from 6 to 30 ng/ml at term [196] (Fig. 1-24). In women with threatened first-trimester abortion, estradiol concentrations are abnormally low for gestational age. During the third trimester, low estradiol concentrations are associated with poor obstetric outcome.

For the first 4 to 6 weeks of pregnancy, [141] estrone originates primarily from maternal sources (ovaries, adrenals, peripheral conversion). After this time, the placenta secretes increasing quantities of estrone from conversion of circulating maternal and fetal DHEA-S. For the remainder of pregnancy, the placenta remains the major source of circulating estrone. [141]

Estrone concentrations are less than 0.1 ng/ml during

22

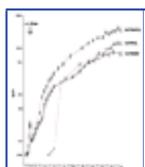

Figure 1-24 Mean concentrations (\pm SEM) of estrone, estradiol, and estriol from conception to term. Unconjugated estriol is first detectable at approximately 9 weeks' gestational age. Gestational ages are calculated from the last menstrual flow. (Composite adapted from Tulchinsky and Hobel, [141], Abraham et al., [195], Lindbert et al., [196], Buster et al., [246], [245] and Williams and Warwick. [250])

the follicular phase of a normal menstrual cycle. [197] Following conception, estrone concentrations remain within the luteal phase range through weeks 6 to 10. Subsequently, there is a gradual increase to a wide range of 2 to 30 ng/ml at term [141], [196], [197] (Fig. 1-24). Estrone concentrations probably reflect the same metabolic processes that are involved in the production of estradiol.

Estriol originates almost exclusively from the placenta and is produced principally from placental conversion of fetal 16-DHEA-S. [158], [198] Estriol is first detectable in maternal serum at 9 weeks. [141], [193], [194], [195], [196], [197], [198], [199] This closely corresponds to the early steroidogenic evolution of the fetal adrenal cortex. [141] Its continued production is therefore dependent on the presence of a living fetus. The concentration of estriol is less than 0.01 ng/ml in nonpregnant women. First detectable at

levels of approximately 0.05 ng/ml at 9 weeks,^[141] ^[197] estriol increases gradually to a range of approximately 10 to 30 ng/ml at term^[157] (Fig. 1-24) . Between 35 and 40 weeks' gestational age, estriol concentrations increase sharply in a pattern that reflects a final surge of intrauterine steroidogenesis just prior to term.

Maternal concentrations of estriol may reflect abnormalities in fetal and placental development including fetal compromise, fetal anomalies, and hydatidiform mole.^[199] Fetal death at any time during the second or third trimester produces a striking drop in estriol concentrations within 1 to 2 hours.^[199] Within 4 to 6 hours, concentrations are consistently less than 1 ng/ml in the second trimester and less than 2.5 ng/ml in the third trimester.^[199] Fetal anomalies associated with adrenal atrophy, such as anencephaly and Down syndrome, are associated with low concentrations.^[199] For this reason, evaluation of unexplained low estriol in the second and third trimesters should include ultrasonography and amniocentesis as appropriate. Hydatidiform moles are associated with low estriol.^[199] Presumably this occurs because of the absence of a fetal adrenal and liver. The resultant deficiency of fetal 16-hydroxylated sulfoconjugated precursors in molar pregnancy would account for the very low estriol values.^[199]

Deteriorating fetoplacental health during the third trimester has long been associated with either falling or low estriol concentrations.^[199] ^[200] ^[201] ^[202] Chronically compromised infants have markedly elevated cord LDL concentrations, low DHEA-S values, and decreased movement, suggesting a depressed fetal central nervous system (CNS).^[201] , ^[202]

HORMONAL FUNCTIONS DURING PREGNANCY

Estrogens affect uterine vasculature, placenta steroidogenesis, and parturition.

Uterine Vasculature.

Estrogens augment uterine blood flow. In ovine models, direct estrogen injection into the uterine arteries through indwelling catheters produces striking increases in blood flow. Estradiol is the most potent estrogen in this role. Estrone and estriol, however, though less active, also produce the effect.^[203] Because exposure of the uteroplacental bed to direct estriol secretion is massive, estriol may be the principal augmentor of uterine blood flow as described previously. This may be the dominant role of estriol in human pregnancy.^[203]

Placental Steroidogenesis.

Estrogen-regulated mechanisms may allow the fetus to govern production and secretion of progesterone during the third trimester. In the baboon, estrogen controls the biosynthesis of placental progesterone by regulating the availability of LDL cholesterol for conversion to pregnenolone and to its downstream steroid products.^[204] Thus, in advanced pregnancy, the fetus may regulate placental progesterone production.

Parturition.

Fetoplacental estrogens are closely linked to myometrial irritability, contractility, and labor. In primates, estrogens ripen the cervix, initiate uterine activity, and augment established labor.^[205] Estrogens also increase the sensitivity of the myometrium to oxytocin

by augmenting prostaglandin biosynthesis.^[206] , ^[207] Because placental release of estrogens is linked to the fetal hypothalamus, pituitary, adrenals, and placenta, the fetal pituitary adrenal axis appears to fine tune parturition timing, in part through its effect on estrogen production.^[205] ^[206] ^[207] ^[208] Thus, in human pregnancy in which the fetus is anencephalic, labor is either too early or too late. Similarly, surgical anencephaly in the fetal macaque disrupts the normal timing of parturition.^[209] Parturition in humans is a precise event with a well-defined frequency distribution surrounding a mean gestational age of 270 days. In macaques, labor most often begins after a preparturitional increase of fetal adrenal steroids (DHEAS) that is maximal between 2300 and 0300 hours.^[207] A diurnal rhythm in uterine activity is also evident in which the maximal hourly values of intrauterine pressure and contraction frequency surround midnight. In human studies, there is a similar entrainment of uterine activity with circulating maternal estrogens and progesterone as labor approaches.^[209] ^[210] ^[211] There is firm evidence of increasing, rhythmic fetal adrenal and placental steroid output over the 5 weeks just before term that is important in preparing for the final cascade of oxytocin and prostaglandins that stimulate labor.^[209] ^[210] ^[211]

The Progestogens

Progesterone and 17-hydroxyprogesterone are the major progestogens in human pregnancy.

VARIATION DURING PREGNANCY

Progesterone.

Progesterone originates almost entirely from the corpus luteum before 6 weeks' gestational age but shifts to the placenta after the seventh week. After 12 weeks, the placenta is the major source of progesterone.^[141] , ^[197] The placenta produces progesterone from circulating maternal LDL cholesterol and is minimally dependant on fetal precursors.^[141] , ^[150] , ^[158]

Progesterone concentrations are less than 1 ng/ml during the follicular phase of the normal menstrual cycle^[195] , ^[197] (Fig. 1-25) . In the luteal phase of conceptual cycles, progesterone concentrations rise from 1 to 2 ng/ml on the day of the LH peak to a plateau of 10 to 35 ng/ml over the subsequent 7 days. Progesterone concentrations remain within this luteal range through the 10th week (dated from last menstrual flow), and then show a sustained rise that continues until term. At term, progesterone concentrations range from 100 to 300 ng/ml.^[141]

Low progesterone levels are well tolerated in patients without ovaries, carrying pregnancies with donor embryos.^[147] , ^[149] In women with first-trimester threatened abortion, progesterone concentrations at the time of the initial evaluation are predictive of the ultimate outcome.^[212] Abortion will occur in approximately 80 percent of those with progesterone concentrations under

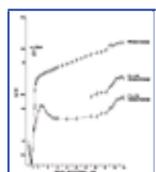

Figure 1-25 Mean concentrations (\pm SEM) of progesterone and 17-hydroxyprogesterone from conception until term. Data are compiled from several reports. 17-hydroxyprogesterone shows a marked rise in concentrations beginning at 32 weeks until term. Gestational ages are calculated from the last menstrual flow. (Composite adapted from Haluska and Novy,^[206] Tulchinsky and Hobel,^[141] Abraham et al.,^[195] and Lindbert et al.,^[197])

10 ng/ml; viable pregnancies are virtually never observed at concentrations below 5.0 ng/ml.^[213]

Conversely, in women with a hydatidiform mole, progesterone concentrations are significantly elevated above the normal range.^[214] In women whose pregnancies are complicated by Rh isoimmunization, progesterone concentrations are elevated approximately twofold above values for normal pregnancies of comparable gestational ages.^[197] This elevation may be related to a two- to threefold increase in placental mass associated with erythroblastosis.

Finally, progesterone concentrations are lower in women with an ectopic pregnancy. Single serum progesterone levels have been widely used in diagnostic algorithms with serum -hCG and ultrasound in the diagnosis of ectopic pregnancy without laparoscopic surgery. Progesterone concentrations of less than 5 ng/ml are diagnostic of fetal death in the first trimester; thus, low progesterone levels prompt the performance of diagnostic curettage, which can help distinguish between

ectopic pregnancy and intrauterine fetal demise. Direct visualization of the ectopic implantation is not required. ^[213]

17-Hydroxyprogesterone.

17-hydroxyprogesterone originates predominantly from the corpus luteum during

24

the first trimester of pregnancy. ^[215] The ovaries continue to be a significant source of 17-hydroxyprogesterone throughout pregnancy. During the third trimester, however, the placenta uses fetal 5-sulfoconjugated precursors to secrete increasing amounts of 17-hydroxyprogesterone. The placenta is probably the major source of this hormone at term. ^[215]

17-hydroxyprogesterone concentrations are less than 0.5 ng/ml during the follicular phase of normal menstrual cycles. In conceptual cycles, 17-hydroxyprogesterone concentrations rise to about 1 ng/ml on the day of the LH peak, fall slightly for about 1 day, rise again over the subsequent 4 to 5 days to a level of 1 to 2 ng/ml, and then increase gradually to a mean of approximately 2 ng/ml (luteal phase levels) at the end of 12 weeks. This level remains relatively stable until a gestational age of about 32 weeks, when there begins an abrupt sustained rise to a mean of approximately 7 ng/ml at 37 weeks, a level that persists until term ^[215] (Fig. 1-25) . The rise beginning at 32 weeks is strongly correlated with the activity of fetal maturational processes known to begin at this time.

During the first 7 weeks of gestation, through the time of the luteal-placental shift, 17-hydroxyprogesterone concentrations reflect primarily the status of corpus luteum steroidogenesis. ^[215] In women undergoing spontaneous abortion, falling concentrations of 17-hydroxyprogesterone parallel falling concentrations of progesterone. ^[215]

HORMONAL FUNCTIONS DURING PREGNANCY

Progestogens affect tubal motility, the endometrium, uterine vasculature, and parturition.

Tubal Motility.

The preimplantation conceptus with its surrounding corona cells secretes progesterone long before implantation. Conceptus-secreted progesterone may itself affect tubal motility as the conceptus is carried to the uterus. ^[142] Progesterone, by action mediated through catecholamines and prostaglandins, is believed to relax uterotubal musculature. Estradiol, also secreted by these structures, may balance the progesterone, maintaining the desired level of tubal motility and tone. ^[142] Excess progesterone, as might occur from pharmacologically induced superovulation, may produce excessive relaxation of tubal musculature and could explain an apparent excess of ectopic pregnancies. Likewise, progesterone deficiency from blighted ova may cause accelerated oviduct transport with premature arrival of these ova to the uterus.

Endometrium.

Progesterone inhibits T-lymphocytemediated tissue rejection and is believed to work in concert with hCG and decidual cortisol. ^[216], ^[217] This inhibition of the rejection response may confer immunologic privilege to the implanted conceptus and developing placenta. It has been suggested that placental progesterone protects the pregnancy by inhibiting T-lymphocytemediated tissue rejection responses. ^[216], ^[217] In rodents, progesterone extends the survival of transplanted human trophoblasts, ^[217] and high local intervillous concentrations of progesterone are of major importance in blocking the cellular immune rejection of the foreign protein originating from the pregnancy. ^[217]

Uterine Vasculature.

Progesterone antagonizes estrogenaugmented uterine blood flow through depletion of cytoplasmic estrogen receptors. ^[218] Estrogen and progesterone appear to balance one another in the maintenance of blood flow at the implantation site.

Parturition Control.

Progesterone and the estrogens are antagonistic in the parturition process. Progesterone produces uterine relaxation, ^[208] stabilizing lysosomal membranes and inhibiting prostaglandin synthesis and release. By contrast, estrogens labilize lysosomal membranes and augment the synthesis of prostaglandins and their release. ^[207]

Although gradual increase in cord DHEA-S and maternal estriol occurs toward term, there is no corresponding drop in either fetal or maternal progesterone concentrations. ^[219] That progesterone is important in the maintenance of uterine quiescence is not doubted, however, because in the first trimester removal of the corpus luteum leads rapidly to myometrial contractions. ^[145] Likewise, labor ensues following administration of antiprogesterone compounds in the third trimester. ^[220] The antiprogesterone agents occupy progesterone receptors and inhibit the action of progesterone, which is clearly essential for maintenance of uterine quiescence. Yet, progesterone administration to women, except in large doses, does not suppress human uterine contractions once begun. ^[220]

The ratios of estradiol and progesterone in various animals models are closely related to the stimulation of myometrial gap junction formation. ^[221]

Adrenocorticoids

VARIATION DURING PREGNANCY

Fetal plasma cortisol and amniotic fluid cortisol and cortisol sulfate concentrations increase considerably with advancing gestational age and approaching parturition. ^[222], ^[223] With the exception of the amniotic membranes and decidua, virtually all fetal organs convert cortisol to cortisone. ^[143], ^[144] The intracellular mechanisms of cortisol-to-cortisone interconversion and its regulatory effect on the biologic expression of cortisol are diagrammed in Figure 1-26 (Figure Not Available) . As parturition approaches, net conversion of cortisol to cortisone is decreased in many tissues such as fetal lung. ^[223] As cortisol-to-cortisone conversion decreases, there is increasing circulating cortisol available to maturing fetal tissues. The

25

Figure 1-26 (Figure Not Available) Mechanism of intrauterine cortisol (F) modulation. Target organ cells autoregulate F interaction with corticoid receptors by diverting F to E (cortisone) through 11-HSD interconversion. (From Murphy BEP: *Cortisol economy in the human fetus*. In James VHT, Serio M, Gusti G, et al [eds]: *The Endocrine Function of the Human Adrenal Cortex*. San Diego, Academic Press, 1978, p 509, with permission.)

final increase in fetal cortisol in pregnancy may be limited to the increase in placental CRH (Fig. 1-13) (Figure Not Available) .

TARGET TISSUE INTERACTION DURING PREGNANCY

The profile of circulating adrenocorticoids in the fetoplacental circulation is determined extensively by steroid interconversions between cortisol and cortisone. The *placenta* contains abundant 11-dehydrogenase activity. Although much of circulating fetal cortisol derives from transplacental passage of maternal cortisol, approximately 80 percent of maternal cortisol is converted to cortisone on entering the fetal circulation. ^[222], ^[223] Corticoid measurements in placental tissues indicate a cortisol/cortisone ratio of far less than 1.0, thus reconfirming active intraplacental conversion of cortisol to cortisone. ^[222], ^[223]

Chorionic membranes contain an abundance of 11-ketoreductase activity and therefore convert cortisone to cortisol. First detectable at approximately 18 weeks'

gestational age, this activity continues through term. ^[222], ^[223] Activity is also found in the adherent decidua and in the juxtaposed myometrium. As a result of chorionic membrane and uterine peripheral interconversion, the concentration of cortisol in uterine tissues is nine times that detectable in nonpregnant myometrium. ^[222], ^[223] It is plausible that the maintenance of high cortisol concentrations in myometrium is part of the same immunosuppressive process of pregnancy maintenance that involves hCG and progesterone. ^[222], ^[223]

Fetal lung contains predominantly 11-dehydrogenase activity and therefore predominantly converts cortisol to cortisone. With advancing gestation, the fetal lung cortisol-to-cortisone interconversion diminishes. ^[222], ^[223] Lung tissue at birth shows no detectable cortisol-to-cortisone conversion. The net result of this transformation is increased pulmonary intracellular cortisol bioavailability, a process that may be related to maturation of the fetal lung, which is accelerating by 34 to 36 weeks' gestational age. ^[176]

HORMONAL FUNCTIONS DURING PREGNANCY

Adrenocorticoids impact with particular relevance on regulation of intrauterine maturation. In normally progressing human pregnancy, multiple enzyme systems accelerate, beginning at approximately 32 weeks' gestational age and finishing at approximately 37 weeks' gestational age. ^[176] Delivery at any time from 37 weeks to term generally produces a newborn free of the hazards of prematurity. Although a variety of interdependent hormonal events are involved, the weight of available evidence indicates that fetal cortisol is the major effector in the induction of these final and essential maturational systems involving fetal lung and liver, the nervous system, and the adrenal medulla. ^[176] Placental CRH, which increases over the last weeks of pregnancy, may be the final common endocrine modulator ^[224], ^[225] (Fig. 1-13) (Figure Not Available) .

PREGNANCY DIAGNOSIS AND MONITORING

The novel hormones of pregnancy may be measured for diagnosis and clinical detection of abnormalities. A variety of assay techniques are available.

26

Human Chorionic Gonadotropin

There are four groups of hCG configurations that affect performance and interpretation of assays.

Dimeric hCG

Dimeric hCG and both subunits, -hCG and -hCG, rise sharply during the first trimester ^[19] (Fig. 1-10) . The dimeric hCG is normally measured, either directly by sandwich-type assays or inferentially by detection of the subunit for diagnosis and monitoring of early pregnancy. HCG is detectable in serum in approximately 5 percent of patients by 8 days after conception, and in virtually all patients by day 11. ^[12] Deviation from the normal doubling patterns suggests that the pregnancy is either an ectopic gestation or is undergoing spontaneous abortion. Thus, if hCG fails to rise 66 percent in 2 days, ancillary procedures are necessary to differentiate between the two conditions. ^[226]

Dimeric and free subunit hCG are produced in the pituitary and released in association with pituitary LH. ^[57] , ^[227] Levels are much higher in postmenopausal women (100 pg/ml vs. 10 pg/ml).^[57] Nonpregnant levels of hCG are, however, well under the sensitivity (approximately 1 mIU/ml) detectable by the most sensitive clinical assays used in pregnancy monitoring. ^[228]

Free - and -hCG Subunits

Following in vitro fertilization and embryo transfer, ^[19] free subunits of hCG may be detected as early as 7 days (1 day earlier than intact hCG). Free subunits are first detectable at gestational week 6 and rise in sigmoid fashion to peak at 36 weeks' gestational age. ^[19] In general, -hCG is rarely used in clinical interpretation, although the concentrations are elevated in persistent gestational trophoblastic neoplasia and are significantly lower in insulin-dependent diabetic women. Persistently elevated free subunits in patients with trophoblastic disease may portend a poor prognosis. ^[229]

-Subunit Core Fragment (-Core)

-Core is a major component of the immunoreactive hCG in urine, particularly during the second trimester. ^[47] -Core circulates in small amounts because of its very short half-life. With a molecular weight of approximately 10.0 kDa, -core consists of two polypeptide chains, composed of residues 640 disulfide bridges to residues 5592 of the subunit.^[47] -Core is detected in -subunit assays. Despite the conformational differences of hCG measured through the subunit, assays in either serum or urine of the same patient produce very similar results. ^[47]

Nicked hCG Subunits

Nicked hCG is an hCG subunit with deleted peptide linkages. ^[229] In the subunit, these linkages are between residues 4784 and between 4445 or 4657. ^[229] In the subunits, they are between 7071. As nicking increases, receptor binding decreases. ^[47] For this reason, nicked hCG is biologically less active. Disparities in levels of nicked versus non-nicked hCG account for major discrepancies in the hormone levels observed with different assay methods. ^[229] ^[230] ^[231] Test results between commercial assays are not necessarily interconvertible. For this reason, investigators in this field believe that hCG assay reports should include information about assay interaction with nicked hCG, free subunit, and -core fragment. In this way, the different standards, though not precisely interconvertible, can still be interpreted. ^[47]

hCG Standards

In comparing hCG measurements by different radioimmunoassays (RIAs), the standard must be specified. Two standards are commonly encountered. The Third International Standard (3rd IS), which is the same as First International Reference Preparation, is less contaminated with free and subunits of hCG than the Second International Standard (2nd IS). The discrepancy is irrelevant in hCG assays specified for the intact hCG molecule (whole molecule or sandwich assays) because neither detects free subunits. However, the standards are important in interpreting results from RIAs that interact with the subunit part of the molecule and are therefore unable to distinguish between free subunits and the intact molecule. Thus, the 3rd IS produces values approximately 1.5- to 2-fold greater for -subunit radioimmunoassay than does the 2nd IS. ^[47] This difference, more or less uniform throughout pregnancy, is illustrated in Figure 1-27 (Figure Not Available) .

hCG Assays

The choice of hCG assay from the variety available depends on the demands required of the test.

Radioimmunoassays

RIAs are the traditional laboratory technique for measuring hCG. These assays bind at the subunit and therefore measure combined concentrations of free subunits plus dimeric hCG. HCG is labeled with a radioactive marker (e.g., ¹²⁵I) and is displaced from binding sites on an antibody directed against it by unlabeled hCG in the patient's serum. If no hCG is displaced, there is no detectable hCG in the patient's serum. ^[232] ^[233] ^[234] If

27

Figure 1-27 (Figure Not Available) Serum concentrations of hCG measured using the 2nd IS as the reference preparation versus results obtained using the 3rd IS (1st IRP) as the standard in hCG radioimmunoassays. Note the 1.5- to 2-fold greater concentrations of hCG measured using the 3rd IS relative to those obtained with the 2nd IS. (From Ren SG, Braunstein GD: *Human chorionic gonadotropin*. *Semin Reprod Endocrinol* 10:95, 1992, with permission.)

displacement does occur, the patient's serum will contain hCG in a quantitative relationship, resulting in displacement of labeled hCG from the antibody. Because RIAs are quantitative, they are useful in determining doubling times, as required for diagnosis of ectopic pregnancy, spontaneous abortion, or gestational trophoblastic neoplasia. Although precise, RIAs have limited sensitivity, require hours to perform, and involve use of radioisotopes. ^[232] ^[233] ^[234] RIAs have therefore been recently replaced in clinical laboratories by the technically simpler immunoradiometric assay (IRMA).

Immunoradiometric Assay

IRMA uses a sandwich principle to detect intact hCG (whole-molecule assay). IRMA hCG assays require only 30 minutes to complete and can detect very low concentrations of hCG. ^[231] ^[232] ^[233] ^[234] ^[235] IRMAs use a radioactive antibody labelled (¹²⁵I) to detect hCG in the serum. Briefly, anti-hCG antibodies are bound to a test tube. The patient's serum is added, and a second labeled antibody binds to the hCG-antibody complex already on the tube. The amount of labeled antibody bound to the tube is proportional to the amount of hCG in the patient's serum. The hCG molecule is thus "sandwiched" between two antibodies. ^[236] Commercial IRMA assays can detect hCG levels as low as 0.05 mIU/ml. This "sandwich" principle is the technique used in the nonradioactive enzyme-linked immunosorbent assay (ELISA). Because IRMA requires ¹²⁵I-labeled hCG, a gamma counter is needed. For this reason, many commercial laboratories are switching to ELISA assays.

Enzyme Linked Immunosorbent Assay

ELISAs do not use radioisotopes. ^[236] The principle is the same as that of IRMA but instead of using a radiolabeled second antibody, the second antibody is labeled with a substance that can be detected by a color change after binding (alkaline phosphatase or horseradish peroxidase colorimetric reaction). Although not as precise as RIA, the assay is sensitive, quick, and ideal for the early diagnosis of pregnancy in urine where the level of hCG does not need to be known. Thus, with one commercial kit used for pregnancy diagnosis, a value exceeding greater than 30 mIU/ml in urine is reported as a positive test (Immulite). ELISA can also detect hCG in serum at concentrations as low as 1 to 2 mIU/ml, allowing for diagnosis of pregnancy as early as 5 days before first missed menses. ^[236] These assays are easily packaged for use in commercial laboratories or in a physician's office equipped with automated chemiluminescence equipment (e.g., Chiron Diagnostics ACS:180 total hCG). This equipment makes the assays quantitative so they can be used for both pregnancy diagnosis and monitoring.

Fluoroimmunoassay

This technique is another "sandwich" assay in which a second antibody is tagged with a fluorescent label. The fluorescence emitted, proportional to the amount of hCG in the test serum, allows for detection of concentrations as low as 1 mIU/ml. ^[237] The technique takes 2 to 3 hours, uses no radioactivity, and is highly precise. FIA is used to detect and follow hCG concentrations.

Clinical Application of hCG Measurements

Pregnancy Diagnosis

hCG is first detectable in maternal blood at approximately 8 to 11 days after conception using very sensitive research assays (sensitivity, 0.1 to 0.3 mIU/ml). ^[12] ^[13] ^[19] Most state-of-the-art rapid pregnancy tests are set to a sensitivity of 25 to 30 mIU/ml ^[238] (Fig. 1-28).

False-positive results occur in the range of 5 to 25 mIU/ml. False-positive results can occur in perimenopausal and postmenopausal women because of endogenous pituitary hCG secretion, which occurs in synchrony

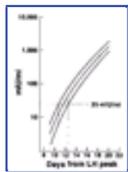

Figure 1-28 Levels of circulating hCG in early pregnancy showing that an assay with a sensitivity of 25 mIU/ml would become positive in some subjects 10 to 11 days after the LH peak and in most subjects 12 to 13 days after the LH peak. (From Chard T: *Pregnancy tests: a review. Hum Reprod* 7:701, 1992, with permission.)

with LH. For practical purposes, a level of less than 5 mIU/ml can be confidently stated as negative. A level exceeding 25 mIU/ml can be confidently stated as positive. ^[238] When there is uncertainty, repeating the test in 2 days normally confirms a trend upwards, which documents the existence of a pregnancy.

Ectopic Pregnancy

With rare exceptions, patients with ectopic pregnancy have hCG titers exceeding 20 mIU/ml (3rd IS standard); 98 percent titers exceeding 40 mIU/ml. Serial hCGs, in combination with vaginal ultrasound and serum progesterone measurements, are used widely for nonsurgical diagnosis of ectopic pregnancy. ^[201]

Spontaneous Abortion

Serum hCG fails to double or falls in patients with spontaneous abortion. Serial hCG showing an abnormally slow rise or decrease may portend spontaneous abortion. Anembryonic gestation should be suspected when there is no fetal pole and the gestational sac exceeds 17 mm or -hCG greater than or equal to 5,100 mIU/ml (3rd IS), and no fetal pole is seen.

Screening for Fetal Down Syndrome

HCG concentrations are elevated in women carrying a fetus affected with Down syndrome. ^[239] This finding has been used in various calculations using maternal age, AFP levels, and hCG concentrations, with or without unconjugated estriol to estimate the risk of carrying an affected fetus. Using serum analytes, one can identify approximately two thirds of affected fetuses with Down syndrome with a 6 percent false-positive (amniocentesis) rate. ^[239] ^[240]

Gestational Trophoblastic Disease

Serial hCG measurements are used to monitor therapy for gestational trophoblastic disease. Disappearance of hCG is used to predict the course of the disease. ^[241]

Early Pregnancy Factor

Pregnancy diagnosis before implantation may be possible through measurement of EPF, which is detectable 26 to 24 hours after fertilization. EPF cannot be detected 24 hours after delivery or termination of either an ectopic or intrauterine pregnancy ^[1] ^[2] (Fig. 1-7).

Detection of EPF currently depends on a cumbersome biologic assay, the rosette inhibition test. ^[1] ^[2] Although recently EPF has been isolated, identified, and sequenced, the exact nature of the molecular species is uncertain and clinical assays are not yet available. ^[1] ^[2]

Diagnosis of conception before implantation will open possibilities for contraception, preimplantation genetics through uterine lavage, and highly accurate dating of intrauterine pregnancies.

Progesterone

Single progesterone measurements in the first trimester are useful in screening for ectopic pregnancy and spontaneous abortion. A single progesterone measurement of less than or equal to 5 ng/ml rules out a viable intrauterine pregnancy [213], [242], [243] and allows the physician to perform a dilatation and curettage without fear of interfering with a viable pregnancy. [213] If villi are found, the patient is unlikely to have an ectopic pregnancy. [141] A value 25 ng/ml or more rules out 98 percent of ectopic pregnancies. [213] Values between 5 and 25 ng/ml are problematic and require further investigation with ultrasound. [243]

Combined Ultrasound and Hormone Measurements

Combined with hCG and progesterone, ultrasound is helpful in determining the viability and location of a pregnancy. [244], [245] Transvaginal ultrasound allows detection of an intrauterine pregnancy as early as 4 weeks from the last menstrual period, when a gestational sac measures 4 to 5 mm [244] (Table 1-2). At 5 gestational

TABLE 1-2 -- GESTATIONAL AGE AT WHICH EMBRYOLOGIC STRUCTURES ARE DETECTABLE BY VAGINAL ULTRASOUND

Embryonic/Fetal Structure	Gestational Age of Detection
Gestational sac	4 weeks, 13 days
Yolk sac	5 weeks
Fetal cardiac activity	5 weeks, 6 days
Limb buds	8 weeks
Head	8 weeks
Ventricles	8 weeks, 24 days
Choroid plexus	9 weeks
Hand, fingers	12 weeks

Modified from Timor-Tritsch IE, Rottem S (eds): *Transvaginal Sonography*. New York, Elsevier Science, 1991.

weeks, the yolk sac becomes visible; at the end of the fifth week, transvaginal ultrasound detects all intrauterine pregnancies with a 95 percent confidence limit. [244], [245] Fetal cardiac activity is detected just before 6 gestational weeks. In a well-timed pregnancy, these ultrasonic milestones are useful in detecting deviations from the norm. Table 1-3 lists the appearance of key embryologic findings associated with rising hCG. [244], [245] When combined with serum measurements of hCG, ultrasonographic findings are vital in the diagnosis of an ectopic gestation and impending abortion. [244], [245]

Using transabdominal ultrasound, all patients with a healthy intrauterine pregnancy whose hCG measured 6,500 mIU/ml had a gestational sac visible by ultrasound. [244] Similarly, transvaginal ultrasound visualizes all intrauterine pregnancies when the hCG exceeds 2,400 mIU/ml [244], [245] (Fig. 1-29). When hCG levels exceed these concentrations and no intrauterine pregnancy is detectable by ultrasound, either uterine curettage to exclude villi or laparoscopy to visualize an ectopic pregnancy is necessary. [245] Conversely, a heart beat detected at 8 gestational weeks assures a patient that her chance of continuing her pregnancy is over 95 percent. [245]

Algorithms

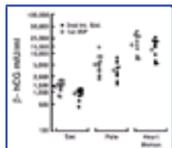

Figure 1-29 Range of -hCG titers (IRP) and predicted developmental landmarks detected by vaginal ultrasound. (From Fossum GF, Davajan V, Kletzky OA: *Early detection of pregnancy with transvaginal ultrasound*. *Fertil Steril* 49:789, 1988. American Society for Reproductive Medicine, with permission.)

have been devised utilizing rapid progesterone assay, serial -hCG, and ultrasound to diagnose ectopic pregnancy nonsurgically. [246], [247] This has been particularly important with the recent advancement of medical therapy for this condition, whereby laparoscopy is eschewed.

CONCLUSIONS

No biologic events can exceed the events considered in this chapter in the long-term importance to human development. Endocrine factors play important roles in the orchestration and outcome of these events. It is a privilege to detect, measure, observe, and occasionally assist nature in the nourishment and protection of the

Key Points

Beginning with conception, a series of proteins specific for and secreted only during pregnancy evolve to facilitate invasion of half-foreign embryonic tissue into the uterine wall.

Cytotrophoblasts, secreting hypothalamic peptides, function in juxtaposition to syncytiotrophoblast, secreting the corresponding pituitary-like, peptides in an anatomic arrangement analogous to the hypothalamic-pituitary axis.

Early pregnancy factor, an analogue of chaperonin 10, is the earliest known circulating marker of fertilization in pregnancy.

Placental GnRH stimulates and is entrained to placental hCG production and release.

Secretion of placental CRH and ACTH into the maternal circulation induces hypercortisolism mediated through the maternal hypothalamic-pituitary axis.

hCG maintains the corpus luteum, stimulates adrenal and placental steroidogenesis, and modulates maternal immunologic response to the pregnancy.

Human chorionic somatomammotropin antagonizes insulin action and induces maternal glucose intolerance, which promotes transfer of glucose and amino acids into the fetus.

Decidual prolactin, a peptide similar to pituitary prolactin, regulates fluid and electrolyte flux through the fetal membranes; it is secreted independently of fetal or maternal dopaminergic control.

Progesterone secreted by the preimplantation conceptus modulates tubal motility in early pregnancy; progesterone secreted by the placenta inhibits maternalfetal tissue rejection, antagonizes the augmentation of uterine blood flow by estrogen, and induces uterine relaxation before parturition.

When pregnancy tests are set to high sensitivity (< 1 mIU/ml) of hCG, false-positives can occur because of endogenous pituitary hCG, which is released in synchrony with pituitary LH and is detected in the assay.

Chapter 2 - Placental and Fetal Physiology

Michael G. ross
m. gore Ervin
Donald Novak

In obstetric practice, recognition of normal fetal growth, development, and behavior often suggests a nonintervention management plan. However, abnormalities may require clinical strategies for fetal assessment and/or intervention. The basic concepts of placental and fetal physiology provide the building blocks necessary for understanding pathophysiology, and thus mechanisms of disease. Throughout this chapter, we have reviewed the essential tenets of placental and fetal physiology, while relating this information to normal and abnormal clinical conditions.

Much of our knowledge of placental and fetal physiology derives from observations made in mammals other than humans. We have attempted to include only those observations reasonably applicable to the human placenta and fetus, and in most instances have not detailed the species from which the data were obtained. Should questions arise regarding the species studied, the reader is referred to the extensive bibliography.

PLACENTAL PHYSIOLOGY

The placenta provides the fetus with its essential nutrients, water and oxygen, and a route for clearance of fetal excretory products, and produces a vast array of protein and steroid hormones and factors essential to the maintenance of pregnancy.

Placental Metabolism and Growth

Anatomic and histologic aspects of placental growth are detailed [in Chapter 1](#) . This section focuses on the physiology of placental metabolism and growth, and its influence on the fetus.

The critical function of the placenta is illustrated by its high metabolic demands. For example, placental oxygen consumption equals that of the fetus, and exceeds the fetal rate when expressed on a weight basis (10 ml/min/kg).^[1]^[2]^[3] Between 22 and 36 weeks of gestation, the number of trophoblast nuclei^[4] increases four-to five-fold, placing increased metabolic demands on the placenta. Glucose is the principal substrate for oxidative metabolism by placental tissue.^[2]^[5] Of the total glucose leaving the maternal compartment to nourish the uterus and its contents, placental consumption may represent up to 70 percent.^[2]^[6]^[7] In addition, a significant fraction of placental glucose uptake derives from the fetal circulation,^[8] and reflects placental oxidative metabolism. Although one third of placental glucose may be converted to the 3-carbon sugar lactate,^[2]^[4]^[5]^[9] placental metabolism is not anaerobic. Instead, placental lactate is thought to be a fetal energetic substrate. The factors regulating short-term changes in placental oxygen and glucose consumption are at present incompletely understood.

The regulation of placental growth is also an area of incomplete understanding. Increases in trophoblast numbers exceed increases in fetal placental capillary endothelial cells^[10] during the second half of gestation. Whether trophoblast cell proliferation is the primary event, or is dependent on endothelial cell growth is not known. Normal term placental weight averages 450 g, representing approximately one seventh, (one sixth with cord and membranes) of fetal weight. Large-appearing placentas, either ultrasonographically or at delivery, may prompt investigation into possible etiologies. Several clinical observations suggest a link between decreased tissue oxygen content and increased placental growth. Thus, increased placental size is associated with maternal anemia,^[11]^[12]^[13] fetal anemia associated with erythrocyte isoimmunization, and hydrops fetalis secondary to fetal -thalassemia with Bart's hemoglobin. The

association of a large placenta with maternal diabetes also has been recognized, possibly a result of insulin-stimulated mitogenic activity. An increased ratio of placental size to fetal weight is associated with increased morbidity, both in the neonatal period and subsequently.^[14]^[15]

Receptors for growth-promoting peptide hormones (factors) characterized in placental tissue^[16] include, among many, the insulin receptor,^[17]^[18]^[19]^[20]^[21]^[22] receptors for insulin-like growth factors I and II (IGF-I, IGF-II), and epidermal growth factor (EGF).^[23]^[24]^[25]^[26]^[27] IGF-I and IGF-II are polypeptides with a high degree of homology to human proinsulin.^[28] Both IGF-I and IGF-II circulate bound to carrier proteins, and are 50 times more potent than insulin in stimulating cell growth.^[29] EGF increases RNA and DNA synthesis and cell multiplication in a wide variety of cell types.^[19] The observation that placental EGF binding is increased at term, relative to 8 to 18 weeks' gestation, led to a suggested role of EGF in placental growth regulation.^[24] The integrated physiologic role of these and other potential placental growth factors^[29]^[30]^[31] in regulating placental growth remains to be fully defined. However, the development of null-mutation mouse models for IGF-I, IGF-II, IGF-I receptor, and IGF-II receptor as well as for the EGF receptor has provided evidence in this regard.^[32]^[33]^[34]^[35]^[36]^[37] Specifically, the EGF receptor appears important in placental development, as does IGF-II. Knockout of IGF-II results in diminished placental size, while deletion of the IGF-II receptor results in an increase in placental size. IGF-I does not appear to impact placental growth.

Placental Transfer

General Considerations

In the hemochorial human placenta, maternal blood and solutes are separated from fetal blood by trophoblastic tissue and fetal endothelial cells. Thus, transit from the maternal intervillous space to the fetal capillary lumen takes place across a number of cellular structures ([Fig. 2-1](#)) . The first step is transport across the microvillus plasma membrane of the syncytiotrophoblast. Since there are no lateral intercellular spaces in the syncytiotrophoblast, all solutes first interact with the placenta at this plasma membrane. The basal (fetal) syncytiotrophoblast membrane represents an additional step in the transport process. The discontinuous nature of the cytotrophoblast cell layer in later gestation suggests this layer should not limit maternal-to-fetal transfer. However, the presence of anionic sites on the glycoprotein backbone comprising the basal lamina^[38] potentially may influence movement of large charged molecules. The fetal capillary endothelial cell imposes two additional plasma membrane surfaces.^[39]

Figure 2-1 Electron micrograph of human placenta demonstrating the cellular and extracellular components with which solutes most interact in moving from the maternal intervillous space (IVS) to the lumen of the fetal capillary (FC). MPM, microvillous plasma membrane of the syncytiotrophoblast; SC, syncytiotrophoblast; BCM, basal cell membrane of the syncytiotrophoblast; BM, basement membrane; CT, cytotrophoblast cell; FCE, fetal capillary endothelial cell; LIS, lateral intercellular space of fetal endothelial cell. (Courtesy of Kent L. Thornburg, Ph.D., Department of Physiology, Oregon Health Sciences University, Portland, OR.)

A number of specific mechanisms allow transit across the placental membranes, including passive diffusion, facilitated diffusion, active transport, and endocytosis/exocytosis. Solute lacking specialized transport mechanisms cross by extracellular or transcellular diffusional transport pathways with permeability determined by size, lipid solubility, ionic charge, and maternal serum protein binding. Lipid-insoluble (hydrophilic) substances, which cross the trophoblast via extracellular pores, are restricted by molecular size in relation to the extracellular pore size. Up to a molecular weight of at least 5,000 daltons, placental permeability is proportional to the free diffusion of a molecule in water.^[40] For example, urea (MW = 60) is at least 1,000 times more permeable than inulin (MW = 5,000).^[40] Thus, transfer of small solutes will be governed primarily by the maternal-fetal concentration gradient. Because transfer is relatively slow, and the extracellular pore surface area is limited, transfer of these molecules is referred to

as "diffusion-limited." Conversely, highly lipid-soluble (lipophilic) substances diffuse readily through the trophoblastic membrane. Thus, molecular weight is relatively less important in restricting diffusion. Ethanol, a molecule similar in size to urea, is 500 times more lipid soluble and 10 times more permeable. ^[41] Because the entire trophoblast surface is available for diffusion and the permeability is high, transfer rates for lipophilic substances to the fetus are limited primarily by placental intervillous and umbilical blood flows ("flow-limited"). Both facilitated diffusion and active transport utilize carrier-mediated transport systems, with the latter requiring energy, either directly or indirectly linked with ionic pump mechanisms. Carrier transport systems are specifically limited to unique classes of molecules (i.e., neutral amino acids). In addition, substances may traverse the placenta via endocytosis (invagination of the cell membrane to form an intracellular vesicle containing extracellular fluids) and exocytosis (release of the vesicle to the extracellular space).

Transfer of Individual Solutes

Respiratory Gases

The exchange or transfer of the primary respiratory gases, oxygen (O_2) and carbon dioxide (CO_2) is likely "flow limited." Thus, the driving force for placental gas exchange is the partial pressure gradient between the maternal and fetal circulations. Estimates of human placental diffusing capacities ^[42] would predict that placental efficiency as an organ of respiratory gas exchange will allow equilibrium of oxygen and carbon dioxide tensions at the maternal intervillous space and fetal capillary. However, this prediction varies from the observed 10 mm Hg difference in oxygen tension between the umbilical and uterine veins ^[43], ^[44] and between the umbilical vein and intervillous space. ^[45] In addition, even though CO_2 is much more soluble than O_2 in water and tissues and will diffuse more readily than O_2 , the P_{CO_2} difference from umbilical to uterine vein is small (3 mm Hg). ^[46] P_{O_2} differences could be explained by areas of uneven distribution of maternal to fetal blood flows or shunting, limiting fetal and maternal blood exchange. The most important contribution is likely the high metabolic rate of the placental tissues themselves. Thus, trophoblast cell O_2 consumption and CO_2 production lower umbilical vein O_2 tension and increase uterine vein CO_2 tension to a greater degree than could be explained by an inert barrier for respiratory gas transfer.

The arteriovenous difference in the uterine circulation (and venoarterial difference in the umbilical circulation) widens during periods of lowered blood flow. Proportionate O_2 uptake increases and O_2 consumption remains unchanged over a fairly wide range of blood flows. ^[47] Thus, both uterine and umbilical blood flows can fall significantly without decreasing fetal O_2 consumption. ^[48] ^[49] ^[50]

Carbon dioxide is carried in the fetal blood both as dissolved CO_2 and as bicarbonate. Due to its charged nature, fetal-to-maternal bicarbonate transfer is limited. However, CO_2 likely diffuses from fetus to mother in its molecular form, and $[HCO_3^-]$ does not contribute significantly to fetal carbon dioxide elimination. ^[51] Thus, diffusion is not limiting, and the important variables for fetal O_2 uptake and CO_2 excretion reside with uterine and umbilical blood flows, and carrying capacities of maternal and fetal bloods for O_2 and CO_2 .

Glucose

Placental permeability for D-glucose is at least 50 times the value predicted on the basis of size and lipid solubility. ^[52] Thus, specialized transport mechanisms must be available on both the microvillous and basal membranes. Membrane proteins facilitating the translocation of molecules across cell membranes are termed "transporters." The human placental glucose transporter, originally identified as an approximately 55,000 MW component of the microvillous membranes ^[53] ^[54] ^[55] has subsequently been identified as GLUT1, ^[56] ^[57] a sodium-independent transporter, as compared to the sodium-dependent transporters found in adult kidney ^[58] and intestine. ^[59] ^[60] This transporter, in contrast to that found in human adipocytes (GLUT4) ^[61] ^[62] is not insulin sensitive. ^[63] ^[64] The placental D-glucose transporter is saturable at high substrate concentrations; 50 percent saturation is observed at sugar levels of approximately 5 mM (90 mg/dl). ^[54] Thus, glucose transfer from mother to fetus is not linear, and transfer rates decrease as maternal glucose concentration increases. This effect is reflected in fetal blood glucose levels following maternal glucose loading. ^[65] A second transporter, GLUT3, has also been noted in the fetal-facing placental endothelium. Its presence within the syncytiotrophoblast remains controversial. ^[67] ^[68]

Amino Acids

Amino acid concentrations are higher in fetal umbilical cord blood than in maternal blood. Like monosaccharides, amino acids enter and exit the syncytiotrophoblast via transport-specific membrane proteins. These transport proteins allow amino acids to be transported against a concentration gradient into the placenta, and subsequently, in most cases, into the fetal circulation. Thus, amino acid transport is considered to be a "two-step" phenomenon.

Multiple systems mediate neutral, anionic, and cationic

amino acid transport into the syncytiotrophoblast. These include both sodium-dependent and -independent transporters. Amino acid entry is, in many cases, coupled to sodium in co-transport systems located at the microvillous membrane facing the maternal intervillous space. ^[69] ^[70] So long as an inwardly directed sodium gradient is maintained, trophoblast cell amino acid concentrations will exceed maternal blood levels. The sodium gradient is maintained by $Na^+ - K^+$ ATPase located on the basal or fetal side of the syncytiotrophoblast. ^[71] In addition, high trophoblast levels of amino acids transported by sodium-dependent transporters can "drive" uptake of other amino acids via transporters that function as "exchangers." Examples of these include System ASC, and System $y^+ L$. ^[72] ^[73] ^[74] Still other transporters function in a sodium-independent fashion. Individual amino acids may be transported by single or multiple transport proteins. Transport systems that have been defined in human placenta are defined [in Table 2-1](#).

Perhaps the most studied amino acid transporter within the placenta is the sodium-dependent System A, responsible for the transport of neutral amino acids with short polar or linear side chains. Trophoblast cells have two mechanisms of regulating amino acid uptake using the A system. The absence of amino acids increases cellular amino acid uptake, ^[75] ^[76] ^[77] partially because of an increase in carrier affinity. ^[75] Conversely, increases in trophoblast amino acid concentrations may suppress uptake (transinhibition). These mechanisms serve to maintain trophoblast cell amino acid levels constant during fluctuations in maternal plasma concentrations. Insulin has also been shown to up-regulate this transport activity, ^[20] ^[78] ^[79] as has IGF-I. System A is not the only sodium-dependent transporter identified on the microvillous membrane; others include that for -amino acids such as taurine, ^[80] as well as perhaps glycine transport via System GLY. ^[81] Sodium-independent transporters mediating neutral amino acid transfer on the microvillous membrane include System L, which exhibits a high affinity for amino acids with bulky side chains such as leucine, ^[82] and perhaps Systems $b^{0,+}$ and $y^+ L$, capable of transporting both neutral and cationic amino acids such as lysine and arginine. ^[83] ^[84] Cationic amino acids are also transported by System y^+ , ^[85] ^[86] while anionic amino acids (glutamate, aspartate) are transported by the sodium-dependent System X_{AG}^- . It is of interest that, as the proteins responsible for amino acid transport have been identified, it has become clear that more than one protein may mediate each previously defined transport activity within a single tissue. Examples include EAAT 1 to 5, associated with sodium-dependent anionic amino acid transfer (System X_{AG}^-), and CAT 1, 2, and 2a, associated with System y^+ activity. ^[85] ^[87] The anionic amino acids glutamate and aspartate are poorly transported from mother to fetus. ^[88] ^[89] Glutamate, however, is produced by the fetal liver from glutamine, and then taken up across the basolateral membrane of the placenta via System X_{AG}^- . Within the placenta, the majority of glutamate is metabolized and utilized as an energy source. ^[89] As a result, System X_{AG}^- activity is of particular importance on the basolateral membrane, as is System ASC activity, responsible for the uptake of serine, also produced by the fetal liver, into the placenta. ^[90] Abundant data now exist to suggest that placental amino acid transport is regulated in a variety of conditions resulting in altered fetal growth, including malnutrition, idiopathic small-for-dates pregnancies, and diabetes. ^[91] ^[92] ^[93] Mechanisms of regulation, however, remain to be completely elucidated.

Lipids

There is scant information regarding the transfer of maternal lipids across the placenta. Although maternal lipids cross the placenta, the relatively low transfer rates ^[94] ^[95] suggest that the majority of fetal fatty acid accumulation in late pregnancy is not caused by placental transfer. ^[94] Due to their hydrophobic nature, free fatty acids are relatively insoluble in plasma and circulate bound to albumin. Fatty acid transfer involves dissociation from maternal protein, subsequent association with

placental proteins (fatty acid-binding, translocase, and transport proteins) that have been identified in both microvillous and basolateral placental membranes, and then subsequent association with fetal plasma proteins. [96], [97] These protein-binding steps are more important in determining mother-to-fetal fatty acid transfer

TABLE 2-1 -- PLACENTAL NEUTRAL AMINO ACID TRANSPORT SYSTEMS

Transport	A	L	ASC
Representative amino acids	Glycine, proline, alanine, serine, threonine, glutamine	Isoleucine, valine phenylalanine, alanine, serine, threonine, glutamine	Alanine, serine threonine, glutamine
Sodium dependency	+		+
Update increased by preincubation	+		+
Transinhibition	+		

Data summarized from Enders et al., [381] Smith et al., [382] Smith and Depper, [383] and Steel et al. [384]

than interaction with the lipid layers of the placenta. [98], [99] Placental fatty acid transfer increases logarithmically with decreasing chain length (C16 to C8) and then declines somewhat for C6 and C4. This latter effect is due to a decrease in lipid solubility of the shorter chain molecules. [99] Essential fatty acids are, in general, transferred more efficiently than are nonessential fatty acids. [100], [101] In general, though, fatty acids transferred reflect those of the mother. [102] Placental uptake of cholesterol is discussed in the section Receptor-Mediated Endocytosis, below.

Water and Ions

Although water transfer across the placenta does not limit fetal water uptake during growth, [103] the factors regulating fetal water acquisition are poorly understood. Water transfer from mother to fetus is determined by a balance of osmotic, hydrostatic, and colloid osmotic forces at the placental interface. Calculation of osmotic pressure from individual solute concentrations is unreliable because osmotic pressure forces depend upon the membrane permeability to each solute. Thus, sodium and chloride, the principal plasma solutes, are relatively permeable across the placenta [104] and would not be expected to contribute important osmotic effects. [105] As a result, although human fetal plasma osmolality is equal to or greater than maternal plasma osmolality, [106], [107] these measured values do not reflect the actual osmotic force on either side of the membranes. Coupled with findings that hydrostatic pressure may be greater in the umbilical vein than in the intervillous space, [108], [109] these data do not explain mechanisms for fetal water accumulation. Alternatively, colloid osmotic pressure differences [110] and active solute transport probably represent the main determinants of water fluxes. Water flux occurs through both transcellular and paracellular pathways. Water channels have been identified within the placenta, but their regulation and relative roles have not been discerned. [111], [112]

In comparison with other epithelia, the specialized placental mechanisms for ion transport are incompletely understood. [113] Mechanisms for sodium transport in syncytiotrophoblast membranes are outlined in Figure 2-2. The maternal facing microvillous membrane contains, at a minimum, multiple amino acid co-transporters, [114] a sodium phosphate co-transporter in which two sodium ions are transported with each phosphate radical, [115] a sodium-hydrogen ion antiport that exchanges one proton for each sodium ion entering the cell, [116] as well as other nutrient transporters. [117], [118] A membrane potential with the inside negative (-30 MV) would promote sodium entry from the intervillous space. [119] The fetal directed basal side of the cell contains the Na⁺-K⁺ ATPase. [71] The microvillous or maternal facing trophoblast membrane has an anion exchanger

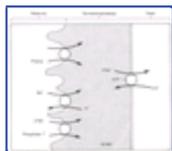

Figure 2-2 Pathways for sodium entry into syncytiotrophoblast and exit to the fetal circulation. (Data from Boyd et al., [376] Whitsett and Wallick, [377] Lajeunesse and Brunette, [378] Balkovetz et al., [379] and Bara et al. [380])

(AE1), [120] which mediates chloride transit across this membrane, in association with Cl⁻ conductance pathways (channels), present in both the microvillous and basolateral membranes. [121], [122] Paracellular pathways also play an important role. The integration and regulation of these various mechanisms for sodium and chloride transport from mother to fetus are not completely understood.

Calcium

Ionized calcium levels are higher in fetal than in maternal blood. [106], [123] Higher fetal calcium levels are caused by a syncytiotrophoblast basal membrane ATP-dependent Ca²⁺ transport system [124] exhibiting high affinity (nanomolar range) for calcium. [125] Calcium transport into the syncytiotrophoblast is mediated by a least one saturable transport process, [126], [127] while transfer across the basal membrane is mediated by the ATPase denoted above, in addition to ATP-independent mechanisms. [128], [129] Calcium transport across the placenta is increased by the calcium-dependent regulatory protein calmodulin [124] transfer may be regulated by 1,25-dihydroxycholecalciferol, calcitonin, and parathyroid hormone. [119] A calcium-binding protein extracted from the placenta [130] differs from the human intestinal calcium-binding protein and may be an important regulator of maternal-to-fetal calcium transport. [131]

Receptor-Mediated Endocytosis/Exocytosis

The microvillous plasma membrane of the syncytiotrophoblast contains receptors specific for insulin, [17] [18] [19] [20] [21] low-density lipoprotein (LDL), [132] [133] [134] and transferrin. [135] [136] [137] In addition, it is known that immunoglobulin G (IgG) is taken up by endocytosis and transferred from the maternal to the fetal circulation. [138], [139] While the precise steps for each protein-receptor complex are not yet defined, general mechanisms for postligand binding, cell entry, and processing can be drawn from available data in other cell types. [140] [141] [142] [143] Following ligand binding, the receptors aggregate on the cell surface and collect in specialized membrane structures termed "coated pits" (Fig. 2-3). These coated pits invaginate, pinch-off, and enter the cell to form vesicles that fuse to form endosomes. The endosomes move deeper into the cytoplasm, where the lower endosome pH facilitates ligand separation from its receptor.

The fate of ligand and receptor differs depending on the specific substrate: whereas insulin receptor is probably recycled to the cell surface, maternal insulin does not reach the fetal circulation because of lysosomal degradation. Cholesterol enters with the LDL receptor and may be used for trophoblast pregnenolone/progesterone synthesis and/or is released into the fetal circulation. [144], [145] IgG remains complexed to its receptor and is

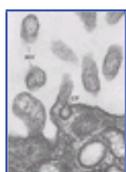

Figure 2-3 Electron micrograph of human placental microvillous plasma membrane demonstrating presence of a coated pit (CP). Note the presence of cytoskeletal components extending into the microvillous space (MV). (Courtesy of Kent L. Thornburg, Ph.D., Department of Physiology, Oregon Health Sciences University, Portland, OR.)

transferred to the fetus intact via exocytosis at the basal trophoblast membrane. [146] Ferrotransferrin carries two ferric ions per molecule and is unique in that it does

not separate from the transferrin receptor. Rather, the iron dissociates and binds to ferritin, a cytoplasmic iron-storing protein. ^[139] Iron is then picked up at the basal side of the cell by fetal apotransferrin.

Placental Blood Flow

The transport characteristics of the placenta allow respiratory gases and many solutes to reach equal concentration between the maternal intervillous space blood (derived from uterine blood flow) and fetal capillary blood (derived from umbilical blood flow). Thus, the rate of blood flow in these two circulations is an important determinant of fetal oxygen and nutrient supply.

Uterine Blood Flow

Uterine blood flow during pregnancy supplies the myometrium, endometrium, and placenta, with the latter

43

receiving nearly 90 percent of total uterine blood flow near term. Thus, interest has focused primarily on regulation of uteroplacental blood flow. Over the course of a normal singleton ovine gestation, uterine blood flow increases more than 50-fold above nonpregnant values. ^[142] This long-term increase in uterine blood flow is accompanied by a doubling of maternal cardiac output and a 40 percent increase in blood volume. Two primary factors contribute to this dramatic increase in uterine blood flow: placental growth and maternal arterial vasodilation. Along with fetal and placental growth, placental intervillous space volume almost triples between 22 and 36 weeks of gestation. Thus, the marked growth of the maternal placental vascular bed is consistent with the increase in placental diffusing capacity. ^[148], ^[149] Second, the increase in blood flow is due in part to a direct estrogen-induced vasodilation of the uterine vasculature. This effect is mediated through the release of nitric oxide. ^[150] These combined effects provide uterine blood flow rates at term of at least 750 ml/min, ^[151], ^[152] or 10 to 15 percent of maternal cardiac output.

The uterine artery behaves as a nearly maximally dilated system. Still, uterine blood flow is subject to short-term regulatory influences. Systemically administered vasodilator agents preferentially dilate systemic vessels, reducing uterine blood flow. ^[153] Thus, concerns regarding administration of antihypertensive agents or regional anesthesia with sympathetic blockade are well founded. Although pregnant women display a refractoriness to infused pressor agents, ^[154] pressor agent-induced increases in uterine vascular resistance may exceed increases in systemic vascular resistance, reducing uteroplacental blood flow. Thus, increased maternal plasma catecholamine levels during preeclampsia or pressor agents administered for treatment of maternal hypotension may have adverse effects on uterine blood flow. Although respiratory gases are important regulators of blood flow in a number of organs, there is no indication that either oxygen or carbon dioxide are responsible for short-term changes in uterine blood flow. ^[155] During uterine contractions, the relationship between uterine arterial and venous pressures and blood flow no longer holds. Since intrauterine pressures are directly transmitted to the intervillous space, ^[156] increases in intrauterine pressure are reflected by decreases in placental blood flow.

Umbilical Blood Flow

Fetal blood flow to the umbilical circulation represents approximately 40 percent of the combined output of both fetal ventricles. ^[157], ^[158] Over the last third of gestation, increases in umbilical blood flow are proportional to fetal growth, ^[159] so that umbilical blood flow remains constant when normalized to fetal weight. ^[160] Human umbilical venous flow can be estimated through the use of triplex mode ultrasonography. ^[161] Although increases in villous capillary number represent the primary contributor to gestation-dependent increases in umbilical blood flow, the factors that regulate this change are not known. A number of important angiogenic peptides and factors have, however, been recently identified. ^[162], ^[163] Short-term changes in umbilical blood flow are primarily regulated by perfusion pressure. The relationship between flow and perfusion pressure is linear in the umbilical circulation. ^[160], ^[164] As a result, small (2 to 3 mm Hg) increases in umbilical vein pressure evoke proportional decreases in umbilical blood flow. ^[160], ^[164] Since both the umbilical artery and vein are enclosed in the amniotic cavity, pressure changes caused by increases in uterine tone are transmitted equally to these vessels without changes in umbilical blood flow. Relative to the uteroplacental bed, the fetoplacental circulation is resistant to vasoconstrictive effects of infused pressor agents, and umbilical blood flow is preserved unless cardiac output decreases. Thus, despite catecholamine-induced changes in blood flow distribution and increases in blood pressure during acute hypoxia, umbilical blood flow is maintained over a relatively wide range of oxygen tensions. ^[165] ^[166] ^[167] ^[168] Endogenous vasoactive autacoids have been identified; nitric oxide may also be important. ^[169], ^[170]

Immunological Properties of the Placenta

The syncytiotrophoblast in contact with maternal blood in the intervillous space and the amniochorion in contact with maternal decidua represent the fetal tissues most prone to immunologic reactions from maternal factors. The rejection of tissue grafts is under genetic control, and the genes responsible for this phenomenon are termed "histocompatibility genes." Their products at the cell surface, major histocompatibility antigens, are integral to the host's recognition of self and non-self. Neither α_2 -microglobulin (which is tightly associated with HLA antigens) nor the HLA antigens A, B, C, DR, or DC can be demonstrated on the surface of syncytiotrophoblast. ^[171], ^[172] Invasive human cytotrophoblasts have been shown to express a trophoblast-specific, nonclassical class 1b antigen, HLA-G. ^[173] Postulated roles for HLA-G include protection of invasive cytotrophoblast from uterine natural killer cells, as well as containment of placental infection. ^[174] The chorionic sac in the first trimester exhibits HLA-A, -B, and -C antigens localized to nonvillous trophoblast of the cytotrophoblast cell columns and cytotrophoblastic shell. ^[175] In addition, histocompatibility antigens can be demonstrated on fetal stromal cells such as fibroblasts and fetal endothelial cells within the placental villi. ^[176] While the normal syncytiotrophoblast at the hemochorial interface

44

within the interstitial space lacks major histocompatibility antigens, the observation that transformed trophoblast in vitro can manifest these antigens suggests the genetic information is present but suppressed in normal tissues in vivo. ^[176] Neither A, B, or H blood group antigens ^[177] nor the H-Y antigens ^[178] are thought to be present on the syncytiotrophoblast surface. The presence of antigens in fetal stroma cells and endothelium of placental villi also may be important to maintenance of the fetus. For example, ^[178] this area may act as an immunologic sink to bind maternal antibodies so they do not reach the fetus.

The syncytiotrophoblast manifests unique antigens, termed trophoblast antigens and trophoblast-lymphocyte cross-reactive antigens. ^[179], ^[179] Distinguishing the two groups is the latter's absorption by leukocytes. These trophoblast antigens are structural components of the plasma membrane and are distinct from soluble proteins produced by the placenta. ^[179] The trophoblast-lymphocyte cross-reactive antigens may be important for the induction of immunologic blocking factors in maternal serum during the second and third trimesters of normal pregnancy. ^[180] Antibodies against these antigens are thought to be important regulators of trophoblast growth. ^[181] The absence of trophoblast antigens, which the mother's immune system can recognize as non-self, may be related to a failure to produce these blocking factors, resulting in abortion. ^[179], ^[181], ^[184] Suppression of lymphocyte activation by local immunoregulatory responses in the decidua plays an important role in preventing rejection of the trophoblast. However, these same responses may also contribute to localized infections at this site in the absence of systemic effects. ^[185] In addition to the placenta, both the mother and the fetus make important contributions to the immunologic maintenance of pregnancy. ^[181], ^[186], ^[187]

Amniotic Fluid Volume

Mean amniotic fluid volume increases from 250 to 800 ml between 16 and 32 weeks' gestation. Despite considerable variability, the average volume remains stable up to 39 weeks and then declines to about 500 ml at 42 weeks. ^[188] The origin of amniotic fluid during the first trimester of pregnancy is uncertain. Possible sources include a transudate of maternal plasma through the chorioamnion or a transudate of fetal plasma through the highly permeable fetal skin, prior to keratinization. ^[189] The origin and dynamics of amniotic fluid are better understood beginning in the second trimester, when the fetus becomes the primary determinant. Amniotic fluid volume is maintained by a balance of fetal fluid production (lung liquid and urine) and fluid resorption (fetal swallowing and flow across the amniotic and/or chorionic membranes to the fetus or maternal uterus).

The fetal lung secretes fluid at a rate of 300 to 400 ml/day near term. ^[190] Chloride is actively transferred from alveolar capillaries to the lung lumen. ^[191] and water follows the chloride gradient. Thus, lung fluid represents a nearly protein-free transudate with an osmolarity similar to that of fetal plasma. ^[192] Fetal lung fluid does not appear to regulate fetal body fluid homeostasis, as fetal intravenous volume loading does not increase lung fluid secretion. Rather, lung fluid likely serves to maintain lung expansion and facilitate pulmonary growth. Lung fluid must decrease at parturition to provide for the transition to respiratory ventilation. Notably, several

hormones that increase in fetal plasma during labor (i.e, catecholamines, arginine vasopressin [AVP]) also decrease lung fluid production. ^[193] ^[194] ^[195] With the reduction of fluid secretion, the colloid osmotic gradient between fetal plasma and lung fluid results in lung fluid resorption across the pulmonary epithelium, and clearance via lymphatics. The absence of this process explains the increased incidence of transient tachypnea of the newborn, or "wet lung," in infants delivered by cesarean section in the absence of labor.

Fetal urine is the primary source of amniotic fluid, with outputs at term varying from 400 to 1,200 ml/day. ^[196] ^[197] Between 20 and 40 weeks' gestation, fetal urine production increases about 10-fold, ^[197] in the presence of marked renal maturation. The urine is normally hypotonic ^[198] and the low osmolarity of fetal urine accounts for the hypotonicity of amniotic fluid in late gestation ^[198] relative to maternal and fetal plasma. Numerous fetal endocrine factors, including AVP, atrial natriuretic factor (ANF), angiotensin II (All), aldosterone, and prostaglandins alter fetal renal blood flow, glomerular filtration rate, or urine flow rates. ^[199] ^[200] In response to fetal stress, endocrine-mediated reductions in fetal urine flow may explain the association between fetal hypoxia and oligohydramnios. The regulation of fetal urine production is discussed further in the section Fetal Kidney, below.

Fetal swallowing is believed to be the major route of amniotic fluid resorption, ^[201] ^[202] ^[203] ^[204] although swallowed fluid contains a mixture of amniotic and tracheal fluids. ^[205] Human fetal swallowing has been demonstrated by 18 weeks' gestation, ^[206] with daily swallowed volumes of 200 to 500 ml near term. ^[202] ^[203] Similar to fetal urine flow, daily fetal swallowed volumes (per body weight) are markedly greater than adult values. With the development of fetal neurobehavioral states, fetal swallowing occurs primarily during active sleep states associated with respiratory and eye movements. ^[206] ^[207] Moderate increases in fetal plasma osmolality increase the number of swallowing episodes and volume swallowed, ^[208] ^[209] indicating the presence of an intact thirst mechanism in the near-term fetus.

Since amniotic fluid is hypotonic with respect to maternal plasma, there is a potential for bulk water removal

at the amniotic-chorionic interface with maternal or fetal plasma. Although fluid resorption to the maternal plasma is likely minimal, intramembranous flow from amniotic fluid to fetal placental vessels may contribute importantly to amniotic fluid resorption. ^[210] Thus, intramembranous flow may balance fetal urine and lung liquid production with fetal swallowing to maintain normal amniotic fluid volumes.

FETAL PHYSIOLOGY

Growth and Metabolism

Substrates

Nutrients are utilized by the fetus for two primary purposes: oxidation for energy and tissue accretion. Under normal conditions, glucose is an important substrate for fetal oxidative metabolism. The glucose utilized by the fetus derives from the placenta rather than from endogenous glucose production. ^[211] However, based on umbilical vein-to-umbilical artery glucose and oxygen concentration differences, ^[212] glucose alone cannot account for fetal oxidative metabolism. In fact, glucose oxidation accounts for only two thirds of fetal carbon dioxide production. ^[213] Thus, fetal oxidative metabolism depends on substrates in addition to glucose. Because a large portion of the amino acids taken up by the umbilical circulation are used by the fetus for aerobic metabolism instead of protein synthesis, amino acids represent one of these substrates. Fetal uptake for a number of amino acids actually exceeds their accretion into fetal tissues. ^[214] In fetal sheep and likely the human fetus as well, lactate also is a substrate for fetal oxygen consumption. ^[215] Thus, the combined substrates glucose, amino acids, and lactate essentially provide the approximately 87 kcal/kg/day required by the growing fetus.

Metabolic requirements for new tissue accretion depend on the growth rate and the type of tissue acquired. Although the newborn infant has relatively increased body fat (16 percent), ^[216] fetal fat content is low at 26 weeks. Fat acquisition increases gradually up to 32 weeks, and rapidly thereafter (82 g [dry weight] of fat per week). Since the necessary enzymes for carbohydrate to lipid conversion are present in the fetus, ^[217] fat acquisition reflects glucose utilization and not placental fatty acid uptake. In contrast, fetal acquisition of nonfat tissue is linear from 32 to 39 weeks, and may decrease to only 30 percent of the fat-acquisition rate in late gestation (43 g [dry weight] per week).

Hormones

The role of select hormones in the regulation of placental growth was discussed previously in the section Placental Metabolism and Growth. Fetal hormones influence fetal growth through both metabolic and mitogenic effects. Although growth hormone and growth hormone receptors are present early in fetal life, and growth hormone is essential to postnatal growth, ^[217] growth hormone appears to have little role in regulating fetal growth. Instead, changes in IGF, IGF-binding proteins, or IGF receptors may explain the apparent reduced role of growth hormone on fetal growth. ^[218] ^[219] ^[220] ^[221] ^[222] Most if not all tissues of the body produce IGF-I and IGF-II, ^[223] ^[224] and both IGF-I and IGF-II are present in human fetal tissue extracts after 12 weeks' gestation. Fetal plasma IGF-I and IGF-II levels begin to increase by 32 to 34 weeks' gestation. ^[225] ^[226] The increase in IGF-I levels directly correlates with increase in fetal raze, and a reduction in IGF-I levels is associated with growth restriction. In contrast, there is no correlation between serum IGF-II levels and fetal growth. However, there is a correlation between small offspring and genetic manipulations resulting in only one allele and decreased IGF-II messenger RNA. Thus, tissue IGF-II concentrations and localized IGF-II release may be more important than circulating levels in supporting fetal growth.

A role for insulin in fetal growth is suggested from the increases in body weight, and heart and liver weights in infants of diabetic mothers. ^[227] Insulin levels within the high physiologic range increase fetal body weight, ^[228] and increases in endogenous fetal insulin significantly increase fetal glucose uptake. ^[229] ^[230] In addition, fetal insulin secretion increases in response to elevations in blood glucose, although the normal rapid insulin response phase is absent. ^[230] Plasma insulin levels sufficient to increase fetal growth ^[228] also may exert mitogenic effects, ^[224] perhaps through insulin-induced IGF-II receptor binding. ^[231] Separate receptors for insulin and IGF-II are expressed in fetal liver cells by the end of the first trimester. ^[232] Hepatic insulin receptor numbers (per gram tissue) triple by 28 weeks, while IGF-II receptor numbers remain constant. ^[232] Thus, although children conceived of diabetic mothers are at increased risk of cardiac defects, the growth patterns of these infants ^[233] ^[234] indicate insulin levels may be most important in late gestation. Though less common, equally dramatically low birth weights are associated with the absence of fetal insulin. ^[219] Experimentally induced hypoinsulinemia causes a 30 percent decrease in fetal glucose utilization and decreases fetal growth. ^[235] ^[237]

As in the adult, -adrenergic receptor activation increases fetal insulin secretion, while -adrenergic activation inhibits insulin secretion. ^[236] ^[238] Fetal glucagon secretion also is modulated by the -adrenergic system. ^[238] However, the fetal glycemic response to glucagon is blunted, probably caused by a relative reduction in hepatic glucagon receptors. ^[240]

In addition to the insulin-like growth factors, a number

of other factors including epidermal growth factor, transforming growth factor, fibroblast growth factor, and nerve growth factor are expressed during embryonic development and appear to exert specific effects during morphogenesis. For example, epidermal growth factor has specific effects on lung growth and growth and differentiation of the secondary palate, ^[241] and normal sympathetic adrenergic system development is dependent on nerve growth factor. ^[241] However, a specific role of these factors in regulating fetal growth remains to be defined. Similarly, the fetal thyroid also is not important for overall fetal growth, but is important for central nervous system development. ^[218] ^[219]

Fetal Circulation

Anatomy

The first step in understanding fetal cardiovascular physiology is to recognize the peculiarities unique to fetal circulatory anatomy. Beginning with well-oxygenated blood from the placenta (Fig. 2-4), the umbilical vein gives off branches to the left lobe of the liver and then continues as the ductus venosus. A major branch to the right then joins the portal vein to supply the right lobe of the liver. Approximately half of the estimated umbilical blood flow (70 to 130 ml/min/kg feed weight ^[242] after 30 weeks' gestation) follows the ductus venosus. ^[243] Left hepatic vein blood combines with the well-oxygenated ductus venosus flow in the inferior vena cava to form a stream that is preferentially directed across the foramen ovale into the left atrium

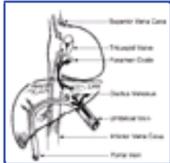

Figure 2-4 Anatomy of the umbilical and hepatic circulation. RHV, right hepatic vein; LHV, left hepatic vein. (From Rudolph AM: *Hepatic and ductus venosus blood flows during fetal life. Hepatology* 3: 254, 1983, with permission.)

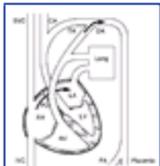

Figure 2-5 Anatomy of fetal heart and central shunts. SVC, superior vena cava; CA, carotid artery; TA, thoracic aorta; DA, ductus arteriosus; RA, right atrium; FO, foramen ovale; LA, left atrium; RV, right ventricle; LV, left ventricle; IVC, inferior vena cava; FA, femoral artery. (From Anderson DF, Bissonnette JM, Faber JJ, Thornburg KL: *Central shunt flows and pressures in the mature fetal lamb. Am J Physiol* 241:H60, 1981, with permission.)

(Fig. 2-4) and (Fig. 2-5). As a result, blood with the highest oxygen content is delivered to the left ventricle, and ultimately supplies blood to the carotid circulation and upper body and brain. Flow across the foramen ovale is approximately one third of combined cardiac output.^[244] Because blood from the ductus venosus to the right side of the liver combines with blood from the portal vein (only a small fraction of portal vein blood passes through the ductus venosus), right hepatic vein blood is less oxygenated than its counterpart on the left.^[249] Right hepatic vein blood joins with inferior vena caval flow (which further lowers the oxygen content) to form a stream that is preferentially directed through the tricuspid valve (Fig. 2-4) into the right ventricle (Fig. 2-5). Superior vena cava blood flow also is preferentially directed through the tricuspid valve to the right ventricle. Thus, right ventricular output, exceeding 50 percent of biventricular output,^[244] is primarily directed through the ductus arteriosus to the descending aorta (Fig. 2-5). The high pulmonary vascular resistance and 2 to 3 mm Hg higher mean pulmonary artery pressure above aortic pressure directs flow to the ductus arteriosus, away from the pulmonary circulation,^[244] which receives only 5 to 10 percent of the combined ventricular output.

Fetal Heart

Estimates of fetal left ventricular output average 20 ml/min/kg body weight.^[245] If left ventricular output is 40 percent of the combined biventricular output,^[244]

then total fetal cardiac output would be about 300 ml/min/kg. The distribution of the cardiac output to fetal organs is summarized in Table 2-2,^[246] ^[247] with fetal hepatic distribution reflecting only the portion supplied by the hepatic artery. In fact, hepatic blood flow derives principally from the umbilical vein and to a lesser extent the portal vein,^[248] and represents about 25 percent of the total venous return to the heart.

Fetal ventricular output depends on contractility, pulmonary artery and aortic pressures, and the heart rate. The relationship between mean right atrial pressure (the index often used for ventricular volume at the end of diastole) and stroke volume is depicted in Figure 2-6. The steep ascending limb represents the length-active tension relationship for cardiac muscle in the right ventricle.^[249] Under normal conditions, fetal right atrial pressure resides at the break point in this ascending limb; increases in pressure do not increase stroke volume. Thus, the contribution of Starling mechanisms to increasing right heart output in the fetus is limited. In contrast, decreases in venous return and right atrial pressure will decrease stroke volume. Because the right ventricle is sensitive to afterload, a linear inverse relationship exists between stroke volume and pulmonary artery pressure.^[249] Thus, the fall in pulmonary artery pressure at birth contributes to the increase in right heart output. Compared to the left, the fetal right ventricle has a greater anteroposterior dimension, increasing both volume and circumferential radius of curvature. This anatomic difference increases the radius/wall thickness ratio for the right ventricle, producing increased wall stress in systole and a decrease in stroke volume when afterload increases.^[250]

The relationship between atrial pressure and stroke volume in the left ventricle is similar to that shown in Figure 2-6 for the right ventricle. Although the break point occurs near the normal value for left atrial pressure, there is a small amount of preload reserve.^[251] In

TABLE 2-2 -- DISTRIBUTION OF FETAL CARDIAC OUTPUT

Organ	Percentage of Biventricular Cardiac Output
Placenta	40
Brain	13
Heart	3.5
Lung	7
Liver	2.5 (hepatic artery)

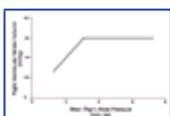

Figure 2-6 Stroke volume of the fetal right ventricle as a function of mean right atrial pressure. (From Thornburg KL, Morton MJ: *Filling and arterial pressures as determinants of RV stroke volume in the sheep fetus. Am J Physiol* 244:H656, 1983, with permission.)

distinction to the fetal right ventricle, the left side is not sensitive to aortic pressure increases. Thus, postnatal increases in systemic blood pressure do not increase stroke volume. Late-gestation fetal heart -adrenergic receptor numbers are similar to the adult,^[252] and increases in circulating catecholamine concentrations may increase stroke volume by 50 percent.^[253] Blood flow to the myocardium reflects the greater stroke volume of the right side; right ventricular free wall and septal blood flows are higher than in the left ventricle.^[254]

Glucose and lactate constitute the major substrates used for oxidative metabolism of the fetal heart. In contrast to the adult heart, free fatty acids are not metabolized in significant amounts by the myocardium in utero.^[255] This may be a function of substrate availability, as palmitate can be oxidized by fetal heart muscle,^[256] although to a lesser extent than in the neonate.

Fetal heart rate decreases during the last half of gestation, particularly between 20 and 30 weeks. If analysis is confined to episodes of low heart rate variability, mean heart rate decreases from 30 weeks to term. However, if all heart rate data are analyzed, mean heart rate is stable at 142 beats per minute over the last 10 weeks of gestation.^[257] Variability in mean heart rate over 24 hours includes a nadir between 2 A.M. and 6 A.M. hours and a peak between 8 A.M. and 10 A.M. hours.^[258] Most fetal heart rate accelerations occur simultaneous with limb movement, primarily reflecting central neuronal brain stem output. Also, movement-related decreases in venous

return and a reflex tachycardia contribute. [259]

Because ventricular stroke volumes decrease with increasing heart rate, fetal cardiac output stays constant over a heart rate range of 120 to 180 beats per min. [260] [261] [262] The major effect of this inverse relationship between heart rate and stroke volume is an alteration in end-diastolic dimension. If end-diastolic dimension is

48

kept constant, there is no fall in stroke volume and cardiac output goes up. [261] , [262]

Autonomic Regulation of Cardiovascular Function

Through reflex stimulation of peripheral baroreceptors, chemoreceptors, and central mechanisms, the sympathetic and parasympathetic systems have important roles in the regulation of fetal heart rate, cardiac contractility, and vascular tone. The fetal sympathetic system develops early, whereas the parasympathetic system develops somewhat later. [263] [264] [265] Nevertheless, in the third trimester, increasing parasympathetic tone accounts for the characteristic decrease in fetal heart rate with periods of reduced fetal heart rate reactivity. As evidence, fetal heart rate increases in the presence of parasympathetic blockade with atropine. [266] Opposing sympathetic and parasympathetic inputs to the fetal heart contribute to R-R interval variability from one heart cycle to the next, and to basal heart rate variability over periods of a few minutes. However, even when sympathetic and parasympathetic inputs are removed, a level of variability remains. [266]

Fetal sympathetic innervation is not essential for blood pressure maintenance when circulating catecholamines are present. [267] Nevertheless, fine control of blood pressure and fetal heart rate requires an intact sympathetic system. [268] In the absence of functional adrenergic innervation, hypoxia-induced increases in peripheral, renal, and splanchnic bed vascular resistances [269] , [270] and blood pressure are not seen. [271] , [272] However, hypoxia-related changes in pulmonary, myocardial, adrenal, and brain blood flows occur in the absence of sympathetic innervation, indicating that both local and endocrine effects contribute to regulation of blood flow in these organs.

Receptors in the carotid body and arch of the aorta respond to pressor or respiratory gas stimulation with afferent modulation of heart rate and vascular tone. Sensitivity of the fetal baroreflex response, in terms of the magnitude of decreases in heart rate per millimeter of mercury increase in blood pressure, is blunted relative to the adult. [273] , [274] However, fetal baroreflex sensitivity more than doubles in late gestation. [275] Although the set-point for fetal heart rate is not believed to depend on intact baroreceptors, fetal heart rate variability increases when functional arterial baroreceptors are absent. [276] The same observation has been made for fetal blood pressure. Thus, fetal arterial baroreceptors buffer variations in fetal blood pressure during body or breathing movements. [275] , [276] Changes in baroreceptor tone likely account for the increase in mean fetal blood pressure normally observed in late gestation. [276] In the absence of functional chemoreceptors, mean arterial pressure is maintained [275] while peripheral blood flow increases. Thus, peripheral arterial chemoreceptors may be important to maintenance of resting peripheral vascular tone. Peripheral arterial chemoreceptors also are important components in fetal reflex responses to hypoxia; the initial bradycardia is not seen without functional chemoreceptors. [277]

Hormonal Regulation of Cardiovascular Function

Adrenocorticotrophic hormone (ACTH) and catecholamines are discussed in the section Fetal Adrenal and Thyroid, below.

ARGININE VASOPRESSIN.

Significant quantities of AVP are present in the human fetal neurohypophysis by completion of the first trimester. [278] Ovine fetal plasma AVP levels increase appropriately in response to changes in fetal plasma osmolality induced directly in the fetus [279] , [280] or via changes in maternal osmolality. [281] , [282] Due to functional high and low-pressure baroreceptors and chemoreceptor afferents, decreases in fetal intravascular volume [283] , [284] or systemic blood pressure [285] , [286] also increase fetal AVP secretion. Thus, in the late-gestation fetus as in the adult, AVP secretion is regulated by both osmoreceptor and volume/baroreceptor pathways. Hypoxia-induced AVP secretion has been demonstrated beyond mid-pregnancy of ovine gestation, [287] and reductions in fetal P_{O_2} of 10 mm Hg (50 percent) evoke profound increases in fetal plasma AVP levels (200 to 400 pg/ml or more) [288] , [289] Thus, because fetal AVP responsiveness to hypoxia is augmented relative to the adult (as much as 40-fold), and fetal responsiveness appears to increase during the last half of gestation, hypoxemia is the most potent stimulus known for fetal AVP secretion. [288]

The cardiovascular response pattern to AVP infusion includes dose-dependent increases in fetal mean blood pressure and decreases in heart rate at plasma levels well below those required for similar effects in the adult. [289] Receptors distinct from those mediating AVP antidiuretic effects in the kidney account for AVP contributions to fetal circulatory, adjustments during hemorrhage, [290] hypotension, [291] and hypoxia. [292] Corticotropin-releasing factor (CRF) effects of AVP may contribute to hypoxia-induced increases in plasma ACTH and cortisol levels. [293] [294] [295] [296] In addition to effects on fetal heart rate, cardiac output, and arterial blood pressure, AVP-induced changes in peripheral, placental, myocardial, and cerebral blood flows [297] [298] [299] [300] directly parallel the cardiovascular changes associated with acute hypoxia. Because many of these responses are attenuated during AVP receptor blockade, [292] AVP effects on cardiac output distribution may serve to facilitate O_2 availability to the fetus during hypoxic challenges. However, other hypoxia-related responses, including decreases in renal

49

and pulmonary blood flows, and increased adrenal blood flow are not seen in response to AVP infusions. [299]

RENIN-ANGIOTENSIN II.

Fetal plasma renin levels are typically elevated during late gestation. [301] A variety of stimuli including changes in tubular sodium concentration, [302] reductions in blood volume, [303] vascular pressure or renal perfusion pressure, [304] and hypoxemia [305] all increase fetal plasma renin activity. The relationship between fetal renal perfusion pressure and log plasma renin activity is similar to that of adults. [306] Consistent with the effects of renal nerve activity on renin release in adults, [307] fetal renin gene expression is directly modulated by renal sympathetic nerve activity. [308]

Although fetal plasma All levels increase in response to small changes in blood volume and hypoxemia, [309] fetal All and aldosterone levels do not increase in proportion to changes in plasma renin activity. [301] This apparent uncoupling of the fetal renin-angiotensin-aldosterone system and the increase in newborn All levels may relate to the significant contribution of the placenta to plasma All clearance in the fetus relative to the adult. [310] Also, limited angiotensin converting enzyme (ACE) availability due to reduced pulmonary blood flow and direct inhibition of aldosterone secretion by the normally high circulating ANF levels may contribute. Thus, reductions in All production and aldosterone responses to All, augmented All and aldosterone clearances, and the resulting reductions in All and aldosterone levels and feedback inhibition of renin may account for the elevated renin and reduced All and aldosterone levels typically observed during fetal life.

All infusion increases fetal mean arterial blood pressure. In contrast to AVP-induced bradycardia, fetal All infusion increases heart rate (after an initial reflex bradycardia) through both a direct effect on the heart, [311] and decreased baroreflex responsiveness. Both hormones increase fetal blood pressure similar to the levels seen with hypoxemia. However, All does not reduce peripheral blood flow, perhaps because circulation to muscle, skin, and bone are always under maximum response to All, thereby limiting increases in resting tone. [311] Angiotensin II infusions also decrease renal blood flow and increase umbilical vascular resistance, although absolute placental blood flow remains the same. While the adult kidney contains both All receptor subtypes (AT_1 and AT_2), the AT_2 subtype is the only form present in the human fetal kidney. [312] Maturation differences in the All receptor subtype expressed would be consistent with earlier studies demonstrating differing All effects on fetal renal and peripheral vascular beds. [309] Thus, the receptors mediating All responses in the renal and peripheral vascular beds differ during fetal life.

Fetal Hemoglobin

The fetus exists in a state of aerobic metabolism, with arterial blood PO_2 values in the 20 to 25 mm Hg range. However, there is no evidence of metabolic acidosis. Adequate fetal tissue oxygenation is achieved by several mechanisms. Of major importance are the higher fetal cardiac output and organ blood flows. A higher

hemoglobin concentration (relative to the adult) and an increase in oxygen-carrying capacity of fetal hemoglobin also contribute. The resulting leftward shift in the fetal oxygen dissociation curve relative to the adult (Fig. 2-7) increases fetal blood oxygen saturation for any given oxygen tension. For example, at a partial pressure of 26.5 mm Hg, adult blood oxygen saturation is 50 percent, whereas fetal oxygen saturation is 70 percent. Thus, at a normal fetal PO_2 of 20 mm Hg, fetal whole blood oxygen saturation may be 50 percent. [313]

The basis for increased oxygen affinity of fetal whole blood resides in the interaction of fetal hemoglobin with intracellular organic phosphate 2,3-diphosphoglycerate (2,3-DPG). The fetal hemoglobin (HgbF) tetramer is comprised of two α -chains (identical to adult) and two γ -chains. The latter differ from the β -chain of adult hemoglobin (HgbA) in 39 of 146 amino acid residues. Among these differences is the substitution of serine in the γ -chain of HgbF for histidine at the -143 position of HgbA, which is located at the entrance to the central cavity of the hemoglobin tetramer. Due to a positively charged imidazole group, histidine can bind with the negatively charged 2,3-DPG. Binding of 2,3-DPG to deoxyhemoglobin stabilizes the tetramer in the reduced form. Because serine is nonionized and does not interact with 2,3-DPG to the same extent as histidine, [314]

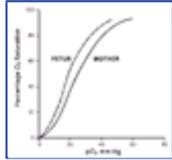

Figure 2-7 Oxyhemoglobin dissociation curves of maternal and fetal human blood at pH 7.4 and 37°C. (Adapted from Hellegers AE, Schrufer JJP: Normograms and empirical equations relating oxygen tension, percentage saturation, and pH in maternal and fetal blood. *Am J Obstet Gynecol* 81:377, 1961.)

50

the oxygen affinity of HgbF is increased and the dissociation curve is shifted to the left. If HgbA or HgbF is removed from the erythrocyte and stripped of organic phosphates, the oxygen affinity for both hemoglobins is similar. However, addition of equal amounts of 2,3-DPG to the hemoglobins decreases the oxygen affinity of HgbA (dissociation curve shifts to the right) to a greater extent than for HgbF. Thus, even though overall oxygen affinities are similar, differences in 2,3-DPG interaction result in a higher oxygen affinity for HgbF.

The proportion of HgbF to HgbA changes between 26 and 40 weeks of gestation, HgbF decreases linearly from 100 percent to about 70 percent, so that HgbA accounts for 30 percent of fetal hemoglobin at term. [315] This change in expression from γ - to β -globulin synthesis takes place in erythroid progenitor cells. [316] Although the basis for this switching is not yet known, our understanding of human globin gene regulation has provided important insights into several fetal hemoglobin disorders such as the thalassemias and sickle cell anemia. Duplication of the γ -genes on chromosome 16 provides the normal fetus with four gene loci. The genes for the remaining globins are located on chromosome 11 and consist of α_1^G , α_2^G , α_1^A , and α_2^A . The two γ -genes differ in the amino acid in position 36; glycine versus alanine. Hemoglobin A synthesis is dictated by the α - and β -genes, HgbF by α and γ , and HgbA₂ by α and β . Sequences in the region may be responsible for the relative expression of the γ -gene, such that fetal hemoglobin persists when these are absent. [317]

Fetal Kidney

Overall fetal water and electrolyte homeostasis is primarily mediated by fetalmaternal exchange across the placenta. However, urine production by the fetal kidney is essential to maintenance of amniotic fluid volume and composition. Although absolute glomerular filtration rate (GFR) increases during the third trimester, GFR per gram kidney weight does not change [318] because GFR and fetal kidney weight increase in parallel. The genesis of new glomeruli is complete by about 36 weeks. [319] Subsequent increases in GFR reflect increases in glomerular surface area for filtration, effective filtration pressure, and capillary filtration coefficient. Although glomerular filtration is related to hydrostatic pressure, and fetal blood pressure increases in the third trimester, both renal blood flow per gram of kidney weight and filtration fraction (GFR/renal plasma flow) remain constant. [318] Newborn increases in filtration fraction parallel increases in arterial pressure, suggesting the lower hydrostatic pressure within the glomerulus contributes to the relatively low filtration fraction and GFR of the intrauterine kidney. [318], [320] A mild glomerulotubular imbalance may describe the early gestation fetus. However, renal tubular sodium and chloride reabsorptions increase in late gestation, such that glomerulotubular balance is maintained in the third-trimester fetus. [320], [321]

Although fetal GFR is low, the daily urine production rate is large (equaling 60 to 80 percent of the amniotic fluid volume). The large urine output results from the large portion of the filtered water (20 percent) that is excreted in the form of hypotonic urine. The positive free water clearance characterizing fetal renal function originally led to the hypothesis that the fetal kidney lacked AVP receptors. However, ovine fetal renal collecting duct responses to AVP can be demonstrated in the second trimester, [322] indicating diminished urine-concentrating ability is not caused by AVP receptor absence. Fetal renal V_2 receptors mediate AVP-induced tubular water reabsorption, and functional V_2 receptors are present in the fetal kidney by the beginning of the last third of gestation. [297], [323] In addition, AVP-induced cyclic adenosine monophosphate (cAMP) production is not different from the adult, [324] and AVP-induced apical tubular water channels (aquaporin II) are expressed in the fetal kidney. In fact, the selective AVP V_2 receptor agonist [deamino¹, D-Arg⁸] vasopressin (dDAVP) appropriately increases fetal renal water reabsorption without affecting blood pressure or heart rate. [291] Thus, V_2 receptors mediate AVP effects on fetal urine production and amniotic fluid volume. [291], [297] Instead, the reduced concentrating ability of the fetal kidney primarily reflects reductions in proximal tubular sodium reabsorption, short juxtamedullary nephron loops of Henle, and limited medullary interstitial urea concentrations.

Although fetal plasma renin activity levels are high, effective uncoupling of All production from plasma renin activity and a high placental clearance rate for All serve to minimize increases in fetal plasma All levels. Limiting fluctuations in fetal plasma All levels may be of advantage to the regulation of fetal renal function. For example, fetal All infusion increases fetal mean arterial pressure, and renal and placental vascular resistances. [325] In contrast, fetal treatment with the ACE inhibitor captopril increases plasma renin activity and decreases arterial blood pressure, renal vascular resistance, and filtration fraction [326] and urine flow effectively ceases. [327] Given the potential for All to decrease placental blood flow, [299] uncoupling of renin-induced angiotensin I production, limited ACE activity, and augmented placental All clearance may protect the fetal cardiovascular system from large increases in plasma All levels. Collectively, plasma All levels appear to be regulated within a very narrow range and this regulation may be important to overall fetal homeostasis.

Atrial natriuretic factor granules are present in the

51

fetal heart, and fetal plasma ANF levels are elevated relative to the adult. [328] Fetal plasma ANF levels increase in response to volume expansion, [329] and ANF infusion evokes limited increases in ovine fetal renal sodium excretion. [330], [331] Fetal ANF infusion also decreases fetal plasma volume, with minimal effect on blood pressure. [329] These observations suggest ANF actions in the fetus are primarily directed at volume homeostasis, with minimal cardiovascular effects.

The ability of the fetal kidney to excrete titratable acid and ammonia is limited relative to the adult. In addition, the threshold for fetal renal bicarbonate excretion (defined as the excretion of a determined amount of bicarbonate per unit GFR) is much lower than in the adult. That is, fetal urine tends to be alkaline at relatively low plasma bicarbonate levels, despite the high fetal arterial PCO_2 . [332] Because fetal renal tubular mechanisms for glucose reabsorption are qualitatively similar to the adult, fetal renal glucose excretion is limited. In fact, the maximum ability of the fetal kidney to reabsorb glucose exceeds that of the adult when expressed as a function of GFR. [333]

Fetal Gastrointestinal System

Gastrointestinal Tract

Amniotic fluid contains measurable glucose, lactate, and amino acid concentrations, raising the possibility that fetal swallowing could serve as a source of nutrient uptake. Fetal swallowing contributes importantly to somatic growth and gastrointestinal development as a result of the large volume of ingested fluid. Ten to 15 percent of fetal nitrogen requirements may result from swallowing of amniotic fluid protein. [334] Amino acids and glucose are absorbed and utilized by the fetus if they

are administered into the fetal gastrointestinal tract. [335], [336] Furthermore, intragastric ovine fetal nutrient administration partially ameliorates fetal growth restriction induced by maternal malnutrition. [337] Further evidence for the role of swallowing in fetal growth results from studies demonstrating that impairment of fetal rabbit swallowing at 24 days gestation (term = 31 days) induces an 8 percent weight decrease (compared to controls) by 28 days. [338] The fetal gastrointestinal tract is directly impacted, as esophageal ligation of fetal rabbit pups results in marked reductions in gastric and intestinal tissue weight and gastric acidity. [1] Reductions in gastrointestinal and somatic growth were reversed by fetal intragastric infusion of amniotic fluid. [1] Similarly, esophageal ligation of 90-day ovine fetuses (term = 145 to 150 days) induces a 30 percent decrease of small intestine villus height [339] and a reduction in liver, pancreas, and intestinal weight. [340] Although ingestion of amniotic fluid nutrients may be necessary for optimal fetal growth, trophic growth factors within the amniotic fluid also importantly contribute. Thus, the reduction in fetal rabbit weight induced by esophageal ligation is reversed by gastric infusion of epidermal growth factor. [166] Studies in human infants support the association of fetal swallowing and gastrointestinal growth as upper gastrointestinal tract obstructions are associated with a significantly greater rate of human fetal growth restriction as compared to fetuses with lower gastrointestinal obstructions. [341], [342]

Blood flow to the fetal intestine does not increase during moderate levels of hypoxemia. The arterymesenteric vein difference in oxygen content is also unchanged so that at a constant blood flow intestinal oxygen consumption can remain the same during moderate hypoxemia. However, with more pronounced hypoxemia, fetal intestinal oxygen consumption falls as blood flow decreases and the oxygen content difference across the intestine fails to widen. The result is a metabolic acidosis in the blood draining the mesenteric system. [343]

Liver

Near term, the placenta is the major route for bilirubin elimination. Less than 10 percent of an administered bilirubin load is excreted in the fetal biliary tree over a 10-hour period; about 20 percent remains in plasma. [334] Thus, the fetal metabolic pathways for bilirubin and bile salts remain underdeveloped at term. The cholate pool size (normalized to body surface area) is one third and the synthetic rate one half adult levels. In premature infants, cholate pool size and synthesis rates represent less than half and one third, respectively, of term infant values. In fact, premature infant intraluminal duodenal bile acid concentrations are near or below the level required to form lipid micelles. [344] The unique attributes of the fetal hepatic circulation were detailed during the earlier discussion of fetal circulatory anatomy. Notably, the fetal hepatic blood supply primarily derives from the umbilical vein. The left lobe receives its blood supply almost exclusively from the umbilical vein (there is a small contribution from the hepatic artery), while the right lobe receives blood from the portal vein as well. The fetal liver under normal conditions accounts for about 20 percent of total fetal oxygen consumption. [345] Because hepatic glucose uptake and release are balanced, net glucose removal by the liver under normal conditions is minimal. [345] During episodes of hypoxemia, -adrenergic receptor-mediated increases in hepatic glucose release account for the hyperglycemia characteristic of short-term fetal hypoxemia. [239] Hypoxia severe enough to decrease fetal oxygen consumption selectively reduces right hepatic lobe oxygen uptake, which exceeds that of the fetus as a

52

whole. In contrast, oxygen uptake by the left lobe of the liver is unchanged. [345]

Fetal Adrenal and Thyroid

Adrenal

The fetal pituitary secretes ACTH in response to "stress," including hypoxemia. [346] The associated increase in cortisol exerts feedback inhibition of the continued ACTH response. [347] In the fetus and adult, proopiomelanocortin posttranslational processing gives rise to ACTH, corticotropin-like intermediate lobe peptide (CLIP), and -melanocortin-stimulating hormone (-MSH). The precursor peptide proenkephalin is a distinct gene product giving rise to the enkephalins. Fetal proopiomelanocortin processing differs from the adult. For example, although ACTH is present in appreciable amounts, the fetal pituitary contains large amounts of CLIP and -MSH. The fetal ratio of CLIP plus -MSH to ACTH decreases from the end of the first trimester to term. [348] Because pituitary corticotropin-releasing hormone (CRH) expression is relatively low until late gestation, AVP serves as the major CRF in early gestation. With increasing gestational age, fetal cortisol levels progressively increase secondary to hypothalamic-pituitary axis maturation. Cortisol is important to pituitary maturation because it shifts corticotrophs from the fetal to the adult type and to adrenal maturation through regulation of ACTH receptor numbers. [349]

On a body weight basis, the fetal adrenal gland is an order of magnitude larger than in the adult. This increase in size is due to the presence of an adrenal cortical definitive zone and a so-called fetal zone, which constitutes 85 percent of the adrenal at birth. Cortisol and mineralocorticoids are the major products of the fetal definitive zone, and fetal cortisol secretion is regulated by ACTH but not human chorionic gonadotrophin (hCG). [350], [351] Low-density lipoprotein-bound cholesterol (see Receptor Mediated Endocytosis/Exocytosis, above) is the major source of steroid precursor in the fetal adrenal. [352], [353] Because the enzyme 3-hydroxy-steroid dehydrogenase is lacking in the fetal adrenal, dehydroepiandrosterone sulfate (DHEAS) is the major product of the fetal zone. At mid-gestation, DHEAS secretion is determined by both ACTH and hCG. [350], [351] Both fetal ACTH and cortisol levels are relatively low during most of gestation, and there is not a clear correlation between plasma ACTH levels and cortisol production. This apparent dissociation between fetal ACTH levels and cortisol secretion [354] may be explained by (1) differences in ACTH processing and the presence of the large-molecular-weight proopiomelanocortin processing products (CLIP and -MSH) may suppress ACTH action on the adrenal until late gestation (when ACTH becomes the primary product), (2) fetal adrenal definitive zone ACTH responsiveness may increase, or (3) placental ACTH and/or posttranslational processing intermediates may affect the adrenal response to ACTH.

Resting fetal plasma norepinephrine levels exceed epinephrine levels approximately 10-fold. [355], [356] The fetal plasma levels of both catecholamines increase in response to hypoxemia, with norepinephrine levels invariably in excess of the epinephrine levels. [356] Under basal conditions, norepinephrine is secreted at a higher rate than for epinephrine, and this relationship persists during a hypoxemic stimulus. [357] Plasma norepinephrine levels increase in response to acute hypoxemia, but decline to remain above basal levels with persistent (>5 minutes) hypoxemia. In contrast, adrenal epinephrine secretion begins gradually, but persists during 30 minutes of hypoxemia. These observations are consistent with independent sites of synthesis and regulation of the two catecholamines. [358] While the initial fetal blood pressure elevation during hypoxemia correlates with increases in norepinephrine, afterward, the correlation between plasma norepinephrine and hypertension is lost. [356]

Thyroid

The normal placenta is impermeable to thyroid-stimulating hormone (TSH), and triiodothyronine (T_3) transfer is minimal. [359] However, appreciable levels of maternal thyroxine (T_4) are seen in infants with congenital hypothyroidism. [360] By the 12th week of gestation, thyrotropin releasing hormone (TRH) is present in the fetal hypothalamus, and TRH secretion and/or pituitary sensitivity to TRH increases progressively during gestation. Extrahypothalamic sites including the pancreas also may contribute to the high TRH levels observed in the fetus. [359] Measurable TSH is present in the fetal pituitary and serum, and T_4 is measurable in fetal blood by week 12 of gestation. Thyroid function is low until about 20 weeks, when T_4 levels increase gradually to term. TSH levels increase markedly between 20 and 24 weeks, then slowly decrease until delivery. Fetal liver T_4 metabolism is immature, characterized by low T_3 levels until the 30th week. In contrast, reverse T_3 levels are high until 30 weeks, thereafter declining steadily until term.

Fetal Central Nervous System

Clinically relevant indicators of fetal central nervous system function are body movements and breathing movements. Fetal activity periods in late gestation are often termed active or reactive and quiet or nonreactive. The active cycle is characterized by clustering of gross fetal body movements, a high heart rate variability,

53

heart rate accelerations (often followed by decelerations), and fetal breathing movements. The quiet cycle is noted by absence of fetal body movements and a low variability in the fetal heart period. [361], [362] Fetal heart period variability in this context refers to deviations about the model heart rate period averaged over short (seconds) periods, [363] and is distinct from beat-to-beat variability. In the last 6 weeks of gestation, the fetus is in an active state 60 to 70 percent of total time. The average duration of quiet periods ranges from 15 to 23 minutes (see Table IV in Visser et al. [363] for a review).

The fetal electrocorticogram shows two predominant patterns. Low-voltage (high-frequency) electrocortical activity is associated with bursts of rapid eye movements and fetal breathing movements.^[364] Similar to rapid eye movement sleep in the adult, inhibition of skeletal muscle movement is most pronounced in muscle groups having a high percentage of spindles. Thus, the diaphragm, which is relatively spindle free, is not affected. Fetal body movements during low-voltage electrocortical activity are reduced relative to the activity seen during high-voltage (low-frequency) electrocortical activity.^[365] Polysynaptic reflexes elicited by stimulation of afferents from limb muscles are relatively suppressed when the fetus is in the low-voltage state.^[366] Short-term hypoxia^[365] or hypoxemia inhibit reflex limb movements, with the inhibitory neural activity arising in the midbrain area.^[366] Fetal cardiovascular and behavioral responses to maternal cocaine use previously have been attributed to reductions in uteroplacental blood flow and resulting fetal hypoxia. However, recent fetal sheep studies indicate acute fetal cocaine exposure evokes catecholamine, cardiovascular, and neurobehavioral effects in the absence of fetal oxygenation changes.^[367] It is not yet clear whether cocaine-induced reductions in fetal low-voltage electrocortical activity reflect changes in cerebral blood flow or a direct cocaine effect on norepinephrine stimulation of central regulatory centers. However, these observations are consistent with the significant neurologic consequences of cocaine use during pregnancy.

Fetal breathing patterns are rapid and irregular in nature, and are not associated with significant fluid movement into the lung.^[364] The central medullary respiratory chemoreceptors are stimulated by carbon dioxide,^[368] and fetal breathing is maintained only if central hydrogen ion concentrations remain in the physiologic range. That is, central (medullary cerebrospinal fluid) acidosis stimulates respiratory incidence and depth and alkalosis results in apnea.^[369] Paradoxically, hypoxemia markedly decreases breathing activity, possibly due to inhibitory input from centers above the medulla.^[370]

Glucose is the principal substrate for oxidative metabolism in the fetal brain under normal conditions.^[371] During low-voltage electrocortical activity, cerebral blood flow and oxygen consumption are increased relative to high-voltage values,^[372] with an efflux of lactate. During high voltage the fetal brain shows a net uptake of lactate.^[373] The fetal cerebral circulation is sensitive to changes in arterial oxygen content. Despite marked hypoxia-induced increases in cerebral blood flow, cerebral oxygen consumption is maintained without widening of the arterial-venous oxygen content difference across the brain.^[374] Increases in carbon dioxide also cause cerebral vasodilation. However, the response to hypercarbia is reduced relative to the adult.^[375]

SUMMARY

The fetus and placenta depend upon unique physiologic systems to provide an environment supporting fetal growth and development, in preparation for transition to extrauterine life. Because specific functions of the various physiologic systems are often gestation specific, differences between the fetus and adult of one species are often larger than the differences between systems. Thus, the clinician or investigator concerned with fetal life or neonatal transition must fully appreciate these aspects of fetal physiology and their application to their area of study or treatment.

Key Points

Pregnancy-associated cardiovascular changes include a doubling of maternal cardiac output and a 40 percent increase in blood volume.
Uterine blood flow at term averages 750 ml/min, or 10 to 15 percent of maternal cardiac output.
Normal term placental weight averages 450 g, representing approximately one seventh (one sixth with cord and membranes) of fetal weight.
Mean amniotic fluid volume increases from 250 to 800 ml between 16 and 32 weeks, and decreases to 500 ml at term.
Fetal urine production ranges from 400 to 1200 ml/day and is the primary source of amniotic fluid.
The fetal umbilical circulation receives approximately 40 percent of fetal combined ventricular output (300 ml/mg/min).
Umbilical blood flow is 70 to 130 ml/min after 30 weeks' gestation.

54

Fetal cardiac output is constant over a heart rate range of 120 to 180 beats/min.
The fetus exists in a state of aerobic metabolism, with arterial PO₂ values in the 20 to 25 mm Hg range.
Approximately 20 percent of the fetal oxygen consumption of 8 ml/kg/min is required in the acquisition of new tissue.

Chapter 3 - Maternal Physiology in Pregnancy

Michael C. Gordon

Major adaptations in maternal anatomy, physiology, and metabolism are required for a successful pregnancy. Hormonal changes, initiated before conception, significantly alter maternal physiology, and continue throughout the entire pregnancy. These alterations are needed to allow the development of a single diploid cell into an infant weighing 3.5 kg. These adaptations profoundly affect nearly every organ system and yet allow the woman to return to her prepregnancy state with minimal residual changes.¹ The obstetrician must fully understand these changes to determine what signs and symptoms are normal and which are potentially due to disease processes either unique to or exacerbated by pregnancy. This chapter will describe maternal adaptations in pregnancy and give examples of how these changes can affect the care of the pregnant woman.

BODY WATER METABOLISM

The increase in total body water of 6.5 to 8.5 L by the end of pregnancy represents one of the most significant adaptations of pregnancy. The water content of the fetus, placenta, and amniotic fluid at term accounts for about 3.5 L. Maternal blood volume is expanded by 1,500 to 1,600 ml, plasma volume by 1,200 to 1,300 ml, and red blood cells (RBCs) by 300 to 400 ml.^[2] The remainder of the increase in water content is attributed to extravascular fluid, intracellular fluid in the uterus and breasts, and expanded adipose tissue. Thus, pregnancy is a condition of chronic volume overload in which hypervolemia is the result of active sodium and water retention due to changes in osmoregulation and the renin-angiotensin system. The increase in body water content is reflected in maternal weight gain and contributes to the hemodilution of pregnancy, physiologic anemia of pregnancy, and elevation in maternal cardiac output.

Osmoregulation

The expansion in the plasma volume begins shortly after conception. It is associated with and partially mediated by a change in maternal osmoregulation and the control of the secretion of arginine vasopressin (AVP) by the posterior pituitary. Water metabolism is controlled by AVP (also known as antidiuretic hormone [ADH]) and thirst. Despite an overall increase in sodium retention of 900 mEq during pregnancy, the serum level of sodium decreases during a normal pregnancy by 3 to 4 mmol/L. In addition, the plasma osmolality decreases by 8 to 10 mOsm/kg by 10 weeks' gestation and remains at this lower level throughout pregnancy and until 1 to 2 weeks postpartum^[3],^[4] (Fig. 3-1). The initial decline in serum sodium and osmolality begins at 5 weeks' gestation and is due to a resetting of the osmotic thresholds for both thirst and AVP secretion. The threshold for thirst changes early in pregnancy. Therefore, during gestational weeks 5 to 8, an increase in water intake occurs and results in increased urinary volume. This transient polyuria is the result of a lowered osmotic threshold for thirst prior to a change in the osmotic threshold for AVP release.^[5]

Lowering the threshold to drink stimulates water intake and dilution of body fluids. Because AVP release is not suppressed at the usual body tonicity, the hormone continues to circulate and the ingested water is retained, increasing in total body water. After 8 weeks' gestation, when the threshold for AVP secretion has been reset and the new steady state for osmolality has been established, little change in water turnover occurs and pregnant women should not be polyuric or polydipsic. The

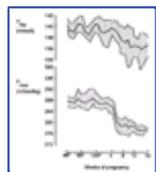

Figure 3-1 Plasma osmolality and plasma sodium during human gestation ($n = 9$: mean values \pm SD). MP, menstrual period; LMP, last menstrual period. (From Davison JM, Vallotton MB, Lindheimer MD: Plasma osmolality and urinary concentration and dilution during and after pregnancy: evidence that the lateral recumbency inhibits maximal urinary concentration ability. *Br J Obstet Gynaecol* 88:472, 1981. Copyright Blackwell Science Ltd, with permission.)

pregnant woman perceives this decrease in plasma sodium and osmolality as normal and defends this lower steady state tonicity by concentrating and diluting normally around the new P_{osm} . Thus the gravid individual responds to fluid challenges or dehydration normally with changes in thirst and AVP secretion but at a new "osmostat."^[6]

Plasma levels of AVP during pregnancy are similar to nonpregnant levels despite a three to fourfold increase in the metabolic clearance of AVP. The increased clearance is caused by the presence of a circulating vasopressinase synthesized by the placenta that rapidly inactivates AVP and oxytocin. This enzyme increases 1,000-fold from 4 weeks' gestation until term. Yet, plasma concentrations of AVP are unchanged due to its heightened production. The need for greater AVP production to maintain normal AVP levels and normal osmoregulation of pregnancy can unmask what are subclinical forms of diabetes insipidus and cause transient diabetes insipidus in pregnancy.^[6] This is one example of how pregnancy may act as a stress test to uncover diseases that were previously latent or compensated when the woman is not pregnant. Gestational diabetes is another.

Salt Metabolism

Sodium metabolism is delicately balanced in pregnancy to permit a net accumulation of about 900 mEq of sodium. Sixty percent of the additional sodium enters the fetoplacental unit including the amniotic fluid and is lost at birth. Pregnancy increases the preference for salt and sodium intake, and this change accounts for some of the sodium accumulation. However, retention by the kidney is the main mechanism because of the enhanced tubular sodium reabsorption from early in pregnancy. During pregnancy, a 50 percent rise in the glomerular filtration rate leads to an increase in the filtered sodium load from 20,000 to about 30,000 mmol/day. Without an increase in tubular sodium reabsorption, greater sodium loss would occur. The adaptive rise in tubular reabsorption not only equals the increase in the filtered load but also is associated with an additional 2 to 6 mEq of sodium reabsorption. Renal sodium handling is another determinant of increased volume homeostasis and represents the largest renal adjustment that occurs during pregnancy.^[7] The mechanisms responsible for the renal tubular adjustments are incompletely understood. Hormonal control of sodium balance is under the opposing actions of the renin-angiotensin-aldosterone system and atrial natriuretic peptide (ANP), and both are modified during pregnancy.

Renin-Angiotensin-Aldosterone System

In normal pregnancy, marked increases in all the components of this system occur. Plasma renin activity is 5 to 10 times the nonpregnant level. Likewise, renin substrate (angiotensinogen) and angiotensin levels are increased four to fivefold and lead to elevated levels of aldosterone.^[8],^[9] In the third trimester, plasma aldosterone levels are twofold higher than in the nonpregnant state. This rise in aldosterone production is most likely the key factor in sodium reabsorption and prevention of sodium loss.^[9] Despite the elevated aldosterone levels in late pregnancy, a normal homeostatic response occurs to changes in salt balance, fluid loss, and postural stimuli. In addition to aldosterone, other hormones might be responsible for increased tubular sodium retention, including deoxycorticosterone and estrogen.

Atrial Natriuretic Peptide

Secreted by atrial myocytes in response to atrial distention, ANP plays a major role in the regulation of extracellular fluid volume. It is a diuretic, a natriuretic, a

and pathologic conditions of volume overload. Whether ANP secretion is increased during gestation is controversial, as some authors have reported higher plasma levels during different stages of pregnancy, whereas others have reported no change.^[10] In a meta-analysis by Castro et al., ANP levels were 40 percent higher during gestation and 150 percent higher during the first postpartum week. The authors speculated that the atrial stretch receptors sensed the expanded blood volume of pregnancy and thus increased production. The increase in postpartum ANP was felt to be consistent with the increased fluid volume postpartum and possibly contributed to postpartum diuresis.^[11] By comparison, Sala et al. found that ANP levels were increased only in the first trimester and only in the supine position. These authors hypothesized that during pregnancy body posture can greatly affect ANP production. Normal ANP levels in later pregnancy may be caused by vena caval compression from the enlarged uterus with decreased atrial blood volume and a decreased stimulus for ANP secretion^[12] (Fig. 3-2) (Figure Not Available) . Therefore, the discrepancies reported in these studies appear to be caused by the effects of body position on ANP secretion. ANP may also contribute to the systemic vasodilation of pregnancy by acting directly as a vasorelaxant or indirectly as an antagonist of the renin-angiotensin system.

Figure 3-2 (Figure Not Available) Bar graphs show plasma atrial natriuretic peptide (ANP) at each trimester (Tm) of pregnancy and postpartum in 15 healthy women in the supine and upright positions (mean \pm SEM). * $p < 0.05$ versus postpartum in the same position; § $p < 0.05$ versus corresponding supine value. (From Sala C, Campise M, Ambroso G, et al: *Atrial natriuretic peptide and hemodynamic changes during normal human pregnancy. Hypertension* 25:631, 1995, with permission.)

CARDIOVASCULAR SYSTEM

Pregnancy causes profound physiologic changes in the cardiovascular system. In most women, these physiologic demands are well tolerated. However, in certain cardiac diseases, maternal morbidity and even mortality may occur.

Heart

Because of the displacement of the diaphragm and the effect of pregnancy on the shape of the rib cage, the heart is displaced to the left and upward. In addition, the heart is rotated on its long axis and as a result the apex is moved somewhat laterally. This results in an apparent increase in the size of the cardiac silhouette on radiographic studies even though no true change in the cardiothoracic ratio occurs. An apparent straightening of the left heart border occurs with increased prominence of the pulmonary conus. These radiographic changes make the diagnosis of cardiomegaly by simple radiography suspect. ^[12]

As a result of the expanded blood volume, there is an increase in left ventricular end-diastolic dimension as measured by M-mode echocardiography. This is observed in the first trimester, continues until term, and is accompanied by an increase in left ventricular wall mass consistent with mild myocardial hypertrophy. These structural changes in the heart are similar to those found in response to physical training and show that the structural heart changes during pregnancy are consistent with the effects of chronic strain on the heart. ^[13] The left and right atrial diameters also increase in dimension beginning early in gestation, with a plateau by 30 weeks. This increase is also a result of the rise in blood volume and suggests an increase in preload. Since there is no increase in the central venous pressure or the pulmonary capillary wedge pressure, there must be an increase in the capacitance of the systemic and pulmonary veins as reflected in a decrease in the systemic and pulmonary vascular resistances.

Cardiac Output

In a review of the literature on cardiac output in pregnancy, van Oppen et al. reviewed 33 cross-sectional and 19 longitudinal studies. They found greatly divergent results on when cardiac output peaked, the magnitude of the rise in cardiac output prior to labor, and the effect of the third trimester on cardiac output. ^[14] However, all of the studies agreed that cardiac output increased significantly during pregnancy by an average of 30 to 50 percent above nonpregnant values. In a longitudinal study by Robson et al. using Doppler

echocardiography, cardiac output was found to increase by 50 percent at 34 weeks from a prepregnancy value of 4.88 L/min to 7.34 L/min ^[14], ^[15] (Fig. 3-3). In twin gestations, cardiac output is raised an additional 15 percent above that of singleton pregnancies. In the review by van Oppen et al. cardiac output was found to increase by 5 weeks' gestation. By 12 weeks, the rise in output was 34 to 39 percent above nonpregnant levels, accounting for about 75 percent of the total increase in cardiac output during pregnancy. The numerous studies in the literature disagree on when cardiac output peaks, but the overall conclusion seems to be somewhere around 25 to 30 weeks of gestation, with a rise from the first to the second trimester. The data on whether the cardiac output continues to increase in the third trimester are very divergent, with equal numbers of good longitudinal studies showing a mild decrease, a

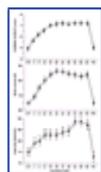

Figure 3-3 Increase in cardiac output from the nonpregnancy state throughout pregnancy. P-P, pre-pregnancy; PN, postnatal. (From Hunter S, Robson S: *Adaptation of the maternal heart in pregnancy*. *Br Heart J* 68:540, 1992, with permission.)

slight increase, or no change. ^[14] The differences in these studies cannot be explained by differences in investigative techniques, position of the women during measurements, or study design. This apparent discrepancy appears to be explained by the small number of individuals in each study and the probability that the course of cardiac output during the third trimester is apparently determined by factors within individual women. If this is true, then within any given patient, cardiac output may rise, fall, or not change during the third trimester ^[14], ^[16] (Fig. 3-3).

Most of the increase in cardiac output is directed to the uterus and placenta, and the breasts. In the first trimester, as in the nonpregnant state, the uterus receives 2 to 3 percent of cardiac output and the breasts 1 percent. By term, the uterus receives 17 percent (450 to 650 ml/min) and the breasts 2 percent, mostly at the expense of a reduction of the fraction of the cardiac output going to the splanchnic bed and skeletal muscle. The absolute blood flow to the liver is not changed but the overall percentage of cardiac output is significantly decreased. The percentage of cardiac output going to the kidneys (20 percent), skin (10 percent), brain (10 percent), and coronary arteries (5 percent) remains at similar nonpregnant percentages, but because of the overall increase in cardiac output this results in an increase in absolute blood flow of approximately 50 percent. ^[17]

Cardiac output (CO) is the product of stroke volume (SV) and heart rate (HR) ($CO = SV \times HR$), both of which increase during pregnancy and contribute to the overall rise in cardiac output. An initial rise in the heart rate occurs by 5 weeks' gestation and continues until it peaks at 32 weeks' gestation at 15 to 20 beats above the pregravid rate, an increase of 17 percent. The stroke volume begins to rise by 8 weeks' gestation and reaches its maximum at about 20 weeks, 20 to 30 percent above nonpregnant values. In the third trimester, it is the changes in the stroke volume that determine whether the cardiac output increases, decreases, or remains stable as described earlier ^[18], ^[19] (Fig. 3-3).

Cardiac output in pregnancy depends on maternal position, being lowest in the sitting or supine position and highest in the right and left lateral and knee-chest positions. In a study in 10 normal gravid women in the third trimester, using pulmonary artery catheterization, the cardiac output was noted to be highest in the knee-chest position and lateral recumbent position at 6.6 to 6.9 L/min. The cardiac output decreased by 22 percent to 5.4 L/min in the standing position ^[19] (Fig. 3-4). In both the standing and the supine positions, a fall in stroke volume takes place as a result of decreased blood return to the heart, which results in the decrease in cardiac output.

In the supine position, the enlarged uterus compresses the inferior vena cava, reducing venous return to the heart and in turn the stroke volume and cardiac

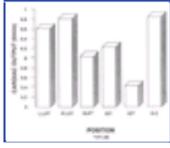

Figure 3-4 Effect of position change on cardiac output during pregnancy. L.LAT, left lateral; R.LAT, right lateral; SUP, supine; ST, standing; SIT, sitting; K-C, knee-chest. (From Clark S, Cotton D, Pivarnik J, et al: Position change and central hemodynamic profile during normal third-trimester pregnancy and postpartum. *Am J Obstet Gynecol* 164:883, 1991, with permission.)

output. In fact, in late pregnancy, the inferior vena cava is completely occluded in the supine position, with venous return from the lower extremities occurring through the dilated paravertebral collateral circulation.^{[20], [21]} The effect of the supine position on cardiac output is most marked in late pregnancy. The decrease in cardiac output in the supine position compared with the lateral recumbent position is 10 to 30 percent.^{[19], [22]} Prior to 24 weeks the effect of the supine position on cardiac output is not observed.

Despite the decrease in cardiac output in the supine position, the majority of women are not hypotensive or symptomatic because of the compensated rise in systemic vascular resistance (SVR). However, 5 to 10 percent of gravidas manifest supine hypotension with symptoms of dizziness, lightheadedness, nausea, and even syncope. Some investigators have proposed that the determination of whether women become symptomatic or not depends on the development of an adequate paravertebral collateral circulation. With inadequate collateral flow, a woman develops a vasovagal attack, with a decrease in heart rate and a fall in blood pressure (Fig. 3-5) (Figure Not Available). Interestingly, with engagement of the fetal head, less of an effect on cardiac output is seen.^[23] The ability to maintain a normal blood pressure in the supine position may be lost during epidural or spinal anesthesia because of an inability to increase the SVR.

Clinically, the effects of maternal position on cardiac output are important when maintenance of the cardiac output is vital, such as occurs with a nonreassuring fetal heart rate pattern or if the woman becomes hypotensive. Also, the finding of a decreased cardiac output in the standing position may give a physiologic basis for the observation of decreased birth weight and placental infarctions in working women who stand.^[23]

Arterial Blood Pressure and Systemic Vascular Resistance

Blood pressure (BP) is the product of cardiac output and resistance ($BP = CO \times SVR$). In spite of the large

Figure 3-5 (Figure Not Available) Summary of hemodynamic effects of supine position in late pregnancy. (From Kerr M: The mechanical effects of the gravid uterus in late pregnancy. *J Obstet Gynaecol Br Commonw* 72:513, 1965, with permission.)

increase in cardiac output, the maternal BP is decreased until later in pregnancy as a result of a decrease in SVR. The SVR decreases to a minimum at midpregnancy followed by a gradual rise until term, when it is still 21 percent lower than nonpregnant values^{[13], [18], [24]} (Fig. 3-6). The most obvious cause for the decreased SVR is the smooth muscle-relaxing effects of the elevated progesterone level; however, the exact mechanism for the fall in SVR is poorly understood. The earlier notion of the uteroplacental circulation acting as an arteriovenous shunt seems unlikely. A more promising theory involves the presence of one or more circulating substances exerting a vasodilatory effect on the arterial and venous vasculature.^[19] This may involve nitric oxide, prostaglandins, or ANP. In addition, despite the overall increase in the renin-angiotensin system in pregnancy, the normal pregnant woman is refractory to the hypertensive effects of angiotensin II. Gant et al. showed that nulliparous women who later become preeclamptic lose this refractoriness prior to developing clinical signs of preeclampsia.^[25]

The decrease in maternal BP parallels that of SVR. A decrease occurs by at least 8 weeks' gestation or earlier. In the normal menstrual cycle, BP is decreased in the luteal phase and rises with menstruation.^[26] The diastolic BP and the mean arterial pressure [MAP = (Systolic BP + Diastolic BP)/3] decrease more than the systolic BP, which changes minimally during pregnancy. The diastolic BP and the MAP nadir at midpregnancy (16 to 20 mm Hg) and return to prepregnancy levels by term. The overall decrease in diastolic BP and MAP is 5 to 10 mm Hg^[27] (Fig. 3-7) (Figure Not Available). In late pregnancy the BP in women without pregnancy-induced hypertension rarely exceeds the prepregnancy or postpartum BP.

The position of the women when the BP is taken and

what Korotkoff sound is used to determine the diastolic BP is important. BP is lowest in the lateral recumbent position, and the BP of the superior arm in this position is 10 to 12 mm Hg lower than the inferior arm. In the clinic setting, BP should be measured in the sitting position and the Korotkoff 5 sound should be used. This is the diastolic BP when the sound disappears as opposed to the Korotkoff 4, when there is a muffling of the sound. In a study of 250 gravidas, the Korotkoff 4 sound could only be identified in 48 percent of patients, whereas the Korotkoff 5 sound could always be determined. The Korotkoff 4 should only be used when the Korotkoff 5 goes to zero.^[28]

Venous Pressure

Venous pressure in the upper extremities remains unchanged in pregnancy but rises progressively in the lower extremities. Femoral venous pressure increases from values near 10 cm H₂O at 10 weeks' gestation to 25 cm H₂O near term.^[29] From a clinical standpoint, it is this increase in pressure in addition to the obstruction of the inferior vena cava that leads to the development of edema, varicose veins, and an increased risk of deep venous thrombosis.

Central Hemodynamic Assessment and Left Ventricular Function

Clark et al. studied 10 carefully selected normal women at 36 to 38 weeks' gestation and again at 11 to 13 weeks postpartum with arterial lines and Swan-Ganz catheterization to characterize the central hemodynamics

of term pregnancy (Table 3-1). They found statistically significant increases in cardiac output and heart rate, accompanied by significant decreases in SVR, pulmonary vascular resistance (PVR), colloidal oncotic pressure (COP), and the COP PCWP difference. No significant changes were found in MAP, pulmonary capillary wedge pressure (PCWP), central venous pressure (CVP), or left ventricular stroke work index.^[24]

They postulated that the higher stroke volume of pregnancy was not associated with an increased end-diastolic pressure because of ventricular dilation. As a result of the marked fall in both SVR and PVR, the CVP and PCWP do not rise despite the increased blood volume of pregnancy. Their finding of a significantly decreased

gradient between COP and PCWP (COP PCWP) explains why pregnant women have a greater propensity for developing pulmonary edema with changes in capillary permeability or elevations in cardiac preload. When the PCWP is more than 4 mm Hg above the COP, the risk of pulmonary edema increases. The colloidal oncotic pressure can fall even further after delivery to 17 mm Hg and, if the pregnancy is complicated by preeclampsia, can reach levels as low as 14 mm Hg.^[31] Therefore, unlike nonpregnant women who will rarely develop signs of pulmonary edema unless the PCWP is 24 mm Hg, pregnant women can experience pulmonary edema at a much lower PCWP, 18 to 20 mm Hg.

Evaluation of left ventricular function (contractility) is difficult in pregnancy because it is strongly influenced by changes in heart rate, preload, and afterload. Despite the increase in stroke volume and cardiac output, normal pregnancy is not associated with hyperdynamic left ventricular function during the third trimester as measured by ejection fraction or left ventricular stroke work index. However, some studies have shown that contractility might be slightly increased in the first two trimesters.^[19]

Normal Changes That Mimic Heart Disease

The physiologic adaptations of pregnancy lead to a number of changes in maternal signs and symptoms that can mimic cardiac disease and make it difficult to determine if true cardiac disease is present.

Dyspnea is common during pregnancy. Most pregnant women complain of dyspnea prior to 20 weeks, and 75 percent experience it by the third trimester. To differentiate the dyspnea of pregnancy from the much less common dyspnea of cardiac disease, certain distinguishing features should be considered. First, the dyspnea of pregnancy occurs early in pregnancy and does not worsen significantly as the pregnancy progresses, whereas the symptoms of heart disease usually worsen in the latter half of pregnancy. Second, physiologic dyspnea is usually mild and does not stop women from performing normal daily activities and does not occur at rest.^[30]

Other normal symptoms, that can mimic cardiac disease include decreased exercise tolerance, fatigue, occasional orthopnea, syncope, and chest discomfort. Symptoms that should not be attributed to pregnancy and need a more thorough investigation include hemoptysis, syncope or chest pain with exertion, and progressive orthopnea, or paroxysmal nocturnal dyspnea.

Normal physical findings that could be mistaken as evidence of cardiac disease include peripheral edema, mild tachycardia, jugular venous distention after 20 weeks of gestation, and lateral displacement of the left ventricular apex.

Pregnancy also alters normal heart sounds. At the end of the first trimester, both components of the first heart sound become louder, and there is exaggerated splitting. The second heart sound usually remains

normal with only minimal changes. Up to 80 to 90 percent of gravid women demonstrate a third heart sound (S_3) after midpregnancy because of rapid diastolic filling. Rarely, a fourth heart sound may be auscultated, but typically phonocardiography is needed to detect this. Systolic ejection murmurs along the left sternal border develop in 96 percent of pregnancies and are thought to be caused by increased blood flow across the pulmonic and aortic valves. Most commonly these are midsystolic and less than grade 3. Diastolic murmurs have been found in up to 18 percent of pregnancies, but their presence is uncommon enough to warrant further evaluation. A continuous murmur in the second to fourth intercostal space may be heard in late pregnancy due to the so-called mammary soufflé caused by increased blood flow in the breast^[32], ^[33] (Fig. 3-8).

Effect of Labor and the Immediate Puerperium

In addition to the dramatic rise in cardiac output that occurs with normal pregnancy, even greater increases in cardiac output occur with labor and in the immediate puerperium. In a study by Robson et al. of 15 uncomplicated women without epidural anesthesia, using Doppler echocardiography, the cardiac output between contractions increased 12 percent during the first stage of labor^[16], ^[34] (Fig. 3-9). Early in the first stage of labor, the increase in cardiac output is caused primarily by an increased stroke volume, but later in labor heart rate also increases. MAP also rises in the first stage of labor, from 82 mm Hg to 91 mm Hg. Furthermore, with uterine contractions the cardiac output and MAP increase even further. By the end of the first stage of labor, the cardiac output during a contraction is 51 percent above baseline term pregnancy values (6.99 L/min to 10.57

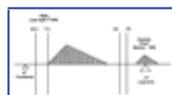

Figure 3-8 Summarization of the findings on auscultation of the heart in pregnancy. M.C., mitral closure; T.C., tricuspid closure; A_2 and P_2 , aortic and pulmonary elements of the second sound. Figure 3-9 Changes in cardiac output and stroke volume during normal labor. (From Hunter S, Robson S: Adaptation of the maternal heart in pregnancy. Br Heart J 68:540, 1992, with permission.)

L/min) and the MAP is 102 mm Hg. The cardiac output with contractions increases as labor progresses from + 1.14 L/min at 3 cm to + 2.69 L/min at 8 cm. At the onset of a contraction, blood is expressed from the uterus, causing a 300 to 500 ml autotransfusion into the maternal circulation. This in turn increases the venous return and leads to a rise in stroke volume, BP, and cardiac output.^[34], ^[35]

Much of the increase in cardiac output and BP is due to pain and apprehension. With epidural anesthesia, the baseline increase in cardiac output is reduced, but the rise observed with contractions persists.^[36] Maternal posture also influences hemodynamics during labor. Changing position from supine to lateral recumbent increases cardiac output. This change is greater than the increase seen prior to labor and suggests that during

labor cardiac output may be more dependent on preload. Therefore, it is important to avoid the supine position in laboring women.^[37]

In the immediate postpartum period (10 to 30 minutes after delivery), cardiac output reaches its maximum, with a further rise of 10 to 20 percent. This increase is accompanied by a fall in the maternal heart rate that is thought to be caused by a greatly increased stroke volume. Traditionally, this rise was thought to be the result of the "squeezing" out of blood from the uterus as seen with contractions, but the validity of this concept is uncertain.^[13] As with vaginal deliveries, in elective cesarean deliveries, the maximal increase in the cardiac output occurs at 10 to 30 minutes after delivery. The increase was 37 percent with epidural anesthesia, and 28 percent with general anesthesia. One hour following either vaginal delivery or cesarean delivery the cardiac output returns to prelabor baseline values.^[38] Over the next 2 to 4 weeks, the cardiac hemodynamic parameters return to near prepregnant levels.^[39]

RESPIRATORY SYSTEM

Upper Respiratory Tract

During pregnancy, the mucosa of the nasopharynx becomes hyperemic and edematous with hypersecretion of mucous due to increased estrogen. These changes often lead to marked nasal stuffiness; epistaxis is also common. Placement of nasogastric tubes may cause excessive bleeding if adequate lubrication is not used.^[39] Polyposis of the nose and nasal sinuses develops in some individuals but regresses postpartum. Because of these changes, many gravid women complain of chronic cold symptoms. However, the temptation to use nasal decongestants should be avoided.^[40]

Mechanical Changes

The configuration of the thoracic cage changes early in pregnancy, much earlier than can be accounted for by mechanical pressure from the enlarging uterus. Relaxation of the ligamentous attachments to the ribs may be responsible. The subcostal angle increases from 68 degrees to 103 degrees, the transverse diameter of the chest expands by 2 cm, and the chest circumference expands by 5 to 7 cm.^[41] As gestation progresses, the level of the diaphragm rises 4 cm; however, diaphragmatic excursion is not impeded and actually increases 1 to 2 cm. Respiratory muscle function is not affected by pregnancy, and maximum inspiratory and expiratory pressures are unchanged.^[42]

Lung Volume and Pulmonary Function

The described alterations in chest wall configuration and the diaphragm lead to changes in static lung volumes. In a review of studies with at least 15 subjects for whom nonpregnant controls were used, Crapo found the following changes in pregnancy^[39]

1. The elevation of the diaphragm decreases the volume of the lungs in the resting state, thereby reducing total lung capacity by 5 percent and the functional residual capacity (FRC) by 20 percent.
2. The FRC (the volume of air in the lungs at the end of quiet exhalation) can be subdivided into expiratory reserve volume and residual volume, and both decrease.
3. The inspiratory capacity, the maximum volume that can be inhaled from the FRC, increases 5 to 10 percent as a result of the reduction in the FRC.
4. The vital capacity does not change^[39] (Fig. 3-10 and Table 3-2).

Spirometric measurements that assess flow are not altered in pregnancy. The forced expiratory volume in 1 second (FEV_1) and the ratio of FEV_1 to forced vital capacity are both unchanged in pregnancy, suggesting that airway function remains stable.^[43] In addition, peak expiratory flow rates measured using a peak flowmeter seem to be unaltered in pregnancy at rates of 450 ± 16 L/min.^[44] Therefore, during gestation both spirometry and peak flowmeters can be used in diagnosing and managing respiratory illnesses.

Because of the increased progesterone levels, pregnancy causes a state of chronic hyperventilation, as reflected by a 30 to 40 percent increase in both tidal volume and minute ventilation (Minute ventilation = Tidal volume \times Respiratory rate). The

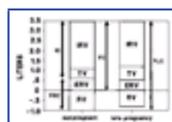

Figure 3-10 Lung volumes in nonpregnant and pregnant women. TABLE 3-2 -- LUNG VOLUMES AND CAPACITIES IN PREGNANCY

Measurement	Definition	Change in Pregnancy
Respiratory rate (RR)	Number of breaths per minute	Unchanged
Vital capacity (VC)	Maximum amount of air that can be forcibly expired after maximum inspiration (IC + ERV)	Unchanged
Inspiratory capacity (IC)	Maximum amount of air that can be inspired from resting expiratory level (TV + IRV)	Increased 5 to 10%
Tidal volume (TV)	Amount of air inspired and expired with normal breath	Increased 30 to 40%
Inspiratory reserve volume (IRV)	Maximum amount of air that can be inspired at end of normal inspiration	Unchanged
Functional residual capacity (FRC)	Amount of air in lungs at resting expiratory level (ERV + RV)	Decreased 20%
Expiratory reserve volume (ERV)	Maximum amount of air that can be expired from resting expiratory level	Decreased 15 to 20%
Residual volume (RV)	Amount of air in lungs after maximum expiration	Decreased 20 to 25%
Total lung capacity (TLC)	Total amount of air in lungs at maximal inspiration (VC + RV)	Decreased 5%

From Cruickshank DP, Wigton TR, Hays PM: *Maternal physiology in pregnancy*. In Gabbe SG, Niebyl JR, Simpson JL (eds): *Obstetrics: Normal and Problem Pregnancies, 3rd ed.* New York, Churchill Livingstone, 1996, p 95, with permission.

respiratory rate does not change. However, the increase in minute ventilation occurs by 8 to 11 weeks or earlier.

Gas Exchange

The rise in minute ventilation results in a 50 to 70 percent increase in alveolar ventilation with an increase in alveolar oxygen (P_{AO_2}) and a decrease in alveolar carbon dioxide (P_{ACO_2}).^[45] Hyperventilation results in a decreased P_{aCO_2} (arterial) from normal levels of 37 to 40 mm Hg to 27 to 32 mm Hg.^[46] The drop in the P_{aCO_2} is important, as it increases the CO_2 gradient between the fetus and mother and facilitates transfer of CO_2 from the fetus to the mother. The low maternal P_{aCO_2} results in a chronic respiratory alkalosis. Partial renal compensation occurs through increased excretion of bicarbonate, which helps maintain the pH between 7.4 and 7.45 and lowers the serum bicarbonate levels to 18 to 21 mEq/L. Early in pregnancy, the arterial oxygen (P_{aO_2}) increases (106 to 108 mm Hg) as the P_{aCO_2} decreases, but by the third trimester a slight decrease in the P_{aO_2} (101 to 104) occurs as a result of the enlarging uterus. The alveolar-to-arterial gradient [$P(A-a)O_2$] increases slightly at the end of gestation from 14 mm Hg to 20 mm Hg. This decrease in the P_{aO_2} late in pregnancy is even more pronounced in the supine position, with a further drop of 5 to 10 mm Hg and an increase in the $P(A-a)O_2$ to 26 mm Hg.^[30]

As the minute ventilation increases, a simultaneous but smaller increase in oxygen uptake and consumption occurs. Most investigators have found maternal oxygen consumption to be 20 to 40 percent above nonpregnant levels. This increase occurs as a result of the oxygen requirements of the fetus and placenta and the increased oxygen requirement of maternal organs. With exercise or during labor, an even greater rise in both minute ventilation and oxygen consumption takes place.^[30] During a contraction, oxygen consumption can triple.^[45] As a result of the increased oxygen consumption and because the functional reserve capacity is decreased, there is a lowering of the maternal oxygen reserve. Therefore, the pregnant patient is more susceptible to the effects of apnea. For example, during intubation, a more rapid onset of hypoxia, hypercapnia, and respiratory acidosis is seen.

Hankins et al. found that interpulmonary shunting was three times higher during gestation, increasing from 2 to 5 percent to 13 to 15 percent. These investigators attributed this observation to the anatomic changes of pregnancy that result in an overall decrease in lung volumes and greater ventilation-perfusion mismatches.^[47] In a second study, Hankins et al. found no increase in oxygen delivery, oxygen extraction, or the arteriovenous oxygen content difference. Surprisingly, no increase in oxygen consumption was documented during pregnancy.^[48]

HEMATOLOGIC CHANGES

Plasma Volume and Red Blood Cell Mass

Maternal blood volume begins to increase at about 6 weeks' gestation. Thereafter, it increases progressively until 30 to 34 weeks and then plateaus until delivery. The average expansion of blood volume is 40 to 50 percent, although increases of 20 to 100 percent may be found. Women with multiple pregnancies have a larger increase in blood volume than those with singletons.^[49] Likewise, the blood volume expansion correlates with infant birth weight, but it is not clear whether this

73

is a cause or an effect. The increase in blood volume results from a rise in both plasma volume and RBC mass. The plasma volume begins to increase by 6 weeks and expands at a steady pace until it plateaus at 30 weeks' gestation, 1,200 to 1,300 ml higher than prior to pregnancy (50 percent higher).

Erythrocyte mass also begins to increase at about 10 weeks' gestation, but initially at a rate slower than plasma volume. The erythrocyte mass grows progressively until term. The plateau seen in plasma volume after 30 to 34 weeks is not observed in RBC mass.^[49] Without iron supplementation, RBC mass increases about 18 percent by term, from a mean nonpregnant level of 1,400 ml up to 1,650 ml. Women whose diet is supplemented with iron show a greater RBC mass increment, increasing about 400 to 450 ml or 30 percent.^[49] Because plasma volume increases more than the RBC mass, maternal hematocrit falls. This so-called physiologic anemia of pregnancy reaches a nadir at 30 to 34 weeks. Since the RBC mass continues to increase after 30 weeks when the plasma volume expansion has plateaued, the hematocrit may rise somewhat after 30 weeks^[50] (Fig. 3-11). The mean and fifth percentile hemoglobin concentrations for normal iron-supplemented pregnant women are listed in Table 3-3.^[51] In pregnancy, erythropoietin levels increase two- to threefold, starting at 16 weeks. Moderate erythroid hyperplasia is found in the bone marrow, and the reticulocyte count is mildly elevated. These changes are thought to be due to the increased erythropoietin.^[52]

The increased blood volume of pregnancy clearly protects the mother from the possibility of hemorrhage during pregnancy or at delivery. The larger blood volume

also helps fill the expanded vascular system created by vasodilation and the large low-resistance vascular pool within the uteroplacental unit. This protects the mother and fetus from hypotension.^[39]

Vaginal delivery of a singleton infant at term is associated with a mean blood loss of 500 ml; an uncomplicated cesarean birth, about 1,000 ml; and a cesarean hysterectomy, 1,500 ml.^[49] In a normal delivery, almost all of the blood loss occurs in the first hour. Pritchard et al. found that over the next 72 hours only 80 ml of blood is lost. Gravid women respond to blood loss in a different fashion. In the nonpregnant state, with blood loss, the blood volume falls immediately and then expands via volume redistribution so that by 24 hours the blood volume approaches the prehemorrhage level. Therefore, isovolemia with anemia proportional to the blood loss occurs with an appropriate drop in hematocrit. In pregnancy, the blood volume drops after postpartum bleeding, but there is no reexpansion to the prelabor level, and there is less of a change in the hematocrit. After delivery with average blood loss, the hematocrit will drop moderately for 3 to 4 days followed by an increase. By days 5 to 7, the postpartum hematocrit will be similar to the prelabor hematocrit. If the postpartum hematocrit is lower than the prelabor hematocrit, then potentially the blood loss was larger than appreciated or the hypervolemia of pregnancy was less than normal as in preeclampsia.^[49]

Iron Metabolism in Pregnancy

Iron is absorbed from the duodenum only in the ferrous (divalent) state, its form in iron supplements. Ferric (trivalent) iron from vegetable food sources must first be converted to the divalent state by the enzyme ferric reductase. If body iron stores are normal, only about 10 percent of ingested iron is absorbed, most of which remains in the mucosal cells or enterocytes until

74

sloughing leads to excretion in the feces.^[53] Under conditions of increased iron needs, the fraction of iron absorbed increases. After absorption, iron is released from the enterocytes into the circulation, where it is carried bound to transferrin to the liver, spleen, muscle, and bone marrow. In those sites, iron is freed from transferrin

and incorporated into hemoglobin (75 percent of iron), and myoglobin, or stored as ferritin and hemosiderin. ^[55] Menstruating women have about half the iron stores of men with total body iron of 2 to 2.5 g and iron stores of only 300 mg. Prior to pregnancy, 8 to 10 percent of women in Western nations have iron deficiency. ^[55]

The iron requirements of gestation are about 1,000 mg. This includes 500 mg used to increase the maternal RBC mass (1 ml of erythrocytes contains 1.1 mg iron), 300 mg transported to the fetus, and 200 mg to compensate for the normal daily iron losses by the mother (1 mg/day is lost from sloughing of enterocytes). ^[56] Thus, the normal expectant woman needs to absorb an average of 3.5 mg/day of iron. In actuality, the iron requirements are not constant but increase remarkably during the third trimester to 6 to 7 mg/day. The fetus receives its iron through active transport, primarily during the last trimester. Adequate iron transport to the fetus is maintained despite severe maternal iron deficiency. Thus, there is no correlation between maternal and fetal hemoglobin concentrations.

In the past, whether the nonanemic pregnant woman should receive routine iron supplementation was controversial. Most American obstetricians favored the practice, while those in Europe generally considered it unnecessary. With the availability of serum ferritin levels that closely mirror body iron stores, it has become apparent that the unsupplemented patient, although not anemic, is significantly iron deficient at term. [Table 3-4](#), adapted from the work of Romslo et al. demonstrates that women who are not anemic at the beginning of gestation and who do not take iron supplementation have a significant drop in hemoglobin concentration, serum iron, serum ferritin, and transferrin saturation by term. The reason for these changes is the majority of women do not have sufficient iron stores to meet the demands of pregnancy. Such changes do not occur in women supplemented with iron (200 mg elemental iron given), although the total iron-binding capacity rises. ^[57] ^[58] ^[59]

It is important to remember that the purpose of iron supplementation during pregnancy is not to raise or even maintain the maternal hemoglobin level; instead, the goal is to maintain or restore normal maternal iron levels. Typically, this cannot be achieved by simply increasing the intake of iron-rich food such as meats, nongreen beans, iron-fortified cereals, egg yolk, dark green vegetables, and dried raisins. Therefore, iron supplementation is often needed during pregnancy, but

TABLE 3-4 -- EFFECT OF IRON SUPPLEMENTATION DURING PREGNANCY

	Iron-Treated	Placebo-Treated
Hemoglobin (g/dl)		
10 to 12 weeks	12.8	12.4
37 to 40 weeks	12.6	11.3*
Serum iron (mol/L)		
10 to 12 weeks	19.2	20.4
37 to 40 weeks	21.9	9.5*
Serum ferritin (g/L)		
10 to 12 weeks	28.0	27.0
37 to 40 weeks	24.0	6.0*
Serum iron-binding capacity (m/dl)		
10 to 12 weeks	58.1	64.1
37 to 40 weeks	75.4*	92.3*

* Significant change between first trimester (10 to 12 weeks) and term (37 to 40 weeks).

rarely needs to be started prior to 20 to 28 weeks. The recommended dose is 30 mg elemental iron per day, or one tablet of ferrous gluconate 325 mg. Taking iron prior to 20 weeks can worsen the nausea and vomiting of pregnancy. If a woman enters pregnancy with iron deficiency anemia, she will need to take additional iron above the 1,000 mg required for a normal pregnancy. Available iron supplements include ferrous sulfate 325 mg (65 mg elemental iron), ferrous gluconate 325 mg (35 mg elemental iron), and ferrous fumarate 325 mg (107 mg elemental iron). The usual dose to treat anemia is ferrous sulfate 325 mg twice daily, along with a stool softener such as docusate 100 mg twice daily.

Platelets

Prior to the introduction of automated analyzers, 11 studies of platelet counts during pregnancy reported conflicting results, with some showing a decrease, an increase, or no change with gestation. Unfortunately, even with the availability of automated cell counters, the data on the change in platelet count during pregnancy are still somewhat unclear. ^[60] ^[61] ^[62] Two studies have utilized true longitudinal methods with serial measurements in the same women. Pitkin et al. measured platelet counts in 23 women every 4 weeks and found that the counts dropped from $322 \pm 75 \times 10^3 / \text{mm}^3$ in the first trimester to $278 \pm 75 \times 10^3 / \text{mm}^3$ in the third trimester. ^[63] Similarly, O'Brien, in a study of 30 women, found a progressive decline in platelet counts. ^[64] Therefore, most recent studies show a decline in the platelet count during pregnancy possibly caused by increased

destruction. ^[61] In addition to the mild decrease in the mean platelet count in pregnancy, Burrows and Kelton have demonstrated that in the third trimester approximately 8 percent of gravid women develop gestational thrombocytopenia, with platelet counts between 70,000 and 150,000/mm³. These women have no increased complications of pregnancy and their counts return to normal by 1 to 2 weeks postpartum. Gestational thrombocytopenia is thought to be due to accelerated platelet consumption similar to that seen in normal pregnancy, but more marked in this subset of women. ^[65] ^[66]

Immune System and Leukocytes

The peripheral white blood cell (WBC) count rises progressively during pregnancy. During the first trimester, the mean WBC count is 8,000/mm³, with a normal range of 5,110 to 9,900/mm³. During the second trimester and third trimester, the mean is 8,500/mm³, with a range of 5,600 to 12,200/mm³. ^[67] In labor, the count may rise to 20,000 to 30,000/mm³, after which it gradually returns to the nonpregnant level by the end of the first week of the puerperium. The increase in the WBC count during pregnancy and delivery is largely because of increased numbers of circulating segmented neutrophils or granulocytes. The reason for the increased leukocytosis is unclear, but may be caused by the elevated estrogen and cortisol levels.

Successful pregnancy is dependent on maternal tolerance or immunononreactivity to paternal antigens. Maternal tolerance appears to be associated with the development of several specific mechanisms that protect the fetus from a maternal cytotoxic immune response. ^[67] Pregnancy is not a state of immunodeficiency but is a state of altered immune functions. ^[68] The major change observed is a modulation away from cell-mediated immune responses toward humoral or antibody-mediated immunity. T helper 1 cells and natural killer cells decline whereas T helper 2 cells increase. Clinically, the decrease in cellular immunity leads to the increased susceptibility to intracellular pathogens such as cytomegalovirus virus, varicella, and malaria. The decrease in cellular immunity may explain why women with rheumatoid arthritis frequently improve during gestation, since it is a cell-mediated immunopathologic disease. ^[67] Although pregnancy is characterized by enhanced antibody-mediated immunity, the levels of immunoglobulins A, G, and M all decrease in pregnancy.

Coagulation System

Pregnancy places women at increased risk for thromboembolic disease caused by increased venous stasis, vessel wall injury, and changes in the coagulation cascade that lead to hypercoagulability. In pregnancy, several procoagulant coagulation factors are increased, and changes occur to some of the natural inhibitors of coagulation. In addition, pregnancy causes a decrease in the fibrinolytic system with reduced levels of available circulating plasminogen activator. ^[1] These physiologic

changes provide some defense against peripartum hemorrhage.

The majority of the procoagulant factors from the coagulation cascade are markedly increased, including factors I, VII, VIII, IX, and X. Factors II, V, and XII are unchanged or mildly increased and levels of factors XI and XIII decline [1], [69], [70] (Fig. 3-12). Plasma fibrinogen (factor I) levels begin to increase in the first trimester and peak in the third trimester at levels 50 percent higher than prior to pregnancy. The rise in fibrinogen is associated with an increase in the erythrocyte sedimentation rate. [71] The prothrombin time (PT), activated partial thromboplastin time (APTT), and thrombin time all fall slightly, but remain within the limits of normal nonpregnant values, whereas the bleeding time and whole blood clotting times are unchanged. Levels of coagulation factors normalize 2 weeks postpartum.

Increasingly in the medical literature, familial causes for thromboembolic diseases are being discovered that are related to isolated deficiencies of proteins involved in coagulation inhibition called thrombophilias. These disorders include abnormalities in the formation of natural inhibitors to coagulation such as antithrombin III, protein C, protein S, and activated protein C (APC) resistance. Resistance to APC is caused in the majority of individuals by a point mutation in the gene for procoagulant factor V, called the factor V Leiden mutation, that impairs inactivation of factor V by APC. This change prevents protein C from acting as an inhibitor to factor V. [72] Pregnancy has been shown to cause a progressive and significant decrease in the levels of total and free protein S from early in pregnancy but to have no effect on the levels of protein C and antithrombin III. [73], [74] Pregnancy has also been shown to cause a decline in the APC sensitivity ratio (APC:SR), which is the ratio of the clotting time in the presence and the absence of APC. The APC:SR ratio is considered abnormal if less than 2.6. In a study of 239 women by Clark et al., the APC:SR ratio decreased from a mean of 3.12 in the first trimester to 2.63 by the third trimester. By the third trimester, 38 percent of women were found to have an acquired APC resistance, with APC:SR values below 2.6. [75] Whether the change in the protein S level and the APC:SR ratio are responsible for some of the hypercoagulability of pregnancy is unknown; however, if a work-up for familial thrombophilias is done during pregnancy, the clinician should use caution when attempting to interpret these levels if abnormal.

During pregnancy, some investigators have found evidence to support the theory that there is a state of low-level

Figure 3-12 The normal components of the coagulation cascade. (From Johnson RL: *Thromboembolic disease complicating pregnancy*. In Foley MR, Strong TH [eds]: *Obstetric Intensive Care: A Practical Manual*. Philadelphia, WB Saunders Company, 1997, p 91, with permission.)

intravascular coagulation. Investigators have found low concentrations of fibrin degradation products in maternal blood (markers of fibrinolysis), elevated levels of fibrinopeptide A (a marker for increased clotting), and increased levels of platelet factor 4 and -thromboglobulin (markers of increased platelet activity). [75] The most likely cause for the low-level intravascular coagulation involves localized physiologic changes needed for maintenance of the uterine-placental interface.

URINARY SYSTEM

Anatomic Changes

The kidneys enlarge during pregnancy, with the length as measured by intravenous pyelography increasing about 1 cm. This growth in size and weight is due to increased renal vasculature, interstitial volume, and urinary dead space. The increase in urinary dead space is attributed to dilation of the renal pelvis, calyces, and ureters. Pelvicalyceal dilation by term averages 15 mm (range, 5 to 25 mm) on the right and 5 mm (range, 3 to 8 mm) on the left with the right greater than the left in most gravid women.^[76]

The well-known dilation of the ureters and renal pelvis begins by the second month of pregnancy and is maximal by the middle of the second trimester, when ureteric diameter may be as much as 2 cm. The right ureter is almost invariably dilated more than the left, and the dilation usually cannot be demonstrated below the pelvic brim. These findings have led some investigators to argue that the dilation is caused entirely by mechanical compression of the ureters by the enlarging uterus and ovarian venous plexus.^[77] However, the early onset of ureteral dilation supports the hypothesis that smooth muscle relaxation caused by progesterone plays an additional role. Also supporting the role of progesterone is the finding of ureteral dilation in women with renal transplants and pelvic kidneys.^[78] By 6 weeks postpartum, ureteral dilation resolves.^[76] A clinical consequence of ureterocalyceal dilatation is an increased incidence of pyelonephritis among gravid women with asymptomatic bacteriuria. In addition, the ureterocalyceal dilatation makes interpretation of urinary radiographs more difficult when evaluating possible urinary tract obstruction or nephrolithiasis.

Anatomic changes are also observed in the bladder. From

midpregnancy on, an elevation in the bladder trigone occurs with increased vascular tortuosity throughout the bladder. This can cause an increased incidence of microhematuria during pregnancy. Due to the increasing size of the fetus and uterus, a decrease in bladder capacity develops, with an increased frequency of urinary incontinence.

Renal Hemodynamics

Renal plasma flow increases markedly from early in gestation. Dunlop showed convincingly that the effective renal plasma flow (ERPF) rises 75 percent over nonpregnant levels by 16 weeks' gestation^[79] (Table 3-5). The increase is maintained until 34 weeks' gestation, when a decline in ERPF of about 25 percent occurs. The fall in ERPF has been demonstrated in subjects studied serially in both the sitting and the left lateral recumbent positions.^[79],^[80] (Table 3-5).

Like ERPF, glomerular filtration rate (GFR) as measured by inulin clearance increases by 5 to 7 weeks. By the end of the first trimester, GFR is 50 percent higher than in the nonpregnant state, and this is maintained until the end of pregnancy. Three months postpartum, GFR values have declined to normal levels.^[79],^[81] Because the ERPF increases more than the GFR early in pregnancy, the filtration fraction falls from nonpregnant levels until the late third trimester. At this time, because of the decline in ERPF, the filtration fraction returns to nonpregnant values of 20 to 21 percent.

Clinically, GFR is not determined by measuring the clearance of infused inulin (inulin is filtered by the glomerulus and is unaffected by the tubules), but rather by measuring endogenous creatinine clearance. This test gives a less precise measure of GFR, because creatinine is secreted by the tubules to a variable extent. Therefore, endogenous creatinine clearance is usually higher than the actual GFR. The creatinine clearance in pregnancy is greatly increased to values of 150 to 200 ml/min (normal nonpregnant, 120 ml/min). As with GFR, the increase in creatinine clearance occurs by 5 to 7 weeks' gestation, and in normal patients is maintained until the third trimester.

The clinical consequences of glomerular hyperfiltration are a reduction in maternal plasma levels of creatinine, blood urea nitrogen (BUN), and uric acid. Serum creatinine falls from a nonpregnant level of 0.8 mg/dl to 0.5 mg/dl by term. Likewise, BUN falls from nonpregnant levels of 13 mg/dl to 9 mg/dl by term.^[7] Serum uric acid declines in early pregnancy because of the rise in GFR, reaching a nadir by 24 weeks with levels of 2.0 to 3.0 mg/dl.^[82] After 24 weeks, the uric acid level begins to rise, and by the end of pregnancy, the levels in most women are essentially the same as before pregnancy. The rise in uric acid levels is caused by increased renal tubular absorption of urate. Patients with preeclampsia have elevated uric acid level concentrations; however, because uric acid levels normally rise during the third trimester, overreliance on this test should be avoided in the diagnosis and management of preeclampsia.^[82]

During pregnancy nocturia is more common. In the standing position, sodium and water are retained and, therefore, during the daytime pregnant women tend to retain an increased amount of water.^[83] At night, while in the lateral recumbent position, this added water is excreted, resulting in nocturia.

Renal Tubular Function/Excretion of Nutrients

Despite high levels of aldosterone, which would be expected to result in enhanced urinary excretion of potassium, pregnant women retain about 350 mmol of potassium. The majority of the excess potassium is stored in the fetus and placenta. The mean potassium concentrations in maternal blood are just slightly below nonpregnant levels. The kidney's ability to conserve potassium has been attributed to the increased progesterone levels of pregnancy.^[84]

Glucose excretion increases in almost all pregnant women, and the presence of glycosuria during pregnancy is not necessarily abnormal. The urinary loss of glucose in the nonpregnant state is less than 100 mg/day, but 90 percent of pregnant women with

^a Data from Dunlop W: Serial changes in renal haemodynamics during normal pregnancy. *Br J Obstet Gynaecol* 88:1, 1991.

Data from Ezimokhai M, Davison J, Philips P, et al: Non-postural serial changes in renal function during the third trimester of normal human pregnancy. *Br J Obstet Gynaecol* 88:465, 1991.

normal blood glucose levels excrete 1 to 10 g of glucose per day.^[85] The glycosuria is intermittent and not necessarily related to blood glucose levels or the stage of gestation. Glucose is freely filtered by the glomerulus, and with the 50 percent increase in GFR a greater load of glucose is presented to the proximal tubules. There may be a change in the reabsorptive capability of the proximal tubules themselves, but the old concept of pregnancy leading to an overwhelming of the maximum tubular reabsorptive capacity for glucose (T_m) is misleading and oversimplified.^[85],^[86] The exact mechanisms underlying the altered handling of glucose by the proximal tubules remains obscure. Even though glycosuria is common during pregnancy, women with repetitive glycosuria should be screened for diabetes mellitus.

No increase in proteinuria occurs during a normal pregnancy in women without proteinuria prior to pregnancy. Higby et al. collected 24-hour urine samples on 270 gravid women over the course of pregnancy and determined the amount of proteinuria and albuminuria.^[87] These investigators found that the amount of protein and albumin excreted in urine did not increase significantly by trimester (Table 3-6). They observed that in normal women without preeclampsia, underlying renal disease, or urinary tract infections the mean 24-hour urine protein across pregnancy is 116.9 mg with a 95 percent confidence limit of 259.4 mg. They also noted that patients do not normally have microalbuminuria, defined as urinary albumin excretion greater than 30 mg/dl.^[87] In women with preexisting proteinuria, in the absence of preeclampsia, pregnancy causes increases in the amount of proteinuria in both the second and third trimesters and potentially in the first trimester. In a study by Gordon et al. of women with diabetic nephropathy, the amount of proteinuria increased from a mean of 1.74 ± 1.33 g/24 h in the first trimester to a mean of 4.82 ± 4.7 g/24 h in the third trimester.^[88]

Other changes in tubular function during pregnancy include an increase in excretion of amino acids in the urine (aminoaciduria)^[89] and an increase in calcium excretion (for more details, see Calcium Metabolism, below). Also, the kidney responds to the respiratory alkalosis of pregnancy by enhanced excretion of bicarbonate; however, renal handling of acid excretion is unchanged.^[90]

ALIMENTARY TRACT

Appetite

Most women experience an increase in appetite throughout pregnancy. In the absence of nausea or "morning sickness," women eating according to appetite will increase food intake by about 200 kcal/day by the end of the first trimester. ^[91] The recommended dietary allowance (RDA) calls for an additional 300 kcal/day during pregnancy. Energy requirements vary depending on the population studied, and a greater increase may be necessary for pregnant teenagers and women with high levels of physical activity. ^[92]

Extensive folklore exists about dietary cravings and aversions during gestation. Many of these are undoubtedly due to an individual's perception of which foods aggravate or ameliorate such symptoms as nausea and heartburn. The sense of taste may be blunted in some pregnant women, leading to an increased desire for highly seasoned food. Pica, a bizarre craving for strange foods, is relatively common among pregnant women, and a history of pica should be sought in those with poor weight gain or refractory anemia. Examples of pica include the consumption of clay, starch, toothpaste, and ice.

Mouth

The pH and the production of saliva is probably unchanged during pregnancy. ^[93] Ptyalism, an unusual complication of pregnancy, most often occurs in women suffering from nausea and may be associated with the loss of 1 to 2 L of saliva per day. Most authorities believe ptyalism actually represents inability of the nauseated woman to swallow normal amounts of saliva rather than a true increase in the production of saliva. A decrease in the ingestion of starchy foods may help.

No evidence exists that pregnancy causes or accelerates

TABLE 3-6 -- COMPARISON OF 24-HOUR URINARY PROTEIN AND ALBUMIN EXCRETION FOR EACH TRIMESTER OF PREGNANCY.

	First Trimester (n = 19)	Second Trimester (n = 133)	Third Trimester (n = 118)	Significance
Protein (mg/24 h)	80.0 ± 60.6	116.7 ± 69.3	115.3 ± 69.2	p = 0.13
Albumin (mg/24 h)	9.9 ± 5.3	10.8 ± 6.9	12.8 ± 9.5	p = 0.12

* Values are expressed as mean ± SD.

the course of dental caries. However, the gums (gingiva) swell and may bleed after tooth brushing, giving rise to the so-called gingivitis of pregnancy. ^[94] At times a tumorous gingivitis may occur, presenting as a violaceous pedunculated lesion at the gum line that may bleed profusely. Called either epulis gravidarum or pyogenic granulomas, these lesions consist of granulation tissue and an inflammatory infiltrate. It is thought to be an abnormal tissue response to trauma and can occur elsewhere besides the mouth. These lesions usually remit 1 to 2 months after delivery. If the lesion persists or bleeds excessively during pregnancy, it should be excised. ^[95]

Stomach

The tone and motility of the stomach are decreased during pregnancy, probably because of the smooth musclerelaxing effects of progesterone. Decreased levels of motilin, a gut hormone that stimulates smooth muscle, have also been noted. ^[96] Nevertheless, scientific evidence regarding delayed gastric emptying is inconclusive. Davison et al. showed that during pregnancy the mean total emptying time was significantly longer in pregnant women with heartburn versus a control group of nonpregnant women, but no clear evidence of a delay in emptying was found in gravid women without heartburn. More recently, Macfie and colleagues, using paracetamol absorption as an indirect measure of gastric emptying, failed to demonstrate a delay in gastric emptying when comparing 15 nonpregnant controls to 15 women in each trimester of pregnancy. ^[97] An increased delay was seen in laboring women, with the etiology ascribed to the pain and stress of labor. ^[98]

Pregnancy causes a decreased risk of peptic ulcer disease (PUD), but at the same time causes an increase in gastroesophageal reflux disease (GERD). ^[99] This apparent paradox can be partially explained by physiologic changes of the stomach and lower esophagus. The increase in GERD is attributed to esophageal dysmotility caused by gestational hormones and gastric compression from the enlarged uterus. In addition, the decrease in the tone of the gastroesophageal sphincter may also lead to increased reflux of stomach acids into the esophagus. Theories proposed to explain the decreased incidence of PUD include increased placental histaminase synthesis with lower maternal histamine levels; increased gastric mucin production leading to protection of the gastric mucosa; reduced gastric acid secretion; and enhanced immunological tolerance of *Helicobacter pylori*, the infectious agent that causes PUD. ^[99]

Intestines

Perturbations in the motility of the small intestines and colon are common in pregnancy, resulting in an increased incidence of constipation (11 to 38 percent) in some women and diarrhea in others. Up to 34 percent of pregnant women in one study noted an increased frequency of bowel movements, perhaps related to increased prostaglandin synthesis. ^[100] , ^[101] The motility of the small intestines is reduced in pregnancy, with increased orocecal transit times presumably caused by progesterone. ^[102] , ^[103] No studies on the colonic transit time have been performed in pregnancy, but limited information suggests reduced colonic motility. ^[101] Absorption of nutrients from the small bowel (with the exception of increased iron and calcium absorption) is unchanged, but the decreased transit times may allow for more efficient absorption. In the colon, Parry et al. demonstrated an increase in both water and sodium absorption. ^[104]

The enlarging uterus displaces the intestines and, most importantly, moves the position of the appendix. Thus, the presentation, physical signs, and type of surgical incision are affected in the management of appendicitis. Portal venous pressure is increased in gestation, leading to dilation wherever there are portosystemic venous anastomoses. This includes the gastroesophageal junction and the hemorrhoidal veins, which results in the common complaint of hemorrhoids.

Gallbladder

The function of the gallbladder is markedly altered during pregnancy because of the effects of progesterone. After the first trimester, the fasting and residual volumes are twice as great, and the rate at which the gallbladder empties is much slower.^[105] In addition, the biliary cholesterol saturation is increased, and the chenodeoxycholic acid level is decreased.^[106] This change in the composition of the bile fluid favors the formation of cholesterol crystals and, with incomplete emptying of the gallbladder, the crystals are retained and gallstone formation is more likely.

Liver

The size and histology of the liver are unchanged in pregnancy.^[107] Many clinical and laboratory signs usually associated with liver disease are present in pregnancy, however. Spider angiomas and palmar erythema, caused by elevated estrogen levels, are normal and disappear soon after delivery. The serum albumin and total protein levels fall progressively during gestation. By term, albumin levels are 25 percent lower than nonpregnant levels. Despite an overall increase in total body protein, decreases in total protein and albumin concentrations occur as a result of hemodilution. In addition, serum alkaline phosphatase activity rises during the third trimester to levels two to four times that of nonpregnant women. Most of this increase is caused

80

by placental production of the heat-stable isoenzyme.^[1], ^[108] During pregnancy, the serum concentrations of many proteins produced by the liver increase. These include elevations in fibrinogen, ceruloplasmin, and transferrin, and the binding proteins for corticosteroids, sex steroids, thyroid hormones, and vitamin D.^[1]

With the exception of alkaline phosphatase, the other "liver function tests" are unaffected by pregnancy, including serum levels of bilirubin, aspartate aminotransferase (AST, formerly SGOT), alanine aminotransferase (ALT, formerly SGPT), -glutamyltransferase, 5'-nucleotidase, creatinine phosphokinase (CPK), and lactate dehydrogenase (LDH). In some studies the mean levels of ALT and AST are mildly elevated but still within normal nonpregnant values.^[108], ^[109] Levels of CPK and LDH can increase with labor.^[1]

Finally, pregnancy may cause some changes in bile acid production and secretion. Pregnancy may be associated with mild subclinical cholestasis due to the high concentrations of estrogen. Reports on bile acid concentrations are conflicting, with some studies showing an increase and others no change. It does appear that the fasting levels are unchanged, and the measurement of a fasting level appears to be the best test for diagnosing cholestasis of pregnancy.^[109]

Nausea and Vomiting of Pregnancy

Nausea and vomiting, or "morning sickness," complicate up to 70 percent of pregnancies. Typical onset is between 4 and 8 weeks' gestation, with improvement before 14 to 16 weeks.^[110] Although the symptoms are often quite distressing, morning sickness seldom leads to significant weight loss, ketonemia, or electrolyte disturbances. The cause is not well understood, although relaxation of the smooth muscle of the stomach probably plays a role. Elevated levels of human chorionic gonadotropin (hCG) may be involved, although a good correlation between maternal hCG concentrations and the degree of nausea and vomiting does not exist.^[111] Interestingly, women admitted to the hospital for nausea and vomiting more often have a female than a male fetus (56 vs. 44 percent).^[112] Also of interest, pregnancies complicated by nausea and vomiting generally have a more favorable outcome than do those without such symptoms.^[113] Treatment is largely supportive, consisting of reassurance, psychological support, avoidance of foods found to trigger nausea, and frequent small meals. Eating dry toast or crackers prior to getting out of bed may be beneficial. A recent review of alternative therapies to antiemetic drugs found that acupressure with wristbands and treatment with ginger root or vitamin B₆ may be helpful.^[114]

Hyperemesis gravidarum, a more pernicious form of nausea and vomiting associated with weight loss, ketonemia, electrolyte imbalance, and dehydration, often persists throughout pregnancy. For these patients, the clinician must rule out other diseases such as pancreatitis, cholecystitis, hepatitis, and thyroid disease. Hospitalization with intravenous replacement of fluids and electrolytes is often needed. Options of antiemetics include the phenothiazines: promethazine (Phenergan), chlorpromazine (Thorazine), and prochlorperazine (Compazine) or metoclopramide (Reglan) or droperidol (Inapsine). On admission to the hospital, the patient should be kept totally NPO for 24 to 48 hours, given intravenous hydration, and tried on one of the above medications (intravenously or intramuscularly initially). Care must be given not to combine the phenothiazines with metoclopramide because of the additive risks of causing extrapyramidal reactions. Chlorpromazine given rectally (25 to 50 mg every 8 hours) may be highly effective in the more refractory cases. Recently, use of oral methylprednisolone, 16 mg three times daily for 3 days and then tapered over 2 weeks, has been shown to be more effective than promethazine.^[115] Because of potential risks, use of parenteral calorie replacement should only be used after the patient has failed multiple antiemetic treatments and attempts at enteral tube feedings.

THE SKELETON

Calcium Metabolism

Pregnancy was initially thought to be a state of "physiologic hyperparathyroidism," with maternal skeletal calcium loss needed to supply the fetus with calcium. It was thought that this could result in long-term maternal calcium bone loss. This theory was shown to be incorrect and it is now evident that fetal calcium needs are met through a series of physiologic changes in calcium metabolism without long-term consequences to the maternal skeleton.^[116] This allows the fetus to accumulate 21 g (range, 13 to 33 g) of calcium, 80 percent of this amount during the third trimester, when fetal skeletal mineralization is at its peak.^[117] Calcium is actively transported across the placenta. In addition, calcium is excreted in greater amounts by the maternal kidneys so that by term the urinary loss of calcium is doubled.^[118]

Maternal total calcium levels decline throughout pregnancy. However, the serum ionized calcium level is unchanged and constant during pregnancy. The fall in total calcium is caused by the reduced serum albumin concentration which results in a decrease in the albumin-bound fraction of calcium^[116],^[120] (Fig. 3-13). Fifty percent of calcium is ionized, and it is this form that is physiologically important. It appears that the maternal serum calcium levels are maintained and the fetal calcium

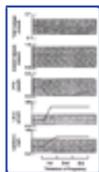

Figure 3-13 Schematic illustration of the longitudinal changes in calcium and calcitropic hormone levels that occur during human pregnancy. Normal adult ranges are indicated by the shaded areas. (From Kovacs C, Kronenberg H: *Maternal-fetal calcium and bone metabolism during pregnancy, puerperium, and lactation*. *Endocr Rev* 18:832, 1997.)

needs are met through increased intestinal calcium absorption. Calcium is absorbed through the small intestines and its absorption is doubled by 12 weeks' gestation.^[116],^[121] The early increase in absorption may allow the maternal skeleton to store calcium in advance of the peak third-trimester fetal demands. Maternal serum phosphate levels are likewise unchanged.^[116]

Older studies showed an increase in maternal parathyroid hormone (PTH) levels.^[122] These studies used less sensitive PTH assays that measured multiple different fragments of PTH, most of which are biologically inactive. In five recent prospective studies, all utilizing the newer PTH assays, maternal levels of PTH were not elevated and actually remained in the low-normal range throughout gestation.^[116] Therefore, pregnancy does not cause hyperparathyroidism (Fig. 3-13). Levels of 1,25-dihydroxyvitamin D increase during gestation, doubling in the first trimester as a result of increased production from the maternal kidneys and potentially the fetoplacental unit, which appears to be independent of PTH control.^[119] The elevated levels of 1,25-dihydroxyvitamin D are thought to be primarily responsible for the important increase in intestinal calcium absorption.^[116] Calcitonin levels rise 20 percent during pregnancy and may help protect the maternal skeleton from bone loss.^[116],^[123]

Skeletal and Postural Changes

Bone turnover appears to be low in the first half of gestation and then increase in the third trimester, corresponding to the peak rate of fetal calcium needs. This may represent turnover of previously stored skeletal calcium.^[116] In the only study of bone biopsies performed in pregnant women, Shahtaheri et al. observed a change in the microarchitectural pattern of bone, but there was no change in overall bone mass by the end of pregnancy. This change in the microarchitectural pattern seems to result in a framework more resistant to the bending forces and biomechanical stresses needed to carry a growing fetus.^[124]

Pregnancy results in a progressively increasing anterior convexity of the lumbar spine (lordosis). This compensatory mechanism keeps the woman's center of gravity over her legs, and prevents the enlarging uterus from shifting the center of gravity quite anteriorly. The unfortunate side effect of this necessary alteration is low back pain, a common complaint during gestation.

The ligaments of the pubic symphysis and sacroiliac joints loosen during pregnancy, probably from the effects of the hormone relaxin.^[125] Marked widening of the pubic symphysis occurs by 28 to 32 weeks' gestation, with the width increasing from 3 to 4 mm in 7.7 to 7.9 mm.^[126] This commonly results in pain near the symphysis that is referred down the inner thigh with standing and may result in a maternal sensation of snapping or movement of the bones with walking.

ENDOCRINE CHANGES

Thyroid

Despite alterations in thyroid morphology, histology, and laboratory indices, the pregnant woman remains euthyroid. These changes are primarily the result of increases in thyroxine-binding globulin (TBG) concentration and to the decrease in the size of the circulating pool of extrathyroidal iodide. Serum iodide levels fall because of increased renal loss of iodide. In addition, in the latter half of pregnancy, iodine is also transferred to the fetus, further decreasing maternal iodine levels. These alterations cause the thyroid to synthesize and secrete thyroid hormone actively. ^[127]

During pregnancy, the thyroid gland increases in size, but not as much as was commonly believed. If adequate

iodine intake is maintained, the size of the thyroid gland remains unchanged or undergoes a small increase in size that can only be detected by ultrasound. ^[128], ^[129] In pregnancy, the World Health Organization recommends that iodine intake be increased from 100 to 150 g/day to 200 g/day. In an iodine-deficient state, the thyroid gland is up to 25 percent larger, and goiters may be seen in 10 percent of women. ^[127] The development of a goiter during pregnancy is abnormal and should be evaluated. ^[130] Histologically, there is an increase in thyroid vascularity, with evidence of follicular hyperplasia.

Although there is increased uptake of iodine by the thyroid during gestation, the pregnant woman remains euthyroid by laboratory evaluation. ^[131] Total thyroxine (TT₄) and total triiodothyronine (TT₃) levels begin to increase in the first trimester and peak at midgestation as a result of increased TBG. The concentration of TT₄ increases from 5 to 12 g/dl in nonpregnant women to 9 to 16 g/dl during pregnancy. The increase in TBG is seen in the first trimester and plateaus at 12 to 14 weeks. Only a small amount of TT₄ and TT₃ is unbound, and it is these free (normally about 0.04 percent for T₄ and 0.5 percent for T₃) fractions that are the major determinant of whether an individual is euthyroid. The free T₄ levels rise slightly in the first trimester and then decrease so that by delivery the free T₄ levels are 10 to 15 percent lower than in nonpregnant women. However, these changes are small and in most pregnant women serum free T₄ concentrations remain within the normal nonpregnant range ^[127], ^[132], ^[133] (Fig. 3-14) (Figure Not Available). Free T₃ levels follow a parallel pattern.

Thyroid-stimulating hormone (TSH) concentrations decrease transiently in the first trimester and then rise to prepregnant levels by the end of the first trimester. TSH levels then remain stable throughout the remainder of gestation. ^[127], ^[132], ^[133] The transient decrease in TSH coincides with the first-trimester increase in free T₄ levels,

Figure 3-14 (Figure Not Available) Relative changes in maternal thyroid function during pregnancy. (From Burrow G, Fisher D, Larsen P: *Maternal and fetal thyroid function*. *N Engl J Med* 331:1072, 1994, with permission.)

and both appear to be caused by the thyrotropic effects of hCG. Women with higher peak hCG levels have more TSH suppression. It clearly appears that hCG has some thyrotropic activity, but conflicting data on the exact role of hCG in maternal thyroid function remain. ^[127], ^[132], ^[133], ^[134] While thyrotropin-releasing hormone (TRH) crosses the placenta, TSH does not.

The influence of maternal thyroid physiology on the fetus appears much more complex than previously thought. Whereas the maternal thyroid does not directly control fetal thyroid function, the systems interact by means of the placenta, which regulates the transfer of iodine and a small but important amount of thyroxine to the fetus. It was thought that little if any transplacental passage of T₄ and T₃ occurred. ^[135] It is now recognized that T₄ crosses the placenta and, in fact, in early pregnancy the fetus is critically dependent on the maternal T₄ supply for normal neurologic development. ^[136] Neonates with thyroid agenesis or a total defect in thyroid hormone synthesis were found to have umbilical cord thyroxine levels between 20 percent and 50 percent of those in normal infants. ^[137] These data demonstrate that the placenta is *not* impermeable to T₄. However, as a result of the deiodinase activity of the placenta, a large percentage of T₄ is broken down prior to transfer to the fetus. Evidence that the fetus is dependent on the maternal thyroid for normal development has recently been published. In women living in iodine-deficient areas, maternal hypothyroidism is associated with neonatal hypothyroidism and defects in long-term neurologic function and mental retardation or endemic cretinism. These abnormalities can be prevented if maternal iodine intake is initiated at the beginning of the second trimester. ^[138], ^[139] Haddow et al. have found that maternal hypothyroidism during pregnancy results in slightly lower IQ scores in children at ages 7 to 9. ^[140]

Since iodine is actively transported across the placenta, the fetus is susceptible to iodine-induced goiters when the mother is given pharmacologic amounts of iodine. Similarly, radioactive iodine crosses the placenta, and, if given after 12 weeks' gestation, when the fetal thyroid is able to concentrate iodine, profound adverse effects on the fetus can occur. ^[132]

Adrenal Glands

Pregnancy is associated with marked changes in adrenocortical function, with increased serum levels of aldosterone, deoxycorticosterone (DOC), corticosteroid-binding globulin (CBG), cortisol, and free cortisol ^[141], ^[142], ^[143] (Table 3-7). Although the combined weight of the adrenal glands does not increase significantly in pregnancy, expansion of the zona fasciculata, which primarily produces glucocorticoids, is observed. The plasma concentration of CBG doubles by the end of the sixth

month of gestation when compared to nonpregnant values. ^[144] The increase in CBG results in elevated levels of total plasma cortisol concentrations. The levels of total cortisol rise after the first trimester, and by the end of pregnancy are nearly three times higher than nonpregnant values (12.5 ± 1.3 g/dl vs. 30.1 ± 6.6 g/dl). ^[141] During pregnancy, the diurnal variations in cortisol levels are maintained, with the highest values in the morning.

Only free cortisol, the fraction of cortisol not bound to CBG, is metabolically active, and direct measurements of free cortisol levels are difficult to perform. However, urinary free cortisol concentrations, the free cortisol index, and salivary cortisol concentrations, all of which reflect active free cortisol levels are all elevated after the first trimester. ^[141], ^[143], ^[145] In a study of 21 uncomplicated pregnancies, Goland et al. found that the urinary free cortisol concentration doubled from the first to the third trimester ^[143] (Table 3-7). Although the increase in total cortisol concentrations can be explained by the increase in CBG, this does not explain the higher free

cortisol levels.

The elevation in free cortisol levels seems to be caused in part, by a marked increase in corticotropin-releasing hormone (CRH) during pregnancy. CRH levels are low in nonpregnant women and rise exponentially during the third trimester ^[143] (Table 3-7). CRH is produced by the placenta and fetal membranes and is secreted into the maternal circulation. It is thought to stimulate maternal pituitary production of ACTH. In support of this theory, Goland et al. have shown that despite the increased levels of total and free cortisol levels, maternal afternoon adrenocorticotrophic hormone (ACTH) concentrations rise and mirror the third-trimester increase in CRH. These investigators observed a significant correlation between the rise in CRH levels and maternal ACTH and urinary free cortisol concentrations. ^[143], ^[146] Other possible causes for the hypercortisolism of pregnancy include delayed plasma clearance of cortisol as a result of changes in renal clearance and a resetting of the hypothalamic-pituitary sensitivity to cortisol feedback on ACTH production. ^[141]

DOC, like aldosterone, is a potent mineralocorticoid. Marked elevations in the maternal plasma concentrations of DOC are present by midgestation, reaching peak levels in the third trimester. In contrast to the nonpregnant state, plasma DOC levels in the third trimester do not respond to ACTH stimulation, dexamethasone suppression, or salt intake. ^[142] These findings suggest that an autonomous source of DOC, specifically the fetoplacental unit, may be responsible for the increased maternal concentrations of DOC.

Dehydroepiandrosterone sulfate (DHEAS) levels are decreased in gestation because of a marked rise in the metabolic clearance of this adrenal androgenic steroid. Most studies have found a modest decline in circulating levels of DHEA as well. Maternal plasma concentrations of testosterone and androstenedione are slightly higher, testosterone because of an elevation in sex hormonebinding protein and androstenedione because of a small increase in its synthesis. ^[147]

Pituitary Gland

The pituitary gland enlarges in pregnancy, principally because of proliferation of prolactin-producing cells in the anterior pituitary. Gonzalez et al. recently demonstrated that the mean pituitary volume increased by 136 percent at term. ^[148] The enlargement of the pituitary makes it more susceptible to alterations in blood supply and increases the risk of postpartum infarction (Sheehan's syndrome) should a large maternal blood loss occur.

The pituitary hormone levels are affected by pregnancy. Serum prolactin levels begin to rise a 5 to 8 weeks' gestation and by term are 10 times higher. ^[149] Despite the increase, prolactin levels remain suppressible by bromocriptine therapy. ^[150] The principal function

of prolactin in pregnancy is to prepare the breast for lactation. Maternal follicle-stimulating hormone (FSH) and luteinizing hormone (LH) are decreased to undetectable levels as a result of feedback inhibition from the elevated levels of estrogen, progesterone, and inhibin. ^[150] Maternal growth hormone levels are also suppressed because of the action of placental growth hormone variant on the hypothalamus and pituitary. ^[150]

PANCREAS AND FUEL METABOLISM

Glucose

Pregnancy is associated with significant physiologic changes in carbohydrate metabolism. This allows for the continuous transport of nutrients from the gravid woman to the developing fetus and placenta. Pregnancy taxes maternal insulin and carbohydrate physiology, and in all pregnancies some deterioration in glucose tolerance occurs. In most women, only mild changes take place, whereas in others pregnancy is diabetogenic, with the impairment in glucose metabolism significant enough to result in gestational diabetes.^[151] Overall, pregnancy results in fasting hypoglycemia, postprandial hyperglycemia, and hyperinsulinemia.^[152] To accommodate the increased demand for insulin there is hypertrophy and hyperplasia of the β -cells (insulin-producing cells) within the islets of Langerhans in the maternal pancreas.^[153]

Early in pregnancy, glucose homeostasis is affected by increased insulin release that appears to be caused by increased estrogen stimulation of the β -cells within the pancreas. During the first trimester, normal insulin sensitivity is maintained and this causes a 10 percent lowering of glucose levels because of the heightened peripheral muscle glucose utilization. Since insulin is lipogenic, the increased insulin levels favor enhanced lipogenesis, with storage of fat apparently in preparation for the rise in energy needs later in gestation.^[154]

With the accelerated growth of the fetus, changes in maternal maintenance of the fasting state and insulin sensitivity take place. During normal pregnancy, maternal fasting is characterized by accelerated starvation. The fasting blood glucose level after a 12- to 14-hour fast is 10 mg/dl lower than that observed in the nonpregnant individual.^[155],^[156] This exaggerated response to fasting is largely a result of the constant drain of maternal glucose by the fetoplacental unit. In the third trimester, glucose uptake by the fetus has been estimated to be approximately 6.0 mg/kg/min.^[157] This results in a more rapid conversion from predominantly carbohydrate to predominantly fat utilization because of earlier depletion of liver glycogen stores. In addition, the fetus also withdraws amino acids from the maternal circulation and limits the availability of gluconeogenic amino acids such as alanine. Thus in pregnancy, during prolonged fasting increased utilization of fat stores occurs. Lipolysis generates glycerol, fatty acids, and ketones for gluconeogenesis and fuel metabolism.^[158],^[159] This produces exaggerated starvation ketosis and preserves the utilization of glucose and amino acids for the maternal central nervous system and fetus. The increased utilization of fat stores is caused by decreased levels of insulin seen during prolonged fasting and the effects of human placental lactogen (hPL).^[154] In summary, maternal hypoglycemia, hypoinsulinemia, hyperlipidemia, and hyperketonemia characterize the maternal response to starvation.

By contrast, hyperglycemia, hyperinsulinemia, hyperlipidemia, and reduced tissue sensitivity to insulin characterize the maternal response to feeding^[152] (see Fig. 3-15). Insulin secretion rises progressively during gestation, with the maximal increase in the third trimester. The insulin response to an intravenous glucose tolerance test or an intravenous infusion of amino acids is also enhanced in pregnancy.^[151] Insulin resistance is observed after the first trimester,^[158],^[159] with a 50 to 80 percent decline in insulin sensitivity in the third trimester. Thus, despite this increase in postprandial hyperinsulinemia, the blood glucose response to the same carbohydrate load is greater in pregnancy.^[151] In normal gestation, glucose homeostasis is maintained by the exaggerated response. If a woman has borderline pancreatic reserve prior to pregnancy and is unable to increase her insulin production, then gestational diabetes mellitus will be revealed during pregnancy.

The factors responsible for the diabetogenic effects of pregnancy include a variety of hormones secreted by the placenta, especially hPL. hPL is produced by syncytiotrophoblast cells and has strong lipolytic and anti-insulin actions. hPL secretion is proportional to total placental mass and parallels the development of insulin resistance. Other hormones potentially responsible for insulin resistance include cortisol, prolactin, estrogen, and progesterone. The diabetogenic effects of pregnancy are advantageous to the growing fetus, providing increased maternal levels of nutrients after a meal.^[151],^[154]

The fetus is primarily dependent on maternal glucose for its fuel requirements. The concentration of glucose in the fetus is about 20 mg/dl less than maternal values.^[160] Placental glucose transport occurs via carrier-mediated facilitated transporter that is energy-independent.^[161] Normal maternal glucose levels are critically important in providing adequate glucose to the fetus. Maternal hyperglycemia can cause birth defects if present in the first trimester and fetal macrosomia if present in the latter half of pregnancy.^[162]

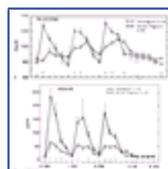

Figure 3-15 Mean (\pm SEM) values for (A) glucose and (B) insulin at intervals of 1 hour from 8:00 A.M. to midnight and 2 hours thereafter in eight nonpregnant and eight normal pregnant women in the third trimester. Mealtimes are indicated by arrows along the abscissa. Pregnant women demonstrate a greater amplitude in plasma glucose excursion after meals. The increased postprandial insulin secretion is apparent. (From Phelps R, Metzger B, Freinkel N: Carbohydrate metabolism in pregnancy. *Am J Obstet Gynecol* 140:730, 1981.)

Proteins

Amino acids are actively transported across the placenta, where they are used by the fetus for protein synthesis and as an energy source. In late pregnancy, the fetoplacental unit contains approximately 500 mg of protein. During pregnancy, fat stores are preferentially used as a substrate for fuel metabolism, and thus protein catabolism is decreased.

Fats/Lipids

Plasma lipids and lipoproteins increase in pregnancy. A gradual two- to threefold rise in triglyceride levels occurs by term and levels of 200 to 300 mg/dl are normal.^[163] Total cholesterol and low-density lipoprotein (LDL) levels are also higher, so that by term a 50 to 60 percent increase from nonpregnant values takes place. High-density lipoprotein (HDL) levels initially rise in the first half of pregnancy and then fall in the second half. By term, HDL concentrations are 15 percent higher than nonpregnant levels. Both cholesterol and triglyceride concentrations return to normal by 6 weeks postpartum (Fig. 3-16) (Figure Not Available). The mechanisms for the pregnancy-induced changes in lipids are not completely understood, but appear to be partly caused by the elevated levels of estrogen, progesterone, and hPL. The rise in LDL appears to be necessary for placental steroidogenesis. Despite the increase in cholesterol and lipids during pregnancy, no increase in the long-term risk for atherosclerosis seems to occur.^[163] However, pregnancy

Figure 3-16 (Figure Not Available) Triglycerides (*upper pane*) and cholesterol (*lower pane*) in plasma and in lipoprotein fractions before, during, and after pregnancy. (*From Salameh W, Mastrogiannis D: Maternal hyperlipidemia in pregnancy. Clin Obstet Gynecol 37:66, 1994.*)

can worsen the lipid profiles of women with preexisting hyperlipidemia.

THE BREASTS

The breasts begin to change early in pregnancy, with tenderness, tingling sensations, and a feeling of heaviness within 4 weeks of the last menstrual period. The breasts rapidly enlarge in the first 8 weeks as a result of vascular engorgement. Thereafter, breast size increases progressively throughout pregnancy because of both ductal growth stimulated by estrogen and alveolar hypertrophy stimulated by progesterone. Little if any of the increase in breast size is attributed to the deposition of fat. The degree of breast enlargement is quite variable. ^[164] The nipples enlarge and become more mobile during pregnancy. Likewise, the areolae enlarge and are more deeply pigmented.

The interaction of numerous hormones including estrogen, progesterone, prolactin, hPL, cortisol, and insulin are all necessary to prepare the breasts for milk production. The profound drop in estrogen and progesterone levels after delivery seems to be the initiating stimulus for lactation. In the latter half of gestation, colostrum, a thick yellow fluid, may leak or be expressed from the nipples. This normal finding is more common in parous women.

SKIN CHANGES

Pigmentation

Hyperpigmentation occurs in approximately 90 percent of pregnancies.^[165] It may be generalized or localized only to areas of increased melanocyte density. Darkening of the areolae, umbilicus, vulva, and perianal skin may occur as early as the first trimester. The linea alba often becomes the hyperpigmented linea nigra. Pigmented nevi, freckles, and recent scars may also deepen

in color. Hyperpigmentation on the face, known as melasma or chloasma, will often prompt complaints from pregnant women. Chloasma is usually manifested by well-defined hyperpigmented centrofacial patches and appears in various shades of brown. Chloasma occurs in at least 70 percent of women and affects all races equally.^[166] The role of hormonal factors such as melanocyte-stimulating hormone is unclear.^[95] Chloasma normally regresses or disappears; however, nearly 30 percent of women will have persistent hyperpigmentation at 10-year follow-up.^[165] During pregnancy, some nevi may increase in size and new nevi may develop. A biopsy may be necessary if there is clinical suspicion for melanoma. In general, no evidence exists that pregnancy causes malignant transformation of nevi to melanoma.^[167]

Hair Changes

Mild degrees of hirsutism are common during pregnancy. The face is frequently affected, although hair growth may be pronounced on the extremities as well. Abdominal hair growth is less common but may be exacerbated in women with a prominent male pattern escutcheon. Hirsutism is believed to be primarily an endocrinologic phenomenon and may result from placental androgen production as well as elevated levels of cortisol. Mild hirsutism rarely requires therapy. It normally regresses following delivery but does recur with subsequent pregnancies. Excessive hirsutism with virilization should warrant investigation for an androgen-secreting tumor. Occasionally, pelvic examination or ultrasound imaging will reveal large ovarian tumors in such women. These usually are luteomas of pregnancy, which represent exaggerated luteinization of normal ovaries rather than true neoplasms. Because luteomas regress after pregnancy, surgical intervention is not indicated.

The anagen (growing) phase of normal scalp hair lasts 2 to 6 years, after which hair enters the telogen (resting) phase. After about 3 months of telogen, the old hair strand is lost, and a new one grows to replace it. During normal pregnancy, the proportion of hair in the anagen phase is increased compared to that in telogen. Then after delivery, the number of hairs entering telogen increases remarkably. Therefore, it is normal to see a marked increase in scalp hair loss 2 to 4 months after delivery called telogen effluvium. Patients should be reassured of the normality of this phenomenon and told that their hair will regrow in 6 to 12 months.

Striae Distensae

Striae distensae begin to appear in the late second trimester in up to 90 percent of pregnant women.^[95] Striae are thin atrophic pink or purple linear bands that are found on the abdomen, breasts, and thighs. Striae are believed to result from a combination of two factors. Stretching is necessary to produce striae; however, adrenocorticosteroids and estrogen also promote tearing in the collagen matrix of the dermis and weakening of elastic fibers.^[165] While many creams and ointments have been employed to treat striae distensae, these therapies are not believed to be of any benefit. Striae are permanent, yet the purplish color most often fades with time and becomes white or silvery.

Vascular Changes

Vascular changes are evident within the skin of most pregnant women. High levels of estrogen are believed to be responsible for proliferation of blood vessels and congestion. Vasomotor instability may also produce pallor, flushing, and mottling of the skin in response to temperature changes. Increased capillary fragility is common in late pregnancy. Scattered petechiae are often seen on the lower extremities as a result of increased capillary hydrostatic pressure and capillary fragility. Spider angiomas may be observed in up to 70 percent of Caucasian women. These lesions consist of a central red arteriole with tortuous radiating branches resembling a spider. Also common to liver disease, spider angiomas are found on the face, trunk, and upper extremities in the areas drained by the superior vena cava. Most lesions fade during the first 3 postpartum months. Similar to spider angiomas, palmar erythema is more common in Caucasians than in black women, with nearly two thirds of pregnancies affected. It typically resolves following delivery.^[168]

Gabbe: Obstetrics - Normal and Problem Pregnancies, 4th ed. , Copyright © 2002 Churchill Livingstone, Inc.

THE EYE

The two consistent and significant ocular changes during pregnancy are increased thickness of the cornea and decreased intraocular pressure. Edema causes a 3 percent increase in corneal thickness. It is apparent by 10 weeks' gestation and regresses by the sixth postpartum week. This change in corneal thickness may cause women to have problems with contact lenses and is the reason patients should be advised to wait several weeks postpartum for new eyeglass or contact prescriptions. ^[169] Intraocular pressure falls by about 10 percent during pregnancy, and individuals with preexisting glaucoma typically improve. Pregnancy either does not cause or minimally decreases visual fields. Therefore, any complaints of visual field changes are atypical and need further evaluation. ^[169]

Key Points

Plasma osmolality decreases during pregnancy as a result of reduction in the serum concentration of sodium and associated anions. The osmolality set point for AVP release and thirst is decreased in pregnancy.

Cardiac output increases 30 to 50 percent during pregnancy. This is dependent on maternal position. Supine positioning and standing are both associated with a fall in cardiac output. The cardiac output is maximal during labor and the immediate postpartum period.

As a result of the marked fall in systemic vascular resistance and pulmonary vascular resistance, pulmonary capillary wedge pressure does not rise, despite an increase in blood volume.

Maternal blood pressure decreases early in pregnancy. The diastolic blood pressure and the mean arterial pressure nadir at midpregnancy (16 to 20 weeks) and return to prepregnancy levels by term.

P_{aCO_2} and P_{aO_2} fall during pregnancy secondary to increased minute ventilation. This facilitates transfer of CO_2 from the fetus to the mother and results in a mild respiratory alkalosis.

Maternal plasma volume increases 50 percent during pregnancy. As RBC volume increases approximately 18 to 30 percent, the hematocrit normally decreases during gestation, but not below 30 percent.

Pregnancy is a hypercoagulable state, with increases in the levels of the majority of the procoagulant factors and a decrease in the fibrinolytic system and in some of the natural inhibitors of coagulation.

BUN and creatinine normally decrease during pregnancy as a result of the increased glomerular filtration rate.

Despite alterations in thyroid morphology, histology, and laboratory indices, the normal pregnant woman is euthyroid, with the levels of free T_4 and TSH within nonpregnant norms.

Pregnancy is associated with a peripheral resistance to insulin, primarily mediated by human placental lactogen. Insulin resistance increases as pregnancy advances and results in hyperglycemia, hyperinsulinemia, and hyperlipidemia in response to feeding, especially in the third trimester.

Chapter 4 - Physiology and Endocrinology of Term and Preterm Labor

John R.G. Challis
Stephen J. Lye

Preterm birth occurs in approximately 5 to 10 percent of all pregnancies in North America. This figure is even higher in certain population groups. Although some preterm births may be elective, approximately 30 percent occur in association with an underlying infectious process, and about 50 percent are so-called idiopathic preterm births, of unknown cause. In the developed world the incidence of preterm birth is, in fact, increasing. There are no effective diagnostic indicators of preterm birth, and there are no effective treatments for this condition. Thus, the direction of current research remains to understand this condition, to use that information to develop diagnostic and prognostic indicators, and to develop better methods of therapeutic management.

Currently, preterm birth is associated with 70 percent of neonatal deaths and up to 75 percent of neonatal morbidity. Infants born preterm have an increased incidence of cerebral palsy, neurologic handicap, and pulmonary disorders. The cost of caring for preterm babies in the United States has been estimated at around \$8 billion annually.

Recent studies have shown that the incidence of spontaneous preterm labor in a very large population base relates to fetal size (R. Gagnon, unpublished information). Studies of over 30,000 deliveries in a tertiary care center in southwestern Ontario, Canada, showed that only 10.9 percent of spontaneous preterm labors were appropriate for gestational age. Remarkably, 24.6 percent of infants with spontaneous labor showed marked fetal growth restriction (<5th percentile), while 19.8 percent of spontaneous preterm deliveries were associated with "large-for-gestational-age" (LGA) (>95th percentile) weights at delivery. This study clearly indicates that preterm labor can arise through different causal mechanisms. The growth-restricted babies had reduced cord oxygen tensions, and were likely chronically hypoxemic, with precocious activation of the fetal stress responses in utero. The LGA babies had appropriate cord blood gases, and their premature delivery was likely associated with alternative mechanisms, including mechanical stretch of the uterus.

PHASES OF UTERINE ACTIVITY

For descriptive purposes it is helpful to think of different patterns of uterine contractility during pregnancy as being divisible into different phases. Thus, phase 0 of parturition corresponds to pregnancy, with relative *quiescence* of the myometrium maintained through the separate or combined activities of one or more inhibitors of uterine contractility. Phase 1 of parturition is associated with activation of uterine function, wherein mechanical stretch or uterotrophic priming leads to up-regulation of a cassette of contraction-associated protein (CAP) genes, essential for the development of myometrial contractility. CAP genes include Connexin-43 (Cx-43), the major constituent protein of GAP junctions, agonist receptors, and proteins encoding myometrial cell ion channels. In phase 2 of parturition, the activated uterus can then be *stimulated* through one or more uterotonins including prostaglandins, oxytocin, and potentially corticotropin-releasing hormone (CRH; see below). Phase 3 of parturition includes *expulsion* of the placenta and the involution process and has been attributed primarily to the effects of oxytocin. In this sequence, the "initiation" of parturition corresponds to the transition from phase 0 to phase 1 (uterine quiescence to uterine activation), although it is clear that the initiation process evolves gradually, rather than precipitously at a specific time in gestation. This sequence of events is also helpful in developing strategies for managing

uterine activity during gestation. While current therapies have been directed at diminishing the stimulus to the uterus, it is evident that maintenance of quiescence or attenuation of the activation phase might be preferable treatment strategies. Of course, that strategy requires delineation of those pregnancies where fetal compromise is such that delivery preterm remains the preferred outcome.

Regulation of uterine quiescence during pregnancy has been discussed extensively in several review articles. ^[1], ^[2] The major agents appear to include progesterone, relaxin, prostacyclin (PGI₂), parathyroid hormone-related peptide (PTH-rP), nitric oxide, and potentially CRH. These agents act in different ways, but in general increase the intracellular levels of cyclic nucleotides cyclic adenosine monophosphate (cAMP) or cyclic guanosine monophosphate (cGMP). In turn, these nucleotides inhibit release of calcium from intracellular stores, and/or reduce the activity of the enzyme myosin light chain kinase (MLCK) that is required for shortening of the myofilaments.

ACTIVATION OF MYOMETRIAL FUNCTION

It has been proposed^[1] that activation of myometrial function can proceed through endocrine or mechanical pathways, driven through the fetal genotype. Studies involving embryo transfer clearly indicate that the fetal genotype controls the length of gestation. The classical view of parturition described in species such as the sheep through pioneering studies of Liggins and Thorburn (and others) reveals that fetal neuroendocrine signals originating in the hypothalamus initiate a cascade of events that activate the fetal hypothalamic-pituitary-adrenal (HPA) axis to increase fetal glucocorticoid production.^[2] The fetal glucocorticoids then act on the placenta to effect changes in placental steroidogenesis and prostaglandin output. Maternal plasma concentrations of progesterone fall, estrogen increases, and this alteration in the estrogen/progesterone ratio is considered central to activation of the myometrium. In species such as the rat, expression of putative CAP genes is low during pregnancy and increases just before the onset of labor in association with an increase in the estrogen/progesterone ratio. Expression of CAP genes can be induced experimentally by uterine stretch, ovariectomy, or administration of the progesterone receptor antagonist RU-486.^[3] In contrast, exogenous progesterone given to prevent the normal prepartum fall in the plasma progesterone concentration inhibited the increase in Cx-43, oxytocin receptor, and F-prostaglandin receptor (FP) mRNA in the myometrium, and blocked the onset of labor. Recent studies suggest that the action of estrogen to increase Cx-43 mRNA in rat myometrium is effected indirectly through one or more transcription factors, including *c-fos*. Levels of *c-fos* in myometrium are highly correlated with Cx-43 during labor, and manipulation of CAP gene expression is associated with coincident changes in *c-fos*. The promoters of both Cx-43 and oxytocin receptor contained putative Fos-binding sites and mutation at this site reduces basal promoter activity for Cx-43.^[4]

It is likely that fetal growth contributes to uterine stretch and increases uterine wall tension. During gestation, uterine growth follows an initial phase of hyperplasia regulated by endocrine factors, a second phase in the 2nd and 3rd trimesters during which uterine growth is closely matched to fetal growth, and a final, third phase during which the rate of uterine growth declines relative to increasing fetal growth. Lye and colleagues^[5] have speculated that with the fall in progesterone at term (in most species), uterine stretch no longer stimulates uterine growth and the increase in wall tension caused by continued fetal growth becomes translated into increased expression of CAP genes.

ACTIVATION: THE FETAL ENDOCRINE PATHWAY

The classic description of parturition in species such as sheep is that increased levels of fetal cortisol during late pregnancy up-regulate expression of the enzyme P450C17 hydroxylase in the placenta.^[2], ^[3] This allows metabolism of progesterone through to C19 steroids, which in turn can be converted to estrogen. Thus, progesterone output from the placenta falls and estrogen increases. The altered estrogen/progesterone ratio provokes increased prostaglandin synthesis and birth. Over the past few years it became evident that there were reasons to challenge this hypothesis. For example, fetal placental expression of prostaglandin H synthase type 2 (PGHS-2) mRNA increases progressively over the last 25 days of late gestation, coincident with the rise in fetal PGE₂ concentrations, and preceding changes in placental output of estrogen and progesterone.^[4] Furthermore, using immunohistochemistry and Western blotting techniques, we showed that expression of P450C17 in placental trophoblast uninucleate cells followed rather than preceded expression of PGHS-2.^[5] Finally, while estrogen administration increases expression of PGHS-2 in uterine tissues of nonpregnant sheep, intrafetal estrogen administration completely failed to increase levels of placental PGHS-2 in late-gestation sheep. In contrast, intrafetal cortisol administration at amounts that reproduced the circulating levels of cortisol

95

in the fetal plasma near term provoked an increase in placental PGHS-2 mRNA and a subsequent increase in PGHS-2 protein.^[6] In the placenta, immunoreactive PGHS-2 localizes exclusively to the trophoblast cells, and is absent from the maternal component. In the uterus, PGHS-2 localizes predominantly to the maternal endometrial epithelium.

To examine the relationship between cortisol, estrogen, and increased PGHS-2 expression more closely, we treated late pregnant sheep with either cortisol or cortisol and 4-hydroxyandrostenedione, an inhibitor of aromatase activity. After 72 to 80 hours' treatment of cortisol infusion alone, there were increased concentrations of PGE₂ in the fetal circulation, increased 13, 14-dihydro-15-keto-PGF₂ (PGFM, reflecting PGF₂ levels) in the maternal circulation, and increased PGHS-2 mRNA and protein in the placenta and maternal inter-caruncular endometrium. However, in animals treated with cortisol and 4-hydroxyandrostenedione there was no increase in maternal PGFM concentrations and no increase in PGHS-2 mRNA or protein levels in the maternal tissues, although placental PGHS-2 expression increased in a manner similar to that in animals treated with cortisol alone. Thus, we have proposed a new model to explain the sequence of events occurring at the time of parturition in sheep^[5], ^[7], ^[8] (Fig. 4-1). We describe this model in some detail, because its underlying characteristics coincide more closely with key steps in the control of human labor. We propose that increased fetal cortisol up-regulates PGHS-2 gene expression in fetal trophoblast cells. These cells express glucocorticoid receptors (GR) that are absent from the maternal

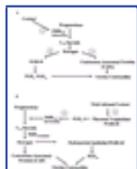

Figure 4-1 Current (A) and proposed (B) sequence of events occurring at the time of parturition in sheep.

96

component of the placenta. Increased placental expression of PGHS-2 results in a progressive increase in PGE₂ output from the placenta into the fetal compartment during late gestation. This accounts for the close temporal association between rising levels of cortisol and PGE₂ in the fetal circulation during late pregnancy. Furthermore, this relationship is suggestive of a positive feed-forward loop by which placental PGE₂ activates and stimulates activity of the fetal HPA axis, the end product of which, cortisol, promotes further placental PGE₂ production. We propose that in an autocrine or paracrine fashion, placental PGE₂ in turn up-regulates expression of P450C17. This enzyme co-localizes with PGHS-2 in fetal trophoblast cells. Up-regulation of this enzyme allows conversion of pregnenolone to C19 steroids and subsequently to estrogen. Thus, increased placental production of PGHS and P450C17 depends upon the elevation of fetal cortisol, but is independent of changes in estrogen. Support for a direct effect of PGE₂ on P450C17 expression is derived from studies in bovine adrenal tissue, and from measurements showing expression of EP (E-prostaglandin) receptor subtypes in ovine placental tissue.

Within the placenta, C19 steroids, formed locally from pregnenolone, are converted to estrogen. Estrogen up-regulates CAP gene expression in maternal uterine tissues. Estrogen is also critical for up-regulation of PGHS-2 in maternal endometrium, since increased endometrial PGHS-2 expression is blocked in animals treated with cortisol plus an aromatase inhibitor. Endometrial expression of PGHS-2 results in increased output into the maternal circulation of PGF₂ (reflected in concentrations of PGFM). The dependence of this response on estrogen is clear from experimental observations showing that the cortisol-induced increase in maternal PGFM concentrations does not occur after inhibition of placental aromatase activity.^[9]

Thus, parturition in sheep (as in the human, see below) depends upon increased expression of PGHS-2 in intrauterine tissues. This finding immediately offers new therapeutic possibilities. We and others have shown that infusion of specific PGHS-2 inhibitors results in a rapid inhibition of uterine activity in sheep, either in the basal state, or after administration of RU-486 to induce uterine contractions.^[9] The inhibition of uterine activity with PGHS-2 inhibitors such as meloxicam or nimesulide is associated with decreased output of PGE₂ into the fetal circulation and of PGFM into the maternal circulation. Importantly, while RU-486-induced preterm labor in sheep is associated with increased activity of the fetal HPA axis, attenuation of uterine contractility by administration of PGHS-2 inhibitor is associated with reduced concentrations of fetal plasma adrenocorticotrophic hormone (ACTH) and cortisol. Thus, suppression of uterine activity is associated with a basal level of fetal HPA axis activity, compatible with pregnancy maintenance. The effect of meloxicam in inhibiting uterine activity is prolonged through at least 48 hours. This is clearly superior to the reappearance of uterine activity that occurs during -sympathomimetic administration. Further studies are required to address the efficacy, safety, and reversibility of meloxicam action before this drug can be utilized in clinical therapeutic management.

FETAL HPA ACTIVATION IN PRIMATES

There is now an increasing body of evidence to suggest that the primate fetus exerts similar controls on gestation length through increased activity of the HPA axis. ^[10] The pattern of steroids produced by the primate fetal adrenal gland differs, however, from that in the sheep. In the latter species, there is no hypertrophied fetal zone, and cortisol is the major steroid produced. In the primate fetus, however, cortisol is produced from the transitional zone of the fetal adrenal cortex, whereas the predominant fetal zone, which lacks 3-hydroxysteroid dehydrogenase, produces mainly 5 steroids, especially dehydroepiandrosterone (DHEA). There is now convincing evidence for increased concentrations of fetal adrenal steroids in the circulation of primate fetuses in late gestation. In the fetal baboon there is increased expression of proopiomelanocortin (POMC) in the pars distalis of the fetal pituitary, and this appears to be driven by fetal hypothalamic CRH. ^[11] In the primate, especially the human, the placenta is an additional source of CRH, and expression of prepro-CRH mRNA increases exponentially in placental tissue during the latter part of gestation (see below). Recent studies have suggested that in addition to effects of placental CRH at the level of the fetal pituitary, this neuropeptide may also have a direct stimulatory effect on the fetal adrenal gland, promoting increased output of 5-DHEA during the latter part of gestation. The regulation of placental CRH is discussed below.

Several studies have led investigators to argue strongly in favor of cortisol, presumably of fetal origin, having a major role to play in the mechanisms associated with human parturition. In particular, fetal glucocorticoids affect the expression and/or activity of enzymes of prostaglandin synthesis and metabolism, and promote, paradoxically, up-regulation of placental CRH gene expression. ^[6]

PROSTAGLANDINS AND HUMAN PARTURITION

There is now extensive evidence for a role of prostaglandins in the labor process of animals and humans. ^[10] Mice

97

lacking the ability to generate prostaglandins (PGHS-1 knockouts) have protracted labors. There is an increased capacity for prostaglandin synthesis by intrauterine tissues at the time of parturition, whether at term or preterm. Inhibitors of prostaglandin synthesis, such as indomethacin, block uterine contractility and prolong gestational length in subhuman primates and in women. Furthermore, the primate uterus is exquisitely sensitive to the stimulatory effect of exogenously applied prostaglandins.

The production of prostaglandins in human intrauterine tissues is compartmentalized discretely within the tissues of the pregnant uterus. ^[10] PGE₂ is formed predominantly in amnion, and its output increases at the time of labor. Chorion also produces predominantly PGE₂, although in chorion trophoblasts the metabolizing enzyme 15-hydroxyprostaglandin dehydrogenase (PGDH) metabolizes eicosanoids extensively, and may serve as a metabolic barrier to prevent passage of prostaglandins generated in amnion or chorion to the underlying decidua and myometrium. Decidua and myometrium both produce prostaglandins. Recent studies on changes in myometrial prostaglandin production in women at the time of labor have led to divergent findings, with some investigators reporting increased prostaglandin output, while others have reported no change or even decreased prostaglandin production.

Primary prostaglandins are formed from arachidonic acid through the activity of the PGHS enzyme complex. There are two forms of PGHS: PGHS-1 and PGHS-2. The former has been described as constitutive, the latter as an inducible gene product. Both forms may be up-regulated in response to certain stimuli, but it is apparent that major increases in PGHS-2 in amnion and chorion occur at the time of labor at term; PGHS-2 is also up-regulated in amnion collected from patients in preterm labor. Prostaglandin action is effected through specific receptors including the four main subtypes: EP1, EP2, EP3 and EP4 for PGE₂, and FP for PGF₂. EP1 and EP3 receptors mediate contractions of smooth muscle in a number of tissues through mechanisms that include increased calcium mobilization and inhibition of intracellular cAMP generation. EP3 receptors exist as a number of isoforms produced after alternative splicing of a single gene product. Activation of EP2 and EP4 receptors increases cAMP formation and relaxes smooth muscle. Theoretically, inhibition of uterine activity might be achieved through antagonism of EP1, EP3, or FP receptor action, or through agonist activation of the inhibitory EP2 and EP4 receptors. At present, however, there is little information concerning regulation and regional changes in any prostaglandin receptor subtype in human myometrial tissue at the time of parturition. ^[10]

Regulation of PGHS activity is a key step controlling conversion of arachidonic acid to biologically active prostaglandins. Experimental studies have shown that PGHS can be up-regulated in response to a variety of growth factors including epidermal growth factor (EGF), cytokines, interleukin-1 (IL-1), tumor necrosis factor (TNF), and interleukin-6 (IL-6). The action of cytokines appears to be mediated through an NF- κ B consensus sequence in the promoter region of PGHS-2. This promoter also contains a cAMP response element, and early studies demonstrated convincingly that -mimetics and cAMP analogs were capable of increasing PGE₂ output by human decidual cells and fetal membranes. Glucocorticoid also appeared to stimulate prostaglandin output and up-regulate levels of PGHS-2 mRNA in primary cultures of human amnion cells and in chorion trophoblast cells. ^[12] The mechanism of this action remains particularly controversial, since glucocorticoids appear to decrease PGHS expression in some other cell types. However, there is a consensus sequence corresponding to a glucocorticoid response element (GRE) at approximately +760 base pairs from the PGHS-2 transcription start site, and it has been speculated that, in trophoblasts, glucocorticoids may act either directly through this site, or through some other intermediate transcription factor.

Gibb and Lavoie were the first to show that human amnion cells, maintained in mixed monolayer culture, increased output of PGE₂ in a dose-dependent manner with increased exposure to dexamethasone. ^[13] This effect was observed once the cells had reached confluency; glucocorticoids inhibited PGE₂ output in freshly dispersed amnion cells. Several other investigators have subsequently confirmed this observation, although others have recently reported an inhibitory effect of glucocorticoids on amnion epithelial cells. Whittle and colleagues ^[12] developed techniques to separate human amnion and mesenchymal cells prior to in vitro culture. They found that the basal output of PGE₂ was considerably higher by mesenchymal fibroblast cells than by epithelial cells. Addition of arachidonic acid stimulated PGE₂ output by the epithelial cells, and glucocorticoids stimulated a further increase in PGE₂ accumulation into the incubation medium. This observation contrasts with the apparent stimulatory effect of glucocorticoids on fibroblast cells of mixed amnion cultures reported by Economopoulos et al. ^[14] This work has shown increased PGE₂ output and increased immunoreactive (ir)-PGHS-2 staining predominantly in cells derived from the amnion mesenchymal layer after exposure to corticosteroids. Clearly, this action of glucocorticoids is of great interest and the discrepancies in the literature as well as the mechanism of glucocorticoid action urgently need resolution.

Proinflammatory cytokines increase PGHS-2 gene expression, mRNA, protein, and PGE₂ output by cultured amnion and chorion cells. The opposing action of anti-inflammatory cytokines on prostaglandin output has recently been described. Pomini et al. ^[15] showed that interleukin-10 (IL-10) alone generated a modest stimulatory

98

effect on PGHS-2 gene expression in villous and chorion trophoblast cells, but IL-10 completely attenuated stimulation of PGHS-2, mRNA, protein, and PGE₂ output produced by addition of interleukin-1 (IL-1). Thus, in vivo it is apparent that the relative amounts of eicosanoids and cytokines produced from an interactive cytokine-eicosanoid cascade will be critical in regulating the final response of the tissue and level of prostaglandin produced.

The effect of cytokines on prostaglandin production is particularly important in circumstances of preterm labor associated with an underlying infections. Many investigators have suggested that approximately 30 percent of preterm labor is associated with an infection, although some have maintained that infection-driven prostaglandin release is a result rather than a cause of preterm birth. ^[16], ^[17] Others have maintained that subclinical inflammatory responses with elevated cytokine production is a more common event, and may contribute to term labor as well as preterm labor. Infection-associated preterm labor is associated with increased concentrations of cytokines, including IL-1, IL-6, and TNF in the amniotic fluid. Administration of cytokines such as IL-1 or of bacterial endotoxin to pregnant mice provokes premature delivery, and this is associated with increased output of prostaglandin by intrauterine tissues. Cytokines increase phospholipase A₂ and PGHS-2 gene expression in a time- and dose-dependent fashion by amnion and choriondecidual tissue maintained in vitro. Thus, a currently accepted model is that, in the presence of an ascending bacterial infection, organisms pass between the fetal membranes and later reach the amniotic cavity. ^[18] Bacterial organisms may release phospholipases, which in turn stimulate prostaglandin production within the membranes. They may also release endotoxins such as lipopolysaccharide (LPS), which provoke prostaglandin or further cytokine release from macrophages. These cytokines would in turn stimulate PGHS-2 expression and prostaglandin output from amnion and/or decidual stroma cells. IL-1 stimulates output of other cytokines including IL-6 and IL-8 from decidua, thereby establishing a positive feed-forward

cascade. IL-1 may also elicit release of other uterotonins including CRH and oxytocin from the decidua, membranes, and/or placenta. [\[18\]](#)

PROSTAGLANDIN METABOLISM

Recent studies have placed cortisol as a central mechanism of human parturition.^[19] Glucocorticoids may stimulate prostaglandin synthesis. It is now apparent that glucocorticoids may also decrease prostaglandin metabolism (thereby allowing increased output of unmetabolized prostaglandin). Glucocorticoids in turn stimulate CRH output from human intrauterine tissues, and CRH in turn increases PGHS-2 expression by fetal membranes in culture (see below).

A substantial body of evidence has revealed that the prostaglandin-metabolizing enzyme PGDH is extensively localized throughout the chorion trophoblast layer.^[19] Of particular interest was the observation that immunostaining for PGDH was decreased in membranes collected from patients in idiopathic preterm labor, and in patients where preterm labor was associated with an underlying infective process and infiltration of leukocytes into the chorion trophoblast layer. In the latter circumstance, the number of trophoblast cells was diminished. In stage 3 chorioamnionitis, there was further loss of trophoblast cells and corresponding decrease in ir-PGDH. In situ hybridization studies showed that changes in PGDH protein reflected the pattern of change in PGDH mRNA in chorion trophoblast cells. In addition, the activity of PGDH in chorion was assessed by measurement of the conversion of PGF₂ to its metabolites 13,14-dihydro-PGF₂ and 13,14-dihydro-15-keto-PGF₂. PGDH activity in chorion was greatest in tissue collected from patients at term in the absence of labor.^[20] There was a modest decrease in PGDH activity in chorion from patients at term in the presence of labor and a further decrease in mean PGDH activity in tissue collected from patients in preterm labor in the absence of an underlying infection. In this latter group, however, a subset of approximately 15 percent of patients had essentially undetectable PGDH activity, even though abundant chorion trophoblast cells were present. Thus, we surmised that deficient or diminished expression of PGDH in chorion trophoblasts might be causal to preterm labor in this subset of patients. PGDH activity was further reduced in preterm labor in association with infection; this was an expected observation, given the loss of trophoblast cells in membranes from such patients. Importantly, changes in PGDH in these chorion cell types were specific to chorion because there were no significant differences in PGDH activity in placental preparations from the same four groups of patients. Thus, we^[19],^[20] proposed that during pregnancy, chorion PGDH effectively metabolizes prostaglandins generated within amnion and chorion, preventing their passage to decidua and myometrium. In this circumstance it is likely that prostaglandins responsible for stimulating myometrial contractility are generated within decidua or within the myometrium itself. In a subset of patients, PGDH activity in chorion trophoblasts is diminished in preterm labor in the absence of infection, allowing transmembrane passage of bioactive prostaglandins. In preterm labor with an underlying infective process, loss of trophoblasts is associated with loss of PGDH activity, and allows increased prostaglandin transfer through the membranous layer.

We used in vitro tissue culture techniques to examine regulation of PGDH expression and activity in trophoblast cells.^[19],^[21] We found that cortisol inhibited PGDH activity and lowered PGDH mRNA levels in placenta and chorion trophoblast cells collected from patients at term spontaneous labor or at term elective cesarean delivery. Thus, glucocorticoids, which increase PGHS-2 expression in these cell types, decrease expression of the metabolizing enzyme PGDH. We reasoned that the availability of glucocorticoids within membranes could be altered through the activity of the steroid-metabolizing enzyme 11-hydroxysteroid dehydrogenase-1 (11-HSD-1). 11-HSD exists in at least two isoforms; 11-HSD-2, which acts predominantly as a dehydrogenase to inactivate cortisol by conversion to cortisone, and 11-HSD-1, which acts predominantly as a reductase, converting cortisone to cortisol, and is present in kidney and placenta, where it may reduce transplacental transfer of cortisol from mother to fetus. In intrauterine tissues, 11-HSD-1 predominates in amnion and in chorion trophoblast cells. We found that cortisone was equally effective as cortisol in decreasing PGDH activity in human chorion cells maintained in culture. However, the effect of cortisone, but not that of cortisol, was completely abolished in the presence of carbenoxolone, an inhibitor of the 11-HSD-1 enzyme. Thus, while cortisone can influence PGDH expression in fetal membranes, it does so through conversion to cortisol.^[22]

In our initial experiments, we were surprised that progesterone appeared to have no significant effects on PGDH activity. However, the fetal membranes and syncytiotrophoblasts of the placenta express 3-HSD and synthesize abundant progesterone from available pregnenolone. Given that glucocorticoids might affect PGDH activity in an autocrine fashion, we considered the possibility that progesterone might act similarly. Placenta and chorion trophoblast cells were treated, therefore, with trilostane, an inhibitor of 3-HSD. In the presence of trilostane, PGDH activity was reduced in a dose-dependent fashion. When the highest concentration of trilostane was held constant, and progesterone was added back to the cells, PGDH activity could be restored again in a dose-dependent fashion. The effect of trilostane on PGDH activity was associated with a significant reduction in levels of PGDH mRNA in both chorion and placental trophoblast cells. The stimulatory effect of progesterone in the presence of trilostane was associated with a parallel increase in PGDH mRNA levels. Thus, we have concluded that progesterone may regulate PGDH activity in trophoblast cells but in a tonic matter; local generation of progesterone appears important for sustained PGDH activity.

Further support for these observations was derived from studies showing that PGDH activity and expression in chorion trophoblasts were increased by progesterone agonists, R5020 and medroxyprogesterone acetate (Fig. 4-2). Basal PGDH output was inhibited in the presence of progesterone receptor antagonists onapristone and RU-486. Synthetic glucocorticoids, betamethasone and dexamethasone, mimic the action of cortisol in inhibiting PGDH activity, and glucocorticoids were able to modulate the effects of progesterone on this enzyme. In related studies we showed that cytokines such as IL-1 and TNF decreased PGDH activity, whereas IL-10 stimulated PGDH activity. Others have reported that cAMP decreases PGDH. Thus, the actions of glucocorticoids, cAMP, and cytokines on PGDH (inhibition) are the same, and the opposite of the effects of these compounds on prostaglandin synthesis (PGHS-2 expression and stimulation) (Table 4-1).

To investigate further whether there might be regional changes in PGDH activity, chorion was obtained from the cervical, middle, and placental region of the uterus from patients at cesarean section in the absence

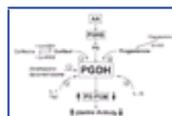

Figure 4-2 Regulation of 15-hydroxyprostaglandin dehydrogenase (PGDH) by glucocorticoids, cytokines, and progestins results from a balance between these different activities. We suggest that alterations in PGDH expression locally in chorion or villous trophoblasts alter the ratio of primary prostaglandin (PG) to prostaglandin metabolite (PGM), and the level of uterotinin available to alter myometrial contractility. AA, arachidonic acid; PGHS, prostaglandin H synthase; IL-1, interleukin-1; IL-10, interleukin-10; TNF, tumor necrosis factor; 11-HSD, 11-hydroxysteroid dehydrogenase type 1 or type 2; 3-HSD 3-hydroxysteroid dehydrogenase.

or presence of labor. PGDH was highest in cervical chorion from patients not in labor. However, the activity of PGDH in cervical chorion from patients in labor was significantly lower than in the other two regions of the uterus. These were not significantly different between "labor" and "not in labor" patients. We speculated that the marked diminution in PGDH of the cervical chorion at the time of labor might reflect inhibition of PGDH expression by cytokines generated within the local environment of the vagina and cervix. The correlation between PGDH activity and 3-HSD in midregion chorion suggested that alternative regulation (e.g., by progesterone) might be more important at this site. It was speculated that the reduction in PGDH activity of cervical chorion at the time of labor may have considerable physiologic importance. If prostaglandin synthesis is specifically up-regulated in this region, then those prostaglandins would not be metabolized by PGDH in chorion trophoblasts. There is only residual adherent decidual tissue in the cervical region, hence prostaglandins generated within amnion or chorion would find easy passage to the cervix, where they might participate in the process of effacement and dilatation. If this thesis is correct, it clearly offers opportunity for therapeutic regulation of PGDH activity in the cervical membranes, and potentially for chemical regulation of cervical function.

In addition to individual uterotonic actions, there is evidence to suggest that different myometrial stimulants might interact to regulate their own expression and action. For example, oxytocin has been shown to stimulate production of PGE₂ and PGF₂ from human and rat decidua, an effect blocked by oxytocin antagonists. Inhibitors of prostaglandin synthesis or antagonists of prostaglandin action have been reported to block oxytocin-stimulated contractions of uterine strips in rabbits. Oxytocin and CRH may also interact to increase myometrial contractions in human myometrium, although this action may also involve increased prostaglandin output. [\[9\]](#)

CRH AND HUMAN PARTURITION

Over the past decade there has been considerable interest in the role of placental CRH in the processes of parturition, and in the regulation of placental function.^[16] Prepro-CRH mRNA increases in placental tissue exponentially during late gestation, and concentrations of CRH in maternal peripheral plasma rise with a similar time course. In maternal blood, CRH is associated with a high-affinity circulating CRH-binding protein (CRH-BP) produced in the liver, placenta, and also in other sites including brain. CRH-BP effectively blocks the action of placental CRH on the maternal pituitary and on maternal myometrium. However, near term and in association with preterm labor, CRH-BP concentrations decline, whereas CRH concentrations continue to increase. Thus, it has been surmised that there is a dramatic increase in free CRH concentrations in these different circumstances. Regulation of CRH output from placenta and fetal membranes has been examined mostly through the use of in vitro experiments. Placental CRH output and gene expression is inhibited by progesterone and nitric oxide; stimulated by oxytocin, cytokines, and catecholamines; and paradoxically markedly up-regulated by glucocorticoids. Thus, it has been suggested that increases in circulating cortisol concentration, within either the maternal compartment in response to stress or in the fetal compartment in response to HPA activation or stresses such as hypoxemia, would result, in the human, in a stimulus to increase placental CRH generation. Several groups have suggested that within placenta and fetal membranes CRH increases expression of PGHS-2 and thus output of biologically active prostaglandins. In vivo evidence in support of these observations has been obtained in two independent studies in which increased maternal plasma CRH concentrations were measured in patients who had presented in preterm labor and had received antenatal glucocorticoids for fetal lung maturation.^[17] As discussed earlier, CRH and corticosteroids increased PGHS-2 expression by intrauterine tissues, and glucocorticoids decreased PGDH activity in human fetal membranes. These results suggest a close interrelationship between glucocorticoids, CRH, and prostaglandin production, and might provide an explanation of the transient increase in uterine activity seen in patients with multiple gestations treated prenatally with corticosteroids.^[23]

Various studies have suggested that maternal plasma CRH concentrations are markedly elevated in patients at risk of preterm labor. Thus, McLean et al.^[24] described elevations in circulating CRH concentrations in maternal blood as early as 14 to 15 weeks of gestation in patients destined to enter preterm labor. CRH concentrations

in maternal blood were lower in those patients who subsequently delivered postterm. In our own studies, we found that CRH concentrations were not different, at 22 to 26 weeks of gestation, in the plasma of patients in preterm labor from those whose pregnancies would continue to term. However, maternal CRH concentrations were elevated significantly in the plasma of patients with the diagnosis of preterm labor at 28 to 32 weeks' gestation and 32 to 36 weeks' gestation.^[25] This study suggested that maternal plasma CRH might be valuable as a means of discriminating those patients truly in preterm labor and requiring tocolytic management from those patients with a diagnosis of preterm labor but in whom uterine contractions would subsequently subside, and pregnancy continue through until close to term. Several clinical trials are currently underway to test this possibility and to compare the value of CRH measurements with those of other markers of preterm labor, including salivary estriol, cervical length, and oncofetal fibronectin.

The action of CRH on intrauterine tissues is mediated by specific CRH receptors. It is now apparent that there is an extensive network of high-affinity CRH receptors of different specificities within human myometrium, and there are several distinct receptor subtypes.^[26] The predominant form in human myometrium is CRH-R1, which exists in at least two variant forms. The type II CRH receptors have tissue distribution distinct from the type I receptors, and exist in at least three splicevariant forms. These receptors couple with G-protein subtypes and activate adenylate cyclase. Human myometrial cells stimulated with CRH produced increased amounts of cAMP in culture. One would envisage that this activity should decrease calcium availability and decrease uterine contractility in vivo. However, as indicated above, cAMP may also stimulate PGHS-2 gene expression, and addition of CRH to human fetal membranes leads to increased output of PGE₂, and up-regulation of PGHS-2 mRNA. The CRH receptor appears to exist in different affinity forms during gestation; during pregnancy the receptors change to a high-affinity state and this is reversed at term. It appears that oxytocin may exert an inhibitory influence on myometrial adenylate cyclase activity and switch the CRH receptor to a low-affinity state and uncouple it from adenylate cyclase.^[26] Thus, further studies on the effects of CRH on the human myometrium are clearly warranted.

Stevens and colleagues showed that the expression of CRH-R1 was increased in myometrium collected from patients at term, and preterm.^[27] Of particular importance in that study, however, was the observation that expression of CRH-R1 in myometrium from pregnant women, and in tissue from a patient at term, was significantly higher in the lower uterine segment than in the fundal region. This observation would be compatible with CRH acting through CRH-R1 to stimulate adenylate cyclase and promote uterine relaxation in the lower uterine segment at term. CRH may then act in conjunction with other uterotonins to promote prostaglandin production, which would affect contractility in the fundal region of the uterus at this time. We have suggested that the failure to determine up-regulation of other CAP genes in the lower uterine segments of women at term is indicative of regional activation of the human uterus.^[1] This suggestion may be of particular importance in relation to the continuing conundrum concerning changes in circulating progesterone concentrations before birth. In virtually all animal species, maternal plasma progesterone levels decline prior to parturition, an observation described by Csapo as withdrawal of the progesterone block that exists to reduce myometrial contractility during pregnancy (see Thorburn and Challis^[2]). In primates, and particularly in the human, attempts to describe a similar decrease in maternal progesterone concentrations have been unsuccessful. Various investigators have proposed mechanisms for local withdrawal of progesterone that would obviate the need for a systemic change in hormone concentrations. We have suggested recently, however, the possibility that withdrawal of systemic progesterone in human gestation in fact should not occur in order to maintain the lower uterine segment in a nonquiescent state at the time of labor.^[1] Withdrawal would then be confined to the upper segment, the region of greater activation and excitability. Verification of this proposition would give considerable importance in generating a unifying hypothesis for the control of labor between different animal species.

OXYTOCIN

Oxytocin is a nonapeptide, synthesized in the hypothalamus and released in a pulsatile fashion from the posterior pituitary into the systemic circulation. Pulses of oxytocin secretion increase in late pregnancy, but more important, the expression and numbers of oxytocin receptors in intrauterine tissues rises substantially; hence, increased end-organ response does not appear to require systemic oxytocin concentrations. It is clear that while oxytocin cannot be considered as an initiator of parturition, increased secretion through a neuroendocrine reflex occurs in stage 2 and 3 and contributes to expulsion of the placenta and uterine involution. Recent reports have suggested that mice bearing a null mutation in the oxytocin gene have a normal pregnancy and labor, raising some question as to the importance of this peptide in the labor process, certainly in small rodent species.

Oxytocin may also act as a local mediator of parturition. Oxytocin gene expression has been demonstrated in the pregnant rat uterus and fetal membranes and, at term, uterine oxytocin mRNA transcripts increase to values that were higher than those in the hypothalamus. Oxytocin is also synthesized in human fetal membranes, chorion, and decidua, and levels of oxytocin mRNA increase in these tissues at the time of parturition. In vitro studies with rat and human choriodecidual tissue have suggested that estrogen up-regulates oxytocin gene expression. More recently, studies from Hillhouse and colleagues have suggested that oxytocin may promote uterine activity by antagonizing the relaxant effect of CRH through receptors coupled to adenylate cyclase (see above).

GLUCOCORTICOIDS: GOOD NEWS AND BAD NEWS

The preceding argument has been that activation of HPA function with the resultant increase in glucocorticoids promotes parturition through increased prostaglandin synthesis, increased CRH expression, and decreased prostaglandin metabolism. Evidence is accumulating in support of this proposition. Glucocorticoids also participate in maturation of those organ systems, including the lung, that are required for postnatal survival. Glucocorticoids, however, may exert adverse effects on the developing fetal organism, and the elevations of fetal corticoids may occur with potential inhibition of fetal growth and altered programming of the fetal cardiovascular system, pancreas, and brain, particularly the hippocampus. It is imperative, therefore, that the fetus is protected from the excesses of maternal glucocorticoids through the activity of the 11-HSD-2 enzyme in the placenta. Regulation of this enzyme is multifactorial. In vitro studies indicate that it is inhibited by progesterone, and inhibited by nitric oxide through a pathway that is partially dependent on the generation of cGMP. In contrast, 11-HSD-2 in placental tissue is up-regulated by cAMP and by adenylate cyclase agonists. It is also up-regulated by transforming growth factor- (TGF-). Evidence has been presented in several species, including the rat and rhesus monkey, that the level of placental 11-HSD-2 may be critical in determining the amount of glucocorticoid passing from the mother to the fetus. Maternal glucocorticoids affect the development of the fetal HPA axis. In addition, elevations of maternal glucocorticoid and/or decreased levels of placental 11-HSD-2 result in growth restriction at birth and predispose to the development of hypertension in later life. ^[28]

In related experiments, we have examined regulation of 11-HSD-1 in human fetal membranes. Previous studies have failed to demonstrate changes in 11-HSD-1 mRNA levels or activity with cyclic nucleotides, nitric oxide, or steroids. However, Alfaidy and Challis (unpublished observations) have shown that PGF₂ upregulates 11-HSD-1 activity in a dose-dependent fashion in human chorion trophoblast cells maintained in culture. Moreover, this is a direct effect on 11-HSD-1 activity, since it is observed within a very short time frame (minutes) and involves increased levels of intracellular calcium, apparently from intracellular stores rather than from an extracellular source. Thus, it appears that within the fetal membranes there exists a local feed-forward mechanism that results in elevated levels of glucocorticoid. Cortisol promotes prostaglandin synthesis and decreases prostaglandin metabolism, hence increasing output of prostaglandin from chorion trophoblast cells. If that prostaglandin, in turn, elevates 11-HSD-1 expression, it would result in increased conversion of cortisone to cortisol, locally by these cells, and lessened opportunity for cortisol oxidation by this enzyme. It remains unclear whether this pathway is primarily concerned with the generation of prostaglandins required for myometrial activity, or whether it leads to the stimulated expression of various matrix metalloproteinases within the membranes, which in turn contribute to collagen breakdown and membrane rupture.

The effectiveness of the placental 11-HSD barrier is reduced by the use of synthetic glucocorticoids, which are poor substrates for 11-HSD. Studies in southwestern Australia have shown that pregnant sheep treated with clinically relevant amounts of betmethasone at 1-week intervals, on days 104, 111, and 118 of gestation (term, 145 days), produced lambs of reduced weight at day 125 and at term. At term, these lambs have decreased femur length, abdominal circumference, brain weight, liver weight, kidney weight, adrenal weight, but increased brain/liver weight ratio. At 6 and 12 months of life they have altered HPA responses to CRH stimulation tests. At 6 months and at 12 months of life the insulin response to a glycemic load is much greater than in controls, despite achieving similar circulating glucose concentrations, and is consistent with the acquisition of early insulin resistance.

These observations are not only of physiologic interest, they are of clinical importance. ^[29] Exogenous glucocorticoids are utilized, with very great benefit, in clinical practice to promote fetal pulmonary maturity. These observations, however, suggest the necessity of utilizing exogenous glucocorticoids with caution. They also indicate the necessity of distinguishing clearly those patients who truly are in preterm labor and warrant treatment with glucocorticoids as opposed to those patients with an initial diagnosis of preterm labor, but in whom pregnancy will continue to term, and weekly

corticosteroid administration is unwarranted. An understanding of the processes of term and preterm labor should facilitate identification of appropriate markers (such as CRH). An understanding of the processes of labor should also facilitate development of new and more effective management protocols for suppressing uterine activity in those patients in true preterm labor where the health of the fetus is enhanced by continued intrauterine development.

Key Points

Preterm birth is a major problem in obstetrics for which there are currently no good diagnostic tests or effective management strategies.

During pregnancy (phase 0 of parturition), relative uterine quiescence is maintained by a variety of endocrine and paracrine/autocrine factors.

Labor is associated with myometrial activation (in response to uterine stretch and endocrine stimuli) and myometrial stimulation (in response to increased uterotonin production and/or action).

Uterine activation involves increased hypothalamic-pituitary-adrenal (HPA) activity in the fetus at term. Increased fetal (and maternal) HPA function in response to stress may contribute to preterm labor.

Prostaglandins have a key role in phase 2 of parturition as uterotonins. In women, prostaglandin production in the fetal membranes is increased, and prostaglandin metabolism in the chorion is decreased at term and preterm labor.

Corticotropin-releasing hormone (CRH) is produced by human placenta and fetal membranes at term, and in response to elevated glucocorticoids. CRH may inhibit (via cAMP) or stimulate (through increased prostaglandin output) uterine activity.

Factors leading to preterm birth may vary in different patients, and different factors may be of greater importance at different times in gestation.

The human uterus at term may undergo regionalization into a lower segment that is relatively relaxed, and a contractile fundal region. Regional differences in the production/action of various agonists likely drive this process.

Concern is expressed about the long-term effects on the fetus/newborn of repeated administration of maternal glucocorticoid during pregnancy; hence, the further need to differentiate patients in true preterm labor from those who are not and should not receive glucocorticoid treatment.

Further basic research in animals and in humans should improve our understanding of birth, at term and preterm, leading to better diagnosis of this condition and its treatment.

Chapter 5 - Physiology of Lactation and Breast-Feeding

Edward R. Newton

Breast-feeding and breast milk are the global standard for infant feeding in undeveloped and developed countries. This statement is supported by the World Health Organization, the U.S. Surgeon General, the American Academy of Pediatrics, the American College of Obstetrics and Gynecology, the American Academy of Family Practice, and the Academy of Breastfeeding Medicine. The American Academy of Pediatrics has recently published an endorsement for breast-feeding at least through the first year of life and as an exclusive method for the first 6 months.^[1] Unfortunately, the majority of American infants are not given this opportunity. [Figure 5-1](#) describes the incidence of breast-feeding in the United States. These data are the result of serial mail surveys sent to postpartum women. The response rate is consistently about 50 percent and minority women are underrepresented. The data for minority women are derived by major statistical manipulation. Despite the potential bias, no other national database exists. The latest survey (1995)^[2] reports that 59.7 percent of women initiate breast-feeding in the hospital and only 21.6 percent of those are still breast-feeding at 6 months. Less than 10 percent of American infants meet the standard of breast-feeding 1 year or more.

Specific populations are at greater risk for the failure to initiate and continue breast-feeding. Lower socioeconomic classes, lack of education, and teenagers initiate breast-feeding at about one half to two thirds the rate of middle and upper class, mature high school graduates ([Table 5-1](#)). Fortunately, since 1989 more women at greatest risk for feeding their infants artificial breast milk are initiating breast-feeding in the hospital.^[2] Perceived breast milk insufficiency, sore nipples and breasts, the lack of family and professional support, and the decision to return to work are the most often cited reasons for early weaning. Cultural attitudes underlie many of these risk factors for failure to breast-feed successfully.

Dysfunctional cultural and familial attitudes are outside the direct control of medicine, and may directly affect the care delivered by physicians. The normal function of the breasts, to produce breast milk, is muted by two cultural attitudes. One cultural attitude is the association of breasts with sexual attraction. The media is replete with examples that show beautiful, well-formed breasts as a sexual ideal. A corollary, of this attitude is that breast-feeding will cause the breasts to sag and lose their sex appeal. The other opposing cultural attitude is that breast-feeding restricts self-fulfillment; mothers who stay at home to breast-feed and care for their babies are considered poor examples of the modern, independent professional woman. These attitudes are exacerbated by a lack of knowledge about breast-feeding and lactation. The normal function of the breasts is excluded from the curriculum of primary and secondary schools on the basis of the connection between breasts and sex. After completion of their education, few women experience any examples of successful breast-feeding. Only 25 percent of grandmothers initiated breast-feeding, and few of the new mothers have breast-fed more than a few weeks. The lack of exposure to successful, experienced breast-feeding mothers seriously compromises the chances of success for the women who attempt to breast-feed.

Physicians are products of the same culture of the women they help. Unfortunately, many have the same cultural biases as their patients and the same lack of primary and secondary education regarding the normal physiology of breast-feeding. The curricula of medical school and residency training programs compound the lack of education. Most physicians reflecting on their own education on breast-feeding will identify neither a structured curriculum nor practical experiences with

successfully breast-feeding mother/infant dyads. At most, he or she has experienced only one or two lectures regarding breast-feeding, often focused on breast anatomy or the endocrinology of lactation. In fact, the most commonly cited resource for physicians is another nonmedical individual or their breast-feeding spouse. On obstetric rotations, medical students and obstetrics residents rarely see normal breast-feeding dyads longer than 1 to 3 days postpartum. On pediatric rotations, learners often see the baby only in the nursery and rarely see the normal mother breast-feed as an inpatient or at newborn visits. While pediatric residents observe and support the mother who pumps or nurses her growing preterm infant, the exposure is not normal, and often is negative. As a result, there are serious gaps in physician knowledge as they attempt to serve the over 2 million newborns and mothers per year who attempt to breast-feed. A recent national survey of physician knowledge revealed that 20 to 40 percent of physicians (obstetricians, pediatricians, and family practitioners) did not know that breast-feeding is the "gold standard" for infant feeding, and similar percentages have serious and sometimes dangerous gaps in their knowledge in the management of breast-feeding problems.^[3] A 1999 survey of fellows of the American Academy of Pediatrics revealed that only 65 percent recommended exclusive breast-feeding during the first month of life, and more than half agreed with or had a neutral opinion about the statement that breast-feeding and formula-feeding are equally acceptable methods for feeding infants.^[4]

The purpose of this chapter is to begin the educational process through which obstetricians will adopt the lactating mother as their patient. In order to support the breast-feeding mother, the obstetrician must be

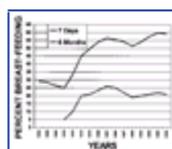

Figure 5-1 Incidence of breast-feeding.

TABLE 5-1 -- DEMOGRAPHIC PREDICTORS OF BREAST-FEEDING: USA 1995

		In Hospital (%)	At 6 Months (%)
Race	White	64.3	24.1
	African-American	37.0	11.2
	Hispanic	61.0	19.6
Age	<20 years	42.8	9.1

	>35 years	70.0	33.8
Family income	<\$10,000 per year	41.8	11.4
	\$25,000 per year	71.0	28.5
Education	Grade school	43.8	17.1
	College	74.4	31.2
Employment	Full-time	60.7	14.3
	Not employed	58.0	25.0

convinced of the biologic superiority of breast-feeding and human breast milk over artificial breast milk (formula). This chapter discusses the limitations of the current research and reviews the morbidity and mortality associated with infant feeding using artificial breast milk. Subsequently, this chapter addresses breast anatomy and physiology of lactation in a framework pertinent to breast-feeding management. This chapter describes the vast differences between breast milk and artificial breast milk, a difference directly related to unique needs of the human infant. Specific issues related to the obstetrician (or other health care provider) will be addressed and include the role of the obstetrician in preconceptional counseling, prenatal care, delivery room management, and postpartum care for the breast-feeding mother.

LIMITATIONS OF BREAST-FEEDING RESEARCH

In the past there have been major flaws in the designs and conclusions of epidemiologic research regarding the benefits (or lack of benefits) of breast-feeding. In the last 10 years the quality has improved, but several cautions are warranted. A major confounder is the difference in the demographic characteristics between women who breast-feed and women who use artificial breast milk (Table 5-1). Many breast-feeding outcomes, such as infections and chronic diseases, are also more prevalent in the latter population. When comparing outcomes between breast-feeding and artificial breast milk feeding, the effect of demographic differences should be analyzed and controlled in the analysis. In addition,

107

cultural support and demographic differences of women who breast-feed their infants have changed. In the 1950s and 1960s cultural pressures pushed better educated, more wealthy middle class women away from breast-feeding; the incidence of initiation of breast-feeding reached its nadir in the early 1970s. This change is important when considering recall data used in studies evaluating differences in chronic diseases in the older adult, especially breast cancer.

Much of the older epidemiologic research has relied on self-report and recall data, usually long after the event has occurred. Memory is not perfect and biases are often introduced, such as combining events into convenient ages or socially acceptable times of weaning. One major area of recall bias is the definition of partial breast-feeding. An example of the confounding nature of this bias is a serial survey of nurses.^[5] The study showed no significant benefit of breast-feeding in the reduction of premenopausal breast cancer, which was touted by the authors as evidence of no relationship between infant feeding and breast cancer. As this was a population of nurses, where a significant number were working at the time they were feeding their infant (this was not measured), the definition of breast-feeding may reflect intent more than actual degree of breast-feeding.

After statistical control for demographic variables, an unavoidable bias remains self-selection. Intrinsic personality characteristics may be determinants of feeding choice; a random allocation of feeding method is not possible. There is also evidence that women who breast-feed exhibit more nurturant behavior than women who feed their infants artificial breast milk.^[6]

When analyzing any article involving breast-feeding, it is important to understand the author's definition of breast-feeding. Exclusive breast-feeding is considered when the infant does not receive any additional food or nutriment other than breast milk. Partial breast-feeding needs to be defined by the proportion of feeds that are breast milk or artificial breast milk. If an infant consumes 700 ml of artificial breast milk per day, then the proportion of breast milk consumed is small regardless of the frequency of breast-feeding episodes. Control for the "dose" effect is important in physiologic as well as epidemiologic studies. The content and character of breast milk are affected by the frequency of feeds, the duration of the feed, when in the feed the breast milk is collected, the method of breast milk collection, and the time of day of the collection.

One common design mistake is the failure to understand the effect of duration of breast-feeding. Breast-feeding has immediate and long-term benefits. The immediate benefits accrue only when a significant proportion of the infant's diet is breast milk. For example, the protection against gastroenteritis is afforded by the presence of antigen-specific immunoglobulin A (IgA) in breast milk. This protection is present only when the infant is breast-feeding. On the other hand, breast milk modulates the infant's immune system and improves response to infection well after breast-feeding has ceased. While it appears there is a dose-dependent relationship between the duration of exclusive breast-feeding and many long-term benefits, the effective dose (duration of exclusive breast-feeding) varies by benefit and is unknown. Most studies have arbitrarily determined the "effective" dose and challenge the benefits of breast-feeding based on that "effective" dose. For example,^[7] Agre concluded that exclusive breast-feeding for 3 months had no bearing on the frequency of infection in the first year of life. However, his outcome variable, frequency of infection in first 12 months, did not stratify the outcome by when the infant was actually breast-feeding. An episode of gastroenteritis at 10 months was counted as a breast-feeding "failure" even though the infant breast-fed only 6 months.

In summary, good breast-feeding research must demonstrate appropriate definitions of breast-feeding, control for the "dose" effect, control for demographic differences between breast-feeding and nonbreast-feeding populations, and appropriate linkage between behavior and outcomes.

BENEFITS OF BREAST-FEEDING

Epidemiologic research shows that human milk and breast-feeding of infants provide significant advantages to general health, growth, and development. In contrast, infant feeding with artificial breast milk is associated with higher incidences of acute and chronic diseases than in infants who are fed human milk through breast-feeding. The studies of predominantly, middle class populations in developed countries show that infant feeding with artificial breast milk is associated with higher incidences and greater severity of diarrhea, ^[8] ^[9] ^[10] ^[11] ^[12] lower respiratory infection, ^[13] ^[14] ^[15] otitis media, ^[9] , ^[16] ^[17] ^[18] bacteremia, ^[19] , ^[20] bacterial meningitis, ^[19] , ^[21] urinary tract infection, ^[22] and necrotizing enterocolitis ^[23] , ^[24] than similar populations who were breast-fed. Numerous studies show higher incidences of sudden infant death syndrome, ^[25] ^[26] ^[27] type I (insulin-dependent) diabetes, ^[28] , ^[29] adolescent obesity, ^[30] Crohn's disease, ^[31] , ^[32] ulcerative colitis, ^[32] lymphoma, ^[33] allergic diseases, ^[34] ^[35] ^[36] ^[37] ^[38] and other chronic digestive diseases among infants fed artificial breast milk. ^[36] ^[37] ^[38] In high-risk populations, preterm infants, and phenylketonurics, as well as healthy middle class populations of infants, breast-feeding has been associated with enhancement of cognitive development and intelligence quotients. ^[39] ^[40] ^[41] ^[42] ^[43] ^[44]

Increase in acute medical diseases will manifest as increased costs of medical care for those families who

choose to feed their infant artificial breast milk. Among Medicaid populations in Colorado, ^[45] California, ^[46] and health maintenance organizations in Arizona, ^[47] the medical cost of artificial breast milk feeding amounts to \$300 to \$500 dollars per year per infant. Among patients who belonged to a large health maintenance organization in Tucson, Arizona, the excess yearly medical costs of 1,000 never-breast-fed infants versus 1,000 infants who were exclusively breast-fed for at least 3 months was \$331,041 ^[48] (Table 5-2) .

The nonmedical costs of artificial breast milk feeding are considerably higher than breast-feeding. The direct costs of artificial breast milk feeding includes the cost of the artificial formula (900 ml/day), bottles, and supplies. In eastern North Carolina (January 2000), the average retail cost of 900 ml of prepared formula was \$4.45 daily (\$1,622 yearly); of concentrate, \$3.25 daily (\$1,181 yearly); and of powdered formula, \$2.74 daily (\$1,001 yearly). A major indirect cost of artificial breast milk feeding is the environmental impact of large dairy herds to supply the milk substrate.

Breast-feeding provides the right amount of a superior product at precisely the right time and at the right temperature. The nonmedical costs of breast-feeding include the cost of increased calorie and protein needs (\$1 to \$2 daily), nursing bras and breast pads, and increased number of diapers in the first 2 to 3 months. If an electric breast pump is used when the woman returns to work, the cost of breast-feeding will increase \$2 to \$4 per day.

Breast-feeding accrues multiple benefits to the mother that are not shared by women who feed their infants artificial breast milk. Breast-feeding through increased release of oxytocin results in faster uterine involution and less postpartum blood loss ^[49] the incidence of postpartum anemia may be reduced. Breast-feeding is associated

TABLE 5-2 -- EXCESS MEDICAL COST (U.S. DOLLARS) AMONG 1,000 NEVER-BREAST-FED VERSUS 1,000 EXCLUSIVE (>3 MONTHS) BREAST-FED INFANTS

	Excess Services per year/1,000 Never-Breast-Fed	Total Excess Cost
Office visits	1,693	\$111,315
Follow-up visits	340	\$22,355
Medications [*]	609	\$7,669
Chest radiography	51	\$1,836
Days of hospitalization	212	\$187,866
Total excess cost per year		\$331,031

with 1 to 3 kg (more in African-American women) less retained postpartum weight. ^[49] , ^[50] Decreased retained postpartum weight may reduce or delay the onset of chronic disease in older women, obesity, ^[49] type II (insulin-resistant) diabetes, ^[49] and hypertension. ^[49] Recent research demonstrates that exclusive breast-feeding delays ovulation with increased child spacing, ^[51] improved bone mineralization postpartum with reduction in hip fractures in the postmenopausal period, ^[52] ^[53] ^[54] a reduced risk of ovarian cancer ^[55] and premenopausal breast cancer. ^[50] , ^[54] , ^[55]

BREAST ANATOMY AND DEVELOPMENT

The size and shape of the breast vary greatly by stage of development, physiologic state, and phenotype. The breast is located in the superficial fascia between the second rib and sixth intercostal cartilage in the midclavicular line. There is usually a projection of the central disk into each axilla, the *tail of Spence*. The mature breast weighs about 200 g in the nonpregnant state; during pregnancy, 500 g; and during lactation, 600 to 800 g. As long as glandular tissue and the nipple are present, the size or shape of the breast has little to do with the functional success of the breast. The adequacy of glandular tissue for breast-feeding is ascertained by inquiring whether a woman's breasts have enlarged during pregnancy. If there is failure of the breast to enlarge as the result of pregnancy, especially if associated with minimal breast tissue on examination, the clinician should be wary of primary failure of lactation.

The nipple, or *papilla mammae*, is a conical elevation in the middle of the areola, or *areola mammae*. The areola is a circular pigmented area, which darkens during pregnancy. The contrast with the fairer skin of the body provides a visual cue for the newborn who is attempting to latch-on. The areola contains multiple small elevations, *Montgomery's tubercles*, which enlarge during pregnancy and lactation. Montgomery's tubercles contain multiple ductular openings of sebaceous and sweat glands. These glands secrete lubricating and anti-infective substances (IgA) that protect the nipples and areola during nursing. These substances are washed away when the breasts and nipples are washed with soap or alcohol-containing compounds, leaving the nipple prone to cracking and infection.

Unlike the dermis of the body of the breast, which includes fat, the areola and nipple contain smooth muscle and collagenous and elastic tissue. With light touch or anticipation, these muscles contract and the nipple erects to form a teat. The contraction pulls the lactiferous

sinuses into the nipple-areola complex, which allows the infant to milk the breast milk from these reservoirs.

The tip of the nipple contains the openings (0.4 to 0.7 mm in diameter) of 15 to 20 milk ducts (2 to 4 mm in diameter). Each of the milk ducts empties one tubuloalveolar gland, which is embedded in the fat of the body of the breast. A sphincter mechanism at the opening of the duct limits the ejection of milk from the breast. The competency of this mechanism is variable. About 20 percent of women do not demonstrate milk ejection from the contralateral breast when milk ejection is stimulated. If milk leakage is demonstrated from the contralateral breast during nursing, there is supporting evidence of milk transfer to the infant.

Five to 10 mm from their exit, the milk ducts widen (5 to 8 mm) into the lactiferous sinuses (Fig. 5-2). When these sinuses are pulled into the teat during nursing, the infant's tongue, facial muscles, and mouth squeeze the milk from the sinuses into the infant's oropharynx.^{[56], [57]} The tubuloalveolar glands (15 to 20) form lobes, which are arranged in a radial fashion from the central nipple-areola complex. The lobes and lactiferous ducts extend into the tail of Spence. Ten to 40 lactiferous ducts connect to each lactiferous sinus, each forming a lobule. Each lobule arborizes into 10 to 100 alveoli for tubulosaccular secretory units. The alveoli are the critical units of the production and ejection of milk. A sac of alveolar cells is surrounded by a basket of myoepithelial cells. The alveolar cells are stimulated by prolactin to produce milk. The myoepithelial cells are stimulated by oxytocin to contract and eject the recently produced milk into the lactiferous ducts, lactiferous sinuses, and beyond.

The radial distribution of lactiferous ducts prompts important considerations relative to breast surgery on women who are breast-feeding or who will breast-feed. Surgical skin incisions parallel to the circumareolar line, especially at the circumareolar line, have better cosmetic healing and are often chosen by surgeons. However, if the incision is taken deep into the parenchyma, the lactiferous ducts may be compromised; a superficial, parallel skin incision and a radial deep incision are preferred. In women who intend to breast-feed, a circumareolar incision is to be avoided. The incision compromises breast-feeding in three ways: occlusion of lactiferous ducts, restriction of the formation of a teat during nursing, and injury to the lateral cutaneous branch of the fourth intercostal nerve.

Surgical disruption of the lateral cutaneous branch of the fourth intercostal nerve can have devastating effects on the success of breast-feeding.^{[58], [59]} This nerve is critical to the production and ejection of breast milk (see The Physiology of Lactation, below). Furthermore, the nerves provide organ-specific control of regional blood flow, and a tremendous increase in mammary blood flow occurs during a nursing episode.^[60] Disruption of this autonomic control may severely compromise lactation performance. The rate of breast-feeding failure is two to three times higher when a circumareolar incision is performed.^[59] The obstetrician needs to be alert to old surgical incisions when a pregnant patient expresses a desire to breast-feed or when a breast biopsy is anticipated in a reproductive-aged woman.

As a mammal, humans have the potential to develop mammary tissue, glandular or nipple tissue, anywhere along the milk line (*galactic band*). The milk line extends from the axilla and inner upper arm to its current position, down the abdomen along the midclavicular line to the upper lateral mons and upper inner thigh. When accessory glands occur, this is termed hypermastia. This may involve accessory glandular tissue, supernumerary nipples, or both. Two to 6 percent of women have hypermastia, and the response to pregnancy and lactation is variable. The most common site for accessory breast tissue is the axilla. These women may present at 2 to 5 days postpartum (galactogenesis) with painful enlargements in the axilla. Ice and symptomatic therapy for 24 to 48 hours is sufficient. Supernumerary nipples (*polythelia*) are associated with renal abnormalities (11 percent).

Full alveolar development and maturation of the breast must await the hormones of pregnancy (progesterone, prolactin, and human placental lactogen) for completion of the developmental process. By midpregnancy, the gland is competent to secrete milk (colostrum), although full function is not attained until the tissues are released from the inhibition of high levels of circulating progesterone. This is termed *lactogenesis stage 1*. Lactogenesis stage 2 occurs as the progesterone levels fall after delivery of the placenta, during the first 2 to 4 days after birth. Stage 2 includes dramatic increases in mammary blood flow and oxygen/glucose uptake by the breast. At 2 to 3 days postpartum, the secretion of milk is copious and "the milk comes in." This is the most common time for engorgement if the breasts are not drained by efficient, frequent nursing. Until lactogenesis stage 2 is developed, the breasts secrete colostrum. Colostrum is very different than mature milk in volume and constituents.^{[61], [62]} Colostrum has more protein, especially secretory immunoglobulins, lactose, and lower fat content than mature milk. Prolactin and glucocorticoids play important promoter roles in this stage of development.

After lactogenesis stage 2 (4 to 6 days postpartum) lactation enters an indefinite period of milk production formerly called galactopoiesis, now termed lactogenesis stage 3. The duration of this stage is dependent on the continued production of breast milk and the efficient transfer of the breast milk to the infant. Prolactin appears

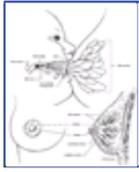

Figure 5-2 Anatomy of the breast.

to be the single most important galactopoietic hormone, since selective inhibition of prolactin secretion by bromocriptine disrupts lactogenesis. Oxytocin appears to be the major galactokinetic hormone. Stimulation of the nipple and areola or behavioral cues cause a reflex contraction of the myoepithelial cells that surround the alveoli and ejection of milk from the breast.

The final stage of development is involution and cessation of breast-feeding. As the frequency of breast-feeding is reduced to less than six episodes in 24 hours and milk volume is less than 400 ml/24 h, prolactin levels fall and a cyclic pattern ends in the total cessation of milk production. After 24 to 48 hours of no transfer of breast milk to the infant, intraductal pressure^[63] and lactation inhibitory factor^[64] appear to initiate apoptosis of the secretory epithelial cells and proteolytic degradation of the basement membrane. Lactation inhibitory factor is a protein secreted in the milk, whose increasing concentration in the absence of drainage appears to decrease milk production by the alveolar cells.^[64]^[65]^[66] It counterbalances pressures to increase milk supply (increased frequency of nursing) and allows for the day-to-day adjustment in infant demands.

THE PHYSIOLOGY OF LACTATION

Prolactin is the major hormone promoting milk production. Prolactin induces the synthesis of mRNAs for the production of enzymes and milk proteins by binding to membrane receptors of the mammary epithelial cells. Thyroid hormones selectively enhance the secretion of lactalbumin. Cortisol, insulin, parathyroid hormone, and growth hormone are supportive metabolic hormones in the production of carbohydrates and lipids in the milk. Ovarian hormones are not required for the maintenance of established milk production and are suppressed by high levels of prolactin.

The alveolar cell is the principal site for the production of milk. Neville^[67] describe five pathways for milk synthesis and secretion in the mammary alveolus, including four major transcellular and one paracellular pathway. They are (1) exocytosis (merocrine secretion) of milk protein and lactose in Golgi-derived secretory vesicles, (2) milk fat secretion via milk fat globules (apocrine secretion), (3) secretion of ions and water across the apical membrane, (4) pinocytosis-exocytosis of immunoglobulins, and (5) paracellular pathway for plasma components and leukocytes. During lactation as opposed to during pregnancy, very few of the constituents of breast milk are transferred directly from maternal blood. The junctions between cells, *tight junctions*, are closed. As weaning occurs, the tight junctions are released and sodium and other minerals easily cross to the milk, changing the taste of the milk.

The substrates for milk production are primarily absorbed from the maternal gut or produced in elemental form by the maternal liver. Glucose is the major substrate for milk production. Glucose serves as the main source of energy for other reactions and is a critical source of carbon. The synthesis of fat from carbohydrates plays a predominant role in fat production in human milk. Proteins are built from free amino acids derived from the plasma.

A sizable proportion of breast milk is produced during the nursing episode. In order to supply the substrates for milk production, there is increased blood flow to the mammary glands (20 to 40 percent), gastrointestinal tract, and liver. Cardiac output is increased by 10 to 20 percent during a nursing episode.^[60] The vasodilation of the regional vascular beds is under the control of the autonomic nervous system. Oxytocin may play a critical role in directing the regional distribution of maternal cardiac output through an autonomic, parasympathetic action.

Given that milk is produced during the nursing episode, variation in content during a feed is expected. During a feeding episode the lipid content of milk rises by more than two to threefold (1 to 5 percent) with a corresponding 5 percent fall in lactose concentration.^[68] The protein content remains relatively constant. At the extreme, there can be a 30 to 40 percent difference in the volume obtained from each breast.^[69],^[70] Likewise, there are intra-individual variations in lipid and lactose concentrations.

The rising lipid content during a feed has practical implications in breast-feeding management. If a woman limits her feeds to less than 4 minutes, but nurses more frequently, the calorie density of the milk is lower and the infant's hunger may not be satiated. The infant wishes to feed sooner and the frequency of nursing accelerates. This stimulates more milk production and creates a scenario of a hungry infant despite apparent good volume and milk transfer.^[71] Lengthening the nursing episode or using one breast for each nursing episode often solves the problem.

The volume and concentration of constituents also vary during the day.^[69],^[70] Volume per feed increases by 10 to 15 percent in the late afternoon and evening. Nitrogen content peaks in the late afternoon and falls to a nadir at 5 A.M. Fat concentrations peak in the early morning and reach a nadir at 9 P.M. Lactose levels stay relatively stable throughout the day. The variation in milk volume and content in working women who nurse only when at home has not been studied. Presumably, the variation in volume and content is preserved if the woman pumps during the day.

Does diet affect the volume and constitution of breast milk? For the average American woman with the

range of diets from teenagers to mature, health-conscious adults, the answer is "no." There is no convincing evidence that the macronutrients in breast milk, protein, fats, and carbohydrates, vary across the usual range of American diets. Volume may vary in the extremes. In developing countries where there is wide-spread starvation and daily calorie intake is less than 1,600 kcal during pre-pregnancy and pregnancy in underweight breast-feeding mothers, milk volume and calorie density are minimally decreased (5 to 10 percent), if at all.^[72] In a controlled experiment,^[73] well-nourished European women reduced their calorie intake by 33 percent for 1 week. Milk volume was not reduced when the diet was maintained at greater than 1,500 kcal/day. If the daily energy intake was less than 1,500 kcal/day, milk volume was reduced 15 percent. Moderate dieting and weight loss postpartum (4.5 lb/mo) are not associated with changes in milk volume,^[50] nor does aerobic exercise have any adverse effect.^[74]

In the first year of life, the infant undergoes tremendous growth; infants double their birth weight in 180 days. Infants fed artificial breast milk lose up to 5 percent of their birthweight during the first week of life, while breast-milk-fed infants lose about 7 percent of their birthweight. A maximum weight loss of 10 percent of birthweight is tolerated in the first week of life in breast-fed infants. If this threshold is exceeded, the breast-feeding dyad needs immediate intervention by a trained health care provider. While supplementation with donor breast milk or artificial breast milk may be a necessary part of the intervention, the key focus of intervention is establishing good breast milk transfer by ensuring adequate production, correct nursing behavior, and adequate frequency. Once stage 3 of lactogenesis occurs, "the milk has come in"; the term breast-fed infant will gain about 1 oz/day with adequate milk transfer. By 14 days, the breast-fed infant should have returned to birthweight.

Food intake and energy needs are not constant. The infant's need for energy and/or fluids varies by day or week with growth spurts, greater activity, fighting illness, or greater fluid losses as in hot weather. Mammals have developed an extremely efficient mechanism to adjust milk supply within 24 to 48 hours depending on demand via oxytocin and the let-down reflex, and prolactin production. The prolactin and oxytocin travel to their target cells, prolactin to the alveolar epithelium in the breast, oxytocin to the myoepithelial cells that shroud the alveolar epithelium. The pituitary's prolactin and luteinizing hormone (LH) response to nursing frequency is depicted in [Figure 5-3](#). In lactating women, baseline prolactin levels are 200 ng/ml at delivery, 75 ng/ml between 10 and 90 days postpartum, 50 ng/ml between 90 and 180 days postpartum, and 35 ng/ml after 180 days postpartum. Maternal serum prolactin levels rise by 80 to 150 percent of baseline levels within seconds of nipple stimulation. As long as nursing frequency is maintained at greater than eight times for 10 to 20 minutes with each episode in 24 hours, the serum prolactin levels will suppress the LH surges and ovarian function.^[75]

Serum oxytocin levels also rise with nipple stimulation. However, the oxytocin response is much more affected by operant conditioning, and its response may precede the rise in prolactin levels. The maternal cerebrum is influenced by exposure to nursing cues as well as the influences of nipple stimulation. The cerebrum either stimulates or inhibits the hypothalamus to increase or decrease the production of prolactin inhibitory factor (dopamine) and, subsequently, the release of oxytocin from the posterior pituitary. Cerebral influences have a lesser effect on the release of prolactin. Positive sights, sounds, or smells related to nursing often stimulate the production of oxytocin, which, in turn, causes the myoepithelial cells to contract and milk to leak from the breasts. This observation is a good clinical clue indicating an

uninhibited *let-down reflex*.

In a classic series of experiments, Newton and Egli^[76] demonstrated the power of noxious influences to inhibit the release of oxytocin and to reduce milk transfer to the infant. The baseline milk production per feed was measured in controlled situations, about 160 g per feed. During a consecutive feed, a noxious event (i.e., saline injection) was administered during the feed. The amount of milk produced was cut in half, 80 to 100 g. Subsequently, the milk production was measured in a trial where a noxious event was administered and intranasal oxytocin was given concomitantly. The milk production was restored to almost 90 percent of baseline production, 130 to 140 g. A wide variety of noxious events were able to elicit the same decrease in milk production. The noxious events included placing the mother's feet in ice water, applying electric shocks to her toes, having her trace shapes while looking only through a mirror, or requiring her to proofread a document in a timed fashion. These observations have important implications concerning the management of breast-feeding. Pain, anxiety, and insecurity may be hidden reasons for breast-feeding failure through the inhibitions of the let-down reflex. In contrast, the playing of a soothing motivational/educational audiotape to women who were pumping milk for their premature infants has improved milk yields.^[77] These observations have been confirmed by measuring the inhibition of oxytocin release by psychological stress.^[78] The positive and negative influences of the cerebrum are further highlighted by the observation^[79] that 75 percent of women who had a positive attitude during pregnancy were likely to be successful at breast-feeding. In contrast, 75 percent of women who had a negative attitude

113

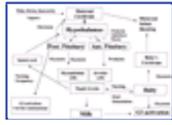

Figure 5-3 Ovarian function postpartum and during weaning. As nursing frequency falls, prolactin falls and ovarian function returns. (From Rolland R, DeJong FH, Schellekens LA, et al: *The role of prolactin in the restoration of ovarian function during the early postpartum period in the human: a study during inhibition of lactation by bromergocryptine. Clin Endocrinol* 4:23, 1975, with permission.)

during pregnancy had an unsuccessful breast-feeding experience.

Oxytocin has additional target cells in the mother. The effect of oxytocin on uterine activity is well known. Uterine involution is enhanced with breast-feeding. Animal and human research suggests that oxytocin is a neurohormone. Oxytocin is associated with an anti-fight/flight response in the autonomic nervous system, the mother tolerates stress better, and maternal-infant bonding is improved. In addition, gastrointestinal mobility and absorption are enhanced.^[80], ^[81]

In addition to the antistress effect, surges in oxytocin levels are associated with the release of gastrointestinal hormones and increased gastrointestinal motility.^[80] In the mother, these actions enhance the absorption of substrates necessary for lactogenesis. In infants, there is a growing body of knowledge that indicates similar associations with oxytocin surges. Skin-to-skin contact and the oral stimulation of nursing stimulate a parasympathetic, anti-fight/flight response in the infant. Kangaroo care of premature newborns (skin-to-skin contact) is associated with a physiologically stable state, improved stress responses, and improved weight gain.^[80], ^[81] Oxytocin appears to mediate this response.^[82] Breast-feeding is associated with far more skin-to-skin contact and maternal behaviors than bottle-feeding.

While the central nervous system locus for imprinting is unknown, imprinting immediately after birth is an important predictor of breast-feeding success. The survival of lambs depends on nursing within an hour after birth. If the lamb has not nursed during the critical period, maternal-infant bonding becomes dysfunctional and the lamb suffers failure to thrive. In humans, the consequences are not nearly as drastic. Several trials with random assignment of subjects to early nursing (delivery room) or late nursing (2 hours after birth) demonstrated a 50 to 100 percent increase in the number of mothers who are breast-feeding at 2 to 4 months postpartum who nursed in the delivery room.^[83] One of the keys to obstetric management is have the mother nurse her newborn in the delivery room.

Milk transfer to the infant is a key physiologic principle in lactation. The initial step of this process is good latch-on. With light tactile stimulation of the

114

cheek and lateral angle of the mouth, the infant reflexively turns its head and opens its mouth, as in a yawn (Fig. 5-4). The nipple is tilted slightly downward using a "C-hold", or *palmar grasp*. In this hand position, the fingers support the breast from underneath and the thumb lightly grasps the upper surface 1 to 2 cm above the areola-breast line. The infant is brought firmly to the breast by the supporting arms while being careful to not push the back of the baby's head. The nipple and areola are drawn into the mouth as far as the areola-breast line (Fig. 5-5 and Fig. 5-6). The posterior areola may be less visible than the anterior areola, and the lower lip of the infant is often curled out. The infant's lower gum lightly fixes the teat over the lactiferous sinuses. A slight negative pressure exerted by the oropharynx and mouth holds the length of the teat and breast in place and reduces the "work" to refill the lactiferous sinuses after they are drained. The milk is extracted, not by negative pressure, but by a peristaltic action from the tip of the tongue to the base. There is no stroking, friction, or in-and-out motion of the teat; it is more of an undulating action. The buccal mucosa and tongue mold around the teat, leaving no space.

The peristaltic movement of the infant's tongue is most frequent in the first 3 minutes of a nursing episode;

Figure 5-4 The latch-on reflex.

Figure 5-5 Appropriate latch-on.

the mean latency from latch-on to milk ejection is 2.2 minutes. After milk flow is established, the frequency of sucking falls to a much slower rate.^[84] The change in cadence is recognizable as "suck-suck-swallow-breath." Audible swallowing of milk is a good sign of milk transfer. At the start of a feed the infant obtains 0.10 to 0.20 ml per suck. As the infant learns how to suck and as he matures he becomes more efficient at obtaining more milk in a shorter period of time. Eighty to 90 percent of the milk is obtained in the first 5 minutes the infant nurses on each breast, but the fat-rich and calorie-dense hind milk is obtained in the remainder of the time sucking at each breast, usually less than 20 minutes total.^[85], ^[86] A bottle-feeding infant sucks steadily in a linear fashion, receiving about 80 percent of the artificial breast milk in the first 10 minutes.

Sucking on a bottle is mechanically very different than nursing on the human teat (Fig. 5-7). The relatively inflexible artificial nipple resists the milking motion of the infant's tongue and mouth. The diameter of the artificial nipple expands during a suck, whereas the human teat collapses during the milk flow. The infant who is sucking on a bottle learns to generate strong negative pressures (>100 mm Hg) in order to suck the milk out of the bottle. Since rapid flow from the bottle can gag the infant, he or she quickly learns to use the tongue to regulate the flow. When the infant who has learned to bottle-feed is put to the breast, the stopper

115

Figure 5-6 The mechanics of nursing.

function of the tongue may abrade the tip of the nipple and force the nipple out of the infant's mouth. The efficiency of milk transfer falls drastically and the hungry infant becomes frustrated and angry. A similar rejection may occur at 4 to 8 weeks when the exclusively breast-feeding infant is given a bottle in preparation for the mother's return to work.

Milk transfer is made more efficient by proper positioning of the infant to the breast. Proper positioning places the infant and mother chest-to-chest. The infant's ear, shoulder, and hip are in line. The three most common maternal positions are cross arm chest-to-chest, side-lying, or the football hold ([Fig. 5-5](#) , [Fig. 5-8](#) , [Fig. 5-9](#)). Each has their advantages. Rotating positions of nursing allows improved drainage of different lobules, an observation important in the management of a "plugged" duct. Maternal comfort and convenience

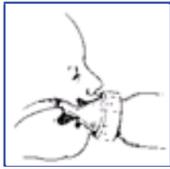

Figure 5-7 The mechanics of bottle-feeding.

are the major reasons for changing nursing positions; the football hold position and the side-lying position are more comfortable if there is an abdominal incision

Baseline prolactin levels appear to be the major determinant of the hormonal state during lactation, a state of high-prolactin, low-estrogen, and low-progesterone levels. As the frequency of nursing decreases below eight in 24 hours, the baseline prolactin levels drop to below a level where ovulation is suppressed (35 to 50 ng/ml), LH levels rise, and menstrual cycling is initiated. ^[74] , ^[85] , ^[87] The intensity (adjusted odds ratio [OR]) of factors that initiate the onset of menses are the duration

Figure 5-8 Side-lying nursing.

116

Figure 5-9 The football hold.

of sucking episodes less than 7 minutes (OR 2.4), night feeds less than four per 24 hours (OR 2.3), maternal age 15 to 24 years (OR 2.1), maternal age 25 to 34 years (OR 1.7), and day feeds less than seven per 24 hours (OR 1.6). ^[88] Serum prolactin levels in women who feed their infants artificial breast milk exclusively drop to prepregnant levels (8 to 14 ng/ml) within days. The total number of nursing episodes per day (more than eight per 24 hours) and night nursings are critical to the successful management of breast-feeding.

One of the major determinants of nursing frequency is the introduction of substitute nutrient sources for the infant, artificial breast milk or solids. Breast milk has the nutritional content to satisfy the growth needs of the infant for at least 6 months postpartum. In the first 6 months, feeding with artificial breast milk affects the physiology of successful lactation in three ways. Substitution with artificial breast milk reduces proportionally the nutrient requirements from breast milk, increases the gastric emptying time (slower digestion than breast milk) with a subsequent decrease in frequency of nursing episodes, and reduces the efficiency of nursing by the use of an opposing sucking technique on the artificial nipple. As depicted in [Figure 5-3](#) , prolactin falls and menses resumes.

Solid food (e.g., eggs, cereals, pureed food) have a similar effect on the hormonal milieu of the lactating woman. One of the errors in Western child care is the early, forced introduction of solids. In most cases, the infant's gut is filled with slowly digesting food with less nutritional quality than either artificial breast milk or breast milk. The long-term result may be childhood and adolescent obesity. The most logical time to start solid food substitution is when the infant has reached the neurologic maturity to grasp and bring food to its mouth from his or her mother's plate. The required neurologic maturity to perform this behavior usually occurs at about 6 months. As the infant matures, his or her ability to feed improves and the proportion of the diet supplied by solid food gradually increases.

The failure to develop good milk transfer is the major cause of lactational failure and breast pain, especially in the neonatal period. Inhibition of the let-down reflex and failure to empty the breasts completely leads to ductal distention and parenchymal swelling (engorgement). Engorgement compromises the mechanics of nursing ([Fig. 5-10](#)) and alveolar distention reduces secretion of milk by the alveolar cells. Without adequate transfer of milk to the infant, lactation is doomed to fail. Distention of the alveoli by retained milk causes a rapid (6 to 12 hours) decrease in milk secretion and enzyme activity by the alveolar epithelium. The decreased production of milk is explained by pressure inhibition and by an inhibitor that is secreted in breast milk. ^[63] ^[64] ^[65] ^[66] Distention of the alveoli inhibits secretion directly

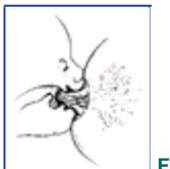

Figure 5-10 Breast-feeding and engorgement. The firm swollen breast parenchyma pushes the newborn's face away and she is unable to pull the teat into her mouth. Her tongue abrades the tip of the nipple.

117

rather than indirectly by a decrease in nutrient or hormonal access.

BREAST MILK: THE GOLD STANDARD

One of the most common misperceptions by physicians and the lay public is that modern formulas for artificial breast milk are equivalent to breast milk. Human breast milk is uniquely suited to our biologic needs and remains the best source of nutrition for the human infant. It has a composition very different than that of bovine milk or soybean plants from which artificial breast milk is produced.

In contrast with most other animals, the human secretory immune system is not completely functional at birth. While the passive transplacental transfer of maternal IgG starts at 20 weeks, fetal levels do not approach maternal levels until term. By 3 months of age, the infant must rely on its own secretory response. The newborn's IgM and IgA responses are naive and incomplete. For example, in the presence of active antigen-positive cytomegalovirus infection at birth, 20 percent of infants will be IgM negative. A newborn's cellular response is likewise immature; functional impairment is evident for months after birth. Breast milk provides necessary support for the developing immune system.^[89] ^[90] The powerful anti-infective qualities of breast milk are measured by decreased infant mortality in developing countries, where exclusive breast-feeding is the norm. In first-world countries, the anti-infective benefits of exclusive breast-feeding are measured by decreased morbidity^[35] and fewer hospitalizations.^[45]

The composition of mature human milk is very different than artificial breast milk or "formula." Most artificial breast milk products use bovine milk as a substrate. Minerals, vitamins, protein, carbohydrates, and fats are added to pasteurized bovine milk for perceived nutritional needs as well as marketing needs in order to make a product that will successfully compete with human breast milk. Human breast milk appears "thinner" than bovine milk. Artificial breast milk manufacturers add constituents to make artificial breast milk appear rich and creamy. Fats such as palm or coconut oil are useful in producing a thick, creamy appearance.

Extensive research describes the unique composition of human milk. The infant formula industry has produced even greater volumes of data concerning their attempts to exactly reproduce human milk. The complete review of the composition of human milk requires the reading of textbooks and chapters specific to human milk, a challenge that is well beyond the scope of this chapter. In 1980, the U.S. Congress passed the Infant Formula Act (with revisions in 1985) as the result of severe health consequences when artificial breast milk failed to include key vitamins and minerals in new formula compositions.^[91] This law now requires that all formulas for artificial breast milk contain minimum amounts of essential nutrients, vitamins, and minerals. Although life-threatening omissions are unlikely, current formulas for artificial breast milk have major differences in the total quantities and qualities of proteins, carbohydrates, and fats when compared to human milk.^[92] ^[93] ^[94] ^[95] ^[96]

The nutritional differences between artificial breast milk and human milk are reflected in differences in the growth patterns of infants who are exclusively breast-fed for 4 to 6 months and infants who are fed artificial breast milk.^[97] In general, breast-fed infants have faster linear and head growth, whereas artificial breast milkfed infants tend to have greater weight gain and fat deposition. The greater deposition in fat may relate in part to the earlier introduction of solid foods in the infant fed artificial breast milk, a factor that has not been adequately controlled in current studies. Regardless of the cause, greater fat deposition in infants fed artificial breast milk has important adverse effects on the child and the future health of the society. Infant feeding using artificial breast milk is associated with a higher incidence of adolescent obesity,^[39] ^[36] which predicts significant increases in adult morbidity such as obesity, type II (insulin-resistant) diabetes, coronary heart disease, and hypertension.^[98]

At birth, the fetus enters an unsterile world with an immature immune system. Full development of the immune system may take up to 6 years. Breast milk has a wide array of anti-infective properties that will support the developing immune system.^[89] ^[90] The major mechanisms for the protective properties of breast milk include active leukocytes, antibodies, antibacterial products, and competitive inhibition. Active leukocytes^[99] are completely eliminated by pasteurization or freezing. Breast milk contains 4,000 cells/mm³: 90 percent macrophages, 5 percent T-cell lymphocytes, 3 percent B-cell lymphocytes, and 2 percent plasma cells/neutrophils. The concentration of these cells is higher in the first week of breast-feeding. Later, the concentration decreases, but the change in the absolute number is not dramatic.

A critical event in host resistance is the recognition of pathogenic agents in the environment and the production of an antigen-specific response. Breast-feeding provides a unique system to help the infant fight infection with antigen-specific responses. The infant is at risk for infection by the same organism that is likely to infect the mother. Through breast milk, the neonate takes

advantage of maternal recognition of these infectious agents. This important mechanism is depicted in [Figure 5-11](#) and reviewed by Slade and Schwartz.^[100] An antigen or infectious agent (virus, bacteria, fungus, and protozoa) stimulates the activity of leukocytes in the gastrointestinal or respiratory tract of the mother. Lymphocytes, which are encoded with the antigen signature, travel to the nearest lymph node and stimulate lymphoblasts to develop cytotoxic T cells, helper T cells, and plasma cells programmed to destroy the initiating antigen through phagocytosis or complement/immunoglobulins produced by the B cells. The response is amplified by the migration of committed helper lymphocytes to other sites of white blood cell production, the spleen and bone marrow, where they stimulate the production of antigen-specific committed white blood cells. Some of the committed, antigen-specific helper lymphocytes travel to the mucosa of the breast in the lactating mother. They may migrate into the breast milk (macrophages) or may produce immunoglobulin (lymphocytes or plasma cells). Both are uniquely programmed to fight the specific infectious agent challenging the mother.

Immunoglobulins are a unique component to breast milk and absent in artificial breast milk.^[89] ^[90] Immunoglobulins constitute a sizable portion of protein content of early milk (colostrum) for the first 2 to 4 days. In serum, the concentration of monomeric IgA is one fifth the concentration of IgG. In breast milk, the ratio is reversed. During the first day of lactation, the concentrations of immunoglobulins are IgA, 600 mg/dl; IgM, 125 mg/dl; and IgG, 80mg/dl. By day 4, the concentration, but not absolute amount, has fallen to a steady level; IgA, 80 mg/dl; IgM, 30 mg/dl; and IgG, 16 mg/dl. Other immunoglobulin classes are found in small amounts, but their function is not well understood. In contrast to monomeric serum IgA, the secretory immunoglobulin A (sIgA) in breast milk is dimeric or polymeric. Polymerization improves transport across the mucous membrane into the breast milk. The sIgA is produced locally by plasma cells. Plasma cells, which produce sIgA, constitute 50 to 80 percent of the leukocytes in the breast submucosa.

The immunoglobulins in breast milk appear to be fully functional. Secretory immunoglobulin A does not activate complement or promote opsonic complement subfragments. As a consequence, sIgA is not bactericidal. It appears that sIgA blocks the mucosal receptors (adhesins) on the infectious agent. The virulence of pathogens is related to their ability to use adhesins capable of interacting with complementary epithelial cell-surface receptors. When the antigen-specific sIgA attaches, the pathogen is effectively neutralized.

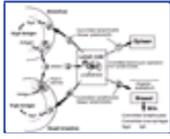

Figure 5-11 The immunology of the breast.

Certain vitamins and minerals are essential for the growth of pathogenic bacteria. A major mechanism by which breast milk protects the infant is the competition for "essential" nutrients for pathogenic bacteria. Iron and vitamin B₁₂ are two essential nutrients for pathogenic bacteria that have been studied relative to breast milk. Breast milk contains lactoferrin, an iron-binding glycoprotein, in large quantities, 5.5 mg/ml in the colostrum to 1.5 mg/ml in mature milk, and is absent in artificial breast milk. The free iron form of lactoferrin competes with siderophilic bacteria for ferric iron, ^[101] ^[102] and thus disrupts the proliferation of these organisms. The binding of iron to lactoferrin also enhances iron absorption; less iron is required in breast milk in order to satisfy the iron needs of the infant. The antibacterial role of lactoferrin is more complex than simple competition for ferric iron. ^[101] Lactoferrin causes a release of lipopolysaccharide molecules from the bacterial cell wall. This appears to sensitize the cell wall to attack by lysozyme. Lactoferrin and lysozyme work together to destroy the pathogenic organisms.

In summary, breast milk is uniquely composed to satisfy the biologic needs of the human infant. In particular, the uniquely human need for brain development and immune system support are provided by breast milk and not by artificial breast milk. Many of the documented benefits of breast-feeding are directly related to the unique composition of breast milk and the failure of artificial breast milk to replicate human milk.

THE ROLE OF THE OBSTETRICIAN

The obstetrician plays the primary role in the initiation of breast-feeding and is largely responsible for which women go home from their postpartum hospitalization breast-feeding. From then on, the obstetrician/gynecologist performs a critical supporting role to the pediatrician in the maintenance of breast-feeding. He or she provides the medical support for breast-specific problems or issues relative to maternal health, as pediatricians are uncomfortable with the examination of the adult breast and accepting the mother as their patient.

The obstetrician/gynecologist amplifies support for breast-feeding by community advocacy, office environment, and personal choices. The office environment needs to be "breast-feeding friendly." Visible, active support of breast-feeding includes the presence of breast-feeding mothers, patient educational programs on breast-feeding, a quiet area for nursing mothers, the absence of material supplied by formula companies, and visible support for office personnel who choose to breast-feed. The physician, especially the bright, young female obstetrician/gynecologist, is a powerful role model for patients. Women will ask the female gynecologist whether and how long she breast-fed her children. Her answers will have a powerful influence.

The support of the obstetrician continues at the first prenatal visit and continues through the mother's total breast-feeding experience. At the first prenatal visit, the method of infant feeding is identified, her choice to breast-feed is verbally reinforced, gaps in her knowledge are identified, and an educational plan is recommended. The educational plan may include reference reading, specific classes on breast-feeding, identification of a "breast-feedingfriendly pediatrician," and introduction to community resources, such as support groups (La Leche League International). At the initial physical examination the breasts are examined for anatomic abnormalities that might influence the success of breast-feeding, such as hypoplasia, nipple inversion and surgical scars.

At the 36-week visit, the obstetrician readdresses the mother's choice and knowledge regarding breast-feeding. Simple concepts of breast-feeding physiology are reinforced: early feeds, frequent feeds (>10 per day), reinforcing environment, and no supplementation unless directed by a pediatrician. The obstetrician reinforces the appropriate way to latch the baby to the breast and ensures that the increase in her breast size reflects the hormonal readiness for breast-feeding. The patient is warned of hospital policies and attitudes that interfere with breast-feeding success. The 36-week visit is a good time to address the appropriateness of medications and breast-feeding.

At delivery and during the postpartum hospitalization, the obstetrician is the champion for the application of breast-feeding physiology; early to the breast (<1 hour) after birth, frequent feeds (>10 per day), appropriate nursing behavior (latch-on), continuous mother/infant contact (rooming-in), and no infant supplementation unless directed by the infant's physician. As an advocate for breast-feeding the obstetrician must be willing to confront administrative and nursing protocols that are designed for control and efficiency rather than optimal care for the breast-feeding dyad.

National and international health organizations have long recognized the challenges and barriers that modern medical care and hospitals raise against successful breast-feeding. In 1989 the World Health Organization initiated the Baby Friendly Hospital initiative. The ten steps by which a hospital might be designated "baby friendly" are outlined in the highlighted box. The United States is the only developed country not to fully endorse the initiative, primarily as a result of the influence on congress by the powerful formula company lobby. As of the year 2000, less than 40 of the more than 1,500 hospitals worldwide who have been designated

baby friendly are in the United States. The biggest challenge to hospitals in the United States in becoming baby friendly is the forbearance of artificial breast milk donations and direct in-hospital marketing by the artificial breast milk companies. The obstetrician has a role in supporting the baby-friendly initiative.

Ten Steps to Successful Breast-Feeding

(Not Available)

*Adapted from WHO/UNICEF: *Protecting, Promoting, and Supporting Breastfeeding: The Special Role of Maternity Services, A Joint WHO/UNICEF Statement.* Geneva, World Health Organization, 1989.*

After postpartum discharge, the obstetrician is primarily focused on maternal concerns about breast-feeding: maternal diet, breast symptoms and signs, hormonal function postpartum, contraception, maternal medications, and as a breast-feeding advocate when the mother is referred to other specialists. A secondary but equally important focus is the growth and development of the infant. Traditionally, the obstetrician sees the mother at 4 to 6 weeks postpartum, but often the obstetrician and the mother communicate before that visit. By inquiring about the growth and feeding of her infant, the obstetrician provides an important reinforcement of the mother's decision to breast-feed and an important screen for the pediatrician regarding the growth and feeding of the infant. The obstetrician can identify critical or developing problems regarding infant growth and feeding for the pediatrician. The obstetrician must know the indicators of adequate infant growth and clinical indicators that milk is being produced and transferred. When the obstetrician remains a verbal participant in the mother's breast-feeding experience at the 4- to 6-week postpartum visit, the likelihood that the mother will continue to breast-feed at 16 weeks is almost doubled. ^[103]

SUCCESSFUL MANAGEMENT OF BREAST-FEEDING

The successful management of breast-feeding requires the active cooperation of the mother, her support group, the obstetric care provider, and infant care provider. In our current culture, a lactation consultant often becomes an active participant in the care of the breast-feeding dyad. There are numerous reliable reference texts for additional information. They include *Breast-feeding: a Guide For The Medical Profession*,^[104] *The Breastfeeding Answer Book*,^[105] *The Womanly Art of Breastfeeding*,^[106] *Drugs In Pregnancy and Lactation*,^[107] and *Medication and Mother's Milk*.^[108]

ANATOMIC ABNORMALITIES OF THE BREAST

The relationship between breast anatomy and lactation should be addressed during the well-woman or family planning visits in women who anticipate future pregnancy. During pregnancy, infant feeding becomes a major focus, and the woman needs this issue addressed, as often there are hidden questions and concerns regarding her adequacy to breast-feed. The breast examination at the first prenatal visit is an excellent opportunity to address infant feeding concerns and myths relative to her breast anatomy. Self-doubt concerning the size or shape of the breasts should be addressed, and the patient should be reassured that less than 5 percent of lactational failures are caused by faulty anatomy.

Congenital abnormalities of the breasts (excluding inverted nipples) are rare, less than 1 in 1,000 women. The most significant defect is glandular hypoplasia. These women have no development or abnormal development of one or both breasts during sexual maturation. Women with no development of the breasts often have normally shaped and sized nipples and areolas, and they may have sought consultation from a plastic surgeon. One manifestation of abnormal development is referred to as the *tubular breast*. The nipple and areola, which are often normal in size, shape, and appearance, are attached to a tube of fibrous cords. Whatever the shape or size of the breasts in a nonpregnant

121

woman, the final evaluation of adequate glandular tissue must await the expected growth during pregnancy. The size of the average breast will grow from 200 g to 600 g during pregnancy; most women will easily recognize this growth. A routine screening question at the 36-week prenatal visit should be, "Have your breasts grown during pregnancy?" If the response is negative in a woman with unusually small or abnormally shaped breasts, lactational failure is a possibility and prenatal consultation with a lactation expert is recommended. Unilateral abnormalities are usually not a problem except for increased asymmetry, as the normal breast can usually produce more than enough milk for the infant. The texture of the breast and tethering of the nipple are also assessed. An inelastic breast gives the impression that the skin is fixed to dense underlying tissue, whereas the elastic breast allows elevation of the skin and subcutaneous tissue from the parenchyma. Lack of elasticity may complicate nursing because of increased rigidity with engorgement. Massage of the periareolar tissue four times a day for 10 minutes is recommended. Engorgement should be assiduously avoided in the postpartum period by early, frequent nursing.

Congenital tethering of the nipple to underlying fascia is diagnosed by squeezing the outer edge of the areola (Fig. 5-12); normally, the nipple will protrude. Severe tethering is manifested by an inverted nipple. The most severe forms of tethering occur in less than 1 percent of women. While successful breast-feeding is possible in these severe cases, prenatal consultation and close follow-up are very important to identify and treat poor milk transfers. Flat or inverted nipples are much less likely to preclude successful breast-feeding. Three prenatal methods of treating tethered nipples have been described: nipple pulling, Hoffman's exercises, and nipple cups (shells). A recent controlled trial failed to demonstrate efficacy^[109] of either shells or Hoffman's exercises and recommended that these should be abandoned.

In the early neonatal period, a breast pump may be of help in women with flat or inverted nipples. The breast is gently pumped at low settings until the teat is drawn out. The infant is immediately offered that breast. The same procedure is performed on the other side. Usually this is only required for a few days. If it is required for more than a few days, a relatively cheap alternative can be created from a 10- or 20-ml plastic syringe, the sizes depending on the size of the nipple.^[110] The end of the syringe where the needle attaches is removed and the plunger is reversed. The nipple is placed in the smooth, plunger end of the syringe and gentle traction is applied until the nipple everts. While pumping and syringe suction are practical solutions, no controlled trials have supported their efficacy.

Figure 5-12 Assessment of nipple tethering.

Modern clothing (especially protective brassieres) prevents friction that toughens the skin and helps protect the nipple from cracking during early lactation. In the second half of pregnancy, nipple skin may be toughened by wearing a nursing brassiere with the flaps open. However, washing with harsh soaps; buffing the nipple with a towel; and using alcohol, benzoin, or other drying agents are not helpful and may increase the incidence of cracking. Normally, the breast is washed with clean water and should be left to air-dry. A cautiously used sunlamp or hair dryer may facilitate drying. Trials involving application of breast cream or expression of colostrum have not shown a reduction in nipple trauma or sensitivity, when compared to those with untreated nipples.

Previous breast surgery may have significant adverse effects on breast-feeding success. The major issues are loss of sensation in the nipple or areola by nerve injury or compromise of the lactiferous ducts. Women who have had breast surgery, breast biopsy, chest surgery,

122

or augmentation, have a threefold higher incidence of unsuccessful breast-feeding.^[58] Circumareolar skin incisions, which are used for cosmetic considerations in breast biopsies or breast augmentation, may compromise both the nerve and ducts. Breast augmentation has significant potential to disrupt breast-feeding.^[111] In a carefully studied, prospective series, 27 of 42 (64 percent) of women who exclusively breast-fed after preconceptional breast augmentation had insufficient lactation, and the infant growth rate was less than 20 g/day. Circumareolar incision was the dominant predictor. One half of women with a submammary or axillary incision had insufficient lactation, whereas all 11 women after a circumareolar incision for breast augmentation had lactation failure. Compromise of the lactiferous ducts and loss of nipple sensation contribute to lactational insufficiency. Loss of nipple sensation occurs in one third to one half of patients after circumareolar incision. Circumareolar incisions between the 7 and 2 o'clock positions may reduce the loss of nipple sensation, but the effect of this maneuver on lactation insufficiency has not been studied. If the woman has had a silicone implant, she can be reassured that there is no evidence that breast-feeding places her infant at risk. The concentration of silicone in artificial formula or cow's milk is 5 to 10 times higher than in breast milk from women who have silicone implants.^[112] Large epidemiologic studies of infants who have nursed from breasts with silicone implants have not shown excess adverse events.^[113]

Reduction mammoplasty is always associated with lactation insufficiency if exclusive breast-feeding is relied upon for infant nutrition. If the reduction involves the removal of greater than 500 g per breast or the procedure uses the free nipple graft technique, the production of a nominal amount of breast milk is rare. If the nipple and areola are relocated on a pedicle of vascular tissue and ducts, partial breast-feeding is a small possibility. In any case of reconstructive surgery on the breast,

augmentation or reduction, the breast-feeding dyad is considered at high risk for lactation failure. Prenatal referral to an expert on lactation is appropriate.

LABOR AND DELIVERY MANAGEMENT

Approximately 15 percent of women who state they wish to breast-feed at the onset of term labor are discharged either completely feeding their infant artificial breast milk or giving the majority of the infant's feeds as artificial breast milk. A combination of obstetric management, hospital policies, and pediatric management contribute to this attrition. Obstetric interventions are often critical for the health of the mother or infant, but they may affect the success of lactation. Few if any interventions directly inhibit the physiology of lactation. Most obstetric interventions reduce the success of lactation by indirect interference with physiology. Induction of labor is not associated with lactation failure, but a long, tiring induction and labor will reduce the likelihood that the mother will get appropriate amounts of infant contact in the delivery room and in the first 24 hours after birth. Cesarean delivery reduces the incidence of breast-feeding by 10 to 20 percent in the first week after birth. After most cesarean sections, the infant is not put to the breast immediately after birth nor will the mother breast-feed her infant more than eight times in the first 24 hours. Well-meaning nurses become concerned for the baby's nutrition and artificial breast milk is given to the infant until the mother "recovers." Labor analgesia (i.e., meperidine and promethazine) has long been associated with poor breast-feeding success. Intrapartum narcotics appear to adversely affect the infant's ability to nurse effectively.^[82] , ^[114] ^[115] ^[116] Epidural anesthesia with local anesthetic agents seems to be better for breast-feeding than parenteral narcotics. Epidural anesthesia with local anesthetics does not appear to have a major effect. The effect of epidural or intrathecal narcotics on sucking behavior and/or lactation success has not been studied. The presence of a doula, or a labor companion other than family, appears to be an effective method to reduce the need for epidural anesthesia and operative deliveries.^[117] , ^[118] An added benefit is earlier initiation and longer duration of breast-feeding.^[118] Postsurgical pain control is best achieved with morphine rather than meperidine, which adversely affects neonatal behavior.^[119] Obstetric and pediatric protocols can be very effective in separating mother and baby. Several prominent examples include magnesium sulfate therapy for preeclampsia, a positive maternal group B streptococcus culture, maternal fever work-up, and diabetes mellitus/hypoglycemia protocols. All of these medical interventions produce major barriers to delivery room nursing and an adequate frequency of nursing in the first 24 to 48 hours.

The peripartum period is critical for achieving successful lactation. The obstetrician must apply the five basic principles of lactation physiology: early imprinting, frequent nursing, good latch-on, a confident and comfortable mother, and no supplementation unless medically indicated. Nursing should be initiated within 30 minutes after birth, preferably in the delivery room.^[83] , ^[114] Contraindications include (1) a heavily medicated mother; (2) an infant with a 5-minute Apgar test result less than 6; or (3) a premature infant at less than 36 weeks' gestation.

The instructor should pay special attention to the mother's position during the first feeding; she should be

in a related, comfortable position. With skin-to-skin contact, the infant is presented to the breast with his ventral surface to the mother's ventral surface. A dry neonate, skin-to-skin contact, and supplemental radiant heating will prevent neonatal cold stress. Routine eye treatment should be delayed, as it may disrupt the important family bonding process.

In the recovery room and on the ward, the best place for the neonate is with the mother. This maximizes mother-infant bonding and allows "on-demand" feeding every 1 to 2 hours. Rooming-in allows the mother to participate in the care of her baby and gives her an opportunity to ask questions. The mother should be encouraged to sleep when the neonate sleeps. Since the hospital runs on an adult diurnal pattern, the patient should be discharged early in order to get her rest.

The frequency of early feeding is proportional to milk production and weight gain in neonates.^[85] , ^[120] ^[121] ^[122] Therefore, supplementation with glucose or formula should be discouraged. Supplementation decreases milk production through a reduction in nursing frequency by satiation of the neonate and slower digestion of formula. Supplementation also undermines the mother's confidence about her lactational adequacy.^[123] ^[124] ^[125] ^[126] When obstetricians give information at the first prenatal visit about breast-feeding that was developed by "breast-feeding-friendly" obstetricians and pediatricians. A randomized trial of giving or withholding free formula samples at the time of discharge demonstrated a significantly reduced incidence of breast-feeding at 1 month and an increased likelihood of solid food introduction by the mothers given the formula samples.^[123] This was most significant in high-risk groups: those less educated, primiparas, and those reporting illness since leaving the hospital.

Other factors influencing the success of lactation are improper positioning and nursing technique, which can lead to increased nipple trauma and incomplete emptying. In the early postpartum period, nursing technique should be evaluated in three areas: presentation and latching-on, maternal-infant positioning, and breaking of the suction. The infant should not have to turn its head to nurse. A ventral surface-to-ventral surface presentation is necessary. When latching-on to the nipple, the neonate should take as much of the areola as possible into its mouth. This is facilitated by gently stimulating the baby's cheek to elicit a yawn-like opening of its mouth and rapid placement of the breast into it. A supporting hand on the breast helps; the C-hold involves four fingers cupping and supporting the weight of the breast, which is especially important in the weak or premature neonate whose lower jaw may be depressed by the weight of the breast. The thumb rests above and 1 to 2 cm away from the areolar edge and points the nipple downward. Retraction by the thumb will pull the areola away from the mouth and cause an incorrect placement. Any position that is comfortable and convenient, while allowing the appropriate mouth-areola attachment, should be encouraged; the sitting position is the most common. In cesarean section patients in whom pressure on the abdomen is uncomfortable, a side-lying or football hold may be better. A rotation of positions is recommended to reduce focal pressure on the nipple and to ensure complete emptying. Removal of the nursing infant can be a problem; suction by the neonate can injure the nipple if it is not broken prior to disengagement. A finger inserted between the baby's lips and the breast will break the suction.

The single most difficult management issue is the control of routines and hospital attitudes detrimental to lactation. Winikoff et al.^[127] studied in the early 1980s how feeding patterns were affected by routine procedures in a hospital. Policies that worked against the physiology of lactation included formula distribution and supplementation without a medical indication, constant questioning of the mother about breast-feeding, preprinted orders for lactation suppression medication, pediatric clearance prior to the first feeding, limited maternal access to the infant, and little educational material for new mothers or staff.

When providers are not well informed or are apathetic about lactation, success of lactation is unlikely. This theme underscores the role of the physician in educating patients, nursing staff, and support personnel about the physiology and benefits of lactation.

BREAST MASSES DURING LACTATION

Breast cancer is the most common cancer of the reproductive organs of the female. While the risk of breast cancer increases tremendously after the age of 40, 1 to 3 percent of all breast cancers occur during pregnancy and lactation. Breast cancer diagnosed during lactation may have its origin before or during pregnancy. As a result of this assumption and small numbers of pregnant or lactating women, most studies have lumped the populations together. Recently, researchers in Japan have analyzed breast cancer in age-matched control women (n = 192), women who were pregnant at diagnosis (n = 72), and women who were lactating at diagnosis (n = 120).^[129] The prognosis for breast cancer that is diagnosed during pregnancy or lactation is poorer than for breast cancer diagnosed at other times. The 10-year survival for age-matched controls without

lymph node metastasis was 93 percent; for women who were diagnosed during pregnancy or lactation the survival was 85 percent. When the lymph nodes are involved, the 10-year survival was 62 percent and 37 percent in controls and women who were diagnosed during pregnancy or lactation, respectively. The difference in survival is partially explained by a longer duration of symptoms prior to diagnosis (6.3 vs. 5.4 months), tumor size on palpation (4.6 vs. 3.0 cm), and tumor size on cut surface (4.3 vs. 2.6 cm), in lactating women versus control women, respectively. The delay in diagnosis and the greater size at diagnosis in lactating women is a failure of the obstetric care provider and/or the lactating woman to aggressively sample a breast mass.

The lactating woman is most likely to recognize a breast mass through her daily manipulations of her breasts. In her framework of reference, she usually considers this mass a "plugged duct." She should be encouraged to report a plugged duct that persists more than 2 weeks despite efforts to initiate drainage of that lobule. Her provider faces an expanded differential diagnosis. Fibromas and fibroadenomas are more common in young women. These solid tumors are rubbery, nodular, and mobile, and they may grow rapidly with the hormonal stimulation of pregnancy. The most common diagnosis is a dilated milk duct, a completely benign diagnosis.

A needle aspiration of the mass is the mainstay of diagnosis. Percutaneous fine-needle aspiration is performed in the same manner as in nonpregnant women. The use of local anesthetic is optional; infiltration of the area around a small lesion may increase the likelihood of a nondiagnostic aspiration. The area over the mass is swabbed with iodine or alcohol and, using sterile techniques, the lesion is fixed between the thumb and fingers of the nondominant hand. Using a 22-gauge needle attached to a 20-ml syringe, the center of the lesion is probed. Initial aspiration usually reveals the nature of the lesion. If milk or greenish fluid (fibrocystic disease) is found and the lesion disappears, no further diagnostic procedures need to be performed. If the tumor is solid or fails to disappear completely after aspiration, the needle is passed several times through the lesion under strong negative pressure. The aspirated tissue fluid is air-dried on a slide and sent for cytologic evaluation. The pathology requisition should note the age and lactating status. Fine-needle aspiration biopsy appears to have the same accuracy in pregnancy and lactation as in the nonpregnant, nonlactating woman. Gupta et al.^[129] performed 214 fine-needle aspirations during pregnancy and lactation. Eight (13.7 percent) were cancer, and the sensitivity, specificity, and positive predictive value was 100, 81, and 61 percent, respectively.

Ultrasound is an expensive but accurate method of determining the cystic nature of a breast mass in lactating women. Mammography is more difficult to interpret during lactation. Young breasts are generally more dense, and the massive increase in functioning glands may obscure small cancers. However, the accuracy is still good if the films are interpreted by experienced radiologists. In general, mammography is a secondary diagnostic modality.

A core biopsy using ultrasound or radiographic guidance is a reasonable option to avoid a surgical procedure. If a surgical biopsy is required, the surgeon will usually need guidance regarding the management of lactation. Most breast biopsies can be performed under local anesthesia. If the mother nurses just before the procedure, she will empty the breast, which makes the surgery easier, and will allow 3 to 4 hours until the next feed. Local anesthetics are not absorbed orally and pose no risk to the infant. The mother should be allowed to nurse on schedule. Most anesthetics used for general anesthesia enter the breast milk in small amounts (1 to 3 percent) of the maternal dose, and minimal behavioral effects in infants have been observed. In most cases the mother can nurse within 4 hours of the anesthetic. The mother's breasts should be pumped 3 to 4 hours after the last feed regardless of the anesthetic status. She will begin to feel the discomfort of engorgement, and the fever of engorgement may confuse the postoperative picture as early as 8 or 10 hours. The failure to empty the breasts within 12 hours will begin to adversely affect milk supply.

Surgical biopsy usually has little effect on breast-feeding performance unless the procedure is done in the periareolar area or the nerves supplying the nipple are compromised. Circumareolar incisions are to be avoided if possible. Milk fistulas are an uncommon risk (5 percent) of central biopsy. The fistulas are usually self-limited and will spontaneously heal over several weeks. Prohibiting breast-feeding does not change the likelihood of ultimate healing.

MATERNAL NUTRITION

The efficiency of conversion of maternal foodstuff to milk is about 80 to 90 percent. If the average milk volume per day is 900 ml, and milk has an average energy content of 75 kcal/dl, the mother must consume an extra 794 kcal/day, unless stored energy is used. During pregnancy, most women store an extra 2 to 5 kg (19,000 to 48,000 kcal) in tissue, mainly as fat, in physiologic preparation for lactation. These calories and nutrients supplement the maternal diet during lactation. As a result, the required dietary increases are easily attainable in healthy mothers and infants.

In lactation, most vitamins and minerals should be increased 20 to 30 percent over nonpregnant requirements. Folic acid should be doubled. Calcium, phosphorus, and magnesium should be increased by 40 to 50 percent, especially in the teenager who is lactating. In practical terms, these needs can be supplied by the following additions to the diet: 2 cups of milk, 2 oz of meat or peanut butter, a slice of enriched or whole wheat bread, a citrus fruit, a salad, and an extra helping ($\frac{1}{2}$ to $\frac{3}{4}$ cup) of a dark green or yellow vegetable. The appropriate intake of vitamins can be ensured by continuing prenatal vitamins with 1 mg of folic acid through the lactation. The mother should drink at least 1 extra liter of fluid per day to make up for the fluid loss through milk.

Vegetarianism has become increasingly more common, and if this is the case, dietary deficiencies may include B vitamins (especially B₁₂), total protein, and the full complement of essential amino acids. The recommendation should be to take a good dietary history with the focus on protein, iron, calcium, and vitamins D and B; supplement with soy flour, molasses, or nuts; use complementary vegetable protein combinations; and avoid excess phytates and bran.

Many women are concerned about losing weight postpartum.^[130], ^[131] If 700 to 1,200 kcal are used daily to nourish an infant, a mother could lose weight by not increasing her caloric intake, but a thoughtful selection of food groups and the elimination of "empty calories" are necessary. A reduction of total calories (<25 kcal/kg) and total protein (<0.6 g/kg) may reduce the daily milk volume by 20 to 30 percent, but not the milk quality, unless the mother is more than 10 percent below her ideal body weight. Since dieting mobilizes fat stores that may contain environmental toxins, women with high exposure to such toxins should not lose weight during lactation.

BREAST AND NIPPLE PAIN

Breast or nipple pain is one of the most frequent complaints of lactating mothers. The frequency is related to failure in the initial management of lactation: late first feed, decreased frequency of feedings, poor nipple grasp, and/or poor positioning. The differential diagnosis of breast pain includes problems with latching-on, engorgement, nipple trauma, mastitis and, occasionally, the let-down reflex.

Symptoms assist with the differential diagnosis. One type of problem with latching-on is the anxious, vigorous infant who sucks strongly against empty ducts until the let-down occurs. The other is the nipple-confused infant who chews on the nipple and abrades the tip with his tongue. In these cases, the nipple and breast pain starts with latching-on and diminishes with let-down. Contact pain suggests nipple trauma and may persist as long as the nipple is manipulated. Engorgement causes a dull, generalized discomfort in the whole breast, worse just before a feed and relieved by it. Localized, unilateral, and continuous pain in the breast may be caused by mastitis. Occasionally, women describe the let-down reflex as painful; this occurs after the first minute of sucking and usually lasts only a minute or two as the ductal swelling is relieved by nursing.

A physical examination and observation of nursing technique can confirm the impression left by a good history. Through observation of a nursing episode, an infant's personality and nursing technique can be assessed. The whole of the nipple and much of the areola should be included in the infant's mouth. An examination of the nipple may reveal a fissure or blood blister. Bilateral breast firmness and tenderness may indicate engorgement. Engorgement may be peripheral, periareolar, or both. Mastitis is characterized by fever, malaise, localized erythema, heat, tenderness, and induration (see below).

Infection may be a co-factor associated with the pain of nipple injury. When the microbiology of the nipple/milk of 61 lactating women with nipple pain was compared to 64 lactating women without nipple pain and 31 nonlactating women, *Candida albicans* (19 percent) and *Staphylococcus aureus* (30 percent) were more common in women with pain and nipple fissures than in controls (3 to 5 percent).^[132]

The management of breast pain consists of general as well as specific steps. Prevention is a key component. Appropriate nursing technique and positioning will prevent, or significantly decrease, the incidence of nipple trauma, engorgement, and mastitis. Rotation of nursing position will reduce the suction pressure on the same part of the nipple, as well as ensuring complete emptying of all lobes of the breast. Frequent nursing will reduce engorgement and milk stasis. The use of soaps, alcohol, and other drying agents on the nipples tends to increase nipple trauma and pain. The nipples should be air-dried for a few minutes after each feed, and clean water is sufficient to cleanse the breast, if necessary. Some experts recommend that fresh breast milk be applied to the nipples and allowed to dry after each feed.

Stimulating a let-down and manual expression of milk is useful in the management of many breast problems. The flow of milk can be improved by placing the mother in a quiet, relaxed environment.^[7] The breast is massaged in a spiral fashion, starting at the top and moving toward the areola; the fingers are moved in a circular fashion from one spot to another, much like a breast examination. After the massage, the breast is stroked from the top of the breast to the nipple with a

light stroke and shaken, while the woman leans forward. Once milk starts to flow, manual expression is begun.

Manual expression is performed by holding the thumb and first two fingers on either side of the areola, in a half circle, but the breast should not be cupped. The hand pushes the breast straight into the chest wall, as the thumb and fingers are rolled forward. Large, pendulous breasts may need lifting prior to this. The maneuver is repeated in all four quadrants of the areola to drain as many reservoirs as possible. The procedure is repeated rhythmically and gently, since squeezing, sliding, or pulling may injure the breast. The sequence of massage, stroke, shake, and express is useful in providing milk immediately for the vigorous infant, in allowing an improved latch-on by reducing periareolar engorgement, and in reducing high suction pressures on a traumatized nipple. The let-down produced by manual expression is never as complete as a normally elicited one. An effective let-down can be elicited by initiating nursing on the side without nipple trauma or mastitis. This will effectively reduce breast pain.

In the first 5 days after birth, about 35 percent of the nipples of breast-feeding mothers show damage, and 69 percent of mothers have nipple pain.^[133],^[134] The management of painful, tender, or injured nipples includes prefeeding manual expression, correction of latching-on, rotation of positions, and initiation of nursing on the less painful side first, with the affected side exposed to air. Drying is facilitated by the application of dry heat (e.g., with hair dryer on low setting) for 20 minutes four times per day. Aspirin or codeine (15 to 30 mg) given ½ hour before nursing may be helpful in severe cases. Engorgement can be avoided, but if it occurs, feeding frequency should be maintained or increased. A wide variety of preparations have been applied to traumatized nipples, including lanolin, A & D ointment, white petrolatum, antibiotics, vitamin E oil, and used tea bags, but few of these have been evaluated scientifically. Soap and alcohol have been shown to injure nipples.^[133],^[134] Nipple shields should be used only as a last resort because of a 20 to 60 percent reduction in milk consumption. Thin latex shields may be better than the traditional red rubber ones, although milk flow is still reduced by 22 percent.^[135]

Engorgement of the breast occurs when there is inadequate drainage of milk.^[136] Swollen, firm, and tender breasts are caused by distention of the ducts and increased extravascular fluid. Aside from the discomfort, engorgement leads to dysfunctional nursing behavior and nipple trauma. The firm breast tissue pushes the infant's face away from the nipple. The widened base of the nipple disrupts the attachment, and the infant's thrusting tongue abrades the tip. This leads to further engorgement, decreased milk production and, in some cases, early termination of breast-feeding.

The best treatment is prevention, but when this has not occurred, management is centered on symptomatic support and relief of distention. Proper elevation of the breasts is important. The mother should wear a firm-fitting nursing brassiere, with neither thin straps nor plastic lining. A warm shower or bath, with prefeed manual expression, is effective. Frequent suckling (every 1 to 2 hours) is the most effective mechanism to relieve engorgement; postfeed electric pumping from each breast may be helpful. In selected cases, intranasal oxytocin may be given just prior to each feed if let-down seems to be inhibited.

GALACTOGOGUES: DRUGS TO IMPROVE MILK PRODUCTION

Obstetricians may interface with the breast-feeding dyad when there is a question of adequate milk production and transfer by the mother. The mother and/or the pediatrician will ask for a galactagogue to be prescribed by the obstetrician.

Numerous agents have been shown to increase prolactin production; and galactorrhea is a clinical issue for women on phenothiazines or metoclopramide. It is reasonable that these drugs might be used where milk supply seems insufficient. ^[137] The most understandable clinical scenarios include premature delivery requiring mechanical pumping, glandular hypoplasia, reduction mammoplasty, and relactation (nursing an adoptive child). The most common clinical presentation is perceived poor milk supply or inhibited milk let-down (oxytocin inhibition). Clinical trials with random assignment of subjects have demonstrated the effectiveness of metoclopramide, ^[138] ^[139] sulpiride, ^[140] ^[141] and nasal oxytocin^[142] for increasing milk production.

Metoclopramide (Reglan) is used to promote gastrointestinal tone; however, a secondary effect is to increase prolactin levels. Most studies demonstrate a multiplefold increase in basal prolactin levels ^[143] and a 60 to 100 percent increase in milk volume. ^[137] The effects of metoclopramide are very dose dependent; the usual dose is 10 to 15 mg three times a day. The side effects, gastric cramping, diarrhea, and depression may limit its use. The incidence of depression increases with long-term use; treatment should be tapered over time and limited to less than 4 weeks. There appears to be little effect on the infant. In Kauppila's et al. study, ^[139] the dose that the infants received was much less than the amount used therapeutically to treat esophageal reflux, regardless of the time postpartum.

Sulpiride is a selective dopamine antagonist used in Europe as an antidepressant and antipsychotic. Smaller doses (50 mg twice daily) do not produce neuroleptic

127

effects in the mother, but prolactin and milk production are increased significantly. ^[144] Clinical studies suggest an increase in milk production (20 to 50 percent) less than that seen with metoclopramide. In a placebo-controlled study with random assignment of 130 subjects, sulpiride 50 mg twice daily for the first 7 days postpartum increased the total milk yield from 916 ± 66 ml in the control group to 1211 ± 65 ml in the sulpiride-treated group. ^[141] The transfer of sulpiride to the breast milk was minimal and no adverse effects were seen in the infants. Sulpiride is not available in the United States.

Intranasal oxytocin substitutes for endogenous oxytocin to contract the myoepithelial cells and cause milk let-down. In theory, its use is to overcome an inhibited let-down reflex. Oxytocin is destroyed by gastrointestinal enzymes and is not given orally. Until recently, oxytocin intranasal spray was available commercially, but it has been taken off the market. A pharmacist can prepare an intranasal spray with a concentration of 2 IU per drop. The let-down dose is a spray (3 drops) to each nostril; the total let-down dose is approximately 12 IU. This is taken within 2 or 3 minutes of each nursing episode. The suggested duration of therapy is unclear. Underlying causes for an inhibited let-down reflex need to be identified and controlled.

There have been few clinical trials using oxytocin alone to improve milk production. In a double-blind group sequential trial, intranasal oxytocin alone was used to enhance milk production in women during the first 5 days after delivery of a premature infant. The cumulative volume of breast milk obtained between the second and fifth days was 3.5 times greater in primiparas given intranasal oxytocin than in primiparas given placebo. ^[142] Because of oxytocin's complementary mechanism to prolactin-stimulating medications, they are often used in combination. ^[145]

While metoclopramide, sulpiride, and oxytocin appear to be effective and relatively safe for the mother and infant, they are only secondary support interventions. The primary focus should be to enhance prolactin and oxytocin through the natural mechanisms, appropriate and frequent stimulation of the nipple and areola. Galactagogues should only be used for a short duration (2 to 4 weeks) and in conjunction with hands-on counseling by an individual with the time, energy, and knowledge to enhance the "natural" production of breast milk.

MASTITIS AND BREAST ABSCESS

Mastitis is an infectious process of the breast characterized by high fever (39° to 40°C), localized erythema, tenderness, induration, and palpable heat over the area. Often these signs are associated with nausea, vomiting, malaise, and other flu-like symptoms. Mastitis occurs most frequently in the first 2 to 4 weeks postpartum and at times of marked reduction in nursing frequency. Risk factors include maternal fatigue, poor nursing technique, nipple trauma, and epidemic *Staphylococcus aureus*. The most common organisms associated with mastitis are *S. aureus*, *S. epidermidis*, streptococci and, occasionally, gram-negative rods. The incidence of sporadic mastitis is 2 to 5 percent in lactating and less than 1 percent in nonlactating mothers.

Until recently, the management of mastitis has been directed by retrospective clinical reviews of experience. In most cases, this consisted of bed rest, continued lactation, and antibiotics, with an 80 to 90 percent cure rate, a 10 percent abscess rate, a 10 percent recurrence rate, and a 50 percent cessation of breast-feeding. Starting in 1982, Thomsen et al. published four important articles concerning pathophysiology, diagnosis, and treatment of mastitis. ^[146] ^[147] ^[148] ^[149] He observed that the diagnosis and prognosis of inflammatory symptoms of the breast could be established by counts of leukocytes and bacteria in breast milk. This is obtained after careful washing of the mother's hands and breasts with a mild soap. The milk is manually expressed, and the first 3 ml discarded. When the leukocyte count was greater than 10⁶ leukocytes/ml, and the bacterial count less than 10³ bacteria/ml, the diagnosis was noninfectious inflammation of the breast. With no treatment, the inflammatory symptoms lasted 7 days; 50 percent developed mastitis, and only 21 percent returned to normal lactation. When the breast was emptied frequently by continued lactation, the symptoms lasted 3 days, and 96 percent returned to normal lactation.

If the breast milk showed greater than 10⁶ leukocytes/ml and greater than 10³ bacteria/ml, the diagnosis was mastitis. Delay in therapy resulted in abscess formation in 11 percent and only 15 percent returned to normal lactation. Frequent emptying of the infected breast by continued nursing eliminated abscess formation, but only 51 percent returned to normal lactation. Additional antibiotic therapy increased the return to normal lactation in 97 percent with resolution of symptoms in 2.1 days.

In summary, the management of mastitis includes the following: (1) breast support; (2) fluids; (3) assessment of nursing technique; (4) nursing initiated on the uninfected side first to establish let-down; (5) the infected side emptied by nursing with each feed (occasionally, a breast pump helps to ensure complete drainage); and (6) dicloxacillin, 250 mg every 6 hours for 7 days. Erythromycin may be used in patients allergic to penicillin. It is important to continue antibiotics for a full 7 days, since abscess formation is more likely with shorter courses. Hand washing before each feed and by

nursing staff reduces nosocomial infection rates. Rooming-in does not reduce the acquisition of hospital strains of *S. aureus* or infection rates. During epidemics, early discharge may reduce infection rates.

Breast abscess will occur in about 10 percent of women who are treated for mastitis. The signs include a high fever (39° to 40°C), and a localized area of erythema, tenderness, and induration. In the center a fluctuant area may be difficult to palpate. The patient feels sick. Abscesses usually occur in the upper outer quadrants and *S. aureus* is usually cultured from the abscess cavity.

The management of breast abscess is similar to that for mastitis, except that (1) drainage of the abscess is indicated and (2) breast-feeding should be limited to the uninvolved side during the initial therapy. The infected breast should be mechanically pumped every 2 hours and with every let-down. The abscess can be drained by serial percutaneous needle aspiration under ultrasound guidance ^[150] however, the most common method is surgical drainage. The skin incision should be made over the fluctuant area in a manner parallel to and as far as possible from the areolar edge. While the skin incision follows skin lines, the deeper extension should be made bluntly in a radial direction. Sharp dissection perpendicular to the lactational ducts increases blood loss, the risk of a fistula, and the risk of ductal occlusion. Once the abscess cavity is entered, all loculations are bluntly reduced and the cavity irrigated with saline. American surgeons pack the wound open for drainage and secondary closure. British surgeons advocate removal of the abscess wall and primary closure. ^[151] In either case, wide closure sutures should be avoided, as they may compromise the ducts. Patients have a protracted recovery of 18 to 32 days and recurrent abscess formation in 9 to 15 percent of cases. Breast-feeding from the involved side may be resumed, if skin erythema and underlying cellulitis have resolved, which may occur in 4 to 7 days.

Candida albicans infection is considered a common cause of breast pain. Candida infection of the breast is commonly diagnosed by clinical presentation. Women describe severe pain when the infant nurses. She will describe the pain as "like a red hot poker being driven through my chest." Often she has received antibiotics recently, she is a diabetic, or the infant has evidence of oral thrush or diaper rash (*Candida albicans*). A potassium hydroxide (KOH) smear can confirm the diagnosis. A drop of midstream milk is combined with a drop of 10 percent KOH and examined under high-power light microscopy. A typical pattern of hyphae and spores will be visualized. The initial treatment is to massage nystatin cream or miconazole oral gel into both nipples after each feed and in the infant's mouth three times a day for 2 weeks. Recurrent or persistent candida mastitis can be treated by swabbing the infant's mouth with gentian violet liquid (0.5 percent) and immediately latching the baby to the breast, twice a day for 3 days. The major disadvantage of this therapy is the permanent staining associated with gentian violet. An alternative therapy in severe cases is oral fluconazole, 200-mg loading dose followed by 100 mg/day for 14 days.

DRUGS IN BREAST MILK

Most medications taken by the mother appear in the milk ([see Chapter 9](#)) , but the calculated dose consumed by the nursing infant ranges from 0.001 to 5 percent of the standard therapeutic doses and are tolerated by infants without toxicity. ^[152] , ^[153] Two good references are *Drugs in Pregnancy and Lactation* ^[107] and *Medications in Mother's Milk*.^[109] Very few drugs are absolutely contraindicated. These include anticancer agents, radioactive materials, lithium, chloramphenicol, phenylbutazone, atropine, and the ergot alkaloids.

The following guidelines are helpful:

1. Evaluate the therapeutic benefit of medication. Diuretics given for ankle swelling provide very different benefits from those for congestive heart failure. Are drugs really necessary, and are there safer alternatives?
2. Choose drugs most widely tested and with the lowest milk/plasma ratio.
3. Choose drugs with the lowest oral bioavailability.
4. Select the least toxic drug with the shortest half-life.
5. Avoid long-acting forms. Usually, these drugs are detoxified by the liver or bound to protein.
6. Schedule doses so that the least amount gets into the milk. The rate of maternal absorption and the peak maternal serum concentration are helpful in scheduling dosage. Usually, it is best for the mother to take the medication immediately after a feeding.
7. Monitor the infant during the course of therapy. Many pharmacologic agents for maternal use are also used for infants. This implies the availability of knowledge about therapeutic doses and the signs and symptoms of toxicity.

MATERNAL DISEASE

In the vast majority of cases of lactating mothers with intercurrent disease, there is no medical reason to stop breast-feeding. However, appropriate management requires individualizing the care of the nursing dyad in

129

order to preserve the supply-and-demand relationship of lactation. For example, a hospitalized nursing mother should have her nursing baby with her in the hospital for on-demand feedings. This situation stretches the flexibility of hospital administrators and nursing services, but the problem can be overcome by education.

The first principle is to maintain lactation. An acute hospitalization for a surgical procedure is a common complication. If breast milk was the neonate's only source of nutrition, an acute reduction in nursing may lead to breast engorgement, confusing postoperative fever, and mastitis. The infant should be put to the breast just before premedication, and the breasts should be emptied in the recovery room. The most effective way is to have the mother nurse. Although some anesthetic may be present in the milk, most are compatible with lactation.^[107],^[108],^[119],^[153] If there is legitimate concern or if the mother cannot communicate (on a ventilator), the breasts should be pumped mechanically and subsequently emptied every 2 to 3 hours by nursing or pumping.

The second principle is to adjust for the special nutritional requirements of nursing mothers. This principle is especially pertinent when intake is restricted postoperatively and when maternal diet must be manipulated, as in diabetes.^[154] In the postoperative period, the surgeon must account for the calories and fluid required for lactation. Until oral intake is established, a lactating mother needs an additional 500 to 1,000 ml of fluid per day. Early return to a balanced diet is essential to offset the additional energy and protein requirements of lactation and wound healing.

The third principle is to ensure that the maternal disease will not harm the infant. This is most pertinent with infectious disease, but it is equally important in cases where a mother's judgment is in question, such as severe mental disease, substance abuse, or a history of physical abuse. The benefits of breast-feeding in the latter situations must be carefully evaluated, using the resources of the patient, her family and social services.

Infection is the most common area where breast-feeding is questioned. In general, the necessary exposure of the infant to the mother in day-to-day care is such that breast-feeding does not add to the risk. This recommendation assumes that appropriate therapy is being given to both mother and infant. Isolation of infected areas should still be practiced, such as a mask in the case of respiratory infection and lesion isolation in herpes. The three acute infections in which breast-feeding is contra-indicated are herpes simplex lesions of the breast, untreated active (not just purified protein derivative [PPD]-positive) tuberculosis, and human immunodeficiency viral (HIV) disease.

The fourth principle is to evaluate adequately the need and type of medication used for therapy ([see Chapter 9](#)). The drug management of chronic hypertension illustrates this principle. First, the need for medication must be scrutinized. There is considerable controversy in the literature as to whether or not to treat patients with mild chronic hypertension (diastolic blood pressure 90 to 100 mm Hg). The desire of a mother with mild hypertension to breast-feed may change the risk/benefit ratio so that antihypertensive drug therapy should be delayed until after lactation. Second, the medication should be evaluated for its effect on milk production. In the first 3 to 4 months of therapy, diuretics reduce intravascular volume and, subsequently, milk volume. On the other hand, if a patient has been on low doses of thiazide diuretics for more than 6 months, the effect on milk volume is minimal as long as adequate oral intake is maintained. Third, the medication should be evaluated for its secretion in breast milk and its possible effects on the infant. Thiazide diuretics, ethacrynic acid, and furosemide also cross into breast milk in small amounts. These agents have the potential to displace bilirubin, and their use during lactation is of concern when the infant is less than 1 month old or is jaundiced. In general, most other antihypertensive drugs are compatible with breast-feeding. Although new drugs come onto the market frequently, it is wise to use drugs that have had a long history of clinical use.

MILK TRANSFER AND INFANT GROWTH

When is an exclusive diet of breast milk insufficient to supply the nutritional needs of the growing infant? Women who wean in the first 8 weeks most often say that insufficient milk is the reason for quitting, and well-meaning family members often ask, "When are you going to start feeding your child real food?"

Correct answers are not readily available.^[97] Many nondietary factors affect the growth of infants, including high birth order, lower maternal age, low maternal weight, poor maternal nutrition during pregnancy, birth interval, birth weight less than 2.4 kg, multiple gestation, infection, death of either parent, and divorce or separation.

In addition, there are inconsistencies in the standard reference charts for growth or nutritional needs.^[97] Most growth charts are based on formula-fed infants, who often receive solid food supplementation earlier and in greater proportion than comparable breast-fed infants. Reference charts with sufficiently large numbers of exclusively breast-fed infants from developed countries are lacking. As milk volume is a quantitative measure of nutrition, variations in volume and concentrations of

constituents caused by individual variation and different methods of collection compound the interpretation.

Despite the latter concerns, it is apparent that a healthy and successfully breast-feeding mother can supply enough nutrition through breast milk alone for 6 months. The clinical markers for adequate breast milk transfer include an alert, healthy appearance, good muscle tone, good skin turgor, six wet diapers per day, eight or more nursing episodes per day, three or four loose stools per day, consistent evidence of a let-down with operant conditioning, and consistent weight gain.

The term "failure to thrive" has been used loosely to include all infants who show any degree of growth failure. For the breast-feeding mother, it may just be a matter of comparing the growth of her infant to growth charts compiled from formula-fed infants. The loosely applied term can seriously undermine the mother's confidence, and ill-advised supplementation further compromises milk volume and may mask other important underlying causes. The infant should be evaluated for failure to thrive or slowed growth if (1) it continues to lose weight after 7 days of life (after "the milk has come in" the infant should gain 1 oz/day); (2) does not regain birth weight by 2 weeks; or (3) gains weight at a rate below the 10th percentile beyond the first months of age. If the infant is premature, ill, or small for gestational age, weight, height, and skin-fold thickness can be used to define adequate growth. The cause of failure to thrive is often complex and is beyond the scope of this chapter.

Gabbe: Obstetrics - Normal and Problem Pregnancies, 4th ed. , Copyright © 2002 Churchill Livingstone, Inc.

JAUNDICE IN THE NEWBORN

Thirteen percent of breast-fed neonates will have jaundice defined by a peak serum bilirubin greater than 12 mg/dl in term infants.^[155] Pediatric concerns include hemolysis, liver disease, or infection as underlying causes, and kernicterus as a consequence. Unconjugated serum bilirubin greater than 20 mg/dl is considered the critical level for the development of kernicterus in term infants. When the serum bilirubin is greater than 5 mg/dl in the first 24 hours, a serious disease process (hemolysis) may be present, and intervention is appropriate.

The focus on breast-feeding as related to neonatal jaundice results from the characterization of two syndromes, breast-feeding jaundice syndrome and breast milk jaundice syndrome.^[155] In the early 1960s, 5 to 10 percent of lactating women were found to have a steroid metabolite of progesterone, 5-pregnane-3(), 20()-diol, in their icterogenic milk, but the compound was not found in the milk of women whose infants were normal (breast milk jaundice syndrome). This metabolite is associated with an inhibition of glucosyl transferase in the liver, differences in the metabolism of long-chain unsaturated fatty acids, and/or increased resorption of bile acids in jaundiced infants.

In breast milk jaundice syndrome, the neonates are healthy and active. The hyperbilirubinemia develops after the fourth day of life and may last several months, with a gradual fall in level. When breast-feeding is stopped for 24 to 48 hours, there is a 30 to 50 percent decline in bilirubin levels. With resumption of nursing, serum levels will rise slightly (1 to 2 mg/dl), plateau, and then start to fall slowly, regardless of feeding method. After excluding other causes of jaundice, and with careful monitoring of serum bilirubin, breast-feeding can continue.

Unfortunately, the focus on rare breast-milk jaundice cases, the concern about kernicterus, and the increased bilirubin in many breast-fed neonates between 2 and 7 days old led to routine supplementation of infants with water, glucose, and formula, even when bilirubin concentrations were in the moderate range of 8 to 12 mg/dl. These interventions have led to the breast-feeding jaundice syndrome, or starvation jaundice. The cause of the elevated bilirubinreduced feeding frequency or low milk transferis often unrecognized. It has been clearly demonstrated that feeding frequency greater than eight feedings per 24 hours is associated with lower bilirubin levels.^[129] Likewise, water supplementation studied in a controlled fashion does not decrease the peak serum bilirubin.^[156] Management consists of prevention by improvement in the quality and frequency of nursing. Rooming-in and night feedings should be encouraged.

Gabbe: *Obstetrics - Normal and Problem Pregnancies, 4th ed.* , Copyright © 2002 Churchill Livingstone, Inc.

BACK-TO-WORK ISSUES

In 1984, approximately 26 percent of new mothers had full-time employment, and an additional 15 percent had part-time employment.^[157] At 5 or 6 months postpartum, 12.3 percent of full-time employees were breast-feeding, as were 29 percent of part-time employees or unemployed mothers. Two thirds of the working mothers were supplementing their infants' diets with formula. In 1992, approximately 34 percent of new mothers had full-time employment, and an additional 15 percent had part-time employment. Full-time employees were breast-feeding at one half (13 percent) the rate of breast-feeding among part-time employees (26 percent) or the unemployed (27 percent).^[104]

The separation between mother and infant adversely affects the psychology and physiology of lactation through a decrease in the frequency of nursing, breast engorgement, and unsatisfied needs of the baby. The

anxiety and fatigue associated with the combination of employment and lactation inhibits the let-down reflex, weakens maternal host defenses, and disrupts family dynamics. The infant must adapt to another caregiver, a new sucking technique, and unfamiliar infectious agents found in day-care settings. Therefore, it is not surprising that formula feeding is viewed as an improvement in mothers' lives, but it does create feelings of inadequacy and guilt in some women.

Breast-feeding during employment is both possible and fulfilling.^[157] Preparation, milk storage, and choice of child-care are the cornerstones to easy adaptation to employment. Preparation involves preemployment change in lifestyle to accommodate the increased stresses. Lactation should be well established with frequent nursing (10 to 14 times per day) and no supplementation prior to return to work. Return to full-time work prior to 4 months has a greater negative impact than return to work after 4 months.^[157], ^[158] Part-time work lessens the impact. About 2 weeks prior to work, the mother should change her nursing schedule at home. During the workday, she should express or pump her breasts two or three times, while increasing her nursing with short, frequent feeds before and after work times. The infant is fed bottles of stored breast milk by a different person in a different place to allow it to adapt more easily.

During the 2 weeks prior to employment, the day-care arrangements should be carefully selected and observed. In addition to references, several questions are pertinent to the selection of the day-care setting. Is the sitter a mother herself, and does the sitter have experience with nursing babies? Is the mother welcome to use the child-care site for a midday nursing? Does the day-care center provide in-arm feeding, or does it use high chairs and propped bottle-feedings. Is the time and activity of the center highly structured and rigid, or is it flexible to mother or infant needs and requests? Does the staff treat the parents and children with respect? Many of these questions can be answered by an extended (1 to 2 hours) observation of the center and its children.

Fatigue is the number one enemy of the working mother. Emotional and physical support of the mother is critical. Some helpful suggestions include (1) bringing the infant's bed into the parent's room, or the construction of a temporary extension to the parents' bed; (2) use of labor saving devices, division of domestic chores, and the elimination of less important household chores to reduce the workload; and (3) taking naps and frequent rest periods to conserve energy.

Continued stimulation of the breast during working hours is important. Pumping not only improves milk supply but it also supplies human milk for the infant. Manual expression and/or mechanical pumping should be performed more frequently (two to three times) in the first 6 months postpartum. After 6 months, the frequency can be reduced and eliminated as the infant is supplemented by fluids or solids during the day.

The collection of breast milk has become simple with the wide variety of mechanical pumps available in the market. Mechanical pumps that employ a bulb syringe produce the least amount of milk and have the highest rate of bacterial contamination. Cyclic electric pumps produce the most milk with the least amount of nipple trauma. Water-driven pumps are both cheap and relatively effective. The most efficient pumps are not as effective as the efficiently nursing body in increasing milk volume and raising prolactin levels.^[155]

The concern about bacterial growth in expressed and stored milk has been alleviated by recent studies showing that bacterial contamination does not increase significantly for up to 6 hours after expression, when the milk is stored at room temperature, nor were there differences in bacterial counts between specimens stored at room temperature and those stored under refrigeration for 10 hours.^[160] Freshly refrigerated milk should be used within 2 days. Four to 6 oz of human milk can be frozen in partially filled resealable (Ziploc) plastic bags. When human milk is frozen, it should be cooled briefly prior to transfer to the freezer. The milk will keep for 2 to 4 weeks in the refrigerator freezer and up to 6 months in a freezer set at 0°F. The milk should be stored in layers and thawed quickly in warm tap water. Frozen milk should not be thawed in the microwave, as the heating is uneven and severe oral burns have been reported. After it is thawed it should be used within 6 to 8 hours.

WEANING

The American Academy of Pediatrics recommends exclusive breast-feeding for the first 6 months of life and continuation at least through the first 12 months of life. This recommendation in 1997 initiated a firestorm of controversy regarding "the excessive duration of breast-feeding." Breast-feeding is both a biologic process and a culturized activity. In the United States, breast-feeding has been culturized to no breast-feeding or breast-feeding for less than 6 months. From a broader biologic and historical perspective, the United States experience reflects cultural bias, not biologic reality. In a remarkable review, Dettwyler ^[16] makes a very cogent argument for the "natural" age of weaning in the human to be 3 to 4 years. She has several arguments. Traditional and prehistoric societies wean between the third and fourth year. Based on weaning when the infant weight is four times its birthweight, similar to other primates, weaning should occur between

2 and 3 years. If weaning corresponds to attainment of one third the adult weight, then weaning would occur between 3 and 4 years. If humans behaved like chimpanzees or gorillas and weaned at six times the gestational period, humans would wean at 4.5 years. The dental, neurologic, and immunologic systems are still developing until 6 years of age; breast-feeding and breast milk provide unique support for these systems up to 4 to 6 years. Developmentally, the infant is able to place solid food in its mouth at 6 months, but this intake, if left to the infant's own skills, would not reach a significant proportion of the nutritional requirements until 18 to 24 months. The ability to drink from a cup occurs close to the second year. As the infant supplements an increasing proportion of its nutritional needs with solid or liquid food, the mother will begin to ovulate. Subsequent pregnancy is increasingly more likely. Breast-feeding, through its suppression of gonadal function, maintains a birth interval of 3 to 4 years. Clearly, breast-feeding into the third or fourth year is a cultural exception in the United States, but prolonged breast-feeding does not constitute abnormal or deviant behavior as expressed by many "modern" Americans. As we learn more about the benefits of long-term lactation, our culture may return to more reasonable expectations for duration of breast-feeding.

Key Points

The World Health Organization, the U.S. Surgeon General, the American Academy of Pediatrics, the American Academy of Family Practice, the American College of Obstetricians and Gynecologists, and the Academy of Breastfeeding Medicine endorse breast-feeding as the gold standard for infant feeding.

Breast-feeding accrues many health benefits for the infant, including protection against infection, less allergy, better growth, better neurodevelopment, and lower rates of chronic disease such as insulin-dependent diabetes and childhood cancer.

Breast-feeding accrues more health benefits for the mother, including faster postpartum involution, improved postpartum weight loss, less premenopausal breast cancer, better mother-infant bonding, and less economic burden.

Artificial breast milk lacks key components including defenses against infection, hormones and enzymes to aid digestion, polyunsaturated fatty acids, which are necessary for optimal brain growth, and adequate composition for efficient digestion.

Contact with the breast within one half hour after birth increases the duration of breast feeding. A frequency of nursing greater than eight per 24 hours, night nursing, and a duration of nursing longer than 15 minutes are needed to maintain adequate prolactin levels and milk supply.

Prolactin is the major promoter of milk synthesis. Oxytocin is the major initiator of milk ejection. The release of prolactin and oxytocin results from the stimulation of the sensory nerves supplying the areola and nipple.

Oxytocin released from the posterior pituitary can be operantly conditioned and is influenced negatively by pain, stress, or loss of self-esteem.

The nursing actions on a human teat versus on an artificial teat are very different. Poor lactation is the major cause of nipple injury and poor milk transfer.

Perceived or real lack of milk transfer is the major reason why lactation fails.

Milk production is reduced by an autocrine pathway through a protein that inhibits milk production by the alveolar cells, and by distention and pressure against the alveolar cells.

Section 2 - Prenatal Care

139

Chapter 6 - Preconception and Prenatal Care: Part of the Continuum

Timothy R. B. Johnson
Jennifer R. Niebyl

Primary care is defined as follows:

Integrated, accessible health care services by clinicians who are accountable for addressing a large majority of personal health care needs, developing a sustained partnership with patients, and practicing in the context of family and community. ^[1]

It is obvious that pregnancy and child birth are major life events. Preconception and prenatal care are not only part of the pregnancy continuum that culminates in delivery, the postpartum period, and parenthood, but they should increasingly be considered in the context of women's health throughout the life span.

Prenatal care is an excellent example of preventive medicine and is very much a phenomenon of the 20th century. In 1929, the Ministry of Health of Great Britain issued a memorandum on the conduct of prenatal clinics. In 1942, vitamin tablets were provided for all women in the last 6 months of pregnancy. Maternal mortality declined from 319 per 100,000 live births in 1936 to 15 per 100,000 live births in 1985. The decline in maternal mortality was partly attributed to prenatal care and partly to medical advances in availability of blood transfusions, antibiotics, and management of fluid and electrolyte balance.

Recent guidelines addressing the content and efficacy of prenatal care have focused on the medical and the psychosocial and educational aspects of the prenatal care system. Prenatal care satisfies the definition of primary care from the Institute of Medicine. ^[1] In fact, prenatal care services can be used by obstetricians/gynecologists and other primary care providers as a general model for primary care. ^[2] Prenatal care satisfies other criteria for primary care in that it is comprehensive and continuous, and provides coordinated health care. ^[3] Preconception care planning to ensure the healthiest possible pregnancy outcome is consistent with this model. We will further argue that the preconception and prenatal care periods just as labor, delivery, and the puerperium must be seen as episodes in a woman's life and that they provide important opportunities to advance wellness and prevention. A medical model of care with separate encounters and ambulatory and inpatient visits does not represent any personal reality. It must be recognized that for pregnant women all these events are part of a life continuum with birth leading to the multiple challenges of parenting. They are opportunities to introduce and reinforce habits, knowledge, and life-long skills in self-care, health education, and wellness, to inculcate principles of routine screening, immunization, and regular assessment for psychological, behavioral, and medical risk factors.

The prenatal care record describes in a consistent fashion the comprehensive care that is provided and allows for documentation of coordinated services.

The goal of prenatal care is to help the mother maintain her well-being and achieve a healthy outcome for herself and her infant. Education about pregnancy, childbearing, and childrearing is an important part of prenatal care, as are detection and treatment of abnormalities. This process is best realized when begun even before pregnancy. Two documents ^[4], ^[5] addressing the content and efficacy of prenatal care have suggested changes in the current prenatal care system, and current standards are continuously evolving. ^[6] ^[7] ^[8] ^[9] ^[10] ^[11] ^[12] ^[13] Many services provided traditionally during the intrapartum hospital stay will be provided at prenatal and postpartum outpatient visits. ^[14] Too often, hospitalization for childbirth has been seen as an opportunity for education about self-care, child-care and parenting, and parenthood rather than as a time to ensure safe passage. Educational interventions have thus far been targeted for the intrapartum stay, when they can better and more cheaply be performed in the preconceptional, antenatal, or home care environment. ^[14], ^[15]

MATERNAL MORTALITY

Maternal death is the demise of any woman from any pregnancy-related cause while pregnant or within 42 days of termination of pregnancy, irrespective of the duration and the site of pregnancy. A direct maternal death is an obstetric death resulting from obstetric complications of the pregnancy state, labor, or puerperium. An indirect maternal death is an obstetric death resulting from a disease previously existing or developing during the pregnancy, labor, or puerperium; death is not directly due to obstetric causes but may be aggravated by the physiologic effects of pregnancy. A nonmaternal death is an obstetric death resulting from accidental or incidental causes unrelated to the pregnancy or its management.

The maternal mortality rate is the number of maternal deaths (direct, indirect, or nonmaternal) per 100,000 women of reproductive age but, since this denominator is difficult to determine precisely, the National Center for Health Statistics,^[16] the World Health Organization, and others utilize the maternal mortality ratio defined as the number of maternal deaths (indirect and direct) per 100,000 live births.

Direct obstetric deaths arise from six major areas: hypertensive diseases of pregnancy, hemorrhage, infections/sepsis, thromboembolism and, in developing countries, obstructed labor and complications from illegal abortion. There are other direct causes of death, such as ectopic pregnancy, complications of anesthesia, and amniotic fluid embolism. The main causes of indirect obstetric deaths are asthma, heart disease, type I diabetes, systemic lupus erythematosus, and other conditions that are aggravated by pregnancy to the point of death.^[17]

Maternal mortality has been an underrecognized issue worldwide despite an estimated 600,000 maternal deaths per year from pregnancy-related causes.^[18],^[19] Put in numerical perspective, this is equivalent to six jumbo jet crashes per day with the deaths of all 250 passengers on board, all of them women in the reproductive years of life. There is also a marked inequity in geographic distribution, since 95 percent of these deaths occur in developing countries (Fig. 6-1).

The Centers for Disease Control and Prevention (CDC) and the American College of Obstetricians and Gynecologists (ACOG) have introduced the concept that pregnancy-associated mortality is defined as "the death of a woman, from any cause, while she is pregnant or within one year of termination of pregnancy." Unfortunately, the United States is seeing an increase in nonmaternal deaths of pregnant women resulting from trauma and violence, many of these related to illegal drugs (Fig. 6-2).

In North Carolina from 1992 to 1994, 167 deaths to pregnant and postpartum women were identified through an enhanced surveillance system. When all deaths to pregnant women were categorized, direct and indirect obstetric deaths (classically defined maternal deaths) accounted for only 37 percent of deaths to pregnant and postpartum women. Injuries accounted for 38 percent of deaths to pregnant women, with homicide being the most common (36 percent), followed by motor vehicle accidents (32 percent), drug-related death (13 percent), other (11 percent), and suicide (8 percent).^[20]^[21]^[22]^[23] Acceptance of pregnancy-associated mortality as the appropriate measure will

Figure 6-1 Worldwide distribution of live births and maternal deaths by region. (From WHO 861663.)

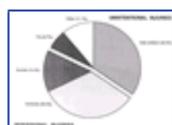

Figure 6-2 Distribution of deaths due to injury in the United States, 1980-1985 (N = 90). (From MMWR Morb Mortal Wkly Rep 37:[SS5]:26, 1988.)

lead to increased recognition of these important problems.

The prenatal care provider can play a role in preventing these common causes of death in women by advocating use of seat belts and screening for alcohol, drug use, depression, and violence.

Significant disparities exist between the maternal mortality ratios of white and black women. In the United States, maternal mortality occurs four times more often in black women than in white women. In a *Morbidity and Mortality Weekly Report* review of maternal deaths in 1990, the maternal mortality ratio for white women was 5.7; for black women it was 18.6, a 3.3-times greater mortality. On a state-by-state basis, maternal mortality ratios for black women were higher in every state.^[24],^[25]

NEONATAL MORTALITY AND MORBIDITY

Historically, in developed countries, when decreased maternal mortality was achieved, attention was then turned to fetal mortality and later to fetal morbidity. The stillbirth rate (fetal death rate) is the number of stillborn infants per 1,000 infants born. The neonatal mortality rate is the number of neonatal deaths (deaths in the first 28 days of life) per 1,000 live births. The perinatal mortality combines these two the number of fetal deaths (stillbirths) plus neonatal deaths per 1,000 total births.

In 1990, the U.S. infant mortality rate was 9.2 per 1,000 live births, ranking the United States 19th internationally. [\[2\]](#) However, there are international differences in the way live births are classified, as some countries exclude infants weighing less than 1 kg and those with fatal anomalies.

PRENATAL CARE

During the past 20 years, new technology has been introduced to assess the fetus antepartum, including electronic fetal monitoring, sonography, and amniocentesis, with the fetus emerging as a patient in utero. Prevention of morbidity as well as mortality is now the goal. This has made the task of the prenatal clinic more complex, since mother and fetus now require an increasingly sophisticated level of care. At the same time, pregnancy is basically a physiologic process, and the normal pregnant patient may not benefit from application of advanced technology.

Prenatal care is provided at a variety of sites, ranging from the private office, to the public health and county hospital clinics, to the patient's home. Obstetricians must optimize their efforts by resourceful use of other professionals and support groups, including nutritionists, childbirth educators, public health nurses, nurse practitioners, family physicians, nurse midwives, and specialty medical consultants. Most pregnant women are healthy, with normal pregnancies, and can be followed by an obstetric team including nurses, nurse practitioners, and nurse-midwives, with an obstetrician available for consultation. These women can be followed by practitioners who have adequate time to

spend on patient education and parenting preparation, while physicians can appropriately concentrate on complicated problems requiring their medical skills. This also provides for improved continuity of care, which is recognized as extremely important for patient satisfaction. ^[10]

There have been no prospective controlled trials demonstrating efficacy of prenatal care overall. However, many individual components have been shown to be effective (e.g., treatment with corticosteroids to prevent respiratory distress syndrome and screening for and treating asymptomatic bacteriuria for prevention of pyelonephritis).^[27] In retrospective studies, however, patients with increased numbers of visits have improved maternal and fetal outcomes. This may be because of self-selection of patients for care who are motivated to take care of themselves in other ways, as women with no prenatal care often come from underprivileged socioeconomic groups.

Efficacy of prenatal care also depends on the quality of care provided by the caretaker. If a blood pressure is recorded as elevated and no therapeutic maneuvers are recommended, this will not change the outcome. Recommendations must be made and must be carried out by the patient, whose compliance is essential to alter outcome.

Gabbe: Obstetrics - Normal and Problem Pregnancies, 4th ed. , Copyright © 2002 Churchill Livingstone, Inc.

RISK ASSESSMENT

The concept of risk in obstetrics can be examined at many levels. All the problems that arise in pregnancy, whether common complaints or more hazardous diseases, convey some risk to the pregnancy, depending on how they are managed by the patient and her care provider. Risk assessment has received detailed attention in recent years. It has been shown that most women and infants suffering morbidity and mortality will come from a small segment of women with high-risk factors; by reassessing risk factors before pregnancy, during pregnancy, and again in labor, our ability to identify those at highest risk increases.^[28] However, previous preterm birth is the most significant risk factor for prematurity; thus, risk scoring of primigravidas is of limited value.^[29] Cervical length assessment, fetal fibronectin, and salivary estriol determination have been proposed to assess risk of prematurity (see Chapter 23), and prevention programs have been proposed.^[31]

It is important to individualize patient care and to be thorough. The initial visit will include a detailed history and physical and laboratory examinations. The initial history requires that the patient be seen in an office setting. She should not be first seen undressed sitting on an examining table.

Gabbe: Obstetrics - Normal and Problem Pregnancies, 4th ed. , Copyright © 2002 Churchill Livingstone, Inc.

PRECONCEPTIONAL EDUCATION

We have reached a level in prenatal care where the optimal time to assess, manage, and treat many pregnancy conditions and complications is before pregnancy occurs.^[32] , ^[33] The best time to see a woman for prenatal care is when she is considering pregnancy. At gynecologic visits, patients should be asked about their plans for pregnancy. At that time, much of the risk assessment described later in this chapter can be performed, as well as the basic physical and laboratory evaluations. If there are questions about the history, such as diethylstilbestrol (DES) exposure, family history of fetal anomaly, or previous cesarean delivery, further details can be obtained from family members or the appropriate medical facility. This is the time to draw a rubella titer and immunize the susceptible patient. Varicella titers or immunization is recommended in women with no history of chickenpox. Patients need to use contraception for 3 months thereafter ([see Chapter 40](#)) . Toxoplasmosis screening may be indicated at this time. Patients who have negative screens are at risk for congenital toxoplasmosis and should be counseled to avoid risks such as contact with wild felines and ingestion of raw meat. Patients who screen positive can be reassured of lack of risk. Hepatitis B immunization can be given to appropriate patients and human immunodeficiency virus (HIV) testing offered.

Before pregnancy is the time to screen appropriate populations for genetic disease carrier states such as Tay-Sachs disease, Canavan's disease, cystic fibrosis, or hemoglobinopathies.^[34] Resolution of these issues is much easier and less hurried without the time limits placed by an advancing pregnancy. Medical conditions such as anemia, urinary tract infection, or hypothyroidism can be fully evaluated and the woman medically treated before pregnancy. If the patient is obese, weight reduction should be attempted before pregnancy. Patients in whom risks are very serious should be so counseled, and every attempt should be made to let them make a fully informed decision about pregnancy. Often, significant risk factors can be treated or managed so as to reduce risk during pregnancy.

The value of prepregnancy counseling needs to be emphasized to all those who treat women at significant risk for pregnancy problems. Women who are followed by other physicians (family physicians, pediatricians, general internists) for such problems as diabetes, hypertension, or systemic lupus erythematosus should be seen, evaluated, and counseled before pregnancy.

There is evidence that for some conditions, such as diabetes mellitus and phenylketonuria, medical disease management before conception can positively influence pregnancy outcome. Medical management to normalize the biochemical environment should be discussed with the patient and appropriate management plans outlined before conception. This is also the time to review drug usage and other practices, such as alcohol ingestion and smoking ([see Chapter 9](#)) . Advice can be given about avoiding medications in the first trimester, and general advice can be given concerning diet, exercise, and occupational exposures.

Periconceptional supplements with folic acid can reduce the incidence of neural tube defects (NTDs). In a randomized prospective trial of women with a previously affected child, 4 mg folic acid daily lowered the recurrence risk of neural tube defects by 72 percent.^[35] In a prospective trial of women planning their first pregnancy, 0.8 mg of folic acid daily prevented first-occurrence neural tube defects and other defects.^[36] The CDC recommends that all women of childbearing age who are capable of becoming pregnant should consume 0.4 mg of folic acid daily, which is most easily achieved by taking a supplement. For women with a previously affected child, the recommendation is that the patient take 4 mg daily from 4 weeks before conception through the first 3 months of pregnancy.

The importance of gestational age dating can be discussed with the patient. Great precision can be achieved with an accurate menstrual calendar predating pregnancy.

THE INITIAL PRECONCEPTIONAL OR PRENATAL VISIT

Social and Demographic Risks

Extremes of age are obstetric risk factors. The pregnant teenager has particular nutritional and emotional needs. She is at special risk for sexually transmitted diseases; it has been shown that she benefits particularly from education in areas of childbearing and contraception. The pregnant woman over age 35 is at increased risk for a chromosomally abnormal child,^[37] and she must be so advised. Patients should be asked about family histories of Down syndrome, neural tube defects, hemophilia, hemoglobinopathies, and other birth defects, as well as mental retardation (see Chapter 8). Consultation for genetic counseling and genetic testing, if desired, may be appropriate. The age of the father may be important, as there may be genetic risks to the fetus when the father is older than 55 years.^[38] Certain diseases may be race related. Black patients should be screened for sickle cell disease; those of Jewish and French Canadian heritage should be screened for Tay-Sachs disease, Canavan's disease, and cystic fibrosis; and those of Mediterranean descent should be screened for -thalassemia.

Low socioeconomic status should be identified and attempts to improve nutritional and hygienic measures undertaken. Appropriate referral to federal programs, such as that for women, infants, and children (WIC), and to public health nurses can have real benefits. If a patient has a history of previous neonatal death or stillbirth, records should be carefully reviewed so that the correct diagnosis is made and recurrence risk appropriately assessed. A history of drug abuse or recent blood transfusion should be elicited. The history of the patient's mother's reproductive record may lead to discovery of DES exposure. The history of medical illnesses should be detailed and records obtained if possible. A new rapid procedure for diagnosing mental disorders in primary care may be useful in pregnancy.^[39]

Occupational hazards should be identified. If a patient works in a laboratory with chemicals, for example, she should be advised to limit her exposure. Patients whose occupations require heavy physical exercise or excess stress should be informed that they may need to decrease such activity.

Tobacco, alcohol, and recreational drug use can all adversely affect pregnancy and are a critical part of the history. Specific questions concerning smoking, alcohol, and drugs (prescriptive, over-the-counter, and illicit) should be asked.^[40] Regular screening for alcohol and substance use should be carried out using such tools as the T-ACE questionnaire (Table 6-1)^[41] or other simple screening tools, and appropriate directed therapy should be made available to those women who screen positive. Women should be urged to stop smoking prior to pregnancy and to drink not at all or minimally once they are pregnant. Drug addiction confers a particularly

TABLE 6-1 -- ALCOHOL ABUSE SCREENING: THE T-ACE QUESTIONNAIRE

T	How many drinks does it take to make you feel "high" (can you hold)? (<i>tolerance</i> ; a positive response consists of two or more drinks)
A	Have people <i>annoyed</i> you by criticizing your drinking?
C	Have you ever felt you ought to <i>cut down</i> on your drinking?
E	Have you ever had a drink first thing in the morning to steady your nerves or to get rid of a hangover (<i>eye-opener</i>)?

Scoring: The tolerance question has substantially more weight (2 points) than the three other questions (1 point each).

From Sokol RJ, Martier SS, Ager JW: The T-ACE questions: practical prenatal detection of risk-drinking. Am J Obstet Gynecol 160:863, 1989, with permission.

* These questions were found to be significant identifiers of risk drinking in pregnancy (i.e., alcohol intake potentially sufficient to damage the embryo/fetus).

high risk, and addicted mothers require specialized care throughout pregnancy (see Chapter 9).

Violence against women is increasingly recognized as a problem that should be addressed, with reports suggesting that abuse occurs during 3 to 8 percent of pregnancies. Questions addressing personal safety and violence should be included during the prenatal period, and such tools as the Abuse Assessment Score (Fig. 6-3) (Figure Not Available) are recommended.^{[41] [42] [43]}

Medical Risk

Family history of diabetes, hypertension, tuberculosis, seizures, hematologic disorders, multiple pregnancies, congenital abnormalities, and reproductive wastage should be elicited. Often, a family history of mental retardation, birth defect, or genetic trait is difficult to elicit; these areas should be emphasized at the initial history. A better history may be obtained if patients are asked to fill out a preinterview questionnaire or history form. Any significant maternal cardiovascular, renal, or metabolic disease should be defined. Infectious diseases such as urinary tract disease, syphilis, tuberculosis, or herpes genitalis should be identified. Surgical history with special attention to any abdominal or pelvic operations should be noted. A history of previous cesarean birth should include indication, type of uterine incision, and any complications. A copy of the surgical report may be informative. Allergies, particularly

Figure 6-3 (Figure Not Available) Determination of frequency and severity of physical abuse during pregnancy. (From McFarlane J, Parker B, Soeken K, Bullock L: Assessing for abuse during pregnancy. JAMA 267:3176, 1992, with permission. Copyright 1992, American Medical Association.)

drug allergies, should be prominent on the problem list.

Obstetric Risk

Previous obstetric and reproductive history are essential to care in subsequent pregnancy. The gravidity and parity should be noted and the outcome for each prior pregnancy recorded in detail. Previous miscarriages not only confer risk and anxiety for another pregnancy loss but can increase the risk of genetic disease as well as preterm delivery.^[44]

REPEAT PRENATAL VISITS

A plan of visits is outlined to the patient. This has been traditionally every 4 weeks for the first 28 weeks of pregnancy, every 2 to 3 weeks until 36 weeks, and weekly thereafter, if the pregnancy progresses normally. The Public Health Service ^[4] suggested that this number of visits can be decreased, especially in parous, healthy women, and another study suggests that this can be done safely. ^[9], ^[46] If there are any complications, the intervals can be increased appropriately. For example, patients with hypertensive disease may require weekly visits. Fetal heart tones can be documented before the 12th week by Doppler devices and generally by the 20th week by Hillis-Delee stethoscope, and this information can be used for gestational dating purposes.

At regular visits, the patient is weighed, the blood pressure is recorded, and the presence of edema is evaluated. Fundal height is regularly measured with a tape measure, fetal heart tones are recorded, and fetal position is noted. The goal of subsequent pregnancy visits is to assess fetal growth and maternal well-being. In addition, at each prenatal visit, time should be allowed for the following questions: Do you have any problems? Do you have any questions? Family members should be encouraged to come to prenatal visits, ask questions, and participate to the degree that the patient wishes.

A pelvic examination is usually only performed on

the first visit. In patients at risk of prematurity or in those with a history of DES exposure, however, frequent cervical checks may reveal premature dilation or effacement.

Prenatal screening to include early ultrasound for genetic screening, triple test screening for NTDs and aneuploidy, as well as fetal anatomic survey at 18 to 20 weeks are also common practice.

Further laboratory evaluations are routinely performed at 28 weeks, when the hemoglobin or hematocrit and Rh type and the screen for antibodies, as well as the serologic test for syphilis and possibly HIV testing, can be repeated. If the patient is Rh negative and unsensitized, she should receive Rhesus immune globulin (RhIG) prophylaxis at this time. A glucose screening test for diabetes is also appropriately performed at this time ([see Chapter 32](#)) ^[48] and routine fetal movement counting can begin using a organized system. ^[49] At 36 weeks, a repeat hematocrit, especially in those women with anemia or at risk for peripartum hemorrhage (multipara, repeat cesarean), may be performed. Also, appropriate cultures for sexually transmitted disease (gonorrhea, chlamydia) should be obtained as indicated in the third trimester.

After 41 weeks from the last menstrual period, the patient should be entered into a screening program for fetal well-being, which may include electronic monitoring tests or ultrasound evaluation ([see Chapter 27](#)).

Gabbe: Obstetrics - Normal and Problem Pregnancies, 4th ed. , Copyright © 2002 Churchill Livingstone, Inc.

INTERCURRENT PROBLEMS

It is the practice in prenatal care to evaluate the pregnant patient for the development of certain complications. Inherent in these checks is surveillance for intervening problems, an important one being preeclampsia. If a patient shows a tendency to blood pressure elevation at 28 weeks, for example, she should be seen again in a week, not a month. Blood pressure will change physiologically in response to pregnancy, but development of hypertension must be recognized and evaluation and hospitalization appropriately instituted.

Weight gain in pregnancy has been shown to be an important correlate of fetal weight gain and is therefore closely monitored. Too little weight gain should lead to an evaluation of nutritional factors and an assessment of associated fetal growth. Excess weight gain is one of the first signs of fluid retention, but it may also reflect increased dietary intake or decreased activity. Dependent edema is physiologic in pregnancy, but generalized or facial edema can be a first sign of disease. It is critical here, as in all areas, for the practitioner to understand the normal changes associated with pregnancy in order to accept and explain the normal, but also to manage aggressively any abnormal changes.

Proteinuria reflects urinary tract disease, generally either infection or glomerular dysfunction, possibly the result of preeclampsia. Urinary tract infection should be looked for, and the degree of protein quantitated in a 24-hour urine collection.

Glycosuria, while common because of increased glucose filtered through the kidney in pregnancy, warrants evaluation for diabetes with a measurement of capillary glucose.

Fetal abnormalities are usually first detected by deviation from the clinical expectation. In some conditions, risk of fetal anomaly will be so high as to prompt some kind of baseline screening or testing (e.g., amniocentesis, sonography, fetal echocardiography). At other times, risk only becomes evident during the course of prenatal care. Growth restriction and macrosomia can often be suspected clinically, usually on the basis of an abnormality in fundal growth. For the patient who has a history of these conditions or other predisposing factors, such as hypertension, renal disease, or diabetes, particular vigilance is in order. Excess amniotic fluid is another condition that can be clinically detected, and an etiology for the hydramnios should be sought. In addition to maternal conditions, hydramnios may be caused by fetal disease that can also be defined using sonography and that may alter management of the pregnancy.

Gabbe: Obstetrics - Normal and Problem Pregnancies, 4th ed. , Copyright © 2002 Churchill Livingstone, Inc.

THE PRENATAL RECORD

Prenatal care should be documented by a prenatal record of good quality such as the antepartum record designed by the ACOG.^[6] Many of the advances in risk assessment and in regionalization result directly from an improvement in this record. Technology allows sophisticated recording, display, and retrieval (often computer-based) of prenatal care records, but quality relies on accurate compiling and recording of the information. The record must be complete, yet simple; directive, but flexible; and transmittable, legible, and able to display necessary data rapidly. European nations often have one record for uniform care; many states and regions have adopted records to permit internal consistency.

The commonly used records accurately reflect the following:

1. Demographic data, obstetric history
 2. Medical and family history, including genetic screening
-

148

3. Baseline physical examination, with emphasis on gynecologic examination
4. Menstrual history, especially last normal menstrual period
5. Record of individual visits
6. Routine laboratory data
7. Problem list
8. Space for special notations and plans

These records must be made available to consultants, and they should be available at the facility where delivery is planned. If transfer is expected, a copy of the prenatal record should accompany the patient.

PRENATAL EDUCATION

Patient education leads to better self-care. As maternal and neonatal outcomes improve, efforts become more sophisticated to improve understanding, involvement, and satisfaction with pregnancy and the perinatal period. In this area, more than any other, the options for paramedical support have expanded. Practitioners and patients have access to a vast array of support persons and groups to assist and advise in the pregnancy and subsequent parenthood. The wise practitioner stays abreast of these advances and integrates them into practice. Patients should be educate about care options and participate in decision-making.

Informed Consent and VBAC

During the educational components of prenatal care there is significant opportunity to accomplish most if not all the informed consent required for the delivery process. There are also advantages to securing documentation of appropriate informed consent for management of labor and associated obstetric procedures, possible interventions, and risks and benefits when they can be thoroughly reviewed and discussed rather than in the throes of labor. It is our practice to obtain consent, whenever possible, in the third trimester for "delivery and related procedures including IV fluids, fetal monitoring, labor augmentation, operative vaginal delivery including forceps and vacuum and cesarean delivery," and this is documented on institutional consent forms and signed by the patient (Fig. 6-4). Consent for anesthesia can also be obtained prior to admission.

The special benefits and risks of vaginal birth after cesarean section are particularly important to discuss prior to labor, and it is common to document both the components of the informed consent process as well as the patient's choice with respect to route of delivery (Fig. 6-5).

Drugs and Teratogens

At the preconceptional or first prenatal visit, recommendations for nonpharmacologic remedies for common ailments can be given. This can often be integrated into a discussion of the common side effects of pregnancy. Because of widespread use of over-the-counter drugs, the patient should be warned to take only those drugs specifically approved or prescribed by her practitioner (see Chapter 9).

Radiologic Studies

Dental and radiologic diagnostic procedures should be performed during pregnancy when they are indicated. Dental restorative work especially should be performed to allow optimal maternal nutrition. Elective radiologic studies can safely be delayed until completion of the pregnancy.

Nutrition

One of the earliest purposes of prenatal care was to counsel and ensure that women received adequate nutrition for pregnancy. The health care provider may be influential in correcting inappropriate dietary habits.^[50] Strict vegetarians may need supplemental vitamin B₁₂. Occasionally, consultation with a registered dietitian may be necessary when there is poor compliance or a special medical need such as diabetes mellitus.

The U.S. Department of Agriculture has published the new food guide pyramid.^[51] Americans are encouraged to eat 6 to 11 servings per day of bread, cereal, rice, and pasta; three to five servings per day of vegetables; two to four servings per day of fruit; two to three servings per day of milk, yogurt, and cheese; and two to three servings per day of meat, poultry, fish, beans, eggs, and nuts. Fats, oils, and sweets should be used sparingly. Pregnant women need three servings per day of dairy products, a serving being a cup of milk or yogurt, 1 ½ oz of natural cheese, or 2 oz processed cheese.

Dietary allowances for most substances increase during pregnancy. According to the 1989 recommended dietary allowances (RDAs), only the recommendations for iron, folic acid, and vitamin D double during gestation.^[52] The RDA for calcium and phosphorus increase by one half; the RDA for pyridoxine and thiamine increase by about one third. The RDA for protein, zinc, and riboflavin increase by about one fourth. The RDA for all other nutrients except vitamin A increase by less than 20 percent (Table 6-3 and Table 6-4) and vitamin A not at all, as that is felt to be stored adequately. All of these nutrients, with the exception of iron, are supplied by a well-balanced diet.

The National Academy of Sciences currently recommends

that 30 mg of ferrous iron supplements be given to pregnant women daily, since the iron content of the habitual American diet and the iron stores of many women are not sufficient to provide the increased iron required during pregnancy. For those at high nutritional risk, such as some adolescents, those with multiple gestation, heavy cigarette smokers, and drug and alcohol abusers, a vitamin/mineral supplement should be given. Increased iron is needed both for the fetal needs and for the increased maternal blood volume. Thus, iron-containing foods should also be encouraged. Iron is found in liver, red meats, eggs, dried beans, leafy green vegetables, whole-grain enriched bread and cereal, and dried fruits. The 30-mg iron supplement is

TABLE 6-4 -- SUMMARY OF RECOMMENDED DIETARY ALLOWANCES FOR WOMEN AGED 25-50 YEARS, CHANGES FROM NONPREGNANT TO PREGNANT, AND FOOD SOURCES

Nutrient	Nonpregnant	Pregnant	Percent Increase	Dietary Sources
Energy (kcal)	2,200	2,500	+13.6	Proteins, carbohydrates, fats
Protein (g)	50	60	+20	Meats, fish, poultry, dairy

From National Academy of Sciences: *Recommended Dietary Allowances*, 10th ed. Washington, DC, National Academy Press, 1989.

contained in approximately 150 mg of ferrous sulfate, 300 mg of ferrous gluconate, or 100 mg of ferrous fumarate. Taking iron between meals on an empty stomach will facilitate its absorption.

Since women of higher socioeconomic status have better reproductive performance and fewer low-birth-weight babies than do women of lower socioeconomic status, and since they also consume more protein, it is probably prudent to continue to recommend a generous amount of dietary protein. However, it has not been documented that protein supplementation will improve pregnancy outcome.^[53] Acute caloric restriction in a well-nourished population such as occurred during the Dutch famine of 1944 to 1945 caused the average birth weight to drop about 250 g, yet no adverse effect on long-term outcome was observed. These mothers ate a calorie-restricted, balanced diet in their second and third trimesters.

Weight Gain

The total weight gain recommended in pregnancy is 25 to 35 lb for normal women.^[54] Underweight women may gain up to 40 lb, and overweight women should limit

weight gain to 15 to 25 lb. About 2 to 3 lb are from increased fluid volume, 3 to 4 lb from increased blood volume, 1 to 2 lb from breast enlargement, 2 lb from enlargement of the uterus, and 2 lb from amniotic fluid. At term, the infant weighs approximately 6 to 8 lb and the placenta 1 to 2 lb. A 4- to 6-lb increase in maternal stores of fat and protein are important for lactation. Usually, 3 to 6 lb are gained in the first trimester and ½ to 1 lb per week in the last two trimesters of pregnancy.

If the patient does not show a 10-lb weight gain by midpregnancy, her nutritional status should be reviewed. Inadequate weight gain is associated with an increased risk of a low-birth-weight infant (Fig. 6-6). Inadequate weight gain seems to have its greatest effect in woman who are of low or normal weight before pregnancy. Underweight mothers must gain more weight during pregnancy to produce infants of normal weight. Patients should be cautioned against weight loss during pregnancy. Total weight gain in the obese can be modified downward to 15 lb, but less weight gain is associated with lack of expansion of plasma volume and the risk of intrauterine growth retardation.

When excess weight gain is noted, an assessment for fluid retention is also performed. In the assessment of edema, some dependent edema in the legs is normal as pregnancy advances because of venous compression by the weight of the uterus. Elevation of the feet and bed rest on the left side will help correct this problem. Turning the patient from her back to her left side increases venous return from the legs as the pressure on

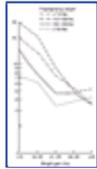

Figure 6-6 Percentage of live-born infants of low birth weight by maternal weight gain during pregnancy according to the mother's prepregnancy weight. Low birth weight is defined as birth weight of less than 2,500 g or 5 lb, 8 oz. (From the National Natality Survey United States. DHHS Pub No. [PHS] 86-1922, 1980.)

the vena cava is relieved. This maneuver increases the effective circulating blood volume, cardiac output, and thus the blood flow to the kidney. A diuresis will follow as well as increased blood flow to the uterus.

Limitation of fluids will neither prevent nor correct fluid retention. Salt is not restricted, although patients with hypertension may be advised to decrease salt load.

Rest

During the first trimester, patients are often more tired and should be advised to go to bed earlier or to try to take a nap during the day, if possible. Fatigue often lessens in the second trimester but, in general, most patients need additional rest during pregnancy.

Activity and Employment

Most patients are able to maintain their normal activity levels in pregnancy. Mothers tolerate pregnancy with considerable physical activity, such as looking after small children, but heavy lifting and excessive physical activity should be avoided. Modification of activity level as the pregnancy progresses is seldom needed, except if the job involves physical danger. Recreational exercises should be encouraged, such as those available in prenatal exercise classes. The patient should be counseled to discontinue activity whenever she experiences discomfort.

Healthy pregnant women may work until their delivery, if the job presents hazards no greater than those encountered in daily life. Strenuous physical exercise, standing for prolonged periods, and work on industrial machines as well as other adverse environmental factors may be associated with increased risk of poor pregnancy outcome, and these should be modified as necessary. ^{[55] [56] [57]}

Travel

The patient should be advised against prolonged sitting during car or airplane travel because of the risk of venous stasis and possible thromboembolism. The usual recommendation is a maximum of 6 hours per day driving, with stopping at least every 2 hours for 10 minutes to allow the patient to walk around and increase venous return from the legs. Support stockings are also recommended.

The patient should be instructed to wear her seat belt during car travel, but under the abdomen as pregnancy advances. It may also be helpful to take pillows along in a car to increase comfort.

If the patient is traveling a significant distance, it might be helpful for her to carry a copy of her medical record with her in case an emergency arises in a strange environment. She could also check into the medical facilities in the area or perhaps obtain the name of an obstetrician in the event of a problem.

Immunizations

Because of a theoretical risk to the fetus, pregnant women or women likely to become pregnant should not be given live, attenuated-virus vaccines. Yellow fever and oral polio may be given to women exposed to these infections. Despite theoretical risks, no evidence of congenital rubella syndrome in infants born to mothers inadvertently given rubella vaccine has been reported. Measles, mumps, and rubella viruses are not transmitted by those immunized and can be given to children of pregnant women. There is no evidence of fetal risk from inactivated virus vaccines, bacterial vaccines, toxoids, or tetanus immunoglobulin, which should be administered if appropriate.

Nausea and Vomiting in Pregnancy

Nonpharmacologic measures are usually recommended initially to treat nausea and vomiting in early pregnancy. Patients should avoid eating greasy or spicy foods. In addition, frequent small feedings in order to keep some food in the stomach at all times is helpful. A protein snack at night is advised, and the patient is instructed to keep crackers at her bedside so that she can have these before arising in the morning. Drug therapy for nausea in pregnancy is covered [in Chapter 9](#).

Heartburn

Heartburn is a common complaint in pregnancy because of relaxation of the esophageal sphincter. Overeating contributes to this problem, as do spicy foods. The patient should be advised to save part of her meal for later if she is experiencing postprandial heartburn and also not to eat immediately before lying down. Pillows at bedtime may help. If necessary, antacids may be prescribed. Liquid antacids coat the esophageal lining more effectively than do tablets.

Hemorrhoids

Hemorrhoids are varicose veins of the rectum. Since straining during bowel movements contributes to their aggravation, avoidance of constipation is preventive, and prolonged sitting should also be avoided. Hemorrhoids will often regress after delivery but usually will not disappear completely.

Constipation

Constipation is physiologic during pregnancy with decreased bowel transit time, and the stool may be hardened. Dietary modification with increased bulk such as with fresh fruit and vegetables and plenty of water can usually help this problem. Constipation is aggravated by the addition of iron supplementation; if dietary measures are inadequate, patients may require stool softeners. Additional dietary fibers such as Metamucil (psyllium hydrophilic muciloid) or surface-active agents such as

Urinary Frequency

Often during the first 3 months of pregnancy, the growing uterus places increased pressure on the bladder. Urinary frequency usually will improve as the uterus rises out of the pelvis by the second trimester. However, as the head engages near the time of delivery, urinary frequency may return as the head presses against the bladder. If the patient experiences pain with urination, it is appropriate to check for infection.

Round Ligament Pain

Frequently, patients will notice sharp groin pains caused by spasm of the round ligaments associated with movement. This is more frequently felt on the right side as a result of the usual dextrorotation of the uterus. The pain may be helped by application of local heat such as with hot soaks or a heating pad. Patients may awaken at night with this pain after having suddenly rolled over in their sleep without realizing it. During the daytime, however, modification of activity with gradual rising and sitting down, as well as avoidance of sudden movement, will decrease problems with this type of pain. Analgesics are rarely necessary.

Syncope

Compression of the veins in the legs from the advancing size of the uterus places patients at risk of venous pooling associated with prolonged standing. This may lead to syncope. Measures to avoid this possibility include wearing support stockings and exercising the calves to increase venous return. In later pregnancy, patients may have problems with supine hypotension, a distinct problem when undergoing a medical evaluation or an ultrasound examination. A left lateral tilt position with wedging below the right hip will help keep the weight of the pregnancy off the inferior vena cava.

Backache

Backache can be prevented to a large degree by avoidance of excessive weight gain. Exercises to strengthen back muscles can also be helpful. Posture is important, and sensible shoes, not high heels, should be worn.

Sexual Activity

No restriction need generally be placed on sexual intercourse. The patient is instructed that pregnancy may cause changes in comfort and sexual desire. Frequently, increased uterine activity is noted after sexual intercourse; it is unclear whether this is due to breast stimulation, female orgasm, or prostaglandins in male ejaculate. For women at risk for preterm labor or with a history of previous pregnancy loss and who note such increased activity, use of a condom or avoidance of sexual activity may be recommended.

Circumcision

Newborn circumcision prevents phimosis and other penile problems. It results in a decreased incidence of urinary tract infections in the first year of life. The American Academy of Pediatrics does not recommend routine neonatal circumcision.^[58] Education in good personal hygiene offers many of the advantages of circumcision without the risks.

Circumcision in the newborn is an elective procedure and should be performed only if the infant is stable and healthy. Local anesthesia is recommended, as it reduces the observed physiologic response to the newborn's pain.^[59]

Breast-Feeding

During prenatal visits, the patient should be encouraged to breast-feed her infant (see Chapter 5). Human milk is the most appropriate nutrient for human infants and also provides significant immunologic protection against infection. Infants who are breast-fed have a lower incidence of infection and require fewer hospitalizations than do infants who are fed formula exclusively.

Other advantages of lactation include economy, convenience, more rapid involution of the uterus, and natural child spacing. The reasons a woman decides to bottle-feed should be explored, as they may be based on a misconception. Encouragement will sometimes convince a hesitant mother who may then be able to nurse successfully.

Working outside the home need not be a contraindication to breast-feeding. Many women who previously would not have considered nursing an option, such as those with careers, are now finding time to breast-feed their infants. Women should be aware that alternative ways of breast-feeding can be used to correspond with their work schedules. They can decrease the frequency of lactation to a few times a day in most cases and still continue to nurse. Other women may pump their breasts at work, leaving milk for the child's caretaker during the day and thus providing breast milk to the infant even more frequently. The milk may be collected in containers and, if refrigerated, is safe to use for 24 hours. For a longer duration, the milk should be frozen. Because freezing and thawing destroy the cellular content, fresh milk is preferred.

There is no need for specific nipple preparation during pregnancy. In one study, women prepared one nipple and not the other with a variety of techniques, including massage and breast creams, and found no difference in the two.^[60] Soap and drying agents should

not be used on the nipples, which should be washed only with water.

Preparation for Childbirth

The introduction of childbirth education and consumerism has had significant impact on the practice of obstetrics. The success of obstetric practice in preventing disasters has allowed interest to focus on the quality of the child and of the perinatal experience. Studies have shown that prepared childbirth can have a beneficial effect on performance in labor and delivery.^[61], ^[62] The prenatal period should be one in which the patient is exposed to information about pregnancy, normal labor and delivery, anesthesia and analgesia, obstetric complications, and obstetric operations (e.g., episiotomy, cesarean delivery, and forceps or vacuum delivery). The prenatal clinic is an appropriate place to obtain informed consent from the patient for her intrapartum care and management. Certainly, this affords a more dispassionate, quiet, and pain-free environment than the labor and delivery suite.

The education mentioned above is more than can be transmitted by the obstetrician at the initial or the shorter return visits, and patients expect more personal involvement than to be given a book or handout to read. The appropriate place for such education is a series of planned, structured prenatal education classes taught by informed, qualified individuals. These classes can be given in the physician's office, at the hospital, or in free-standing classes. National organizations such as the Childbirth Education Association and the American Society for Psychoprophylaxis in Obstetrics have recognized the need for such instruction and teach prepared childbirth. There are also advantages to office- and hospital-based programs, if the patient volume permits it, since specifics of management and alternatives offered by that practice or hospital can be discussed in these programs. On the other hand, free-standing classes offer the advantage of open-endedness and of presenting many options to the patient, who can then discuss them with her care provider. Many advances in family-centered practice (e.g., allowing fathers in the delivery room and operating room) have come from consumer requests and demands. A pregnant patient often makes a list of what she would like in the peripartum period, to discuss with her practitioner. Thus, the care provider can understand her needs and desires, better address these needs and desires if labor and delivery do not

proceed normally or as planned, and, finally, explain why certain requests are not possible or reasonable.

Signs of Labor

It is important to instruct the patient about certain warning signs that should trigger a call to her care provider or a visit to the hospital. All women should be informed of what to do if contractions become regular, if rupture of membranes is suspected, or if vaginal bleeding occurs. Patients should be given a number to call where assistance is available 24 hours a day.

Prepared Parenthood and Support Groups

Routine classes on newborn child care and parenting should be part of the prenatal care program. Many parents are completely unprepared for the myriad of changes in their lives, and some idea of what to expect is beneficial. As pregnancy progresses, special needs can arise. Support groups for families with Down's syndrome infants, for mothers of twins or triplets, and for women who have had cesarean delivery have all shown that they can meet the special needs of these parents. Unsuccessful pregnancies lead to special problems and needs, for which social workers, clergy, and specialized support groups can be invaluable. Miscarriage, stillbirth, and infant death are particularly devastating events, best managed by a team approach, with special attention to the grieving process. Referral to such groups as Compassionate Friends of Miscarriage, Infant Death, and Stillbirth is recommended. Careful follow-up for depression should be part of the postpartum care for all and especially women.

ASSESSMENT OF GESTATIONAL AGE

During the course of the prenatal interview, assessment of gestational age begins with the question, "What was the first day of the last menstrual period?" From that point, the establishment of an estimated date of delivery and confirmation of that date by accumulation of supportive information remains one of the most important tasks of good prenatal care.

Human pregnancy has a duration of 280 days, measured from the first day of the last menstrual period (LMP) until delivery. The standard deviation is 14 days. It is important to remember that clinicians are measuring menstrual weeks (not conceptional weeks) with an assumption of ovulation and conception based on day 14 of a 28-day cycle. This gives pregnancy the 40-week gestational period in common clinical use. Much confusion exists among patients who try to measure pregnancy in terms of 9 months ($40/4 = 10$) or who try to measure in conceptional weeks. Another problem exists in women whose menstrual cycles do not follow a 28-day cycle and who therefore do not conceive on day 14 of the menstrual cycle.

156

It is often helpful to explain to patients and their families that their pregnancy will be described in terms of weeks, rather than months, and that the pregnancy can be broken into three trimesters lasting 1 to 14 weeks, 14 to 28 weeks, and 28 weeks to delivery. The commonly used term "4 months pregnant" has no meaning (one does not know whether this is 16 or 20 weeks) and has no place on a contemporary prenatal record. Every effort should be made to be consistent in usage to prevent confusion among patients and among clinicians who may assume care of the pregnancy.

Knowledge of gestational age is critical for obstetric decision-making. Generally, in a normal pregnancy, we can extrapolate from gestational age to estimate fetal weight. Throughout pregnancy, these are the two most important determinants of fetal viability and survival. Without accurate knowledge of gestational age, diagnosis of such conditions as postterm pregnancy and intrauterine growth retardation is often impossible. Multiple gestation is most often detected early when the size of the uterine fundus is greater than expected for gestation. Appropriate management of preterm labor or a medically complicated pregnancy depends on an accurate estimate of fetal age and size. Within regional perinatal systems, records of gestational age are important for flow of information, and rapid access to consistent, clear data is vital. In such situations, and during prolonged hospitalization, it is sometimes helpful to define gestational age further by using the notation of fractional weeks (27 4/7 weeks). It must be remembered, however, that we are describing a biologic system and that such precision is being used more for ease of communication and organization than for any ability to date the pregnancy with such a degree of accuracy.

Clinical Dating

The most reliable clinical estimator of gestational age is an accurate LMP. Using Naegele's rule, the estimated date of confinement is calculated by subtracting 3 months and adding 1 week from the first day of the LMP. A careful history must be taken from the patient verifying that the date given is the first day of the period as well as whether the period was normal, heavy, or light. The date of the previous menstrual period will help ascertain the length of the cycle. History should also be taken about previous use of oral contraceptives, which might influence ovulation.

Other clinical tools can be used to confirm and support LMP data and, in cases in which the LMP is inaccurate or unknown, it has been shown that accumulated clinical information from early pregnancy can predict gestational age with an accuracy approaching that of menstrual dating. ^[63]

The size of the uterus on early pelvic examination, or by direct measurement of the abdomen from the pubic symphysis to the top of the uterine fundus (over the curve), provides useful information. Experienced practitioners can assess the early pregnancy with reproducibility before 12 to 14 weeks. Fundal height measurement in centimeters using the over-the-curve technique approximates the gestational age from 16 to 38 weeks within 3 cm (Fig. 6-7) .

The uterus also tends to reach the umbilicus at about 20 weeks, and this too can be assessed when uterine fundal measurements are made. ^[48] The uterus may be elevated in early pregnancy in a patient with a previous cesarean delivery, making the fundal height appear abnormally high. Considerable variations in the level of the umbilicus and in the height of patients make this clinical marker variable. Quickening, the first perception of fetal movement by the mother, occurs at predictable times in gestation. In the first pregnancy, quickening is usually noted at about 19 weeks; in subsequent pregnancies, probably because of the experience of the observer, it tends to occur about 2 weeks earlier. ^[63] It is helpful to ask the woman to mark on a calendar the first time she feels the baby move and to report this date.

Audible fetal heart tones, in addition to being absolute evidence of pregnancy, are another marker of gestational age. Using an unamplified Hillis-DeLee fetoscope, they are generally audible at 19 to 20 weeks. ^[48] Observer experience, acuity, and the time spent listening can all affect this number, so this guideline may need to be adapted individually.

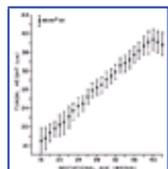

Figure 6-7 Fundal height versus gestational age. (From Knox AJ, Sadler L, Pattison WS, et al: *An obstetric scoring system: its development and application in obstetric management. Obstet Gynecol* 81:195, 1993, with permission.)

157

Use of the electronic Doppler device is widespread and permits detection of the fetal heart by 11 to 12 weeks. Practitioners can set a standard individualized to their own equipment, which can be used as a gestational age marker. If fetal heart tones are not heard at the expected time, an sonogram is appropriate to look for date/examination discrepancy, polyhydramnios, fetal viability, and twins.

The conversion of a negative urinary pregnancy test to a positive one may be helpful in assessing gestational age, but the sensitivity of the test used must be known in order to interpret the data accurately (see Chapter 1) . These tests may be negative if they are performed too early.

Comparison of the various clinical estimators shows a known LMP date to be the most precise predictor. The clinical estimators can be ranked according to

decreasing order of accuracy as follows: (1) last menstrual period; (2) the uterus reaching umbilicus; and (3) fetal heart tone documentation, fundal height measurements, and quickening. Because of inherent biologic variability and differences in the examiner acuity, the estimated date of confinement can be predicted with 90 percent certainty only within ± 3 weeks by even the best single estimator. ^[64]

Ultrasound

Ultrasound plays a major role in assessment of size and duration of pregnancy. The National Institutes of Health (NIH) consensus conference in 1984 concluded that in a low-risk pregnancy followed from the first trimester, routine ultrasound examination was not justified for determining gestational age. However, a long list of indications justify an ultrasound examination. ^[65]

A randomized trial has shown that the risk of being called overdue was reduced from 8 percent to 2 percent for patients who received early ultrasound. ^[66] Also, twins were detected more often and perinatal mortality was reduced in the ultrasound group. The Routine Antenatal Diagnostic Imaging with Ultrasound (RADIUS) study reported no improvement in perinatal outcome with use of routine ultrasound in normal, low-risk women. ^[67], ^[68] However, 61 percent of women were excluded for many reasons such as an uncertain menstrual history, and only 35 percent of anomalies were detected in the ultrasound-screened group (only 17 percent before 24 weeks). The meta-analysis by Bucher and Schmidt ^[69] indicated that routine scanning can detect many more anomalies. The authors' practice is to perform ultrasound at 16 to 20 weeks for a baseline gestational age measurement and as a screening for fetal abnormality or multiple gestation. If ultrasound is not done routinely, the caregiver must be vigilant in detecting problems that are indications for a scan, and more frequent scans may be necessary.

Ultrasound is an accurate means of estimating gestational age in the first half of pregnancy. ^[70] The crown-rump length, biparietal diameter, and femur length in the first half of pregnancy correlate closely with age. As pregnancy progresses, fetal size varies considerably, and measurement of the fetus is a poor tool for estimation of gestational age, especially in the third trimester ([see Chapter 10](#)).

Gabbe: Obstetrics - Normal and Problem Pregnancies, 4th ed. , Copyright © 2002 Churchill Livingstone, Inc.

SUMMARY

Prenatal care is an effective, if incompletely understood and studied, intervention. It provides a model for primary care services for both obstetricians/gynecologists and other primary care providers. It satisfies the Institute of Medicine criteria for primary care, as it is comprehensive, and continuous, and provides coordinated services. Preconceptional care will introduce changes and improve it. Risk assessment, with subsequent elimination or management of risks, health education, advocacy, and disease prevention, as well as appropriate medical management of complications, remain the core of the process, changes in number of visits and improved understanding of the successful components of prenatal care will improve services and efficiency without altering the substance of what has been developed and achieved. Prenatal care should reinforce the importance of lifelong disease surveillance and prevention as well as active participation in personal wellness behavior for women.

Key Points

Maternal mortality is the demise of any woman from any pregnancy-related cause while pregnant or within 42 days of termination of a pregnancy. The most frequent causes of maternal death are hemorrhage and embolism. The perinatal mortality combines the number of fetal deaths (stillbirths) plus neonatal deaths per 1,000 total births.

Preconception evaluation should include rubella testing, hepatitis testing, and possibly toxoplasmosis and HIV testing, in addition to medical and family history. Further tests may be indicated depending on historical genetic risk factors identified.

Preconception supplementation with folic acid can reduce the incidence of NTDs and other

158

defects. All women of childbearing age should consume 0.4 mg of folic acid daily. Women who have had a child previously affected by an NTD should take 4 mg daily from 4 weeks before conception through the first 3 months of pregnancy.

The triple screen (-fetoprotein, hCG, and estriol) can detect women younger than 35 years of age at increased risk for chromosomal abnormalities.

The number of prenatal visits can be decreased in healthy parous women with safety.

The total weight gain recommended for healthy women is 25 to 35 lb. Underweight women may gain up to 40 lb, and overweight women should limit weight gain to 15 to 25 lb.

Bed rest on the side increases venous return from the legs, as pressure on the vena cava is relieved. This maneuver increases the effective circulating blood volume, cardiac output and, thus, the blood flow to the kidney. A diuresis follows, as well as increased blood flow to the uterus.

The pregnant woman should be advised against prolonged sitting during car or airplane travel because of the risk of venous stasis and possible thromboembolism. For infant nutrition, breast is best.

Ultrasound evaluation between 16 and 20 weeks allows accurate assessment of gestational age and screening for fetal abnormality and multiple gestation.

Chapter 7 - Occupational and Environmental Perspectives of Birth Defects

Joe Leigh Simpson
Jennifer R. Niebyl

This chapter substantially reflects the contribution in the previous edition by Lowell E. Sever and Mary Ellen Mortensen.

Pregnant women want to have a normal baby who develops into a healthy child and adult. Unfortunately, this wish is not always fulfilled. This chapter considers prenatal environmental influences acting maternally as potential causes of adverse development. The focus is on structural malformations (birth defects), but some attention is paid to aberrations in behavior and to other adverse reproductive outcomes. The importance of birth defects as a cause of infant mortality, the etiology of birth defects, and basic concepts of teratology, epidemiologic methods used to evaluate possible adverse effects of environmental exposures on reproductive outcomes, and data about some specific environmental and occupational exposures are reviewed.

Gabbe: **Obstetrics - Normal and Problem Pregnancies, 4th ed.** , Copyright © 2002 Churchill Livingstone, Inc.

BASIC PRINCIPLES OF TERATOLOGY

To understand the etiology of birth defects, it is important to consider what is known about the principles of abnormal development (teratogenesis). Although only a small percentage of birth defects currently can be linked to environmental agents, the search for other agents is important.

Teratology has been defined as the study of abnormal development; it is directed at understanding the causes and mechanisms of maldevelopment. A teratogen is a substance, organism, or physical agent capable of causing abnormal development. A teratogen can cause abnormalities of structure or function, growth **restriction**, or death of the organism.

Traditionally, the identification and definition of teratogenic agents was based on the production of structural defects. More recently, the concept has been expanded to include agents acting during embryonic or fetal development that lead to deviation from normal morphology or function. There is growing interest in exploring the role of prenatal factors in more subtle or difficult-to-ascertain effects, such as growth **restriction** and functional abnormalities. Wilson's six general principles of teratogenesis^[1] provide a framework for understanding how structural or functional teratogens may act. These principles provide a conceptual framework to understand and investigate maldevelopment.

Genotype and Interaction with Environmental Factors

The first principle is that susceptibility to a teratogen depends on the *genotype of the conceptus* and on the manner in which the genotype interacts with environmental factors. This is perhaps most clearly shown by experiments in which different genetic strains of mice have varied greatly in their susceptibility to teratogens that lead to oral clefts.^[2] Some of the variability in responses to human teratogens, such as to anticonvulsant drugs like valproic acid and hydantoin, probably relates to genotype of the embryo. The increasing complexity of these potential interactions is illustrated by a series of elegant studies by Musselman and colleagues.^[3]

Timing of Exposure

The second principle is that susceptibility of the conceptus to teratogenic agents varies with the developmental stage at the time of exposure. This concept of *critical stages of development* is particularly applicable to alterations in structure. It is during the second to the eighth weeks of development after conception the embryonic period that most structural defects occur. For

such defects, it is believed that there is a critical stage in the developmental process, after which abnormal embryogenesis cannot be initiated. For example, most investigators believe that the neural tube defects anencephaly and spina bifida result from the failure of the neural tube to close. Since this process occurs between 22 and 28 days postconception, any exogenous effect on development must be present at or before this time. Van Allen et al.^[4] put forward convincing evidence that the neural tube has five distinct closure sites that may respond to different agents and that differ in their timing. Investigations of thalidomide teratogenicity have clearly shown that the effects of the drug differ as a function of the developmental stage at which the pregnant woman took it.^[5]

Mechanisms of Teratogenesis

The third principle is that teratogenic agents act in specific ways (*mechanisms*) on developing cells and tissues in initiating abnormal embryogenesis (pathogenesis). Teratogenic mechanisms are considered separately below.

Manifestations

Irrespective of the specific deleterious agent, the final manifestations of abnormal development are death, malformation, growth restriction, and functional disorder. The manifestation is thought to depend largely on the stage of development at which exposure occurs; a teratogen may have one effect if exposure occurs during embryogenesis and another if the exposure is during the fetal period. Embryonic exposure is likely to lead to structural abnormalities or embryonic death; fetal exposure is likely to lead to functional deficits or growth restriction.

Agent

The fifth principle is that access of adverse environmental influences to developing tissues depends on the nature of the influence (*agent*). This principle relates to such pharmacologic factors as maternal metabolism and placental passage. While most clearly understood for chemical agents or drugs, the principle also applies to physical agents such as radiation or heat. For an adverse effect to occur, an agent must reach the conceptus, by being transmitted indirectly through maternal tissues or by directly traversing the maternal body.

Dose Effect

The final principle is that manifestations of abnormal development increase in degree from the no-effect level to the lethal level as *dosage* increases. What this means is that the response (e.g., malformation, growth restriction) may be expected to vary according to the dose, duration, or amount of exposure. For most human teratogens, this dose-response is not clearly understood but, along with the principle of critical stages of development, these concepts are important in supporting causal inferences about human reproductive hazards. Data regarding in utero exposure to ionizing radiation clearly show the importance of dose on observed effects.^[6] The potential complexity of relationships between dose and observed effects for teratogens has been discussed by Selevan and Lemasters.^[7]

Gabbe: Obstetrics - Normal and Problem Pregnancies, 4th ed. , Copyright © 2002 Churchill Livingstone, Inc.

MECHANISMS OF TERATOGENESIS

In identifying human teratogens, it is important to consider the mechanisms of teratogenesis. A teratogenic insult can initiate changes in developing cells or tissues that can be categorized into nine mechanisms. An agent acts via a mechanism that alters normal cellular or biochemical processes; different alterations can produce similar defects through final common pathways. Among proposed mechanisms are gene mutation, chromosomal abnormalities (e.g., breaks and nondisjunction), mitotic interference, altered nucleic acid integrity or function, lack of normal precursors or substrates, altered energy sources, changes in membrane characteristics, osmolar imbalance, and enzyme inhibition. With these mechanisms in mind, it may be easier to understand why such diverse etiologies for spina bifida as maternal hyperthermia, valproic acid exposure, and folic acid deficiency have been suggested.

In identifying reproductive hazards, relationships among teratogenesis, mutagenesis, and carcinogenesis should be considered, since these processes may occur through similar mechanisms. [Hemminki and associates](#) [illustrated](#) how various manifestations, classified as teratogenic, mutagenic, or carcinogenic, could result from alterations of DNA.

ANIMAL MODELS FOR THE STUDY OF HUMAN TERATOGENS

Premarket testing of drugs and food additives involves animal testing to determine potential teratogenicity. Although important in recognizing potential reproductive toxicants and teratogens, such studies have a number of significant limitations. Extrapolation from animal data may not be relevant to human exposures to an agent because of interspecies differences in metabolism, endorgan

163

response, transport across the placenta, and sensitivity of fetal structures, to name a few. For example, humans and rabbits are sensitive to the teratogenic effect of thalidomide, but rats are relatively insensitive.^[9] There are also problems extrapolating from high doses to low doses, as most teratologic experiments involve exposure at high doses. Since human exposures typically involve lower doses, effects must then be extrapolated. The assumption is often made that teratogenic risk is identical at high- and low-dose exposures (e.g., linearity of dose-response). This may not be true, and it is not surprising that there is little or no evidence for human teratogenicity at low doses for many substances teratogenic in animals at high doses (e.g., arsenic and some solvents).^[10]

Among regulatory agencies, there is increasing interest in the use of risk assessment methods for developmental toxicants. For example, the Environmental Protection Agency has published *Guidelines for the Health Assessment of Suspect Developmental Toxicants*.^[11]

While teratologic testing of drugs and chemicals in animals serves an extremely important public health function, it does not necessarily prevent exposure of pregnant women to teratogens. Two drugs shown to be human teratogens (isotretinoin [Accutane] and valproic acid [Depakene]) were known to be teratogenic based on animal studies, but it was only through human exposure that their teratogenicity in humans was established. Tens of thousands of chemicals have never been tested for reproductive toxicity or teratogenicity.^[12] The limitations of animal testing and the immense number of potentially hazardous substances underscore the need for human studies, the subject of the remainder of this chapter.

CONTRIBUTION OF EPIDEMIOLOGY

Environmental agents are of particular interest and concern because exposure of the conceptus to these factors is considered to be preventable by reducing or eliminating exposure of pregnant women. The combined forces of epidemiology and teratology are needed to study the effects of environmental exposures on reproductive outcomes.

Although most birth defects of public health significance probably involve the interaction of genetic and environmental factors (multifactorial etiology), the relative contributions and specific mechanisms of genetics and environmental agents remain unknown. By applying epidemiologic methods we attempt to determine the relative contributions of both factors to the etiology of these defects. Importantly, epidemiologic methods permit identification of specific agents associated with malformations or other adverse outcomes of pregnancy.^[12]

Epidemiologic Concepts

A fundamental concept is that variation between populations exists in the frequency of disease occurrence. Epidemiology is based on comparisons, determining what is occurring at one place compared with another place, what is going on at one time compared with another time, and what is going on with one group of people compared with another group of people. Rates of occurrence are compared; how these rates are determined is of major importance in epidemiology.

Occurrence rates for birth defects are usually expressed in terms of either rates of incidence or prevalence at birth. An incidence rate, calculated using cases occurring during a specified period of time, consists of a numerator, the number of new cases of a defect; and a denominator, the population at risk of developing the defect. Incidence rates are expressed in terms of some base population, such as per 1,000 births, and give a measure of the risk of the defect occurring within the population. Many investigators believe it is inappropriate to refer to birth defect rates as incidence rates, since the true population at risk, that is, the number of embryos, is unknown. Thus, there is an increasing tendency to refer to the occurrence of birth defects as prevalence at birth.^[13] Prevalence requires knowing the number of cases that exist at a point in time, in this case defined as birth. Thus, we determine prevalence at birth, since we can obtain information on the number of cases born in a population and the total number of births.

Examination of the occurrence rates for birth defects often shows geographic differences.^[14] Such differences are found both between countries and between regions within countries. These differences are studied in an effort to identify possible etiologic factors. Detailed information on birth defect rates in the United States^[15] and internationally^[16],^[17] have been published.

Temporal variations in birth defect rates may occur within a population, and the interpretation of such variation may give insights into etiology. Two kinds of time-related changes are of particular interest: short-term increases that may be termed "epidemics" and long-term secular trends. Examples of the former are the epidemic of phocomelia in several European populations during the early 1960s^[18] and a more recent epidemic of anencephalus in South Texas.^[19] An example of the latter is the recent decline in neural tube defect (NTD) rates in several areas of the world.^[19] The increase in phocomelia was found to be associated with the introduction of the drug thalidomide. The decline in NTD rates has not been explained and is an example

of a trend whose contributing factors need to be identified through epidemiologic study.

EPIDEMIOLOGIC APPROACHES TO THE STUDY OF BIRTH DEFECTS

Epidemiology is the study of the distribution and determinants of disease. Understanding disease distribution often provides insights into disease determinants. Understanding uneven distribution can lead to the identification of factors involved in disease etiology. ^[20] While epidemiologic studies usually are unable to establish causal relationships, such as can be done through animal experiments, associations between exposures and an outcome from well-conducted studies can provide strong, compelling evidence that the outcome results from the exposure.

Three major issues are involved in epidemiologic studies of birth defects that evaluate potential associations between exposures and outcomes: (1) the definition and ascertainment of outcomes of interest; (2) the definition, identification, and quantification of exposures or of other risk factors; and (3) the use of epidemiologic and statistical techniques to determine the strength of that association. ^[20]

Epidemiologic studies of birth defects and other adverse reproductive outcomes often present special challenges in terms of case definition and ascertainment (identification) and determination of exposure. The definition of what constitutes a case can present major problems in studies of birth defects. The completeness of ascertainment may vary by source and by defect. For example, one can argue that recent increases observed in the rates of patent ductus arteriosus (PDA) are due to increases in the incidence of the defect, better diagnosis, or increased survival of low-birth-weight infants in whom PDA frequently occurs. Even for defects that are readily recognizable at birth, such as NTDs, differences in sources of case ascertainment can lead to apparent differences in rates of occurrence, ^[21] which may be unrelated to differences in incidence.

There are three general categories of epidemiologic studies: descriptive, analytical, and experimental. The following discussion briefly considers some of the major features of these study designs, relating them to studies of birth defects and other adverse reproductive outcomes.

Descriptive Epidemiology

Case Reports

Most known teratogens and reproductive toxicants have been identified through case reports of an unusual number of cases or a constellation of abnormalities. These have often come from astute clinicians, who observed something out of the ordinary. ^[22] ^[23] ^[24] Although the importance of astute observations of abnormal aggregations of cases or patterns of malformations must be recognized, we cannot rely on such methods for identifying health hazards. Furthermore, etiologic speculations based on case reports or case series usually do not lead to a causal agent and are often false-positive speculations. Whereas case reports may identify a new teratogen, they can never provide an estimate of the risk of disease after exposure.

Descriptive Studies

Descriptive epidemiologic studies can be used to provide information about the distribution and frequency of some outcome of interest, resulting in rates of occurrence that can be compared among populations, places, or times. Defining the population at risk is the first step in a descriptive study. The population at risk can be defined geographically, such as residents within a state, or medically, such as being a patient at a particular hospital. Definition of the population at risk includes the time period under consideration. The population at risk constitutes the *denominator* for calculating rates of the occurrence of outcomes of interest.

The second step in a descriptive study is to determine the *numerator* for calculating rates for comparison. This involves two important concepts: (1) case definition (what defines a case to be counted) and (2) case ascertainment (how are cases to be identified).

Descriptive studies determine rates so that they can be compared. Possible differences in case ascertainment methods must be kept in mind. Some of the important issues associated with the determination of rates and their comparison have been discussed extensively by Borman and Cryer. ^[25]

Surveillance Programs

In surveillance programs, an at-risk population is identified and then followed over time to detect outcomes of interest. As they occur, cases are included in the database. Surveillance programs provide rates that can be examined for changes over time. They develop baseline data and subsequently permit early recognition of potential problems, based on ongoing data collection and analysis.

Birth defect surveillance (monitoring) systems (BDMSs) are designed to identify cases occurring in a defined population, usually by reviewing vital records or hospital record abstracts or charts. The defined population often is a sociopolitical unit, such as a state, but some monitoring programs have been based on discharge data from particular groups of hospitals or

births to women residing in a specified metropolitan area.

Two BDMSs are operated by the Division of Birth Defects and Developmental Disabilities, National Center for Environmental Health, Centers for Disease Control and Prevention (CDC), Atlanta, Georgia. These two systems—the Birth Defects Monitoring Program (BDMP) and the Metropolitan Atlanta Congenital Defects Program (MACDP)—perform important surveillance functions. ^[26] The two systems follow populations defined differently and differ in sources of case ascertainment. Descriptions and comparisons of both systems are available. ^[27]

In the last 20 years, there has been a dramatic increase in the number of state-based birth defect surveillance systems. As of 1995, approximately half the states have some type of birth defect surveillance system. ^[28] These programs conduct routine reviews of occurrence rates of specific malformations and attempt to identify increases in rates or clusters of cases. Several of the states conducted case-control studies using cases from their surveillance program, and others have linked outcome data with environmental databases in an attempt to identify environmental reproductive hazards. ^[29] ^[30] ^[31] ^[32] The use of cases from surveillance programs for hypothesis testing studies leads to a consideration of analytical epidemiology.

Analytical Epidemiology

Analytical epidemiologic studies are designed to generate or test hypotheses about associations between exposures and outcomes. The detection and quantification of such associations are major epidemiologic concerns. Such associations can be examined at either the group or individual level.

Ecologic Studies

Ecologic studies are important for generating hypotheses about the causes of an outcome such as a birth defect. In such studies, occurrence rates for an outcome are compared between groups thought to differ in terms of some exposure. Studies of this type do not collect information about exposures of individuals and are often used in environmental epidemiology, where residence in a particular area is used as an indicator of exposure. Lack of specific individual exposure data can be a critical limitation of this study design.

Examples of ecologic studies relevant to reproductive outcome include studies of congenital malformations in communities with vinyl chloride production facilities ^[33], ^[34] and in communities with solvent-contaminated drinking water. ^[35] Ecologic studies often lead to hypotheses that can be tested using other study designs. Studies that allow associations between exposure and outcome to be assessed in particular individuals play a much more important role in epidemiologic research.

Case-Control Studies

The case-control study design, where groups of individuals with some outcome or disease of interest (cases), such as a congenital malformation, are compared to controls with regard to a history of one or more exposures, is the one most widely used in reproductive outcomes research. The controls are individuals as similar as possible to the cases, except that they are without the outcome of interest.

After cases and controls have been identified, the hypothesis to be tested is whether these two groups differ in exposure as well as outcome. How accurately exposure and its timing are determined may vary greatly among studies, but in any study the same methods must be used to establish the exposure of both cases and controls. ^[20]

Case-control studies are frequently used in epidemiology for several reasons. In testing etiologic hypotheses, they are applicable to outcomes of infrequent occurrence, and they can be conducted relatively rapidly and inexpensively. A disadvantage is that they have a potential for several important types of bias, including bias in recalling exposure, in selecting appropriate controls, and in ascertaining cases.

These problems can be addressed in part by use of two control groups, one "normal" and the second "abnormal." Any of several abnormal controls seem equally useful, for example, infants with mendelian disorders as well as infants with no specific malformation. ^[36] In the former, mothers have incentive to recall but teratogenesis is not the etiology.

Most human studies of potential teratogens following descriptive studies have been case-control studies. After suspecting on the basis of case observations that thalidomide was teratogenic, Lenz ^[37] conducted a case-control study. Following ecologic studies of ambient exposure to vinyl chloride, the hypothesis of an association between vinyl chloride exposure and congenital malformations was tested using case-control studies. ^[34], ^[38], ^[39] The association between valproic acid use and spina bifida was verified by case-control studies. ^[40]

Cohort Studies

Cohort studies use the reverse approach from case-control studies; individuals who differ in exposure history are examined for differences in the occurrence of outcomes of interest. The groups are defined by the presence or absence of exposure to a given factor and then are followed over time and compared for rates of occurrence (i.e., incidence rates) of the outcome of interest.

Cohort studies have three advantages: (1) the cohort is classified by exposure before the outcome is determined, thereby eliminating the exposure recall bias; (2) incidence rates can be calculated among those exposed; and (3) multiple outcomes can be observed simultaneously.

Cohort studies, often called *prospective studies*, require that groups differing in exposure be followed through time, with outcomes observed. Therefore, these studies tend to be time consuming and expensive. In addition, since occurrence rates for many adverse reproductive outcomes, such as congenital malformations, are low, large samples must be followed for long periods of time. Two main types of cohort studies have been developed: (1) those that identify a cohort and follow it into the future (concurrent cohort study), and (2) those that identify a cohort at some time in the past and follow it to the present (nonconcurrent cohort study).

In both cases, the risks of adverse outcomes are then compared between groups. Cohort studies enable investigators to calculate incidence rates that provide a measure of the risk of an outcome after the exposure. Risk in the exposed group can be compared with the risk in an unexposed group. Most frequently, the ratio of the incidence rate among the exposed to the rate among the unexposed is determined. This ratio, referred to as *relative risk*, is a measure of how much the presence of exposure increases the risk of the outcome.

Only a few large-scale concurrent cohort studies of problems of pregnancy outcome have been conducted. Probably the best known is the Collaborative Perinatal Project, conducted by the National Institute of Neurological and Communicative Disorders and Stroke. In this study, conducted between 1959 and 1966, about 55,000 women and their subsequently born children were studied extensively: the children were examined through age 8 years. ^[41] This study has provided considerable information on the use of drugs in pregnancy and birth defects and on many other topics (see Chapter 9).

Numerous studies of reproductive outcome have been conducted by the noncurrent cohort approach. These studies, also known as *historical prospective studies*, begin by identifying groups who differ in terms of some past exposure and follow them to the present and determine outcomes; exposure groups are defined before outcomes are known. A major advantage is that although the time frame is prospective, investigators do not have to follow the cohort into the future, waiting for events to occur. A disadvantage is that these studies require the ability to determine exposure status retrospectively.

A series of noncurrent cohort studies tested associations between smelters and spontaneous abortions. ^[42] Nordstrom and co-workers ^[43] compared histories of spontaneous abortions between women who differed in terms of occupational exposure to smelting processes. Later, Beckman and Nordstrom ^[44] surveyed exposed and unexposed male workers about their wives' histories of spontaneous abortions. In both instances, the findings supported a hypothesis of an association between the smelter and spontaneous abortions.

Experimental Epidemiology

Clinical Trials

The most common experimental study design in epidemiology is the clinical trial, in which the efficiency of a prevention or treatment regimen is evaluated. Ideally, subjects are randomly assigned to different treatment groups. The individuals must be as similar as possible in terms of unknown factors that may affect the response before they are randomly assigned to the treatment groups and receive the different regimens. ^[45]

The role of vitamin supplements taken during the periconception period in preventing NTDs has been evaluated in experimental studies. Smithells and co-workers ^[46], ^[47] suggested that recurrence risks for NTDs were reduced in women who took the supplements during the period. In the original study, subjects were not randomized into different treatment groups, and because of this the conclusions have been criticized. More recent clinical trials of both NTD recurrence ^[48] and occurrence ^[49] have shown a protective effect of periconceptional folic acid supplementation, findings that have led to key public health recommendations regarding the use of folic acid to reduce the risk of these often devastating defects. ^[50]

In summary, experimental studies in epidemiology are unique in that they involve intervention as well as observation. In this way, they compare with approaches used

in animal studies of teratology and other life sciences and yield results that can be analyzed like other experimental findings. They are limited, however, in what can be ethically tested, namely, treatment or preventive measures, rather than etiologic hypotheses.

Exposure Assessment

As a prerequisite to evaluating the reproductive hazards associated with an occupational or environmental agent, one must be able to measure or estimate exposure to potential hazards. A number of investigators have recently addressed the problems associated with this exposure assessment. [\[20\]](#) , [\[51\]](#) [\[52\]](#) [\[53\]](#) [\[54\]](#)

Considerations concerning occupational exposure can be categorized into three areas: defining and determining exposure, timing of exposure, and problems of mixed exposures. [\[20\]](#) In the first area, which can also be labeled exposure occurrence and measurement, [\[53\]](#) the

problems relate to determining what a particular worker is exposed to and then determining the amount of exposure, if possible. Workers often may not be aware of the chemical substances to which they are exposed. If possible, determining exposure history should begin by questioning the worker and taking a job history. Ideally, this should be augmented by reviewing the occupational and job history records that the employer maintains. The job history may make it possible for the investigator to determine the substances to which the worker was exposed. If so, the exposure records the employer maintains may include data from environmental monitoring.

Timing of exposure is crucial in studies of reproductive outcome. The critical stages in human development for teratogenesis were discussed earlier in this chapter. Except for exposures associated with mutational events, damage to the reproductive or endocrine systems, or storage of a substance for long periods in body tissues such as bone (lead) or fat (PCBs), exposures must occur within a limited period to produce teratogenic effects. For example, an agent suspected of causing an NTD could not be implicated as the cause of an infant's neural tube's failing to close if the mother had been exposed to the agent after the tube should have closed.

Employees may be exposed to a variety of potentially hazardous substances, leading to difficulty in demonstrating that a specific substance is a reproductive hazard. Most occupational exposures are to more than one substance, and it may not be possible to determine the reproductive effects of one agent often occupational groups rather than specific exposures are studied. Studies of birth defects and other adverse reproductive outcomes associated with occupational groups have been reviewed recently. [\[55\]](#) [\[56\]](#) [\[57\]](#)

It is particularly difficult to determine exposures in studies of the ambient environment. There is growing interest and research activities in the use of biologic markers of exposure in studies of adverse reproductive outcomes. [\[58\]](#) [\[59\]](#) [\[60\]](#) [\[61\]](#)

An additional concern is confounding by nonoccupational exposure(s) and lifestyle factors, for example, alcohol and tobacco use. Family history also may affect risk of adverse outcomes.

EXPOSURES THAT MAY LEAD TO ADVERSE REPRODUCTIVE OUTCOMES

We shall now review what is known about the effects of prenatal exposure to certain occupational and environmental agents. Agents were selected on the basis of the availability of human data and on the authors' impressions of public concern that the agents may cause adverse reproductive effects.

Known human teratogens number about 30.^[62] To date, only two have caused human maldevelopment (cerebral palsy and mental retardation) as a result of environmental contamination: high-dose ionizing radiation and methylmercury. Agents suspected of being teratogens on the basis of animal studies and limited epidemiologic studies are more numerous. When these agents are found to be polluting the environment, there is justifiable concern about potential prenatal exposure and adverse reproductive effects (Table 7-1). The difficulty of demonstrating an association between an environmental hazard and any adverse reproductive outcome must be appreciated.^[63]

Several recent publications have addressed epidemiologic aspects of studying health effects of environmental contamination, including reproductive effects.^{[63] [64] [65]} In a concise review, Heath^[66] summarized some of the problems in epidemiologic studies of environmental hazards. Using as examples the childhood leukemia cluster in Woburn, Massachusetts, and the population exposure to waste chemicals at Love Canal, Heath identified three problems relevant to our discussion: low-dose, nonquantifiable exposures; the long and variable latency between exposure and outcome (disease); and the nonspecific nature of the outcome or disease. As a corollary to the last problem, Heath^[66] pointed out that multiple factors probably play a causative role in most outcomes of interest including birth defects, low birth weight, spontaneous abortion, and cancer.

Ionizing Radiation

Acute High Dose

During the 1920s and 1930s, ionizing radiation was used to treat women with pelvic disease; soon afterward, it was identified as the first known environmental human teratogen.^[67] Systematic studies of atomic bomb survivors in Japan showed that in utero exposure to high-dose radiation increased the risk of microcephaly and mental and growth **restriction** in the offspring.^{[6] , [68] [69] [70] [71]}

Studies of the Japanese survivors clearly show that distance from the hypocenter the area directly beneath the detonated bomb and the gestational age at the time of exposure were directly related to microcephaly and mental and growth restriction in the infant. Nine and 20 years after exposure, the greatest number of children with microcephaly and mental retardation and growth restriction were in the group exposed at 15 weeks' gestation or earlier. These findings contrast with those of children exposed in utero during the third trimester and whose mothers were farthest from the hypocenter at the time of exposure. Of 55

TABLE 7-1 -- OCCUPATIONAL AND ENVIRONMENTAL AGENTS THAT MAY BE ASSOCIATED WITH HUMAN ADVERSE REPRODUCTIVE OUTCOMES

Agent	Outcome
Ionizing radiation	
Acute high-dose	Microcephaly, mental retardation, growth restriction
Chronic low-dose or before pregnancy	?Down syndrome
Methylmercury	Mental retardation, cerebral palsy, deafness, blindness, seizures (abnormal neuronal migration)
Mercury vapor	Cranial defects, spontaneous abortion, ?stillbirth
Lead	
High-dose	Infertility, spontaneous abortion, growth restriction, psychomotor retardation, seizures, stillbirth
Chronic low-dose	Lower IQ, cognitive impairment in speech and language, attention deficit
Polychlorinated biphenyls	
High-dose	Spontaneous abortion, low birth weight, neuroectodermal dysplasia (skin staining, natal teeth, dysplastic nails, developmental and psychologic deficits), abnormal bone calcification
Chronic low-dose	Lower birth weight, smaller head circumference, ?cognitive impairment
Polybrominated biphenyls	
Chronic low-dose	?Lower birth weight, ?smaller head circumference, ?cognitive impairment
Anesthetic gases	
Chronic low-dose	Spontaneous abortion
Birth defects	
Organic solvents	
Chronic high-dose	Developmental impairment, facial dysmorphism, growth restriction (similar to fetal alcohol embryopathy)
Chronic low-dose	Spontaneous abortion, CNS malformations, orofacial clefts

such children evaluated 20 years later, only 1 was found to be microcephalic, and all were of normal intelligence.^[69] Although teratogenic effects have been found in several organ systems of animals exposed to acute, high-dose radiation, no structural malformations other than those mentioned above have been reported among humans exposed prenatally.

Using data from animals and from outcomes of reported human exposures at various times during pregnancy, DeKaban^[72] constructed a timetable for extrapolating

acute, high-dose radiation (>250 rad) to various reproductive outcomes in humans. Similarities between animal and known human effects support DeKaban's proposal.

Chronic Low Dose

Effects of chronic low-dose radiation on reproduction have not been identified in animals or humans. Increased risk of adverse outcomes was not detected among animals with continuous low-dose exposure (<5 rad) throughout pregnancy. ^[73]

The relationship between human structural malformations and background radiation has been examined in several epidemiologic studies in different geographic areas. Cosmic radiation was thought to be one factor that contributed to increased rates of anencephalus between 1950 and 1969 in several Canadian cities. ^[74] Using geologic estimates of natural radioactivity, some investigators have attributed increased malformation rates, including the rate for Down syndrome, to higher radioactivity levels. ^[75], ^[76] Other studies of the association between estimated cosmic radiation exposure and congenital malformation rates have produced negative results. ^[77], ^[78] Given that low-dose radiation could be one of a multitude of environmental factors that affect the risk of birth defects, perhaps it is not surprising that no consistent relationship is evident.

Mutagenesis

Children exposed in utero to radiation from the atomic bomb were studied over several years for evidence of genetic damage. No evidence for effects was found when six indicators were evaluated: congenital malformations, stillbirths and neonatal death rates, birth weight, sex ratio at birth, anthropomorphic measurements during the first year of life, and mortality in offspring (F1 generation). ^[67], ^[79] ^[80] ^[81]

In contrast to the atomic bomb follow-up studies, other investigations have found that mutagenic effects may occur when women are exposed prenatally to diagnostic radiation. These effects include altered sex ratios among the offspringslightly more females than expected ^[82] abnormal karyotypes in spontaneously aborted fetuses. ^[83]

Mutagenic effects in the offspring of irradiated women may be manifested years after the birth of the infant. Compared with nonirradiated controls, the estimated risk of leukemia was increased 50 percent for children exposed in utero to radiation during maternal pelvimetry examinations. ^[84] ^[85] ^[86] Although this increase seems considerable, it translates into an approximate risk of 1 in 2,000 for exposed versus 1 in 3,000 for

169

unexposed children. As Brent^[73] points out, if one were to recommend that pregnancies be terminated whenever exposure from diagnostic radiation occurred because of the increased probability of leukemia in the offspring, 1,999 exposed pregnancies would have to be terminated to prevent a single case of leukemia.

Questions have been raised about potential risks to children associated with parental (paternal) occupational exposure to low-dose radiation. ^[87] A case-control study by Gardner et al. ^[88], ^[89] in the area around the Sellafield Nuclear Facility in the United Kingdom found a statistically significant association between paternal preconception radiation dose and childhood leukemia risk. A similar association had been observed between paternal preconception radiation and risk in workers at the Hanford Nuclear Facility in the United States. ^[90] The finding regarding childhood leukemia risk is a particularly contentious issue, contradicting studies of the children born to atomic bomb survivors who do not show genetic effects, such as increased risks of childhood cancers. ^[81] A study in the vicinity of nuclear facilities in Ontario also failed to demonstrate an association between childhood leukemia risk and paternal preconception dose (exposure). ^[91]

Video Display Terminals

Since the 1980s, there has been concern about video display terminals (VDTs) linked to adverse reproductive outcomes. Much of the early concern grew out of reports of spontaneous abortion clusters among groups of women who used VDTs at work, and some of the reported clusters also included birth defects. ^[92] While it was suggested that these "unexpected" clusters were actually expected based on the frequency of occurrence of spontaneous abortions (10 to 15 percent of recognized pregnancies) and the extremely large number of women working with VDTs, ^[93] several large epidemiologic studies were carried out to examine the association. ^[94], ^[95] Numerous papers have been published on this topic, along with a number of reviews. ^[56], ^[92], ^[93] Our interpretation of these studies is that VDT use does not increase the risk of adverse reproductive outcomes.

Organic MercuryMethylmercury

Exposure to organic mercury compounds, such as methyl- or ethylmercury, is not common. In the United States, methylmercury was widely used as a fungicide until the 1960s, when U.S. production was halted because of the compound's toxicity and bioaccumulation. Today in the United States, exposure mainly occurs through the consumption of contaminated fish. Fish may become contaminated when organomercurials are present in water or when bacteria in water convert inorganic mercury to organic mercury, part of a complex environmental mercury cycle. ^[96]

Methylmercury effects were discovered in 1959 after an epidemic of poisoning in Minamata, Japan, that resulted in fetal neurologic damage with psychomotor retardation, seizures, cerebral palsy, blindness, and deafness. ^[97] In 1972, similar fetal effects were observed in Iraq after an epidemic of methylmercury poisoning. ^[98] In both epidemics, breast-fed infants had additional exposure through maternal milk. ^[97]

Unintentional human exposures have permitted a more thorough study of the reproductive effects of methylmercury than of any other environmental pollutant. ^[99] ^[100] ^[101] The persistence of organic mercury in the body (biologic half-life about 70 days) and its accumulation in hair further make it possible to reconstruct prenatal exposure. ^[102] Methylmercury crosses the placenta easily and accumulates in embryonic and fetal tissues, particularly brain tissues, at concentrations exceeding those in the mother. ^[103], ^[104] Methylmercury does not cause obvious structural malformations in humans; thus, the devastating effects are not apparent at birth and are manifested only as the child ages. The developing nervous system of the conceptus and infant is more sensitive to the toxic effects of organic mercury than that of the adult or older child, ^[97] and the infant of an asymptomatic mother can be affected severely. ^[98], ^[101], ^[105]

Little is known of the human effects of methylmercury at low levels of exposure. Minor neurologic differences, mainly brisker deep tendon reflexes, were found among native Quebec boys exposed in utero compared with boys who had no such exposure. ^[106] Low-level methylmercury exposure may be associated with an increased frequency of chromosomal abnormalities^[107] the significance of this finding for adverse health or reproductive effects is unknown.

Nonhuman primates chronically treated with low-dose methylmercury were more likely to experience reproductive failure (nonconception, spontaneous abortion) than nontreated controls. ^[108] Prenatal exposure of nonhuman primates resulted in offspring with impaired visual recognition that was consistent with a developmental teratogenic effect. ^[109] ^[110] ^[111]

While there appears to be no association between congenital malformations and human environmental exposure, methylmercury is embryolethal in laboratory animals and causes various structural malformations (exencephaly, limb abnormalities) when high doses are given during critical periods in development. ^[112] Mattison et al. ^[113] have reviewed experimental and human epidemiologic data regarding mercury and other metals, listing the site(s) of action or reproductive outcome studied. A recent review by Weiss^[114] includes a quantitative risk assessment of the developmental neurotoxicology of methylmercury.

170

Elemental Mercury (Vapor)

Mercury is an unusual element. At room temperature it is liquid, with a high vapor pressure, and vapor concentrations can rise rapidly to toxic concentrations in closed

or poorly ventilated areas. The vapor is odorless and colorless, making it virtually nondetectable without special equipment.

Women at risk for exposure work primarily in health-related occupations such as nursing, medicine, dentistry, and dental hygiene. Exposure may occur when dental amalgams are prepared and when thermometers or manometers are broken or mercury is spilled. In recent years, encapsulated amalgam preparations and electronic methods for measuring blood pressure and temperature have been developed. Consequently, mercury exposure in medicine and dentistry in the United States has probably decreased.

Given that large numbers of women of childbearing age may have been exposed occupationally to mercury vapor, there is a surprising dearth of animal and human epidemiologic studies of reproductive effects. In one study, mercury vapor exposure at 0.5 mg/m³ throughout pregnancy resulted in cranial defects in 2 of 115 fetal rats.^[115] Exposure during days 10 through 15 of gestation produced increased fetal resorption.^[115] This vapor concentration is 10 times greater than the occupational limit of 0.05 mg/m³ established by the Occupational Safety and Health Administration^[116] and probably caused maternal toxicity that contributed to the observed fetal effects. To protect the developing conceptus, Koos and Longo^[99] recommend that women of childbearing age should not be exposed to vapor concentrations exceeding 0.01 mg/m³.

Animal studies demonstrate the ease with which elemental mercury crosses the placenta. Following mercury vapor exposure, fetal rat blood mercury concentrations were 65 times higher than the corresponding maternal values, and the highest mercury concentrations were found in the rat placenta.^[117] Placental and fetal membranes from mercury-exposed dental workers contained two to three times more mercury than tissues taken from unexposed women.^[118] The fetal and maternal blood mercury concentrations were similar in both groups, implying that the placenta and fetal tissues may act as a barrier at low levels of mercury vapor.^[119]

Epidemiologic studies of reproductive effects have been conducted with dental assistants and female dentists. Radiation and anesthetic gases are potential confounding exposures overlooked in many studies. Other methodologic problems, such as nonverification of the outcome, absence of exposure data, and low survey response rates, often are not considered. The limited studies to date do not provide conclusive evidence that occupational exposure to mercury vapor is teratogenic or results in other adverse reproductive outcomes. The need for more animal and human studies of reproductive effects has been recognized.^[119]

At least one case report has suggested a possible association between occupational exposure to mercury vapor and severe brain damage in a newborn.^[120] A female dental surgeon, who worked in a surgery with mercury levels above the threshold limit value, gave birth to a small-for-dates baby with severe brain damage, not otherwise specified. The authors stress that a case report can only suggest an effect, but the finding is consistent with animal teratology.

Rowland^[121] reviewed the reproductive effects of mercury vapor and presented data from studies of female dental assistants in California. Women who prepared 50 or more dental amalgams per week had a statistically insignificantly increased risk for spontaneous abortion. Women who prepared 30 or more amalgams a week in offices with poor mercury hygiene showed evidence of reduced fecundity. A detailed analysis of fecundity, assessed as time to pregnancy in this cohort of dental assistants, was published recently.^[122] To our knowledge, there are no published data on congenital malformations among births to dental assistants in the United States.

Lead

Since the 19th century, exposure to high levels of lead has been known to cause embryotoxicity, growth restriction and mental retardation, increased perinatal mortality, and developmental disability.^[123] These adverse reproductive effects were seen when women in occupational settings were exposed to concentrations of lead in air that far exceeded levels allowable today. As a matter of historic interest, unscrupulous vendors sold pills containing lead as an abortifacient at the turn of the century.^[124]

Sources of nonoccupational lead exposure commonly encountered by U.S. women are unlikely to result in detectable effects. Regulatory and public health efforts are directed at reducing preconceptional and prenatal exposure in order to reduce maternal-to-fetal lead transmission.

Twenty-five years of public health efforts have produced a striking reduction in lead exposure in the United States. The average blood lead level has decreased to less than 20 percent of levels measured in the 1970s. However, elevated blood lead (>20 g/dl) has a higher incidence among immigrants to Southern California. In Los Angeles, 25 of the 30 cases of elevated blood lead occurred in immigrants.^[125]

High lead concentration in maternal blood is associated with an increased risk of delivery of a small-for-gestational-age infant.^[126] The frequency of preterm birth was also almost three times higher among women who had umbilical cord levels greater than or equal to

5.1 g/dl, compared with those who had levels below that cutoff. This was observed in nulliparous women, but not in multiparous women in Mexico City.^[127] One study in Norway found an increased risk of low birth weight and also neural tube defects.^[128]

Eating lead-glazed clay pots (pica) resulted in lead toxicity in pregnancy in a Mexican-American mother.^[129] Asking pregnant women about risk factors for lead exposure can aid in assessing prenatal exposure risk. A questionnaire that combined housing conditions, smoking status, and high consumption of canned foods had a sensitivity of 89.2 percent and a negative predictive value of 96.4 percent.^[130] Consumption of calcium and avoidance of the use of lead-glazed ceramics resulted in lowering of blood lead, especially in pregnant women of low socioeconomic status in Mexico City.^[131]

Because the nervous system may be more susceptible to the toxic effects during the embryonic and fetal periods than at any other time of life^[109] and because maternal and cord blood lead concentrations are directly correlated,^[132] lead concentrations in blood should not exceed 25 g/dl in women of reproductive age.^[133]

Ideally, the maternal blood lead level should be less than 10 g/dl to ensure that a child begins life with minimal lead exposure. A dose-response relationship is strongly supported by numerous epidemiologic studies of children showing a reduction in IQ with increasing blood lead concentrations above 10 g/dl. Of note, these studies measured blood lead concentrations over time (often 2 years or more) and reported averaged values. Other neurologic impairments associated with increased blood lead concentrations include attention deficit disorder ("hyperactivity"), hearing deficits, learning disabilities, and shorter stature. Thus, for public health purposes, childhood lead poisoning has been defined as a blood lead level of 10 g/dl or higher.^[134]

In occupational settings, federal standards mandate that women should not work in areas where air lead concentrations can reach 50 g/cm³, since this may result in blood concentrations above 25 to 30 g/dl.^[135] Subtle but permanent neurologic impairment in children may occur at lower blood lead concentrations.^[136],^[137] Although controversial, such studies raise the possibility that the occupational standard may inadequately protect the fetus. Protection of fetuses from lead exposure was an important concern raised in the Johnson Controls case in the U.S. Supreme Court.^[138] The issues of the neurodevelopmental effects of prenatal lead exposure have been discussed by Bellinger and Needleman.^[139]

Lead screening of pregnant women is highly controversial and not presently recommended. Lead is mobilized from the maternal skeleton during pregnancy and the postpartum period.^[140] In the absence of excessive exposure, most of the lead in blood comes from bone stores, and no intervention is available to reduce the blood lead.^[141] Chelation therapy is potentially hazardous, and some agents are teratogenic.^[142] On the other hand, screening could identify women who may benefit from environmental or other interventions to reduce their lead exposure.

The Phenoxy Herbicide 2,4,5-Trichlorophenoxyacetic acid and Dioxins/Agent Orange

These compounds are considered together because 2,3,7,8-tetrachlorodibenzodioxin (TCDD or dioxin) and other chlorinated dibenzodioxins were produced as contaminants during production of the herbicide 2,4,5-trichlorophenoxyacetic acid (2,4,5-T).^[143] This herbicide is no longer marketed in the United States, largely because of concerns about possible teratogenic and fetotoxic effects (seen after high doses are administered to animals during critical periods of organogenesis).^[144]

Agent Orange, a defoliant used in Vietnam, was a mixture of herbicides, including 2,4,5-T. During the later years of the Vietnam War, public opinion against the ecologic effects of Agent Orange was fueled by reports of birth defects in South Vietnamese babies born to mothers who lived in areas where Agent Orange had been

sprayed. The ensuing debate about the potential human teratogenicity of Agent Orange involved numerous federal agencies, and the use of 2,4,5-T containing any chlorodioxin contaminants was cancelled in 1970. ^[145]

Because 2,4,5-T contained small amounts of TCDD and since long-term human effects were unknown, the U.S. Public Health Service began an immense follow-up of Vietnam veterans. One portion of the study evaluated Vietnam veterans' risks of fathering infants with birth defects. The investigators concluded that "Vietnam veterans who had greater estimated opportunities for Agent Orange exposure did not seem to be at greater risk for fathering babies with all types of defects combined." ^[146] Vietnam service was associated with a few defects, however; Agent Orange exposure, other Vietnam-related experience, or some unidentified risk factor may have been responsible for the associations. ^[146] In a subsequent follow-up study, Vietnam and non-Vietnam veterans were interviewed regarding congenital malformations in their offspring. Although Vietnam veterans were more likely to report birth defects in their offspring, hospital records showed similar rates of birth defects for children born to both veteran groups. ^[147] In contrast, increased central nervous system (CNS), skeletal, and cardiovascular malformations and disease were reported among Australian Vietnam veterans. ^[148] This study was less rigorous than its American counterparts, since it was an unconventional case-control design and relatively few children had diagnoses confirmed by medical record review.

172

Concerns about the reproductive effects of dioxins continue to be expressed. The Environmental Protection Agency has included an extensive discussion of these issues in a recent reassessment of 2,3,7,8-TCDD. ^[149] Overall, the data appear inadequate to support allegations of adverse reproductive outcomes following human exposure to the dioxin-contaminated herbicide, although this is a topic of continuing discussion. ^[149] The 1996 Institute of Medicine report concluded that "limited/suggestive evidence exists of an association between dioxin exposure in veterans and offspring they sired with spina bifida." ^[150] The strength of even this tenuous statement seems arguable to us.

Polychlorinated Biphenyls

Polychlorinated biphenyls (PCBs) were widely used in industry because of their thermal stability and heat transfer properties. ^[151] PCBs are also extremely stable and resistant to metabolic or biologic degradation and have become ubiquitous in the environment because of past dumping or disposal in unregulated landfills and failure to recycle. PCBs are highly lipid soluble, accumulate in fat, and can be found at high concentrations in the breast milk of women despite low concentrations in their blood. ^[152] Details of PCB biochemistry and toxicology are available elsewhere. ^[153], ^[154] Jacobson and Jacobson provide a thorough discussion of clinical effects of in utero PCB exposure. ^[155]

Two epidemics of cooking oil contamination provide evidence that high-dose PCBs are hazardous to human reproduction. In these epidemics, adults consumed cooking oil tainted with thermally degraded PCBs and developed a disease termed "Yusho" (in Japan) and "Yu-cheng" (in Taiwan). The disease was characterized by chloracne (an acneform rash), eyelid swelling and discharge, and skin hyperpigmentation. ^[156] Although PCBs alone are usually blamed for these and subsequent health problems, it is clear that heat-degradation products of PCBs (polychlorodibenzofurans [PCDFs] and polychlorinated quaterphenyls [PCQs]) contributed significantly to toxicity. ^[157], ^[158] A follow up in 1999 compared 795 subjects exposed postnatal to 693 controls. ^[159] Lifetime prevalences in the former were increased for chloracne, abnormal nails, hyperkeratosis, skin allergy, goiter, headache, gum pigmentation, broken teeth, anemia in women, arthritis, and herniated intervertebral disks in men. For other medical conditions no differences were observed.

A teratogenic effect was observed as well, as reviewed by Jacobson and Jacobson. ^[159] High-dose transplacental exposure to the cooking oil resulted in congenital anomalies and low birth weight. ^[160] Skin and mucosal hyperpigmentation were the most often noted abnormalities. ^[160] Other anomalies included natal teeth, gingival hyperplasia, exophthalmos, skull calcifications, and delayed bone age. ^[160]

In 1985, Rogan and coworkers ^[161] examined 117 children with prenatal and/or breast milk exposure to the PCB/PCDF/PCQ-contaminated oil. Compared with unexposed children, those exposed demonstrated delayed developmental milestones, psychological deficits, and behavioral abnormalities. Physical abnormalities included shorter stature, lighter weight, and epidermal disorders such as acne, hyperpigmentation, deformed nails, gingival hypertrophy, and tooth chipping. ^[161] Developmentally, exposed children in Taiwan demonstrated cognitive impairment that persisted up to age 7 years. ^[162] "Catch-up" growth occurred in most of the surviving infants, with attainment of normal body weight by 2 years of age. ^[163], ^[163] In aggregate, these findings suggest a neuroectodermal dysplasia due to combined effects of the PCBs and contaminants. ^[161]

In addition to the teratogenic effects, the contaminated oils led to excessive reproductive losses among exposed women. Increased risks for spontaneous abortion, stillbirth, and infant mortality were documented in follow-up study of a group of Taiwanese women. ^[163] A recent follow-up of 368 of the 596 living Yu-cheng women was performed, comparing reproductive outcome to that of 312 controls. The women exposed in 1979 reported more stillbirths (4.2 percent vs. 1.7 percent controls), more abnormal menstrual bleeding (16 percent vs. 8 percent), and more offspring dying during childbirth (10.2 percent vs. 6.1 percent). ^[164]

Effects of high-level cooking oil contamination should be distinguished from those of ambient or low-level exposure to PCBs. Low-level PCB maternal exposure can occur throughout life by consumption of fish from PCB-contaminated waters as well as other dietary sources. While transplacental transfer of PCBs occurs, ^[165] the largest dose is delivered to the nursing infant via breast milk. ^[162], ^[166] Maternal exposure and PCB transfer to nursing infants has resulted in justifiable concern about reproductive and developmental effects. Studies ongoing in the Great Lakes region are examining such effects.

In these studies, maternal PCB exposure via fish consumption, defined as 11.8 kg of Lake Michigan fish in the 6 years before delivery, was reported to be associated with a slight decrease in infant birth weight (160 to 190 g) and head circumference, relative to unexposed controls. ^[167] Neonatal assessment of the same infants provides some evidence that at low concentrations, PCBs may be behavioral teratogens. ^[168] Short-term memory impairment noted in infancy persisted at 4 years of age only in those children whose cord blood PCB concentrations were in the top 5 percent of values for the cohort. ^[168] A later study on the Lake Michigan-exposed cases also showed a small decrease in IQ in

173

children exposed to in utero. ^[169] The difference was 6.2 points in the most highly exposed group, and only one child was mentally retarded. Others have criticized this conclusion on grounds of the small observed difference and the relatively small subset of the original exposed sample available for study (potential selection bias). ^[170], ^[171]

A cohort of North Carolina children followed since birth appears to be representative of the general population, that is, without unusual PCB exposure. Periodic developmental evaluations, including standardized developmental tests, behavioral ratings, and school report card evaluations, ^[170], ^[171] up to school age have not demonstrated a relationship between prenatal or postnatal (breast-feeding) PCB exposure.

A Dutch cohort of children exposed 42 months earlier in utero reported that scores on the Kaufman Assessment Battery for Children were lowered by 4 points. ^[172] The same cohort showed birth weight to be 165 g less. ^[173]

Overall, the developmental effect of low-level PCB exposure remains unclear. Any deleterious effect is not substantive and potentially explainable on the basis of confounding variables. Additional studies of congener-specific effects on a variety of reproductive and developmental endpoints are desirable, especially in determining propriety of breast-feeding. ^[174]

Polybrominated Biphenyls

Polybrominated biphenyl (PBB) compounds are structurally similar to PCBs and share characteristics of high lipid solubility and resistance to metabolic or biologic degradation. Fortunately, PBBs are not as widespread environmental contaminants as PCBs because their use has been more limited.

PBBs were used as fire-retardants in the United States until 1974. In 1973 and 1974, cattle feed distributed in Michigan inadvertently became contaminated with PBBs. Before the contamination was recognized, people in the state consumed PBB-tainted meat and poultry. Reviews of the incident and subsequent health studies

are available. ^[175] ^[176] ^[177] ^[178]

Fetal mortality in high- versus low-exposure regions of Michigan was not appreciably different after the PBB contamination. ^[179] The study of fetal mortality is not conclusive because of potential inaccuracies in exposure estimates, the inability to control for confounding variables, and the possibility that fetal mortality may not be the best indicator of PBB reproductive effects. In addition, this study was based on fetal deaths occurring at greater than 20 weeks gestation, and risks for early fetal losses could be different than those for later deaths. ^[180]

Transplacental and breast milk exposure of infants was documented in the Michigan incident. ^[181] An early follow-up study reported that children with higher PBB body burdens scored lower on standardized tests of perceptual motor, attentional, and verbal abilities. ^[182] Later testing of these children showed that their overall developmental scores were within the normal range. ^[183]

Nitrates and Nitrite

Nitrate contamination of drinking water supplies may result from agricultural (fertilizer) run-off, sewerage, or industrial waste. Nitrates and nitrite appear not to be teratogenic in animals. ^[184] , ^[185] Administration of sodium nitrite to pregnant mice stimulated fetal erythropoiesis but did not affect fetal mortality, resorptions, average weight, number of offspring, or incidence of skeletal malformations. ^[186]

Although some results are suggestive, human epidemiologic studies provide no conclusive evidence that pregnant women who consume low levels of nitrates from drinking water are at increased risk for having a malformed baby. In South Australia, an excess of birth defects prompted a case-control study examining the relationship between maternal drinking water source (groundwater vs. rainwater) and risk of malformations. ^[187] The risk of having a malformed infant was increased among women who drank groundwater. Risks for NTDs and oral clefts particularly were increased. Using estimated nitrate concentration, a doseresponse relationship was found with a threefold increased risk at 5 to 15 mg/L nitrates and fourfold increased risk for greater than 15 mg/L nitrates. Study strengths include case ascertainment and monitoring of water nitrate concentrations during the study period; limitations include the assumption that water concentrations were constant during monitoring intervals and that subjects used the same source of drinking water throughout pregnancy. Most notable is the assumption that nitrates rather than some unmeasured drinking water contaminant was responsible. In fact, the seasonal variation in malformation risks suggests that dietary, nutritional, or other environmental factors may have contributed to the increased malformation rates.

A Canadian case-control study found that nitrate exposure from private wells was associated with an increased risk for delivering an infant with a CNS malformation. However, the opposite was found with drinking water obtained from other sources: increased nitrates were associated with a decrease in CNS malformations. To assess exposure, the investigators analyzed nitrates in water samples collected at addresses where study subjects lived at the time of delivery. Once again, the study is limited by the lack of information about other possible water contaminants. The contradictory risks associated with drinking water source, independent

174

of nitrate concentration, also suggests that other factors contributed to the observed effects. ^[54]

The Iowa Health Department guidelines state that there is no toxicity under 10 parts per million of nitrates. The reason for toxicity is that infants under 6 months of age exposed to higher levels of nitrates are at risk of methemoglobinemia. Toxic effects of nitrates on pregnant women and fetuses have not been studied extensively, but no adverse effects have been found.

Organic Solvents

Large numbers of women are employed in industries that use organic solvents, and women also may be exposed through use of household products or drinking water contamination. Not surprisingly, concerns have arisen that such exposures may cause any of several adverse reproductive outcomes.

Acute human health effects of high-dose solvent exposure are well known. Central nervous system effects including cortical atrophy, cerebellar degeneration, and loss of intellectual functioning have been documented as a result of chronic, high-dose solvent abuse ("sniffing" or "huffing"). ^[188] Solvent intoxication is an established occupational hazard in such diverse groups as painters and rubber, semiconductor, and dry-cleaning workers. Symptoms may follow inhalation, dermal, or ingestion exposure routes and may include headache, nausea, dizziness, and confusion progressing to CNS depression with loss of consciousness. Chronic exposure to low levels of solvents may lead to neuropsychiatric impairment and peripheral nerve damage. ^[189]

Analogous to the health effects described above, maternal solvent abuse by "sniffing" is reported to cause an embryopathy similar to the fetal alcohol syndrome (FAS), Hersch and associates^[190] described three children with developmental and intellectual impairment, facial dysmorphism, and intrauterine growth restriction whose mothers abused spray paint throughout their pregnancies. Similar dysmorphic features and neurologic impairment have been described in other children born to mothers who chronically abused toluene or unnamed solvents during pregnancy. ^[191] ^[192] ^[193] A fetal solvent syndrome and toluene embryopathy have been described that may be similar in pathogenesis to FAS. ^[194] , ^[195]

At lower levels of maternal exposure there is no clear evidence of embryopathic, fetal, or neurobehavioral adverse effects. Epidemiologic studies have examined reproductive outcomes of occupationally as well as environmentally exposed women. Most occupational studies of this subject are case-control studies, with exposure status based on job descriptions and no actual exposure data available (e.g., air concentrations or duration of exposure). Multiple solvent exposures often are likely. ^[196]

Using occupational codes from birth certificates, Olsen ^[197] reported that mothers who were painters or worked in a laboratory were no more likely than unexposed mothers to have children with CNS, gastrointestinal, or congenital limb anomalies. Heidam ^[198] surveyed Danish women in selected occupations that could result in various chemical exposures. Compared with unexposed women, female painters had a slightly higher risk for spontaneous abortion. In a study of pregnancy outcomes among women employed at a semiconductor manufacturer, Pastides and associates^[199] found an increased risk of spontaneous abortions for women working in the diffusion area. Materials used in the diffusion area include glycol ethers, toxic gases, and various solvents, providing potentially numerous and mixed exposures. Given the small number of pregnancies in exposed and unexposed groups, the authors consider their results as tentative, pointing out the need for larger prospective studies that include monitoring data to quantify exposure. ^[199]

Two subsequent studies have supported the earlier findings of associations between semiconductor manufacturing and spontaneous abortion risk. In a study of IBM employees, investigators from Johns Hopkins University reported an association between spontaneous abortion risk and working with ethylene glycol ethers in "clean rooms" (R.H. Gray, personal communication, 1993). Similarly, a study by investigators at the University of California, Davis, carried out for the Semiconductor Industry Association, found a significant increase in spontaneous abortion risk among fabrication workers. This increase was suggested to be associated with exposure to glycol ethers. ^[200]

Occupational exposure to organic solvents in the first trimester of pregnancy is also associated with an increased risk of major fetal malformation ^[201] (relative risk, 13.0; 95 percent confidence interval, 1.8 to 99.5). The risk is increased in women with symptoms associated with the exposure. ^[201]

On numerous occasions, drinking water contamination by organic solvents has resulted from storage tank leaks or hazardous waste leachate. Affected communities may identify a temporal or geographic clustering of adverse reproductive effects, believing that the contamination has caused the epidemic. To date, there is no published evidence to support such a cause-and-effect relationship, but at least one study demonstrated an increased risk of spontaneous abortions among women during the time that their drinking water supply was contaminated with trichloroethane and other organic solvents. ^[35] A hospital-based study also was undertaken in response to community concerns that there were increased numbers of children born with congenital cardiac anomalies to women living in the contaminated area. The increased prevalence of cardiac anomalies

175

was confirmed but found to be temporally unrelated to the drinking water contamination, making a causal relationship unlikely. [202]

With all the limitations of a questionnaire study, one author found an association between spontaneous abortion and the number of hours worked per day in cosmetology, the number of chemical services performed, and work in salons where nail sculpturing was performed. There was no association among cosmetologists who performed few chemical services or who worked less than 35 hours per week. [203]

In conclusion, toluene and possibly other organic solvents are probably teratogenic at high exposure levels seen with solvent abuse. The risk for the "fetal solvent syndrome" is unknown, and no exposure threshold for effect can be identified at this time. Occupational exposure to organic solvents in the first trimester is also associated with an increased risk of major fetal malformations, [204] especially in women with symptoms.

In a similar vein, when a pregnant woman asks if it is safe for her to paint the baby's nursery, Scialli [204] wisely advises counseling to minimize exposure without giving the impression that paint is an established developmental toxicant. Similar advice can be offered to women who want to color their hair, (e.g., recommending a well-ventilated area).

Anesthetic Gases

Large numbers of women working in medical and dental professions may be exposed occupationally to anesthetic gases, raising serious concerns about the reproductive hazards of such exposures. There is evidence that chronic first-trimester exposure may increase the risk of spontaneous abortion. [205], [206] Despite numerous studies, the question of whether or not a mother's exposure to anesthetic gas increases the risk of her bearing a congenitally malformed infant is still debated. One argument against a causal relationship is that no pattern of malformations has been found in studies reporting increased birth defect rates following maternal exposure during pregnancy. [207] On the other hand, animal studies have shown that anesthetic gases can be teratogenic at concentrations similar to those experienced by operating room personnel in the absence of gas scavenging systems. [208] [209] [210] Some investigators have found increased rates of birth defects in infants born to exposed women and have observed a dose-related effect. [205], [206], [211] In two studies, the rate of congenitally malformed infants was increased among female anesthetists who worked during the first 6 months of pregnancy compared with the rate among female anesthetists who did not work during pregnancy. [212], [213] A criteria document prepared by the National Institute for Occupational Safety and Health (NIOSH) reviews animal data and epidemiologic studies published before 1977. [206] More recent reviews are also available. [214], [215]

In a retrospective study of reproductive outcomes and anesthetic gas exposure in Ontario hospital personnel, Guirguis et al. [216] observed significantly more congenital malformations among female workers with anesthesia exposure than among a comparison group without such exposure. Increases were also observed in wives of exposed males. These findings were based on self-reports, with an excess of minor malformations, and reporting bias is a potential problem. Statistically significantly increased risk of spontaneous abortion was also observed in the exposed cohort.

A recent study in France compared the rates of spontaneous abortions and birth defects in nurses who worked in operating rooms with those of nurses who worked in other departments of the same hospitals. [217] A total of 776 pregnancies was identified among 418 nurses. The rate of spontaneous abortions among nurses who worked in operating rooms during the pregnancy was significantly higher than among nurses working in other parts of the hospital. Self-reported first-trimester exposures to anesthetics, ionizing radiation, formol, and all three were also significantly associated with increased risks of spontaneous abortion. While an increased risk following exposure to antineoplastic agents was reported, it was not statistically significant. The only significantly increased risk of birth defects was observed with formol exposure. Adjusted odds ratios based on logistic regression showed a significantly increased risk of birth defects associated with the combination exposure of anesthetics, ionizing radiation, and formol. The methods suggest that there may be potential recall bias associated with exposures to specific agents that do not apply to the general work location, such as the operating room.

Using a case-control approach, Matte et al. [218] studied potential associations between parental employment in health care occupations and birth defects. Cases for the study came from the Metropolitan Atlanta Congenital Defects Program registry and controls were randomly selected from live births without malformations occurring in the five-county metropolitan Atlanta area. A statistically significant association was observed between maternal employment as a nurse and congenital defects as a group. The risks for several specific birth defects were also significantly elevated for nurses. Of particular relevance to our discussion here, potential maternal exposure to anesthetic gases was significantly associated with risk of spina bifida, based on three exposed cases.

Virtually all epidemiologic studies of exposure to waste anesthetic gas and reproductive outcomes have design problems that affect the interpretation of reported

results. Crude estimates of anesthetic gas exposure have been used because no actual measurements of gas concentrations were available. The specific gases were usually not identified, and exposure to mixtures of anesthetic agents is likely. [206] Many studies have been conducted by survey, with no validation of the responses and, often, poor response rates. In such studies, selection bias cannot be evaluated because there is no information about nonresponders. Also, not validating the reproductive history can lead to misleading results for several reasons. Study subjects may forget or inaccurately recall events that took place years before. Women who think they are exposed to an adverse environmental agent may be more likely to recall having a spontaneous abortion or a child with a minor malformation than are unexposed women. [219] One last problem pertains to the inherent difficulty of studying spontaneous abortions. To avoid the criticism that reported spontaneous abortions were not validated, investigators in one study considered only patients whose spontaneous abortions required them to be hospitalized. [219] The problem with this approach is that women who have spontaneous abortions do not always require hospitalization, particularly if the abortion occurred during the first trimester or before pregnancy was diagnosed.

Specific data are accumulating regarding risks of occupational exposure to nitrous oxide. Rowland et al. [219] reported that exposure to 5 or more hours of unscavenged nitrous oxide per week among a cohort of female dental assistants was statistically significantly associated with reduced fertility. This was based on assessment of time to pregnancy and self-reported nitrous oxide exposure. In a subsequent report from the same cohort, Rowland et al. [219] observed an increased risk of spontaneous abortion among women in the cohort working with nitrous oxide 3 or more hours per week in offices not using scavenging equipment. This recent cohort study has not provided any information on malformation risks. The number of exposed births is too small ($n = 98$) to have sufficient statistical power to yield meaningful results for infrequent events.

Despite problems in study design, epidemiologic evidence supports the view that repeated maternal exposure to waste anesthetic gases during pregnancy should be minimized. Women who work in areas with a potential for repeated anesthetic gas exposure (no gas scavenger system in place) should be aware of the possibility of adverse reproductive effects and decide whether they want to continue to work in the same area during pregnancy or request to be transferred. In settings where anesthetic gases are administered, a gas scavenger system should be used, and particular attention must be given to maintaining that system. A properly functioning gas scavenging system should provide adequate protection from exposure. [206], [222], [223] Because there is always uncertainty about completely avoiding exposure to anesthetic gases, however, a woman with a history of pregnancy loss or having a child with congenital malformations may want to transfer to another work area. [211]

Environmental Contamination and Hazardous Waste Sites

What is the possible role of environmental contamination in causing birth defects? While the topic is controversial and the data are equivocal, there is some evidence that suggests that further study is warranted. Much of the concern focused around specific hazardous waste sites such as Love Canal, New York, and Woburn, Massachusetts. Studies at Love Canal showed an effect on birth weight [224] [225] [226] but no increased risk of congenital malformations. A study at Woburn suggested increased risks of selected birth defects associated with consumption of water from specific wells that had been contaminated with volatile organic compounds. [227] The original Woburn study has been criticized on methodologic grounds, [228] and recently completed studies by the Massachusetts Department of Public Health failed to show elevated birth defect risks. [229]

Three recent studies examined residential proximity to hazardous waste sites, as surrogates for exposure, and the risk of birth defects. Since one of the studies received considerable press coverage, it is worthwhile to examine this issue briefly.

Shaw et al. [32] carried out a case-control study using cases from the California Birth Defects Monitoring Program and controls randomly selected using birth certificate files. Cases and controls came from a five-county area in metropolitan San Francisco. Exposure was defined on the basis of various types of hazardous waste facilities found in the census tract of the mother's residence at the time of the birth of the case or control. It appeared that risk for cardiac/circulatory malformations

was increased for women living near the facilities. When risks were examined by contaminant chemical class, the odds ratios for heart/circulatory malformations were elevated for each class except hydrocarbon solvents, with the odds ratio for cyanides being the highest. Gastrointestinal malformations were associated with hydrocarbon solvents and metals.

In a widely cited study, Geschwind et al.^[31] examined birth defect cases from the New York State Congenital Malformation Registry based on proximity to hazardous waste sites. Cases and controls came from 20 counties in upstate New York, and information on exposure to hazardous waste sites was based on geographic proximity to sites included in a large database. Statistically

significant associations were observed between hazardous waste sites and all birth defects combined and several groups of birth defects (nervous system, musculoskeletal system, and skin). In addition, statistically significant associations were observed between specific types of contaminants and some types of birth defects: pesticides and musculoskeletal system; metals and nervous system; solvents and nervous system; and plastics and chromosomal anomalies. Notably, the observed increases in risk were for the most part small, control of confounding was minimal, there was considerable heterogeneity within the birth defect categories, and the methods used to assign exposure were subject to exposure misclassification.

The potential importance of some of these factors in influencing the results of the Geschwind et al. study is illustrated by a second study in upstate New York. As a follow up, Marshall et al.^[230] studied musculoskeletal system and central nervous system malformations in 18 counties of upstate New York. Their cases included some of the cases studied by Geschwind et al.,^[31] plus additional cases from 2 more recent years. Exposure assessment was based on residential proximity to hazardous waste sites using similar but more precise methods than those employed by Geschwind et al.^[31] In contrast to the earlier study, Marshall et al.^[230] failed to find significant associations between waste site proximity and either group of defects. They did, however, find a statistically significant association between central nervous system malformations and proximity to active industrial facilities. Marshall et al.^[230] attribute the differences between their findings and those reported earlier to uncontrolled confounding, systematic misclassification, or chance. An important difference between the two studies is that the geographic data for the latter study were more refined, allowing for a more accurate determination of residential location.

Dolk et al.^[231] generated more systematic data from seven research centers in five European countries. The seven centers maintained population-based registries of congenital anomalies as part of the EUROCAT Network. Among those within 7 km of a landfill site a total of 1,089 pregnancies with nonchromosomal anomalies occurred; 2,366 control births occurred without malformation. Next, the zone within 3 km was considered the exposed one, and in this zone there was a significantly increased risk for a congenital anomaly. The odds ratio (OR) for residence within 3 km of a landfill site was increased for neural-tube defects (OR, 1.86) cardiac septal defects (OR, 1.49), hypospadias (OR, 1.96), gastroschisis (OR, 3.19), and tracheoesophageal fistula (OR, 2.25); the former two were statistically significant. It was not possible to compare results among individual landfill sites, which obviously were heterogeneous as to composition.

THE OBSTETRICIAN'S ROLE IN EVALUATING REPRODUCTIVE RISKS IN AND BEYOND THE WORKPLACE

Clinical questions about environmental or occupational exposures causing adverse reproductive outcomes are extremely difficult to answer, and the answers are seldom as helpful as they need to be. The difficulty occurs because the exposure for the patient and fetus is seldom known or measurable. If the exposure is known, there is almost never a study of similar exposure, with a sufficient sample size, that enables a physician to give a reliable estimate of risk or lack thereof.

For all the environmental exposures discussed in this chapter, no threshold is known below which no adverse reproductive outcome can be expected. Except for ionizing radiation and mercury, maximum recommended exposure levels are difficult to quantify.

Human data usually consist of case reports, which seldom can establish a hazard and never can quantitate the magnitude of the risk. Epidemiologic studies, when available, often have limitations in design, execution, analysis, or interpretation. Thus, in most cases, the questions must be answered on the basis of reasoned judgments in the face of inadequate data.

The process by which a reasoned judgment can be made is summarized in [Table 7-2](#) and the steps are described below. Paul and Himmelstein^[51] provide a more detailed description of a similar evaluation process, and recent books^[222], ^[223] provide helpful guidance for clinicians.

Paul and Welch^[234] have developed a number of recommendations related to improving education and resources about occupational reproductive hazards. They identify problems in clinical risk evaluation and management and develop proposed solutions, including improving information resources for clinicians and improving education for health care providers.

Assessment of potential adverse health effects or toxicity from a chemical exposure begins with correct identification of the agent(s) ([Table 7-2](#)). As workers increasingly demanded their right to know the identity and toxicity of chemicals, the U.S. Occupational Safety and Health Administration (OSHA) drafted a regulation and state and local governments have passed so-called worker right-to-know laws.^[235] One intent of the regulation and laws is to provide workers and physicians with toxicity information about each chemical used in a given workplace. An information sheet, the Material Safety Data Sheet (MSDS), is developed by the chemical manufacturer or distributor and includes basic identifying and specific toxicity information. Other details of the OSHA regulation and right-to-know laws are reviewed elsewhere.^[236], ^[236]

TABLE 7-2 -- STEPS IN EVALUATING EXPOSURES THAT MAY RESULT IN BIRTH DEFECTS OR OTHER ADVERSE REPRODUCTIVE OUTCOMES

Step/Action	Information Resources
1. Identify the exposure(s)	Material Safety Data Sheet (MSDS)
	Industry (supervisors, industrial hygienists)
2. Characterize extent of exposure(s)	Description of job activities
	Monitoring data (e.g., air sampling, radiation badge)
	Assess exposure routes
3. Hazard evaluation	Biologic sampling (e.g., lead, mercury)
	Health professionals (occupational/industrial physicians, medical toxicologists, geneticists)
	Regional poison control centers
	Teratology information services (National Institute for Occupational Safety and Health [NIOSH] Criteria Documents, Technical Bulletins) State Health Departments
4. Risk assessment/judgment	On-line databases (National Library of Medicine, Environmental Teratology Information Center, Environmental Mutagen, Carcinogen and Teratogen Department, ReproTox)
	Textbooks, periodicals
	Steps 12
	Patient's family, medical, and reproductive history, other relevant exposures (e.g., alcohol, tobacco, drugs of abuse), background risk

Obstetricians should be aware that copies of MSDSs are available upon request from an employer to any woman who may be occupationally exposed to a hazardous chemical. Unfortunately, these MSDSs have been found to be of very limited usefulness for assessing reproductive hazards.^[237] Supervisors, managers, and industrial hygienists may be able to provide additional identification, particularly when chemicals are mixed or modified through heating or industrial processes.

The next step is to characterize the extent to which the patient may be exposed. This can be relatively easy for substances such as lead and other heavy metals quantifiable in blood or urine. The radiation badge properly worn can provide exposure monitoring and should be checked frequently during pregnancy. OSHA has published occupational exposure standards for a large number of chemicals associated with adverse health effects.^[119] These chemicals and agents must be monitored in the workplace, and such data may be helpful for exposure assessment.

Most often, however, no biologic or environmental data are available. Instead, the clinician must rely on a detailed description of the patient's job activities, precautions taken to avoid exposure (e.g., gloves, respirator, protective clothing, hand washing), and any clinical signs or symptoms suggesting excess exposure. All feasible routes of exposure should be considered, including ingestion (common if handwashing is not done before eating), inhalation (especially if hot vapors or odorless gases are produced), and dermal absorption (increased through irritated skin or prolonged contact with contaminated clothing). Similar considerations apply

to nonoccupational exposures as well.

The third step is hazard evaluation. In this context, the physician must determine what is known of the reproductive effects of the chemicals or agents. Since no one can be all-knowing and no single information resource is sufficient for all patient questions, prudence dictates consulting a variety of sources. Physicians specializing in occupational or industrial medicine, medical toxicology, and genetics can be helpful. Such physicians may be affiliated with regional genetics centers or certified regional poison control centers. These centers may be able to recommend other helpful consultants as well. Numerous teratology information services (TISs) provide no-cost physician and patient telephone consultation. These services may vary considerably in how the consultation is provided, whether follow-up is done, nature of the staff qualifications, and the extent of medical supervision. In 1994, the Council of Regional Networks for Genetic Services and the Organization of Teratology Information Services developed a framework for the provision of teratology information services. ^[239] This framework is an important step toward the development of recommendations for strengthening existing programs and approaches to quality assurance.

Some TISs provide a written copy of the consultation to the referring obstetrician. One university-affiliated TIS maintains and updates a reproductive toxicology database (ReproTox) containing summaries of more than 3,000 chemicals and agents. ^[239] Obstetricians who choose to refer patients to any of these services should be familiar with the kinds of information and follow-up provided.

The National Library of Medicine in Bethesda, Maryland, maintains several files on the TOXNET database system, including reproductive and developmental toxicology information in bibliographic or text form. Examples include Developmental and Reproductive Toxicology (DART), GENE-TOX (genetic toxicology),

and Environmental Mutagen Information Center (EMIC).

A variety of options are available for searching these databases, including personal computer software (Grateful Med, commercial services) and CD-ROM copies in medical libraries or leased from commercial versions. Information is available from a TOXNET representative, National Library of Medicine, Specialized Information Services, 8600 Rockville Pike, Bethesda, MD 20894, (301)496-6531.

Another federal resource is NIOSH, which publishes current recommendations for occupational exposure to a variety of agents or compounds. NIOSH also has a technical information service at its Cincinnati, Ohio, headquarters that may be able to provide in-house reports of investigations as well as NIOSH technical bulletins and criteria documents.

The American College of Obstetricians and Gynecologists publishes guidelines for several occupational exposures during pregnancy. ^[223] These guidelines include information about metals, solvents, and radiation agents that also may be found as environmental contaminants.

Many state health or labor departments have a division responsible for occupational health issues. Staff may have expertise in industrial hygiene and safety, occupational medicine, and reproductive epidemiology and toxicology. Specific concerns about hazardous occupational exposures or adverse reproductive outcomes related to workplace exposures should be addressed to this division. In addition, state health departments may be helpful in evaluating associations between environmental exposures and adverse reproductive outcomes. Numerous off-the-shelf information resources include texts, ^[9], ^[10], ^[196], ^[232], ^[233], ^[240], ^[241] review articles, ^[51], ^[73], ^[141], ^[244], ^[246], ^[247], ^[248] and periodicals.

The final and most difficult step is formulating an assessment of risk. Chemical identity, extent of exposure, and the reproductive toxicity of the agent must be known. Unfortunately, all these necessary pieces of information are rarely available. If the exposure is known, available information rarely enables a physician to give a reliable estimate of risk. Thus, risk assessment is really a process of reasoned judgment as opposed to a quantitative estimate of risk. Formulating this judgment requires consideration of many factors, including the best estimate of the nature, extent, duration, and timing of exposure; the patient's medical, reproductive, and genetic history; lifestyle habits (especially tobacco, alcohol, and drugs-of-abuse); and, of course, reproductive toxicity information about the agent. Equally important, the patient should understand that with every pregnancy there is always a background risk for an adverse outcome. Birth defects and other adverse outcomes of pregnancy are relatively common events; approximately 12 to 15 percent of pregnancies result in a spontaneous abortion, and birth defects are observed in approximately 3 percent of all newborns. Frustrating though it is, the fact remains that it is usual *not* to know the cause for a given adverse outcome.

After completing this assessment process, the physician will be more familiar with and understand limitations of available information about a particular agent or chemical. The patient's exposure can be considered in the context of other relevant medical information, and this should be explained to the patient in non-technical language. The physician may be able to recommend ways to decrease or minimize maternal exposure and determine if closer monitoring of the pregnancy is warranted.

CONCLUSION

Experimental studies in laboratory animals have identified a number of agents that are capable of causing abnormal development. While we know less about substances that are teratogenic in humans, a limited number of teratogenic drugs and chemicals have been identified. There is increasing evidence that some chemicals found in the occupational setting or in the ambient environment may be reproductive or developmental toxicants. While some of this evidence is for associations between exposures and congenital malformations, our interpretation is that there is more evidence for spontaneous abortions associated with occupational exposures than for congenital malformations. Since we believe that spontaneous abortion is one part of a spectrum of outcomes potentially associated with teratogenic exposures, agents that increase risks for spontaneous abortion are also likely to increase risks for congenital malformations.

It is important to refine exposure assessment and to improve outcome ascertainment to enhance epidemiologic studies that help determine the extent to which occupational and environmental exposures may contribute to birth defects and other adverse reproductive outcomes. This is particularly the case for studies of environmental contamination where residential location has commonly been used as a surrogate for exposure. Better exposure assessment and outcome ascertainment may also lead us to an improved understanding of how such teratogens produce their effects so we can design and test intervention/prevention strategies. In the meantime, prenatal counseling about most occupational and environmental exposures requires a large measure of reasoned judgment and interpretation of imperfect/imprecise animal and epidemiologic data.

Key Points

Teratogens and high-dose occupational toxins have been shown to cause not only structural birth defects but also intrauterine death, growth restriction, and functional abnormalities.

Understanding the principles of teratogenesis can help in identifying and understanding the causes of abnormal development.

Exposure to high-dose ionizing radiation during gestation has been shown to cause microcephaly and mental retardation, but effects of low-dose exposures on the conceptus have not been identified.

Prenatal exposure to metals, such as lead and mercury, has been shown to have adverse effects on the development and function of the central nervous system.

Doses required for deleterious effects are high, usually above ambient exposures.

The herbicides dioxin and Agent Orange are unlikely to increase the frequency of birth defects in offspring subsequently sired by Vietnam war veterans exposed during combat, despite the politically charged nature of allegations.

High doses of polychlorinated biphenyls (PCBs), once ingested in Taiwan through contaminated cooking oil, cause a recognizable pattern of abnormalities: postnatal and prenatal low birth weight, skin hyperpigmentation, and skull calcifications.

Effects of low-dose PCB contamination, through environmental contamination (e.g., eating Great Lakes fish contaminated with PCBs) is uncertain; however, even the largest effect reported alleges no more than a 6.2-point decrease in IQ.

Organic solvent exposure in high doses (e.g., chronic "sniffing") causes teratogenic effects similar to the fetal alcohol syndrome; in lower level exposure (e.g., occupational), the risk is less, although some reports suggest an increased risk for spontaneous abortion.

Concerns have been raised about the reproductive and developmental effects of pregnancies near toxic waste sites. Data are difficult to generate, but increased anomalies plausibly have been observed close to the site.

Occupational exposures to anesthetic gases have been associated with increased risks for spontaneous abortions and birth defects in some studies.

Chapter 8 - Genetic Counseling and Prenatal Diagnosis

Joe Leigh Simpson

Approximately 3 percent of liveborn infants have a major congenital anomaly. About one half of these anomalies are detected at birth; the remainder become evident later in childhood or, less often, adulthood. Although nongenetic factors may cause malformations, genetic factors are usually responsible. In addition, more than 50 percent of first-trimester spontaneous abortions and at least 5 percent of stillborn infants show chromosomal abnormalities ([see Chapter 22](#)). Given such an important role for genetic factors, knowledge of medical genetics clearly becomes integral to the practice of modern obstetrics.

This chapter first considers the principles of genetic counseling and genetic screening. Thereafter, disorders amenable to genetic screening and prenatal diagnosis are discussed.

Gabbe: *Obstetrics - Normal and Problem Pregnancies, 4th ed.* , Copyright © 2002 Churchill Livingstone, Inc.

FREQUENCY OF GENETIC DISEASE

Phenotypic variation normal or abnormal may be considered in terms of several etiologic categories: (1) chromosomal abnormalities, numerical or structural; (2) single-gene or mendelian disorders; (3) polygenic and multifactorial disorders, polygenic implying an etiology resulting from cumulative effects of more than one gene and multifactorial implying interaction as well with environmental factors; and (4) teratogenic disorders, caused by exposure to exogenous factors (e.g., drugs) that deleteriously affect an embryo otherwise destined to develop normally. Principles of these mechanisms are reviewed elsewhere.^[1]

Chromosomal Abnormalities

From surveys of more than 50,000 liveborn neonates, it has been established that the incidence of chromosomal aberrations is 1 in 160. [Table 8-1](#) shows the incidences of individual abnormalities.^[2]

Single-Gene Disorders

Approximately 1 percent of liveborns are phenotypically abnormal as a result of a single-gene mutation. Several thousand single-gene (mendelian) disorders have been recognized, and many more are suspected.^[3] However, even the most common mendelian disorders (cystic fibrosis in whites, sickle cell anemia in blacks, -thalassemia in Greeks and Italians, -thalassemia in Southeast Asians, Tay-Sachs disease in Ashkenazi Jews) are individually rare. In aggregate, however, mendelian disorders account for 40 percent of the congenital defects seen in liveborn infants.

Polygenic/Multifactorial Disorders

Another 1 percent of neonates are abnormal but possess a normal chromosomal complement and have not undergone mutation at a *single* genetic locus. As will be discussed below, it can be deduced that several different genes are involved (polygenic/multifactorial inheritance).^[4]

Disorders in this etiologic category include most common malformations limited to a single organ system. These include hydrocephaly, anencephaly, and spina bifida (neural tube defect [NTDs]); facial clefts (cleft lip and palate); cardiac defects; pyloric stenosis; omphalocele; hip dislocation; uterine fusion defects; and club foot (see the box, Polygenic/Multifactorial Traits). After the birth of one child with such anomalies, the

TABLE 8-1 -- CHROMOSOMAL ABNORMALITIES IN LIVEBORN INFANTS

Type of Abnormality	Incidence
Numerical aberrations	
Sex chromosomes	
47,XYY	1/1,000 MB
47,XXY	1/1,000 MB
Other (males)	1/1,350 MB
47,X	1/10,000 FB
47,XXX	1/1,000 FB
Other (females)	1/2,700 FB
Autosomes	
Trisomies

Total	1/160 LB

LB, live births; MB, male births; FB, female births.

Pooled data tabulated by Hook and Hamerton.^[2]

recurrence risk in subsequent progeny is usually 1 to 5 percent.^[3] This frequency is less than would be expected if only a single gene were responsible but greater than that for the general population. The recurrence risks for malformations are also 1 to 5 percent for offspring of affected parents. That recurrence risks are similar for both siblings and offspring diminishes the likelihood that environmental causes are the exclusive etiologic factor because it is unlikely that households in different generations would be exposed to the same teratogen. Further excluding environmental factors as sole etiologic agents are observations that monozygotic twins are much more often concordant (similarly affected) than are dizygotic twins, despite both types of twins sharing a common intrauterine environment.

The above observations are best explained on the basis of polygenic/multifactorial inheritance. Although more than one gene is involved, only a few genes are necessary to produce the number of genotypes necessary to explain recurrence risks of 1 to 5 percent. That is, large numbers of genes and complex mechanisms need *not* be invoked. Polygenic/multifactorial etiology can thus plausibly be assumed responsible for most liveborns who have an anomaly of a single organ system and who have neither a chromosomal abnormality nor a mendelian mutation.

Polygenic/Multifactorial Traits[*]
Hydrocephaly (excepting some forms of aqueductal stenosis and Dandy-Walker syndrome)
Neural tube defects (anencephaly, spina bifida, encephalocele)
Cleft lip, with or without cleft palate
Cleft lip (alone)
Cardiac anomalies (most types)
Diaphragmatic hernia
Pyloric stenosis
Omphalocele
Renal agenesis (unilateral or bilateral)
Ureteral anomalies
Posterior urethral valves
Hypospadias
Müllerian fusion defects
Müllerian aplasia
Limb reduction defects
Talipes equinovarus (clubfoot)

* Relatively common traits considered to be inherited in polygenic/multifactorial fashion. For each, normal parents have recurrence risks of 1 to 5 percent after one affected child. After two affected offspring, the risk is higher.

Teratogenic Disorders

Perhaps 20 proved teratogens are known, as reviewed in [Chapter 9](#). Although many other agents are suspected teratogens, the quantitative contribution of known teratogens to the incidence of anomalies seems relatively small (with the possible exception of alcohol).

CLINICAL SPECTRUM OF CHROMOSOMAL ABNORMALITIES

A few generalizations concerning chromosomal disorders can be offered that may prove helpful to the obstetrician, who may encounter such abnormalities during prenatal studies or in the delivery room. In this section we briefly review the clinical and cytogenetic features characteristic of the common numerical chromosomal abnormalities. Standard genetic texts cover the broader

spectrum of rare (mosaic) trisomies and autosomal duplications or deficiency syndromes.

Autosomal Trisomy

Trisomy 21

Trisomy 21 (Down syndrome, mongolism) is the most frequent autosomal chromosomal syndrome, occurring in 1 of every 800 liveborn infants (Table 8-1). The relationship to advanced maternal age is well known. Characteristic craniofacial features include brachycephaly, oblique palpebral fissures, epicanthal folds, broad nasal bridge, a protruding tongue, and small, low-set ears with an overlapping helix and a prominent antihelix (Fig. 8-1). The mean birth weight in Down syndrome, 2,900 g, is decreased but not so much as in some other autosomal syndromes. At birth, these infants are usually hypotonic. Other features include iridial Brushfield's spots, broad short fingers (brachymesophalangia), clinodactyly (incurving deflections resulting from an abnormality of the middle phalanx), a single flexion crease on the fifth digit, and an unusually wide space between the first two toes. A single palmar crease (simian line) is not pathognomonic, being present in only 30 percent of individuals with trisomy 21 and in 5 percent of normal individuals. Relatively common internal anomalies include cardiac lesions and duodenal atresia. Cardiac anomalies and increased susceptibility

Figure 8-1 An infant with trisomy 21. (From Simpson JL, Elias S: *Genetics in Obstetrics and Gynecology*, 3rd ed. Philadelphia, WB Saunders Company, [in press], with permission.)

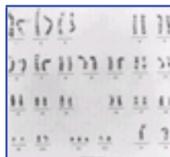

Figure 8-2 Karyotype of a trisomy 21 cell. Trypsin-Giemsa (GTG) banding. (From Simpson JL, Elias S: *Genetics in Obstetrics and Gynecology*, 3rd ed. Philadelphia, WB Saunders Company, [in press], with permission.)

to both respiratory infections and leukemia contribute to a reduced life expectancy. However, the mean survival is still into the fifth decade, and many affected individuals survive to older ages.

Patients with Down syndrome who survive beyond infancy invariably exhibit mental retardation. However, the degree of retardation is generally not as severe as that of many other chromosomal aberrations. Mean IQ ranges approximately from 25 to 70; 46/47, +21 mosaicism should be suspected if Down syndrome cases show IQs in the 70 to 80 range. Females are fertile. Although relatively few trisomic mothers have reproduced, about 30 percent of their offspring are also trisomic. Except possibly very exceptional cases, affected males are not fertile.

Several different cytogenetic mechanisms may be associated with Down syndrome, which is actually the result of triplication of a small portion of chromosome 21, namely, band q22. This triplication may be caused either by the presence of an entire additional chromosome 21 or by addition of only band q22. Of all cases of Down syndrome, 95 percent have primary trisomy (47 instead of the normal 46 chromosomes) (Fig. 8-2). These cases show the well-known relationship to maternal age effect. Autosomal trisomies usually originate in maternal meiosis, especially meiosis I.

Translocations show no definite relationship to parental age and may be either sporadic or familial. The translocation most commonly associated with Down syndrome involves chromosomes 14 and 21. With translocation Down syndrome [t(14q;21q)], one parent

may have the same translocation chromosome, that is, 45,t(14q;21q). For parents with a translocation, the recurrence risk for a child with an unbalanced chromosome complement far exceeds the risk for recurrence of nondisjunction (1 percent). Empiric risks are approximately 10 percent for offspring of female translocation heterozygotes and 2 percent for offspring of male translocation heterozygotes.

Other structural rearrangements resulting in Down syndrome include t(21q;21q), t(21q;21q), and translocations involving chromosome 21 and chromosomes other than a member of group D (13 to 15) or G (21 to 22). In t(21q;21q) no normal gametes can be formed. Thus, only trisomic or monosomic zygotes are produced, the latter presumably appearing as preclinical embryonic losses. Parents having the other translocations have a low empiric risk of having offspring with Down syndrome.

Trisomy 13

Trisomy 13 occurs in about 1 per 20,000 live births. Intrauterine and postnatal growth retardation are pronounced, and developmental retardation is severe. Nearly 50 percent of affected children die in the first month, and relatively few survive past 3 years of age. Characteristic anomalies include holoprosencephaly, eye anomalies (microphthalmia, anophthalmia, or coloboma), cleft lip and palate, polydactyly, cardiac defects, and low birth weight. Other relatively common features include

cutaneous scalp defects, hemangiomas on the face or neck, low-set ears with an abnormal helix, and rocker-bottom feet (convex soles and protruding heels).

Trisomy 13 is usually associated with nondisjunctional (primary) trisomy (47,+13). As in trisomy 21, a maternal age effect exists. Translocations are responsible for less than 20 percent of cases, invariably associated with two group D (13 to 15) chromosomes joining at their centromeric regions (Robertsonian translocation). If neither parent has such a rearrangement, the risk for subsequent progeny is not increased. If either parent has a balanced 13q;14q translocation, the recurrence risk for an affected offspring is increased, but only to 1 to 2 percent. Homologous 13q;13q parental translocation carries the same dire prognosis as 21q;21q translocation.

Trisomy 18

Trisomy 18 occurs in 1 per 8,000 live births. Among liveborn infants, females are affected more often than males (3:1). Among stillborns and abortuses, however, the sex distribution is more equal.

Facial anomalies characteristic of trisomy 18 include microcephaly, prominent occiput, low-set and pointed "fawn-like" ears, and micrognathia. Skeletal anomalies include overlapping fingers (V over IV, II over III), short sternum, shield chest, narrow pelvis, limited thigh abduction or congenital hip dislocation, rocker-bottom feet with protrusion of the calcaneum, and a short dorsiflexed hallux ("hammer toe"). Cardiac and renal anomalies are common.

Mean birth weight (2,240 g) is below average. The mean survival time for these infants is only a few months. Those surviving show pronounced developmental and growth retardation. Fetal movement is feeble, and approximately 50 percent develop fetal distress during labor. Trisomy 18 is often detected among stillborn infants not clinically suspected of being trisomic.

Approximately 80 percent of trisomy 18 cases are caused by primary nondisjunction (47,XX,+18 or 47,XY,+18). In such cases, the recurrence risk is about 1 percent.

Other Autosomal Trisomies

Trisomies exist for all autosomes, but usually these terminate as abortuses. Trisomies for several chromosomes (8, 9, 14, 16, and 22) exist in nonmosaic forms. Mosaic trisomy exists for chromosome 16 and other chromosomes. All show mental retardation, various somatic anomalies, and intrauterine growth retardation. The extent of retardation and the spectrum of anomalies vary.

Autosomal Deletions or Duplications

Deletions or duplications of portions of autosomes also exist. All are characterized by mental retardation and somatic anomalies, but their specific features vary. One example will suffice for illustrative purposes.

In counseling, one should exclude parental chromosomal rearrangements like a balanced translocation or inversion ([see Chapter 7](#)). If the deletion is sporadic, the recurrence risk is no greater than that for any other couple of comparable parental ages.

Sex Chromosomal Abnormalities

Monosomy X (45,X)

45,X individuals account for approximately 40 percent of gonadal dysgenesis cases ascertained by gynecologists. The incidence of 45,X in liveborn females is about 1 in 10,000. Because monosomy X accounts for 10 percent of all first-trimester abortions, it can be calculated that more than 99 percent of 45,X conceptuses must end in early pregnancy loss.

Gonadal dysgenesis is usually associated with an abnormal sex chromosomal constitution. Associated complements include not only monosomy X but structural

abnormalities of the X. Mosaicism is frequent, usually involving a coexisting 45,X cell line. Both the long arm and the short arm of the X chromosome contain determinants necessary for ovarian differentiation and for normal stature, as discussed in detail elsewhere. ^[4]

45,X individuals not only have streak gonads but invariably are short (<150 cm). Growth hormone treatment increases the final adult height 6 to 8 cm. Various somatic anomalies exist: renal and cardiac defects, skeletal abnormalities like cubitus valgus and clinodactyly, vertebral anomalies, pigmented nevi, nail hypoplasia, and a low posterior hairline. Performance IQ is lower than verbal IQ, but mentation should be considered normal. Adult-onset diseases include hypertension and diabetes mellitus.

Klinefelter Syndrome

Males with two or more X chromosomes have small testes, azoospermia, elevated follicle-stimulating hormone (FSH) and luteinizing hormone (LH) levels, and decreased testosterone. The most frequent chromosomal complement associated with this phenotype is 47,XXY; 48,XXX and 49,XXXXY occur less often.

Mental retardation is uncommon in 47,XXY Klinefelter syndrome, although behavioral problems and dyslexia are not rare. Mental retardation is invariably associated with 48,XXX and 49,XXXXY. Skeletal, trunk, and craniofacial anomalies occur infrequently in 47,XXY but are commonly observed in 48,XXX and 49,XXXXY. Regardless of the specific chromosomal complement, patients with Klinefelter syndrome all have unquestioned male phenotypes. The penis may be hypoplastic, but hypospadias is uncommon. Sterility has traditionally been considered certain, but with intracytoplasmic sperm injection (ICSI) and other assisted reproductive technologies (ART) the prognosis is more hopeful.

Polysomy X in Females (47,XXX; 48,XXXX; 49,XXXXX)

About 1 in 800 liveborn females has a 47,XXX complement. 47,XXX individuals are more likely to show mental retardation than are individuals in the general population, and they show IQs 10 to 15 points lower than their sibs. However, the absolute risk for mental retardation does not exceed 5 to 10 percent, and even then IQ is usually 60 to 80. Most 47,XXX patients have a normal reproductive system. The theoretical risk of 47,XXX women delivering an infant with an abnormal chromosomal complement is 50 percent, given one half the maternal gametes carrying 24 chromosomes (24,XX). However, the empiric risk is much less. Somatic anomalies may or may not be more frequent in 47,XXX individuals than in 46,XX females. However, 48,XXXX and 49,XXXXX individuals are invariably retarded and more likely to have somatic malformations than 47,XXX individuals.

Polysomy Y in Males (47,XYY and 48,XXYY)

The presence of more than one Y chromosome is also a frequent chromosomal abnormality in liveborn males (1 in 1,000). Controversy notwithstanding, 47,XYY males seem more likely than 46,XY males to be tall and display sociopathic behavior. The precise prevalence of these features is unknown, but one estimate is that 1 percent of 47,XYY males will be incarcerated compared with 0.1 percent of 46,XY males. 47,XYY males usually have normal male external genitalia.

GENETIC HISTORY

All obstetrician-gynecologists must attempt to determine whether a couple, or anyone in their family, has a heritable disorder or is at increased risk for abnormal offspring. To address this question, some obstetricians find it helpful to elicit genetic information through the use of questionnaires or check lists that are often constructed in a manner that requires action only to positive responses. [Figure 8-3](#) reproduces a form that has been modified from that recommended by the American College of Obstetricians and Gynecologists (ACOG).

One should inquire into the health status of first-degree relatives (siblings, parents, offspring), second-degree relatives (nephews, nieces, aunts, uncles, grandparents), and third-degree relatives (first cousins, especially maternal). Adverse reproductive outcomes such as repetitive spontaneous abortions, stillbirths, and anomalous liveborn infants should be pursued. Couples having such histories should undergo chromosomal studies in order to exclude balanced translocations. Genetic counseling may prove sufficiently complex to warrant referral to a clinical geneticist, or it may prove simple enough for the well-informed obstetrician to manage. If a birth defect exists in a second-degree relative (uncle, aunt, grandparent, nephew, niece) or third-degree relative (first cousin), the risk for that anomaly will usually not prove substantially increased over that in the general population. For example, identification of a second- or third-degree relative with an autosomal recessive trait places the couple at little increased risk for an affected offspring, an exception being if the patient and her husband are consanguineous. However, a maternal first cousin with an X-linked recessive disorder would

Figure 8-3 Questionnaire for identifying couples having increased risk for offspring with genetic disorders. (Modified from a form recommended by the American College of Obstetricians and Gynecologists: *Antenatal Diagnosis of Genetic Disorders. Technical Bulletin No. 108. Washington, DC, ACOG, 1987.*)

identify a couple at increased risk for a similar occurrence.

Parental ages should also be recorded. Advanced maternal age ([Table 8-2](#)) warrants discussion irrespective of a physician's personal convictions regarding pregnancy termination, as knowledge of an abnormality may affect obstetric management. Ethnic origin should be recorded. The above applies for both gamete donors as well as couples achieving pregnancy by natural means.

GENETIC COUNSELING

Although genetic counseling may require referral to a clinical geneticist, it is impractical for obstetricians to refer all patients with genetic inquiries. Indeed, obstetricians performing diagnostic procedures such as amniocentesis must counsel their patients before such a procedure. Salient principles of the genetic counseling process will therefore be described.

Data from Hook^[112] and Hook et al.^[113]

* Because sample size for some intervals is relatively small, confidence limits are sometimes relatively large. Nonetheless, these figures are suitable for genetic counseling. 47,XXX excluded for ages 20 to 32 (data not available).

Communication

A first principle of counseling is to communicate in terms that are readily comprehensible to patients. It is useful to preface remarks with a few sentences recounting the major causes of genetic abnormalities: cytogenetic, single-gene, polygenic/multifactorial (can be labeled "complex"), and environmental (teratogens). Writing unfamiliar words and using tables or diagrams to reinforce important concepts is helpful. Repetition is essential. Allow the couple not only to ask questions but to talk with one another to formulate their concerns.

Written information (letters or brochures) can serve as a couple's permanent record, allaying misunderstanding and assisting in dealing with relatives. Preprinted forms describing common problems (e.g., advanced maternal age) have the additional advantage of emphasizing that the couple's problem is not unique. More

complicated scenarios require a letter.

Irrespective of how obvious a diagnosis may seem, confirmation is always obligatory. Accepting a patient's verbal recollection does not suffice, nor would accepting a diagnosis made by a physician not highly knowledgeable about the condition. The anomalous individual may need to be examined by the appropriate authority, and examining first-degree relatives may be required as well if the possibility of an autosomal dominant disorder (e.g., neurofibromatosis) exists. If a definitive diagnosis cannot be made, the physician should not hesitate to say so. Proper counseling requires proper diagnosis.

Nondirective Counseling

In genetic counseling, one should provide accurate genetic information yet ideally dictate no particular course of action. Of course, completely nondirective counseling is probably unrealistic. For example, a counselor's unwitting facial expressions may expose his or her unstated opinions. Merely offering antenatal diagnostic services implies approval. Despite the difficulties of remaining truly objective, one should attempt merely to provide information and then support the couple's decision.

Psychological Defenses

Psychological defenses permeate genetic counseling. If not appreciated, these defenses can impede the entire counseling process. Anxiety is low in couples counseled for advanced maternal age or for an abnormality in a distant relative. As long as the anxiety level remains low, comprehension of information is usually not impaired. However, couples who have experienced a stillborn infant, an anomalous child, or multiple repetitive abortions are more anxious. Their ability to retain information may be hindered.

Couples experiencing abnormal pregnancy outcomes manifest the same grief reactions that occur after the death of a loved one: denial, anger, guilt, bargaining, resolution. One should pay deference to this sequence by not attempting definitive counseling immediately after the birth of an abnormal neonate. Parents must be supported at that time, and the obstetrician should avoid discussing specific recurrence risks for fear of adding to the immediate burden. By 4 to 6 weeks the couple has begun to cope and is more receptive to counseling.

An additional psychological consideration is that of parental guilt. One naturally searches for exogenous

factors that might have caused an abnormal outcome. In the process of such a search, guilt may arise. Conversely, a tendency to blame the spouse may be seen. Usually, guilt or blame is not justified, but occasionally the "blame" is realistic (e.g., in autosomal dominant traits). Fortunately, most couples can be assured that nothing could have prevented a given abnormal pregnancy.

Appreciating the psychological defenses described above helps one to understand the failure of ostensibly intelligent and well-counseled couples to comprehend genetic information.

GENETIC SCREENING

Genetic screening implies routine monitoring for the presence or absence of a given condition in apparently normal individuals. Screening is now offered routinely for (1) all individuals of certain ethnic groups to identify those individuals heterozygous for a given autosomal recessive disorder (Table 8-3), (2) all pregnant women to detect elevated maternal serum -fetoprotein for diagnosis of fetal neural tube defects, (3) all pregnant women 35 years of age and above to undergo invasive tests and to detect Down syndrome, and (4) all pregnant women *under* age of 35 years to undergo maternal serum screening to detect Down syndrome.

Neonatal Screening

One could theoretically screen neonates for many other genetic disorders. On the other hand, screening is actually recommended for relatively few disorders because prerequisites essential for initiating screening programs are not usually met. A first prerequisite is that wide-spread testing is ordinarily performed only if an abnormal finding would alter clinical management. In the United States, neonates are mandated to be evaluated for phenylketonuria and hypothyroidism, both amenable to dietary or hormonal treatment. Many states screen for additional disorders, such as sickle cell anemia, 21-hydroxylase deficiency (congenital adrenal hyperplasia), and other metabolic disorders. A recent addition is deafness, which is often genetic in origin. Screening is not attempted for neonates with untreatable disorders. Thus, neonatal screening is not recommended

TABLE 8-3 -- GENETIC SCREENING IN VARIOUS ETHNIC GROUPS

Ethnic Group	Disorder	Screening Test	Definitive Test
Ashkenazi Jews	Tay-Sachs disease	Decreased serum hexosamidase-A, possibly molecular analysis	Chorionic villus sampling (CVS) or amniocentesis for enzymatic assay or molecular analysis to detect affected fetus
	Canavans disease	DNA analysis to detect most common alleles	CVS or amniocentesis for molecular analysis to detect affected fetus
African-Americans	Sickle cell anemia	Presence of sickle cell hemoglobin, confirmatory hemoglobin electrophoresis	CVS or amniocentesis for genotype determination (direct molecular analysis)
Mediterranean people	-Thalassemia	Mean corpuscular volume (MCV) < 80%, followed by hemoglobin electrophoresis	CVS or amniocentesis for genotype determination (direct molecular analysis or linkage analysis)
Southeast Asians and Chinese (Vietnamese, Laotian, Cambodian, Filipino)	-Thalassemia	MCV < 80%, followed by hemoglobin electrophoresis	CVS or amniocentesis for genotype determination; (direct molecular studies) (direct linkage analysis)
All ethnic groups	Cystic fibrosis	DNA analysis of specified panel of 25 CFTR mutations (those present in 0.1% of the general U.S. population)	CVS or amniocentesis for genotype determination; definitive diagnosis on all fetuses is not possible, sensitivity varying by ethnic group
	In Caucasians and Ashkenazi Jews should be offered; in other ethnic groups (Asians, Hispanics, African-Americans should be made available)		

for chromosomal abnormalities, Tay-Sachs disease, and Duchenne muscular dystrophy.

Adult Screening

Adult population screening for Tay-Sachs disease, - and -thalassemia, and sickle cell anemia is reasonable in order to determine whether they are heterozygous for autosomal recessive disorders amenable to prenatal diagnosis. Table 8-3 lists disorders for which screening is currently recommended. The most well-known example in the United States is Tay-Sachs disease, an autosomal recessive disorder for which Ashkenazi Jews are at increased risk (heterozygote frequency, 1 in 27). In the United States, Jewish individuals may be uncertain whether they are of Ashkenazic or Sephardic descent (90 percent are Ashkenazi); thus, obstetricians should screen all Jewish couples, and possibly also couples in which only one partner is Jewish. The most recent conditions for which genetic screening can be considered standard are cystic fibrosis (see below) and Canavans disease. Ashkenazi Jews may also benefit from screening for Gaucher disease and Nieman-Pick disease (as well as Tay-Sachs, Canavans, and cystic fibrosis [CF]).⁶⁵ In aggregate, the likelihood of an Ashkenazi Jewish individual being heterozygous for one of these five autosomal recessive disorders is 1 in 7. Heterozygote detection for -thalassemia in Italians and Greeks relies on measurement of mean corpuscular volume (MCV), as does screening for -thalassemia in Southeast Asians and Filipinos. Greater than 80 percent excludes heterozygosity for - or -thalassemia. Values less than 80 percent are more likely to reflect iron deficiency anemia than heterozygosity, so additional confirmatory tests are indicated to exclude heterozygosity for the thalassemias. Genes for all the above disorders have been isolated and cloned. However, molecular heterogeneity is enormous for all except sickle cell anemia (see below for further discussion). Thus, screening preferentially still utilizes the methods listed in Table 8-3. Possible exceptions include sickle cell anemia and Tay-Sachs disease. In the latter, molecular testing is equal but not superior to enzyme testing in the Ashkenazi Jewish population.⁶⁶

Population Screening for Cystic Fibrosis

Routine screening is now standard for cystic fibrosis, but not without difficulty. Recommendations have recently become available as a result of a joint effort of ACOG, the American College of Medical Genetics (ACMG), and the National Institutes of Health (NIH) Genome Center. The gene is large (27 exons) and its gene product is a chloride channel. About 75 percent of the cystic fibrosis mutations are caused by deletion of amino acid 508 (F508), resulting in loss of a phenylalanine residue (Fig. 8-4). About 50 percent of couples at risk for cystic fibrosis offspring can be identified by screening solely for this mutation, offering unequivocal prenatal diagnosis. However, detecting the remaining couples at risk for cystic fibrosis is more difficult. Screening only for F508 would uncover couples in which one parent has the F508 mutation but the other does not. If one parent has F508 but the other does not, the actual risk of that couple having an affected child is 1 in 400. Amniotic fluid

analysis for the cystic fibrosis gene product (protein) is not yet available, meaning prenatal diagnosis is not possible except to exclude the fetus who inherited the F508 from the known heterozygous parent.

The obvious solution is to detect other mutations within the cystic fibrosis locus. Unfortunately, except for one specific mutation (W1282X) in Ashkenazi Jews, all other mutations are individually rare. [Figure 8-5](#) shows increasing detection rate in northern European Caucasian and Ashkenazi Jewish populations as increasing numbers of CF-causing alleles are sought. Sensitivity reaches an asymptote, not exceeding 90 to 97 percent in the two ethnic groups, respectively. Thus, not all at-risk pregnancies will be identified.

Figure 8-4 Schematic drawing illustrating F508 mutation, which accounts for 75 percent of cystic fibrosis cases in couples of northern European ancestry.

196

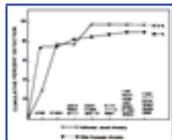

Figure 8-5 Increasing detection rate in northern European Caucasian and Ashkenazi Jewish populations as increasing numbers of CF-causing alleles are sought. Cystic Fibrosis Foundation.

Newly codified recommendations have been made by the ACOG, the American College of Medical Genetics, and NIH.^[7] These guidelines are "to offer" CF heterozygote screening to non-Jewish Caucasians and Ashkenazi Jews, both of which show carrier frequencies of 1 in 25 to 30. In other ethnic group (Asian-Americans, Hispanics, African-Americans) the carrier frequency is lower; thus, it is recommended CF carrier screening be "made available" and that couples "be informed of their detectability through educational brochures." In Caucasians and Ashkenazi Jews, the overall heterozygote detection rates are 90 and 97 percent, respectively, whereas in the three other ethnic groups it approximates 70 percent even using a panel of ethnic-specific markers to maximize detection.^{[9] [9] [10]} At present it is recommended that a panethnic mutation panel be used that includes all mutant CF alleles having a frequency of 0.1 percent in the general U.S. population. This encompasses 25 mutations at present ([Table 8-4](#)) and is subject to yearly review. Screening for other alleles is not discouraged (e.g., as part of ethnic-specific panels); however, screening for more than the 25 alleles is optional.

Of specific note to obstetrician-gynecologists is allele R117H, even though this allele is more commonly associated with congenital bilateral absence of the vas deferens (CBAVD) than the classic cystic fibrosis phenotype characterized by pulmonary, hepatic, and pancreatic complications. CBAVD males usually have two dysfunctional CF alleles. One but not both could be F508^[9] (otherwise, the phenotype would not be CBAVD but classic CF). In CBAVD, the other allele is often R117H. If a male with CBAVD is F508/R117H, the spouse could be heterozygous for F508; thus, the likelihood is 25 percent that any given fetus will have a severe form of CF (F508/F508). The other major CF perturbation contributing to CBAVD involves a polymorphism (5T/7T/9T) in intron 8.^[11] The 5T (thymine) and 7T variants may be observed in CBAVD in homozygous or compound heterozygous forms, or in complementation with F508 or R117H. The 5T and to a lesser extent 7T polymorphisms are deleterious because they lead to splice-junction perturbation and, hence, a truncated dysfunctional CFTR gene product. If R117H is detected on the panel, testing for the 5T/7T/9T polymorphism is recommended. The reason is that 5T/R117H heterozygosity has been observed with classic CF.^[12] If R117H is not detected, testing for the 5T/7T/9T polymorphism is not necessary.

If a couple has already had a child with cystic fibrosis, or recounts an affected close relative, screening as described above is not germane. Rather, case detection strategies become appropriate. The index case, or the couple if the proband is unavailable, should be screened not just for the panel [in Table 8-4](#) but, if uninformative, for a larger panel totaling up to 70 CF mutations. If the mutation is still not evident, family studies to identify polymorphic loci informative for linkage analysis should be considered if prenatal genetic diagnosis are planned (see Disorders Detectable by Molecular Methods, below).

The complexity engendered in cystic fibrosis screening will be repeated for most mendelian disorders because molecular heterogeneity is the rule rather than the exception for single-gene disorders.

TABLE 8-4 -- RECOMMENDED PANEL OF MUTATIONS IN THE CYSTIC FIBROSIS TRANSMEMBRANE REGULATORY (CFTR) GENE THAT SHOULD BE SOUGHT IN CARRIER DETECTION PROGRAMS¹

F508	I507	G542X	G551D	W1282X	N1303K
R553X	621 + 1G > T	R117H	1717 - 1G > A	A455E	R560T

3120 + 1G > A					

* The panel is applicable in all ethnic groups. If R117H is detected, status of the 5T-7T-9T polymorphism should be determined.

197

Maternal Serum -Fetoprotein Screening for Neural Tube Defects

Relatively few (5 percent) NTDs occur in families who have had previously affected offspring. Thus, a method other than a positive family history is needed to identify couples in the general population at risk for an NTD. Maternal serum -fetoprotein (MSAFP) serves this purpose, identifying couples with a negative family history who nonetheless have sufficient risk to justify amniocentesis.

MSAFP is greater than 2.5 multiples of the median (MOM) in 80 to 90 percent of pregnancies in which the fetus has an NTD. Because considerable overlap exists between MSAFP in normal pregnancies and MSAFP in pregnancies characterized by a fetus with an NTD, systematic protocols for evaluating elevated MSAFP values are necessary. Elevated MSAFP occurs for reasons other than an NTD: (1) underestimation of gestational age, inasmuch as MSAFP increases as gestation progresses; (2) multiple gestation (60 percent of twins and almost all triplets having MSAFP values that would be elevated if judged on the basis of singleton values); (3) fetal demise, presumably caused by fetal blood extravasating into the maternal circulation; (4) Rh isoimmunization, cystic hygroma, and other conditions associated with fetal edema; and (5) anomalies other than NTD, usually characterized by edema or skin defects.

The initial MSAFP assay should be performed at 15 to 20 weeks' gestation. Corrections for maternal weight and some other factors are necessary, using various algorithms that provide a weight-adjusted MSAFP appropriate for gestational age. (Without weight adjustment, dilutional effects can result in heavier women having a spuriously low value when in fact MSAFP might actually be elevated for women of their weight.)

Maternal serum values above either 2.0 or 2.5 MOM are usually considered elevated. The precise value above which MSAFP is considered elevated is less important than setting a consistent policy per program. Values above 2.0 MOM are definitely considered elevated in insulin-dependent diabetic women, but in twin gestations MSAFP is judged abnormal only at 4.5 to 5.0 MOM or greater.

Approximately 5 percent of women will have an elevated MSAFP value. If gestational age assessment is determined accurately before MSAFP sampling, the number of women having an abnormal serum value will be lower (3 percent). A second MSAFP sample may or may not be necessary. There is virtue in reasaying MSAFP if the value lies between 2.50 and 2.99 MOM and if gestational age is 18 weeks or less. If not already performed, ultrasound is obviously required to exclude erroneous gestational age, multiple gestations, or fetal demise. Amniocentesis for AFP and acetylcholinesterase (AChE) is necessary if no explanation for elevated MSAFP is evident on ultrasound. The presence of AChE indicates an open NTD or other anomalies.

MSAFP screening identifies 90 percent anencephaly and 80 to 85 percent of spina bifida, albeit at the cost of 1 to 2 percent of all pregnant women undergoing amniocentesis. Approximately 1 in 15 women having an unexplained elevated serum AFP will prove to have a fetus with an NTD. Not well appreciated is that sensitivity of detecting an NTD in twin gestations is less than in singleton gestations, being only about 30 percent for spina bifida given a threshold of 4.5 MOM. The poor sensitivity exists because twins are usually discordant for an NTD. Liberal use of comprehensive ultrasound is recommended in twin gestations.

Second-trimester MSAFP screening to detect neural tube defects is necessary even if first-trimester screening to detect aneuploidy (see below) is employed. First-trimester MSAFP is not a sensitive method of detecting NTDs. Some physicians prefer to utilize comprehensive ultrasound immediately after elevated MSAFP. Thus, amniocentesis might not be performed in the absence of ultrasound evidence of an NTD. Although a logical approach, the sensitivity of NTD detection cannot be assumed to be as high as with MSAFP followed by amniocentesis.

Maternal Serum Screening for Detecting Fetal Trisomy

Soon after maternal serum screening for the detection of NTDs was introduced, it became clear that a low MSAFP level was associated with trisomy 21.^[13] The possibility arose that maternal serum screening could be offered to women under the age of 35 for detection of Down syndrome. Low serum values could confer a risk sufficiently high that women who are not otherwise candidates for invasive procedures like amniocentesis or chorionic villus sampling (CVS) might wish to undergo such. This proposition is attractive because only 25 percent of infants with Down syndrome are born to women aged 35 and above. Thus, decreasing the population incidence requires identifying younger women at sufficient risk to justify an invasive procedure. However, screening for Down syndrome is more complicated than screening for NTDs because the risk of Down syndrome is age specific. An MSAFP value of, say, 0.4 easily raises the age-associated risk of a 34-year-old high enough to justify amniocentesis; however, the same value would not necessarily increase the risk similarly for a 25-year-old woman. For this reason the preferable way to identify couples with sufficient risk to justify invasive procedures is to utilize likelihood ratios. For example, a maternal serum value for AFP of 0.4

198

MOM carries a likelihood ratio of 3.81 for having a child with Down syndrome. If the a priori (age-specific) risk is 1 in 581 (for a 25-year-old woman), the recalculated risk after taking into account MSAFP is 1 in 148.

In addition to the association between low MSAFP and Down syndrome, an association exists for other maternal serum analytes. The analyte having the greatest discriminatory value is human chorionic gonadotropin (hCG), which is elevated in Down syndrome pregnancies.^[14] In the second trimester, either intact hCG or free -hCG will suffice for assay. Irrespective, the combination of hCG, AFP, and maternal age, when analyzed with appropriate software to derive likelihood ratios, allows detection of some 60 percent of cases of Down syndrome at an amniocentesis rate of 5 percent.^[15] Other analytes offer slight added value. Inhibin A (see below) and unconjugated estriol (uE_3) are most widely added. Adding either of these analytes, the sensitivity of detecting trisomy 21 in the general population (all ages) increases to 65 to 70 percent.

Importantly, for accurate counseling, sensitivity of detecting Down syndrome is age dependent; thus, not all cohort studies will show identical results. Detection rates are 90 percent for women aged 35 and above, but much lower for those in their early third decade. Women should be given *precise* answers as to the sensitivity of detecting trisomy in their pregnancy; 65 percent detection is not the correct information to impart to a 25-year-old who inquires about her own detection rate. Confounding factors can affect serum screening. Corrections for maternal weight and ethnic group are routine, but adjustments for other confounding variables are not. Maternal weight affects AFP, uE_3 , and hCG levels, all of which decrease with increasing weight. Insulin-dependent diabetes in mothers results in slightly decreased uE_3 and hCG levels. Maternal smoking increases MSAFP by 3 percent and decreases maternal serum uE_3 and hCG levels by 3 percent and 23 percent, respectively.^[16] Maternal serum hCG has been found to be higher and MSAFP lower in pregnancies that were conceived in vitro when compared with pregnancies that were conceived spontaneously.^[17] The effect of changes other than weight and ethnic group is not great, and may or may not be enough to warrant adjustment. Maternal serum screening to detect Down syndrome in twin gestations has become available. Down syndrome occurs more frequently (20 percent) in twin pregnancies than in singleton pregnancies, which is predictable given the known positive correlation between twinning and maternal age. Unfortunately, Down syndrome screening using multiple serum markers is not as sensitive in twin pregnancies as it is for singleton pregnancies. Using singleton cutoffs, 73 percent of monozygotic twin pregnancies but only 43 percent of dizygotic twin pregnancies with Down syndrome should be detected, with a 5 percent false-positive rate.^[18] The lower sensitivity in dizygotic twins reflects the blunting effect of the concomitant presence of one normal and one aneuploid fetus. Thus, patients should be informed that the detection rate is less than in singleton pregnancies. It may simply be preferable to perform invasive procedures, say in women 32 years or older.^[19] Younger women may still wish to avail themselves of noninvasive screening despite its lower sensitivity.

Despite different policies in other venues (e.g., Europe), the ACOG continues to recommend that women aged 35 years or older be offered invasive procedures without prior serum screening. Women under 35 years of age should be counseled about serum screening. If older women insist on maternal serum screening in lieu of an invasive procedure, they must appreciate that detection is not 100 percent but only 90 percent at best.

Screening for Trisomy 18

Trisomy 18 can also be detected by triple-marker screening. This aneuploidy is associated with decreased hCG, AFP, and uE_3 levels, a pattern that differs from trisomy 21, in which hCG is elevated. One recommendation is to offer invasive prenatal diagnosis whenever serum screening shows each of these three markers to fall below certain thresholds (MSAFP 0.6 MOM; hCG 0.55 MOM; uE_3 0.5 MOM).^[20] Screening for trisomy 18 by simply using these thresholds would detect 60 to 80 percent of trisomy 18 fetuses, with a 0.4 percent amniocentesis rate.^[21] Calculating individual risk estimation on the basis of three markers and maternal age, Palomaki and colleagues reported that 60 percent of trisomy 18 pregnancies can be detected, with an amniocentesis (false-positive) rate of about 0.2 percent.^[20] One in nine pregnancies identified as being at increased risk for trisomy 18 by serum screening would be expected to be actually affected.

Other Markers

One attractive option for maternal screening is dimeric inhibin-A.^[22] Alluded to already, inhibin-A is a dimeric glycoprotein with an α -subunit and a β -subunit linked by a disulfide bond. During pregnancy, inhibin-A is produced by the corpus luteum and the placenta. Serum inhibin-A levels from women carrying fetuses with Down syndrome are elevated, as are hCG levels.

Urinary (as opposed to serum) markers might also be useful in detecting fetal Down syndrome. Canick et al.^[23] compared levels of a metabolite of hCG and urinary gonadotropin peptide (UGP) from 14 women carrying

199

fetuses affected with Down syndrome with urinary samples from 91 control pregnancies and found the MOM to be 5.34. Cole et al.^[24] believe hyperglycosylated hCG is useful.

First-Trimester Screening

Screening in the first trimester is highly desirable because patients at increased risk can be offered CVS, avoiding the increased late-pregnancy terminations if fetal abnormalities are detected. Associations exist between Down syndrome and low MSAFP, low pregnancy-associated placental protein A (PAPP-A), and elevated free

-hCG. Using PAPP-A and free -hCG for first-trimester Down syndrome screening gives a 62 percent detection rate with a 5 percent false-positive rate. ^[25]

Another approach is to measure nuchal translucency thickening, a reproducible method of measurement pioneered by Nicolaides and Snijders in London. ^[26] This group has measured nuchal translucency in over 100,000 pregnancies in London and in surrounding district general hospitals. Risk of trisomy is derived by multiplying the background maternal age and gestational-related risk by a likelihood ratio, which reflects the deviation of nuchal translucency from the normal mean for gestation. In a study of 96,127 pregnant women of median age 31 years, a calculated risk of 1 in 300 or higher for Down syndrome was observed in 8.3 percent. The detection rate was 82.2 percent for trisomy 21 and 77.9 percent for other chromosomal abnormalities. A few of these may have aborted spontaneously had not intervention occurred, but sensitivity is still well over 70 percent.

First-trimester screening with maternal serum analytes (PAPP-A) and free -hCG can be combined with fetal nuchal translucency screening to further refine risks for fetal trisomies. ^[27] In addition, sequential first-trimester (PAPP-A and -hCG; nuchal translucency) and second-trimester (maternal serum so-called integrated test) screening is possible. This approach should theoretically detect nearly 90 percent, with a false-positive rate of 5 percent. ^[28] Alternatively, one can accept a detection rate of 80 percent for a lower (1 percent) rate of amniocentesis. The algorithm utilized by current proponents has the major disadvantage of requiring that first-trimester results be withheld until second-trimester results are obtained. In addition to failing to disclose information in a timely fashion, termination would be deferred until the second trimester, when risks are higher (see Chapter 42). The stated justification is that sensitivity is lowered if calculated with first-trimester serum screening or with first-trimester nuchal translucency alone; ^[23] however, the magnitude of the decreased detection rate has not been made available, making it difficult to comment objectively.

DIAGNOSTIC PROCEDURES FOR PRENATAL GENETIC DIAGNOSIS

Prenatal genetic diagnosis usually requires obtaining fetal tissue, necessitating an invasive procedure like amniocentesis or CVS. In this section we shall consider common techniques and their safety.

Traditional Amniocentesis

Technique

In amniocentesis, amniotic fluid is aspirated, often for the purpose of genetic diagnosis at 15 to 16 weeks' gestation (menstrual weeks). While the procedure has traditionally been performed at 15 to 16 weeks, it can be performed earlier (especially 12 to 14 weeks).^[27] A 22-gauge spinal needle with stylet is usually used. Ultrasound examination is obligatory in order to determine gestational age, placental position, location of amniotic fluid, and number of fetuses. Ultrasound should be performed concurrently with amniocentesis. Rh-immune globulin should be administered to the Rh-negative, Du-negative, unsensitized patient.

Bloody amniotic fluid is aspirated occasionally; however, this blood is almost always maternal in origin and does not adversely affect amniotic cell growth. By contrast, brown, dark red, or wine-colored amniotic fluid is associated with an increased likelihood of poor pregnancy outcome. The dark color indicates that intra-amniotic bleeding has occurred earlier in pregnancy, with hemoglobin breakdown products persisting; pregnancy loss eventually occurs in about one third of such cases. If the abnormally colored fluid is characterized by elevated AFP, the outcome is almost always unfavorable (fetal demise or fetal abnormality). Greenish amniotic fluid is the result of meconium staining and is apparently not associated with poor pregnancy outcome.

In multiple gestations, amniocentesis can usually be performed on all fetuses. Following aspiration of amniotic fluid from the first sac, 2 to 3 ml of indigo carmine, diluted 1:10 in bacteriostatic water, is injected before the needle is withdrawn. A second amniocentesis is then performed at a site determined after visualizing the membranes separating the two sacs. It is important to note the locations of each sac in case selective termination is later required. Aspiration of clear fluid confirms that the second (new) sac was entered. Triplets and other multiple gestations can be managed similarly, sequentially injecting dye into successive sacs. Although cross-contamination of cells in multiple gestations appears to be rare, confusion may sometimes arise in interpreting amniotic fluid AChE or AFP results. Some obstetricians aspirate the second sac without dye injection

or use a single-puncture technique; however, I still prefer dye injection for confirmation.

After amniocentesis, the patient may resume all normal activities. Common sense dictates that strenuous exercise such as jogging or "aerobic" exercise be deferred for a day or so. The patient should report persistent uterine cramping, vaginal bleeding, leakage of amniotic fluid, or fever; however, physician intervention is almost never required, unless overt abortion occurs.

If only one fetus in a multiple gestation is abnormal, parents should be prepared to choose between aborting all fetuses or continuing the pregnancy with one or more normal and one abnormal fetus. Selective termination in the second trimester is possible, but success of this procedure is greater in the first trimester.^[30]

Safety of Traditional Amniocentesis

Any procedure that involves entering the pregnant uterus logically carries risk to the fetus. Amniocentesis is no exception. Amniocentesis carries potential danger to both mother and fetus. Maternal risks are quite low, with symptomatic amnionitis occurring only rarely (0.1 percent). Minor maternal complications such as transient vaginal spotting or minimal amniotic fluid leakage occur in 1 percent or fewer of cases, but almost always these are self-limited in nature. Other very rare complications include intra-abdominal viscus injury or hemorrhage.

The safety of traditional amniocentesis has been addressed by several large collaborative studies. In 1976, the U.S. National Institute of Child Health and Human Development (NICHD)^[31] published the first major prospective study of genetic amniocentesis, encompassing 1,040 subjects and 992 matched controls. Of all women who underwent amniocentesis, 3.5 percent experienced fetal loss between the time of the procedure and delivery compared with 3.2 percent of controls; the small difference was not statistically significant and disappeared completely when corrected for maternal age. In Canada, a collaborative study did not include a concurrent control group,^[32] assessing 1,223 amniocenteses performed during 1,020 pregnancies in 900 women. The pregnancy loss rate was 3.2 percent, similar to that reported in the U.S. collaborative study.

None of the collaborative studies cited above was conducted with high-quality ultrasonography as defined by today's standards, nor was concurrent ultrasonography ever universally applied. A 1986 Danish study was a true randomized, controlled study of 4,606 women aged 25 to 34 years who were without known risk factors for fetal genetic abnormalities;^[33] a control group underwent no procedure. Women with three or more previous spontaneous abortions, diabetes mellitus, multiple gestation, or uterine anomalies or who used intrauterine contraceptive devices were excluded. Maternal age, social group, smoking history, number of previous induced and spontaneous abortions, stillbirths, live-births, and low-birth-weight infants were comparable in the study and control groups, as was gestational age at time of entry into the study. Amniocentesis was performed under real-time ultrasound guidance with a 20-gauge needle by experienced operators. The spontaneous abortion rate after 16 weeks was 1.7 percent in the amniocentesis study group compared with 0.7 percent in controls ($p < 0.01$); a 2.6-fold relative risk of spontaneous abortion was observed if the placenta was traversed. The frequency of fetal postural deformations did not differ between the two groups. However, respiratory distress syndrome was diagnosed more often (relative risk [RR] = 2.1) in the amniocentesis group, and more of these infants were treated for pneumonia (RR = 2.5).

Studies conducted within the past decade have universally shown no statistical difference between outcomes following amniocentesis groups and controls. In British Columbia, children delivered of women who had second-trimester amniocentesis and were identified by a population-based database of congenital anomalies showed disabilities at the same rate as matched controls (i.e., offspring of women who had not undergone amniocentesis).^[34] In Thailand, a randomized study found no statistically significant difference between women undergoing and not undergoing amniocentesis between 15 and 24 weeks; in 2,045 matched pairs the fetal loss rates were 3.18 percent and 2.79 percent, respectively.^[35]

Unfortunately, a sample must be very large (perhaps 5,000 or 10,000 in each arm) in order to distinguish between the loss rate of 0.5 percent and the perhaps 0.2 percent loss rate that many have the clinical impression more closely approximates reality. In the absence of data substantiating the lower risk figure, it may be hazardous to state the lower risk without caveats.

In conclusion, it still seems wise to counsel that the risk of pregnancy loss secondary to amniocentesis is low but in some hands is potentially up to 0.5 percent. At the author's medical center, serious maternal complications and fetal injuries are stated to be "remote" risks. Concurrent ultrasound is now essential.

Early Amniocentesis

Technique

Early amniocentesis is performed with basically the same technique as that used for traditional amniocentesis. A smaller amount of amniotic fluid is removed, usually 1 ml for each completed gestational week. Careful ultrasound needle guidance is essential, given the relatively small target area and the need to avoid the

201

bladder and bowel. One problem is membrane "tenting," probably the most common reason for failing to obtain amniotic fluid in early amniocentesis. Membrane testing becomes increasingly problematic the earlier in gestation one attempts amniocentesis, reflecting incomplete fusion of the chorion and amnion.

Safety of Early Amniocentesis

The safety and efficacy of the procedure is still unknown. Early experiences suggested early amniocenteses could be a promising technique. In 1992, Hanson et al.^[36] performed 936 amniocenteses at 12.8 weeks' gestation, reporting a loss rate of 0.7 percent (7 of 936) within 2 weeks of amniocentesis, an additional 2.2 percent before 28 weeks, and a final 0.5 percent stillbirths or neonatal deaths. Total losses (32 of 936 or 3.4 percent) were considered comparable to the 2.1 percent to 3.2 percent observed in ultrasonographically normal pregnancies not undergoing a procedure; however, maternal age and precise gestational age were not taken into account. Henry and Miller^[37] also reported favorable early results in amniocentesis at 12, 13, and 14 weeks' gestation. Pregnancy losses prior to 28 weeks were 5 of 193 (2.6 percent), 5 of 426 (1.2 percent), and 18 of 1172 (1.5 percent), respectively.

More recently, it has become evident that amniocentesis prior to 13 weeks cannot be recommended. Although preliminary work had been encouraging,^[38]^[39] the definitive study from the same investigators with the Canadian Early and Mid-Trimester Amniocentesis Trial (CEMAT) cohort proved different.^[40] The salient comparison involved 1,916 women having an amniocentesis before 13 gestational weeks versus 1,775 having amniocentesis after 15 gestational weeks. Total fetal loss rates were 7.5 percent versus 5.9 percent ($p = 0.012$). Even more troubling, talipes equinovarus occurred in 1.3 percent in the early amniocentesis group, compared to the expected population incidence of 0.1 percent in the traditional amniocentesis group. Technical factors associated with these adverse results were difficult-to-perform procedures (e.g., multiple needle insertions) and post procedure amniotic fluid leakage.^[41] The ACOG and others recommend that amniocentesis not be performed prior to 12 gestational weeks.^[42]

Chorionic Villus Sampling

CVS allows prenatal diagnosis in the first trimester to permit pregnancy termination early in gestation and also protect patient privacy. Both chorionic villi analysis and amniotic fluid cell analysis offer the same information concerning chromosomal status, enzyme levels, and DNA patterns. The one major difference is that assays requiring amniotic fluid, specifically AFP, necessitate amniocentesis.

Technique

CVS can be performed by transcervical, transabdominal, or transvaginal approaches. *Transcervical* CVS is usually performed with a flexible polyethylene catheter that encircles a metal obturator extending just distal to the catheter tip. The outer diameter is usually about 1.5 mm. Introduced transcervically under simultaneous ultrasonographic visualization (Fig. 8-6), the catheter/obturator is directed toward the trophoblastic tissue surrounding the gestational sac. After withdrawal of the obturator, 10 to 25 mg of villi are aspirated by negative pressure into a 20- or 30-ml syringe containing tissue culture media. The optimal time for transcervical sampling is 10 to 12 completed gestational weeks.

In *transabdominal* chorionic villus sampling (Fig. 8-7), concurrent ultrasound is used to direct an 18- or 20-gauge spinal needle into the long axis of the placenta. After removal of the stylet, villi are aspirated into a 20-ml syringe containing tissue culture media. Unlike transcervical CVS, transabdominal CVS can be performed throughout pregnancy, therefore serving as an alternative to cordocentesis (percutaneous umbilical blood sampling [PUBS]) later in pregnancy. If oligohydramnios is present, transabdominal CVS is preferable to PUBS. The former is widely utilized in Europe in lieu of amnioinfusion techniques prior to PUBS.

A final technique is *transvaginal* CVS, using a spinal needle as in transabdominal CVS. This technique may

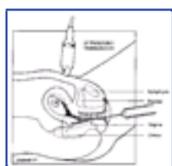

Figure 8-6 Transcervical chorionic villus sampling.

202

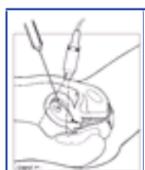

Figure 8-7 Transabdominal chorionic villus sampling.

be useful for a retroflexed uterus having a posterior placenta.

In the author's opinion, facility to perform both transcervical and transabdominal CVS is very helpful. In about one half to three fourths of cases either approach is possible, but in the remaining cases either transabdominal or transcervical CVS is greatly preferable to the other approach. For example, cervical myomas or angulated uteri may preclude transcervical passage of the catheter, whereas transabdominal CVS would permit sampling. The transabdominal approach is obviously preferable in the presence of genital herpes, cervicitis, or bicornuate uteri. A larger sample can more predictably be obtained with transcervical CVS. With either approach sampling women sensitized to Rh(D) should probably be deferred until later in gestation. Sensitization following CVS is probably no greater than that following amniocentesis.

Pregnancy Losses

The U.S. Cooperative Clinical Comparison of Chorionic Villus Sampling and Amniocentesis study^[43] and the Canadian Collaborative CVS-Amniocentesis Trial Group study^[44] have reported that pregnancy loss rates after CVS are no different from loss rates after amniocentesis. In the U.S. study,^[43] 2,278 women self-selected transcervical CVS; 671 women similarly recruited in the first trimester selected amniocentesis. Randomization did not prove possible. The excess loss rate in the CVS group was 0.8 percent, not statistically significant. In a Canadian randomized study,^[44] 1,391 subjects were assigned to transcervical CVS and 1,396 to amniocentesis. The excess loss rate in the former was also 0.8 percent and again not statistically different. Variables shown to influence fetal loss rates adversely in CVS include

fundal location of the placenta, number of catheter passages, small sample size, and prior bleeding during the current pregnancy. Almost all except the last are surrogates for technical difficulty. The frequency of intrauterine growth retardation, placental abruption, and premature delivery are no higher in women undergoing CVS than expected in the general population.^[45]

Transcervical CVS and transabdominal CVS appear to be equally safe procedures.^[46] In another U.S. NICHD collaborative study, 1,194 patients were randomized to transcervical CVS and 1,929 patients to transabdominal CVS. The loss rates of cytogenetically normal pregnancies through 28 weeks were 2.5 percent and 2.3 percent, respectively.^[47] Of considerable interest, the overall loss rate (i.e., background plus procedure-related) following CVS decreased by about 0.8 percent compared with rates observed during the earlier (1985 to 1987) transcervical versus amniocentesis self-selection study. This decrease in procedure-related loss rate probably reflects increasing operator experience as well as availability of both transcervical and transabdominal approaches. In a small randomized trial conducted in Italy, Brambati et al.^[48] also found no difference between transabdominal and transcervical CVS.

The one major investigation substantively differing from all others is the United Kingdom Medical Research Council Study.^[49] In this multicenter randomized study, comparison was made between second-trimester amniocentesis and first-trimester CVS performed in any fashion deemed suitable by the obstetrician. The outcome variable assessed was completed pregnancies. The 4.4 percent fewer completed pregnancies in the CVS cohort reflected both unintended and intended pregnancy terminations. The experience with CVS of the Medical Research Council Study operators was moreover considerably less than in the U.S. studies. For example, the only requirement for participation in the Medical Research Council study was 30 "practice" CVS procedures.

Finally, less formal data exist on the safety of CVS in multiple gestation, but in experienced hands this is quite feasible. In a major U.S. study involving four medical centers, the total loss rate of chromosomally normal fetuses (spontaneous abortions, stillborns, neonatal deaths) was 5.0 percent,^[50] only slightly higher than the 4.0 percent absolute rate observed for singleton pregnancies.^[43] If the placental mass appears fused, amniocentesis is probably a preferred choice. However,

CVS is appropriate in twin gestations when distinct placentas can be visualized by ultrasonography.

CVS is widely used prior to selective reduction in multiple gestation. It is desirable to test the inferior fetus (destined to remain to minimize risk of ascending infection) and at least two or three other fetuses to maximize normalcy in the requisite number.

Limb Reduction Defects

Controversy about the safety of CVS has more recently shifted focus from concerns about the risk of fetal loss to its being the possible cause for congenital abnormalities. In 1991, Firth and colleagues^[51] reported that 5 of 289 (1.7 percent or 17 of 1,000) infants exposed to CVS between 56 and 66 days of gestation (i.e., 42 to 50 days after fertilization) had severe limb reduction deformities (LRDs). Four of the five infants had oromandibular-limb hypogenesis; the fifth had a terminal transverse limb reduction alone. There quickly followed a number of reports both supporting and refuting such an association.^{[52] [53] [54] [55]} In the United States, Burton et al.^[56] reported a second cluster among 394 infants whose mothers had undergone CVS. Thirteen infants (3.3 percent) had major congenital abnormalities, including four with transverse LRD (10 of 1,000 or 1 percent). All four LRDs were transverse distal defects involving hypoplasia or absence of the fingers and toes. Three of these cases followed transcervical sampling, using a device that in the hands of the reporting physicians was associated with an 11 percent fetal loss rate.

Teratogenic mechanisms by which CVS might cause LRDs can be readily hypothesized. These include (1) decreased blood flow caused by fetomaternal hemorrhage or pressor substances released by disturbance of villi or the chorion; (2) embolization of chorionic villus material or maternal clots into the fetal circulation; and (3) amniotic puncture and limb entrapment in exocoelomic gel.

Given this concern, the potential association of LRD with CVS has been explored through various registries. In the Italian Multicenter Birth Defects Registry,^[57] eight cases of oromandibular-limb hypogenesis complex were entered into the registry from January 1988 through December 1991. Of 166 cases of transverse limb defects alone, 4 were exposed to CVS compared with 36 cases among 8,445 controls. A 1994 update of this study, based on 11 CVS-exposed cases, continued to reveal an association with transverse limb defects.^[58] The greatest risk was associated with procedures performed at less than 70 days' gestation (odds ratio [OR], 23.2; 95 percent confidence interval [CI], 1.31 to 41.0); a lower but still increased risk with procedures at 70 to 76 days (OR 17.1; 95 percent CI, 6.7 to 44.0); over 84 days there were no exposed cases, and the risk was interpreted as considerably lower. In contrast, analysis of other European registries in aggregate involving over 600,000 births showed that only 4 of 336 cases (1.2 percent) with limb reduction abnormalities had been exposed to CVS compared with 78 of 11,883 (0.66 percent) cases with other malformations (OR, 1.8; 95 percent CI, 0.7 to 5.0).^[59] A publication from Taiwan reported a number of LRD cases associated with CVS, usually performed at less than 9 weeks.^[60]

In an effort to quantify the risk for LDR associated with CVS, Olney et al.^[61] conducted a case-control study in the United States. Case subjects consisted of 131 infants with nonsyndromic limb deficiency, identified in seven population-based birth defects surveillance programs. Controls consisted of 131 infants with other birth defects, matched to case subjects by the infant's year of birth, mother's age, race, and state of residence. The odds ratio for limb deficiency after CVS from 8 to 12 weeks' gestation was 1.7. This was not significantly increased because the 95 percent confidence limit crosses 1 (95 percent CI, 0.4 to 6.3); however, subsequent analysis by anatomic subtypes revealed a significant association for transverse digital deficiency (OR, 6.4; 95 percent CI, 1.1 to 38.6), an observation that was widely promulgated. There are three problems with this conclusion: (1) only seven exposed cases existed; (2) in several cases procedures were performed earlier than the 10 weeks that is the accepted lower limit for gestational age; and (3) if overall there is no association between CVS and *all* LRD, but there is between CVS and *transverse* LRD, the converse and illogical deduction is that CVS would be protective for longitudinal limb reduction defects. Irrespective, it was concluded that the absolute risk for such defects was approximately 1 in 3,000, a figure that can be considered the upper limit of risk. The World Health Organization (WHO) Committee on Chorionic Villus Sampling has for years analyzed data collected through an international voluntary registry.^{[62] [63] [64] [65]} In the 1998 report,^[65] 77 LRD cases were detected among 138,996 infants born after CVS, reported from 63 registering centers. Types of limb reduction defects were compared to those in a population from British Columbia.^[66] Defects following CVS involved the upper limb in 65 percent, lower limb in 13 percent, and both 23 percent; in the general population, frequencies were 68, 23, and 9 percent, respectively. Transverse limb defects occurred in 41 percent of infants in the cohort exposed to CVS, compared to 43 percent in the general population. Longitudinal limb deficiencies were found in 59 percent of cases, compared to 57 percent in the general population. Thus, pattern analysis of the types of limb defects and calculation of overall incidences failed to reveal a difference between the CVS and background populations. The 1999 WHO^[64] report continued to confirm these results.

In 1995, the Committee on Genetics of the American College of Obstetricians and Gynecologists^[67] reached these conclusions.

1. Transcervical CVS and transabdominal CVS performed at 10 to 12 weeks of gestation are relatively safe and accurate procedures that may be considered acceptable alternatives to second-trimester genetic amniocentesis.
2. CVS should not be performed before 10 weeks' gestation.
3. Chorionic villus sampling requires appropriate counseling before the procedure, an experienced operator, and a laboratory experienced in processing the specimen and interpreting the results. Counseling should contrast the risks and benefits of amniocentesis and CVS.
4. Although further studies were stated as needed to determine whether there is truly an increased risk of transverse digital deficiency following CVS performed at 10 to 12 weeks of gestation, it was considered prudent to counsel patients that such a complication is possible; the estimated risk may be on the order of 1 in 3,000 births.

At Baylor we still follow these 1995 ACOG guidelines, even while doubting that limb reduction defects are actually increased when CVS is performed by experienced hands at 10 gestational weeks and above. We counsel that fetal loss rates are the same as CVS and traditional amniocentesis, and state explicitly that the rate of limb reduction defects *could* be as high as 1 in 3,000 (3 per 10,000) over the background of 6 per 10,000.

Fetal Blood Sampling

Access to the fetal blood circulation was initially accomplished by fetoscopy, a method of directly visualizing the fetus, umbilical cord, and chorionic surface of the placenta using endoscopic instruments. Fetoscopy for this purpose has now been replaced by ultrasound-directed PUBS, also termed cordocentesis or funipuncture.

Fetal blood chromosome analysis is used most commonly in genetics to help clarify chromosome mosaicism detected in cultured amniotic fluid cells or chorionic villi. Fetal blood sampling is used in the prenatal evaluation of many fetal hematologic abnormalities. Fetal blood hematocrit level can be measured directly to assess hemolysis resulting from Rh or other blood antigen isoimmunization states. Fetal blood has been used for the diagnosis of blood factor abnormalities (gene products) like hemophilia A, hemophilia B, or von Willebrand's disease. Recovery of fetal blood permits assessment of viral, bacterial, or parasitic infections of the fetus. Serum studies of fetal blood permit quantification of antibody titers, and serum can be used to initiate viral, bacterial, or parasitic culture.

Cordocentesis (PUBS) is usually performed from perhaps 18 weeks onward, although successful procedures have been reported as early as 12 weeks. ^[68], ^[69] Preliminary ultrasonographic examination of the fetus is performed to assess fetal viability, placental and umbilical cord location, fetal position, and presence or absence of fetal or placental anomalies. Maternal sedation is not usually required, but oral benzodiazepine given before the procedure may be of benefit to the anxious patient.

There are various potential sampling sites, but given its fixed position the placental cord root is the optimal site. Free loops of cord or the intrahepatic vein are alternatives. ^[70] The spinal needle is percutaneously inserted into the fetal blood vessel under direct ultrasound guidance, and a small amount of blood is aspirated.

Maternal complications are rare, but include amnionitis and transplacental hemorrhage. ^[71], ^[72] Fetal risks are more substantive. Data from several large perinatal centers estimate the risk of in utero death or spontaneous abortion to be 3 percent or less following PUBS. ^[73] ^[74] ^[75] ^[76] ^[77] Other collaborative data from 14 North American centers sampling 1,600 patients at varying gestational ages for a variety of indications revealed an uncorrected fetal loss rate of 1.6 percent. ^[78] In selected fetal diagnosis and treatment units in the United States and Japan, the procedure-related fetal loss rate in 1,260 cases was 0.9 percent; excluding diagnoses other than chromosomal abnormalities and severe growth restriction, the procedure-related fetal loss rate was only 0.2 percent. Overall, loss rates for patients undergoing PUBS varies greatly by procedure indication, far more so than in amniocentesis or CVS. However, definitive statements will not be possible until studies directly comparing loss rates in control and treated groups are conducted, unlike CVS and amniocentesis.

INDICATIONS FOR PRENATAL GENETIC STUDIES

Cytogenetic Disorders

Every chromosomal disorder is potentially detectable in utero. It is not appropriate, however, to perform amniocentesis or CVS in every pregnancy because for many couples the risk of an invasive procedure outweighs diagnostic benefits. In addition to couples tested as a result of positive findings in population screening programs (see above), certain indications are considered standard.

Advanced Maternal Age

The most common indication for antenatal cytogenetic studies is advanced maternal age. The incidence of trisomy

21 is 1 per 800 liveborn births in the United States, but the frequency increases with age (see Table 8-2). Trisomy 13, trisomy 18, 47,XXX, and 47,XXY also increase with advanced age.

For approximately 20 years it has been standard medical practice in the United States to offer invasive chromosomal diagnosis to all women who at their expected delivery date will be 35 years or older. The choice of age 35 is largely arbitrary, however, having been chosen during an interval when risk figures were available only in 5-year intervals (i.e., 30 to 34 years, 35 to 39 years, 40 to 44 years). Flexibility is thus appropriate when answering inquiries from women younger than 35 years for, indeed, increasing numbers of women aged 33 or 34 years seek prenatal diagnosis.

The risk figures shown in Table 8-2 are applicable only for liveborns. The prevalence of abnormalities at the time when CVS or amniocentesis is performed is somewhat higher.^[79] For example, the risk for a 35-year-old woman is 1 in 270 for Down syndrome at the time of amniocentesis (second trimester). (Most maternal serum screenings for Down syndrome detection report risks at the time of screening, i.e., second trimester.) That the frequency of chromosomal abnormalities is lower in liveborn infants than in first- or second-trimester fetuses is because of the disproportionate likelihood that fetuses lost spontaneously have chromosomal abnormalities. That is, some abnormal fetuses would have died in utero had iatrogenic intervention not occurred in the second trimester. In fact, 5 percent of stillborn infants show chromosomal abnormalities. (see Chapter 22)

Recall that maternal serum screening is recommended by the ACOG and other groups for women under age 35 years, the goal being identifying couples at sufficient risk for fetal trisomy to justify an invasive procedure. The logical corollary might be that a normal or slightly elevated MSAFP level decreases the risk of aneuploidy for older women to the extent that amniocentesis could be avoided. Most U.S. authorities do not agree because of the potential litigious hazard and because detection rates are not 100 percent but 90 percent. Still, noninvasive screening may be desired by some women, particularly if difficulty has occurred in becoming pregnant. This is most likely to be applicable for women ages 35 to 37; almost all women older than that will prove "screen positive" by maternal serum screening and still eventually require amniocentesis anyway.

Previous Child with Chromosomal Abnormality

After the occurrence of one child or abortus with autosomal trisomy, the likelihood that subsequent progeny will also have autosomal trisomy is increased, even if parental chromosomal complements are normal. Recurrence risks are perhaps 1 percent.^[81] The risk is not so high as once believed, but antenatal chromosomal studies should be offered for couples having a prior trisomic pregnancy.

Recurrence risk data following the birth of a liveborn infant trisomic for a chromosome other than 21 are limited. Counseling that the risk is 1 percent for either the same or for a different chromosomal abnormality seems appropriate. Thus, antenatal studies will usually be necessary.

Parental Chromosomal Rearrangements

An uncommon but important indication for prenatal cytogenetic studies is the presence of a parental chromosomal abnormality. A balanced translocation is the usual indication, but inversions and other chromosomal abnormalities exist. As discussed above (Clinical Spectrum of Chromosomal Abnormalities), empirical data invariably reveal that theoretical risks for abnormal (unbalanced) offspring are greater than empirical risks. Empirical risks approximate 12 percent for offspring of either male or female heterozygotes having reciprocal translocations.^[82] For robertsonian (centric fusion) translocations, risks vary according to the chromosomes involved. For t(14q;21q), risks are 10 percent for offspring of heterozygous mothers and 2 percent for offspring of heterozygous fathers (Fig. 8-8).^[83] For other nonhomologous robertsonian translocations, empirical risks for liveborns are less than 1 percent. For homologous translocations (e.g., 21q;21q), all liveborn offspring should have trisomy 21. For other homologous robertsonian translocations (13q;13q or 22q;22q), almost all pregnancies result in abortions.

Diagnostic Dilemmas in Prenatal Cytogenetic Diagnosis (Amniotic Fluid Cells or Chorionic Villi)

The obstetrician-gynecologist should be aware of the common pitfalls associated with the analysis of chorionic villi or amniotic fluid cells. An obvious problem is that cells may not grow, or growth may be insufficient for proper analysis. Analysis of maternal rather than fetal cells is another theoretical problem, which fortunately has proved uncommon in experienced hands. In amniocentesis, maternal cell contamination can be minimized by discarding the first few drops of aspirated amniotic fluid. In CVS, examination under a dissecting microscope allows one to distinguish villi from decidua.

A more vexing concern is the possibility that chromosomal abnormalities detected in villi or amniotic fluid may fail to reflect fetal status. One reason is that chromosomal aberrations may arise in culture (in vitro). This possibility should be suspected whenever an abnormality is restricted to only one of the several culture flasks or clones from a single amniotic fluid or

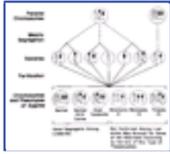

Figure 8-8 Diagram of possible gametes and progeny of a phenotypically normal individual heterozygous for a Robertsonian translocation between chromosomes 14 and 21 (a form of D/G translocation). Three of the six possible gametes are incompatible with life. The likelihood that an individual with such a translocation would have a child with Down syndrome is theoretically 33 percent. However, the empirical risk is considerably less. (From Gerbie AT, Simpson JL: *Antenatal diagnosis of genetic disorders*. *Postgrad Med* 59:129, 1976, with permission.)

CVS specimen. In fact, cells containing at least one additional structurally normal chromosome are detected in 1 to 2 percent of amniotic fluid or chorionic villus specimens.^[83] If these abnormal cells are restricted to a single culture or clone, the phenomenon is termed *pseudomosaicism*; no clinical significance is attached. Defined by the presence of the same abnormality in more than one clone or culture flask, true fetal mosaicism is rarer in amniotic fluid and villi but clinically significant. True mosaicism can be confirmed by studies of the abortus or liveborn in at least 70 to 80 percent of cases^[84] and cannot be truly excluded in the remainder because the abnormality could exist in a tissue not readily analyzable.

Chorionic villi divide more rapidly than amniotic fluid cells. Metaphases from trophoblasts derived from villi can be accumulated within hours of sampling. Analysis of these cells can provide rapid answers. However, discrepancies may arise between short-term trophoblast cultures and long-term cultures initiated from the mesenchymal core of the villi.^[85] Discrepancies may further exist between CVS preparations of either type (short-term or long-term) and the embryo. Fortunately, it is possible to recognize and manage these discrepancies, usually by confirmatory amniocentesis and assessment of the expected interval growth. In most discrepancies, the fetus proves normal at amniocentesis, having shown normal interim growth between 10 and 16 weeks.

The U.S. NICHD Collaborative Study involved 11,473 chorionic villus samples evaluated by direct methods, long-term culture, or both. There were no incorrect sex predictions.^[86] No diagnostic errors occurred in 148 common autosomal trisomies (+13, +18, +21), 16 sex chromosomal aneuploidies, and 13 structural aberrations; a normal cytogenetic diagnosis with CVS was never followed by birth of a trisomic infant. Not confirmed were several rare trisomies (+16, +22, +7), findings consistent with those in other investigations.^[86] Overall, the accuracy of CVS is comparable to that of amniocentesis, but additional tests may be necessary before definitive establishment of nonmosaic rare trisomies and, as in amniotic fluid analysis, polyploidies. Of interest is that the U.S. NICHD study observed increased late loss rates (8.6 percent) in pregnancies showing confirmed placental mosaicism compared with 3.4 percent in pregnancies without mosaicism.^[87] However, no increased frequency of pregnancy complications was observed.

The clinical significance of the above is that the obstetrician must realize that the neonatal phenotype cannot always be predicted on the basis of the amniotic fluid cells or chorionic villi complement.

Structural Chromosomal Abnormalities

If a phenotypically normal parent carries the same balanced translocation as the fetus, reassurance is usually appropriate. On the other hand, if an ostensibly balanced inversion or translocation is detected in the fetus

but in neither parent (de novo rearrangement), the likelihood is increased that the neonate will be phenotypically abnormal at birth. Presumably, the inversion or translocation is not actually balanced, appearances to the contrary. The risk for the fetus being abnormal has been calculated at 6 percent for de novo reciprocal inversion and 10 to 15 percent for de novo translocation.^[88] These risks are not chromosome specific but represent pooled data involving many chromosomes. These risks apply only to structurally anatomic abnormalities evident at birth and do not take into account developmental delay (mental retardation) that would be evident only later in life.

Marker chromosomes, also called supernumerary chromosomes, are those that by definition cannot be fully characterized on the basis of standard cytogenetic analyses. These small chromosomes usually contain a centromere, and a high proportion derive from the short arms of the acrocentric chromosomes (13, 14, 15, 21, and 22). Marker chromosomes are observed in approximately 0.06 percent of the population.^[90]

More specific information can be anticipated in the future because, with the advent of fluorescence in situ hybridization (FISH), the chromosomal origin of marker chromosomes can often be established. Analogous to translocations and inversions, the risk for phenotypic abnormality in a fetus with a marker chromosome depends on whether the marker is de novo or familial. Risk is higher when de novo markers are encountered. Studying 15 cases of marker chromosomes ascertained from 12,699 prenatal samples (11,055 amniotic fluids, 1,644 chorionic villus samples), Brondum-Nielsen and Mikkelsen^[91] used FISH techniques to characterize marker chromosomes. Five cases were familial, all were derived from acrocentric chromosomes (13, 14, 15, 21, and 22), and all resulted in phenotypically normal offspring. The other nine cases represented de novo abnormalities. In two cases, pregnancies resulted in phenotypically normal infants at birth; however, in one of the two, minimal psychomotor retardation at age 2 years was evident. The seven other pregnancies having de novo markers were terminated; three showed significant abnormalities at autopsy.

In reviewing 15,522 prenatal diagnostic procedures, Hume et al.^[92] ascertained 19 marker chromosomes, 5 from CVS specimens and 14 from amniotic fluid samples. Monitoring these pregnancies with high-resolution ultrasonography revealed an association between a de novo marker chromosome and anomalies. When ultrasound examination was normal, the likelihood of a phenotypically normal offspring was high.

Fluorescence In Situ Hybridization (FISH) in Prenatal Diagnosis

FISH merges molecular genetics with cytogenetics. Using DNA sequences unique to the chromosome in question, chromosome-specific probes (e.g., chromosomes 13, 18, 21, the X, or the Y) can be created (see Fig. 8-3). The probe is then labeled with a fluorochrome and used to challenge unknown DNA. Disomic cells (metaphase or interphase) should show two separate signals; trisomic cells should show three signals. Because of geometric vicissitudes, not every trisomic cell will show three signals; however, the modal count readily indicates probes permitting simultaneous assessment of multiple chromosomes. The appeal of FISH is that its use in interphase cells permits rapid (same day) diagnosis of aneuploidy. This is particularly important when a rapid diagnosis is needed to aid in the management of a high-risk fetus (e.g., with ultrasound findings of multiple anomalies).

Mendelian Disorders

Increasing numbers of Mendelian disorders are now detectable in utero. Initially, only metabolic disorders were detectable on the basis of enzyme analysis. Antenatal diagnoses of hemoglobinopathies and hemophilia were later accomplished with fetal blood, originally obtainable only by fetoscopic sampling. DNA analysis now permits many diagnoses using any available nucleated cell (chorionic villi, amniotic fluid cells). The nature of the mutant or absent gene product need not necessarily even be known. We can predict confidently that in the foreseeable future all common Mendelian disorders will be detectable. The rapid progress and increasing complexity required to diagnose Mendelian traits dictate close liaison between the obstetrician-gynecologist and geneticist. Tabulated lists of detectable disorders should be considered suspect for timeliness.

Inborn Errors of Metabolism

Antenatal diagnosis is possible for approximately 100 inborn errors of metabolism. Most are transmitted in autosomal recessive fashion, although a few display X-linked recessive or autosomal dominant inheritance. Couples at increased risk will usually be identified because they previously had an affected child. Most metabolic disorders are so rare that it is unreasonable to expect obstetricians who are not geneticists to be fully cognizant of diagnostic possibilities.

Detection of a metabolic error requires that the enzyme be expressed in amniotic fluid cells or chorionic villi. This requirement is fulfilled by most metabolic disorders, a prominent exception being phenylketonuria (PKU). Fortunately, PKU can be detected by the molecular techniques described below. All metabolic disorders detectable in amniotic fluid have proved detectable as well in chorionic villi. Although cultured cells are usually necessary for diagnosis, occasionally one can arrive at

an elevated value of which indicates adrenal 21-hydroxylase deficiency (congenital adrenal hyperplasia). This disorder can also be detected by analysis of linked human leukocyte antigen (HLA) markers in nuclei obtained by CVS or amniocentesis, and treated in utero by administration of dexamethasone to the mother. [93]

Disorders Detectable Solely by Tissue Sampling

If a gene causing a given disorder is not expressed in amniotic fluid or chorionic villi, enzymatic analysis of such tissues will provide no information concerning presence or absence of the disorder. However, the gene might still be expressed in other tissues—blood, skin, muscle, or liver. Initially, skin was obtained through fetoscopically directed biopsy, under direct vision; however, currently ultrasound-directed sampling permits use of smaller (14-gauge) instruments. Procedure-related losses following skin biopsy or other invasive procedures are presumed to be greater than that following CVS or amniocentesis; however, the severity of some disorders justifies tissue sampling if no other diagnostic method is available. Counseling a procedure-related loss of about 2 to 3 percent seems appropriate. [94]

Increasingly, molecular advances have made tissue sampling obsolete. Sampling fetal skin was once the only available method for diagnosing certain dermatologic abnormalities such as epidermolysis bullosa or congenital ichthyosis (harlequin ichthyosis). [94, 95] Increasingly, molecular advances have allowed prenatal diagnosis simply by CVS or amniocentesis. Occasionally, histologic and electron microscopic analyses of fetal skin are necessary. Muscle biopsy may also be necessary to detect Duchenne, muscular dystrophy if DNA markers are not informative.

Disorders Detectable by Molecular Methods

The power of molecular prenatal diagnosis is that any available nuclear cell can be utilized for diagnosis. All cells contain the same DNA, and the gene need not be expressed, unlike the situation when a gene product (enzyme protein) must be analyzed. Thus, molecular techniques are now widely applicable. Duchenne, muscular dystrophy, CF, adult-onset polycystic kidney disease, Huntington's chorea, and most other undetectable disorders have become diagnosable.

To appreciate these advances, the obstetrician-gynecologist must be aware of the analytic techniques that made possible diagnosis by molecular methods. Principles and applications are now routinely applied and widely taught in medical school curricula. The reader can now find the topic covered in much greater detail elsewhere, ranging from single chapters in volumes intended for obstetrician-gynecologists with no prior knowledge in the field, to definitive volumes designed for the investigator. Here we shall almost perfunctorily define key principles whose understanding is crucial to the application of prenatal genetic diagnosis.

Pivotal was the discovery of *restriction endonucleases*. These bacterial enzymes recognize specific nucleotide sequences five to seven nucleotides in length and cut DNA only at those sites. Use of restriction enzymes permits DNA to be divided into fragments of reproducible lengths (Fig. 8-9).

Also pivotal to clinical diagnosis was development of the *polymerized chain reaction* (PCR) procedure. In PCR, a target sequence can be amplified severalfold (10^5 to 10^6) (Fig. 8-10). For most purposes, PCR amplification utilizes unique DNA primers that flank and are specific for the DNA region in question; thus, the sequence must be known. The region in question may consist of a portion of a gene containing a mutation, a polymorphic DNA sequence closely linked to a given locus, or a repetitive DNA sequence characteristic of a given chromosomal region. Irrespective, a heat-stable DNA polymerase extracted from *Thermus aquaticus* (*Taq* polymerase) is placed in a single tube with the DNA in question, excess deoxyribonucleoside triphosphates (adenine, thymine, guanine, cytosine), and the unique primers specific for the region being studied. DNA synthesis (amplification) is initiated (cycle in Fig. 8-10). Raising the temperature denatures the newly amplified double-stranded DNA back into single-stranded DNA. Upon cooling, another amplification cycle can occur (cycle 2 in Fig. 8-10), this time with twice as many strands. The DNA sequence between primers amplifies in geometric fashion with each replication. In 3 to 4 hours, 30 to 40 amplifications are achieved. PCR can be used not only to amplify DNA, but for diagnosis. If a DNA sequence is absent (e.g.,

Figure 8-9 Simplified diagram illustrating the manner in which a restriction endonuclease cuts DNA at a specific nucleotide sequence. Pvu II recognizes the sequence CAGCTG and only that sequence. DNA is separated into fragments of different lengths on the basis of distances between restriction enzyme recognition sites. The farther the distance between sites, the longer the length of intervening DNA (i.e., 20 vs. 30 base pairs). Shorter DNA fragments (e.g., 20 base pairs) show greater mobility and migrate farther in an agarose cell.

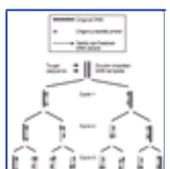

Figure 8-10 Polymerized chain reaction (PCR). Placing the DNA in question, unique primers, and *Taq* polymerase together results in amplification (cycle 1). When the temperature is raised, denaturation into single-stranded DNA occurs. Upon cooling, a second amplification cycle continued. Continued amplification increases the amount of DNA located between primers in logarithmic fashion.

-thalassemia), no DNA is available with which the primers could anneal; thus, no hybridization (reaction) is observed. One can perform PCR concurrently for multiple sequences (multiplex PCR), an approach that permits assessment of presence or absence of deletions throughout a given region.

A modification of this approach involves use of synthetic oligonucleotides 15 to 18 in length, called *allelespecific oligonucleotides* (ASO). An ASO is designed to hybridize to an unknown sample if and only if the latter is characterized by all 15 to 18 nucleotides. ASOs that recognize normal DNA and any known mutant sequence can be designed and used for "dot-blot" DNA analysis or "slot-blot" analysis.

In addition to results of PCR per se (presence or absence of a sequence), several other diagnostic approaches are commonly applied. In Southern blotting (Fig. 8-11), agarose gel electrophoresis is used to separate DNA fragments by size, after exposure to restriction endonucleases. The DNA is then denatured and transferred from the agarose gel to a nitrocellulose filter, on which specific fragments can be located by hybridization. Labeled strands of known DNA sequences act as probes, hybridizing a specific complementary sequence from among the many DNA fragments on the filter. Fragments that contain the sequence that hybridizes with the probe can be detected as bands. Use of size standards facilitates determining whether a particular-sized fragment is or is not present. This technique is called *Southern blotting*.

Diagnosis When the Molecular Basis Is Known

Other molecular techniques taking advantage of hybridization as end points can also be used for diagnosis. Use of FISH to detect numerical chromosomal abnormalities (aneuploidy) in interphase cells has already been noted, and exactly the same principle can be applied to detect presence of a gene. For example, an SRY probe can detect presence of the testes determining region in newborns with genital ambiguity. Two FISH signals can detect gene duplications, such as exists in Charcot-Marie-Tooth disease.

It is convenient for heuristic purposes to divide mendelian disorders into those in which the molecular basis (i.e., precise nucleotide abnormality) is known and those in which the gene is localized to a given chromosomal region but in which the molecular basis is not known. Known causes of mendelian disorders include absence of the gene or point mutations. If a disorder is known to be characterized by absence of DNA, one can determine whether a probe does or does not hybridize with the

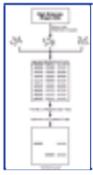

Figure 8-11 Southern blotting cuts DNA at a specific sequence of nucleotides. After DNA is cleaved with restriction enzymes, the cleaved DNA is separated by size using agarose gel electrophoresis. The gel is then laid on a piece of nitrocellulose and buffer allowed to flow through the gel into the nitrocellulose. DNA fragments migrate out of the gel and bind to the filter. A replica of the gel's DNA fragment pattern is thus made on the filter. The filter can then be hybridized to a suitable radioactivity-labeled probe, with DNA fragments hybridizing to the probe identified after autoradiography.

(by PCR) or hybridization (by ASO) indicates that the individual lacks the DNA sequence in question; thus, the disorder is assumed present. This approach is currently used to diagnose all forms of α -thalassemia, many cases of Duchenne-Becker muscular dystrophy, some cases of β -thalassemia, and some forms of hemophilia.

A second general approach becomes applicable if the molecular basis involves a point mutation whose nucleotide sequence is known. Sometimes, the mutation to be sought is obvious, and clinical diagnosis by molecular means is very straightforward. A clear example is sickle cell anemia, in which the triplet (codon) designating the sixth amino acid has undergone a mutation from adenine to guanine. As a result, codon 6 connotes valine rather than glutamic acid, leading to the abnormal protein (HbS). Several different molecular approaches can be exploited to make a diagnosis. For example, restriction enzymes recognize the normal but not the mutant DNA sequence at codons 5, 6, and 7. One could also construct ASOs designed to hybridize only if every single nucleotide is present. Use of a ^{32}P oligonucleotide probe will confirm the specific mutant DNA sequence. Diagnosis with limited amounts of DNA can be achieved by the use of PCR amplification. A hybridized ASO usually appears as a "dot blot" (Fig. 8-12) or "slot blot."

As already discussed in the context of genetic screening, sickle cell anemia is very atypical for mendelian disorders in that its molecular basis is homogeneous. Far more commonly, many different molecular mutations are responsible (heterogeneity), as illustrated by cystic fibrosis. We have already considered this concept with respect to cystic fibrosis, but analogous findings exist for almost all mendelian traits. In the near future, sequencing the entire gene or selected exons is likely to become more widely available. This is more complex technically, but to most obstetricians the diagnostic approach will become more simple conceptually. However, at present, geneticists must often consider the diagnostic approach for prenatal diagnosis case by case. The approach discussed below may become applicable even if the location of the mutant gene responsible for a condition desired to be tested is known.

Diagnosis When the Molecular Basis Is Not Known

The molecular approaches described above are applicable only when the precise molecular basis of a disorder is known. Unfortunately, this requirement is fulfilled less often than one would desire. Certain genes are not yet cloned and isolated. Even if the chromosomal location is known, an interval passes before the sequence is determined. A second reason is the considerable heterogeneity noted previously to exist at the molecular level. Mutations at multiple nucleotide sites within the gene can all produce a dysfunctional product. Given that genes are often very large, diagnostic complexities may be daunting. Sequencing the entire gene for every diagnostic situation is not practical, and even then the mutation might not be detected if it were located in a promoter region or involved in translation.

The problem cited above can be addressed by linkage

Figure 8-12 Dot blot analysis. Oligonucleotides are constructed for sequences complementary to normal DNA (A) and mutant DNA (S). DNA challenged by the oligonucleotide probe will be hybridized if and only if the DNA contains all nucleotides connoted by the probe. Thus, AS individuals will respond to both A and S probes, whereas AA or SS individuals will respond only to one of the two probes (A and S , respectively). Homozygous individuals respond with a stronger (darker) signal than heterozygous individuals.

analysis, taking advantage of the ostensibly innocuous differences in DNA that exist among individuals in the general population. These differences are called *polymorphisms* and are analogous to such well-known polymorphisms as the ABO blood group locus. The initial molecular approach utilized restriction fragment length polymorphisms (RFLPs). The approach was initially possible because of the existence among normal individuals of clinically insignificant differences in DNA fragment lengths following exposure to a given restriction endonuclease, thus the term "restriction fragment length polymorphisms."

More recently, commonly used markers are dinucleotide or trinucleotide polymorphisms. Throughout the genome there exist polymorphisms in which the number of nucleotide repeats (e.g., the dinucleotides cytosine and adenine [CA]) vary among individuals at a given locus. For example, some individuals may show 6 CA repeats, others 8, others 10 at a given locus. The almost innumerable number of such polymorphisms underlies the scientific basis of DNA analysis being used for forensic pathology. In linkage analysis, a diagnosis is made not on the basis of analyzing the mutant gene per se but rather on the basis of the presence or absence of a nearby marker. In RFLPs, the marker is a DNA variant capable of being recognized following exposure to a given endonuclease.

To illustrate, let us assume that a given RFLP or nucleotide repeat is known to lie close to or preferably within the mutant gene of interest. One next needs to deduce the relationship of the mutant to the status of the marker. Starting with an individual of known genotype, usually an affected fetus or child, one determines on which parental chromosome a given DNA marker is located (*cis-trans* relationship). Is the marker located on the chromosome carrying the mutant gene, and is it located on the chromosome carrying the normal gene? Figure 8-13 illustrates a simple example using RFLPs. The principle would be exactly the same using dinucleotide or trinucleotide repeats as the DNA polymorphic marker.

Pitfalls exist in linkage analysis using RFLP or nucleotide repeats. First, the marker may or may not be informative in a given family. If all family members show identical DNA fragment patterns at a given locus, that locus is obviously useless because affected and unaffected individuals cannot be distinguished from each other. If a given marker is uninformative, one searches for another marker that may prove informative. Fortunately, a potentially limitless number of markers exist. Second, the distance between the mutant gene and the marker is crucial because the likelihood of meiotic recombination is inversely related to this distance. Recall that during meiosis I recombination can occur between homologous chromosomes. Genes are linked to one another if, after meiosis I, they remain together more often than expected by chance. Recombination can occur even between closely linked loci; thus, prenatal diagnosis based on linkage analysis is never 100 percent accurate. Using polymorphic markers on both sides of the mutant can minimize but not exclude the possibility of a recombinational event.

Despite these caveats, linkage analysis permits prenatal diagnosis in many situations not otherwise possible. Linkage analysis is particularly applicable to the increasing numbers of single-gene (mendelian) disorders with considerable molecular heterogeneity. These include Huntington disease; hemophilia A and B; adult-onset polycystic kidney disease; and some forms of neurofibromatosis, Duchenne-Becker muscular dystrophy, and β -thalassemia.

Polygenic/Multifactorial Disorders

Amniotic Fluid -Fetoprotein

Failure of the neural tube to close during embryogenesis leads to anencephaly, spina bifida (myelomeningocele or meningocele), encephalocele, and other less common midline defects (e.g., lipomeningocele). Anencephaly is almost never compatible with long-term survival. Spina bifida is compatible with long-term survival, although it is frequently associated with hemiparesis, urinary incontinence, and hydrocephalus.

Anencephaly and spina bifida represent different manifestations of the same pathogenic process and reflect the same genetic etiology. Couples who have had a child with an NTD have approximately a 1 percent risk for any subsequent offspring having spina bifida and a 1 percent risk for subsequent offspring having anencephaly

212

Figure 8-13 Restriction fragment length polymorphisms (RFLPs), which are invaluable for certain prenatal diagnoses. Suppose one mutant gene is linked to another gene (B) that governs whether or not a restriction site (B) is present. If the restriction site is present, DNA is cut by a certain restriction enzyme (arrow) to produce 3,300- and 2,400-bp-long fragments. If the segment conferring the restriction site is not present, the total fragment is 5,700 bp long. The different lengths can serve as markers to allow genotypes to be deduced. Suppose two obligate heterozygotes 1.1 and 1.2 have one affected child. Suppose further that a probe for the gene hybridizes to the region A to C. The probe can thus identify three fragments (2,400, 3,300, and 5,700 bp). If the affected child shows only the 2,400- and 3,300-bp fragments, it can be deduced that the mutant allele is in association (i.e., on the same chromosome) with the gene-conferring restriction site B and thus is producing both 2,400- and 3,300-bp fragments. The normal allele must be in association with the allele not conferring restriction B and thus is designated by the 5,700-bp fragment. Genotypes can thus be predicted from DNA analysis of chorionic villi and amniotic fluid cells. Fetus 11.3 can be assumed to be heterozygous because all three fragments (2,400, 3,300, and 5,700 bp) are present.

(2 percent for any NTD).^[96] This holds true irrespective of the type of NTD present in the index case (proband). If a prospective parent has an NTD, the risk is also about 2 percent. Second-degree relatives (nieces, nephews, grandchildren) and third-degree relatives (first cousins) are less likely to be affected. A woman whose sister or brother had a child with an NTD carries a lower 0.5 to 1.0 percent risk for NTD offspring.^[96] For reasons that are unclear, risks are slightly lower if the father's sibling had an NTD.

Antenatal diagnosis of an NTD is best accomplished by amniotic fluid -fetoprotein (AF-AFP) assay. Through AF-AFP analysis, diagnosis of an NTD is possible in all anencephaly cases and in all spina bifida cases except the 5 to 10 percent in which skin covers the lesion. Closed lesions are somewhat more common in encephaloceles. Ultrasonography by experienced physicians should readily exclude anencephaly, and spina bifida theoretically can be detected by serial views of the vertebral column, shape of the cranium, ventricles, cerebellum, and cisternal magna. Unfortunately, few ultrasonographers know the sensitivity or specificity for detecting NTDs. Until such data are available, AF-AFP analysis should be considered the standard method for detecting an NTD despite frequent hopes and statements to the contrary.

AF-AFP may be spuriously elevated if the amniotic fluid is contaminated with fetal blood. This pitfall can be eliminated if AChE is assayed concurrently. AChE is present in the amniotic fluid of fetuses with open NTDs but is absent in normal amniotic fluid. If AChE is absent but fetal hemoglobin is present, the elevated AFP is probably because of fetal blood. Some confusion may arise if amniocentesis is performed earlier than 13 weeks.

Elevated AFP is also associated with certain other polygenic/multifactorial anomalies (e.g., omphalocele, gastroschisis, cystic hygroma). In these disorders, AChE may or may not be elevated. With certain mendelian traits (e.g., congenital nephrosis), AFP is elevated but

213

AChE is not. Ultrasonographic studies should therefore be undertaken to corroborate elevated AF-AFP and to determine the nature of any defect present. On the other hand, failure to detect an anomaly by ultrasound does not necessarily indicate that elevated AF-AFP was spurious. If AF-AFP is elevated and AChE is present, the fetus should be considered abnormal irrespective of ultrasound findings.

Folic acid deficiency is a major cause of NTD. This conclusion has been accepted for a decade, after a prospective, randomized study that found that folic acid supplementation decreased the recurrence rate of NTD, by 71 percent in women who had a previous child with an NTD.^[97] The ACOG recommends 0.4 mg folate daily, beginning at least 1 month prior to conception.^[97] In women who have had a child with a prior NTD, 4 mg daily is recommended.

Disorders Detectable Only by Ultrasound

Anomalies inherited in polygenic/multifactorial fashion usually carry recurrence risks of 1 to 5 percent for first-degree relatives (siblings, offspring, parent), a risk sufficiently high to justify prenatal diagnosis for many couples. The number of genes responsible for these defects is unknown, but presumably more than one; thus, diagnosis on the basis of enzyme assays or DNA cannot seriously be entertained at present. Except for the few conditions amenable to AF-AFP analysis, the principal method of assessment involves visualization of fetal anatomy by ultrasound.

The typical couple at risk already has had a child with the anomaly in question, thus incurring a 1 to 5 percent risk for another affected child. To alter clinical management, a diagnosis should be made by 20 to 24 weeks' gestation. This is sufficiently early to weigh the alternative options of termination, fetal surgery, or preterm delivery followed by neonatal surgery. PUBS and second-trimester transabdominal CVS can exclude chromosomal abnormalities if either of the latter options are contemplated. A careful search for other defects is also necessary. For some anomalies (e.g., hydrocephaly), an isolated anomaly is rare, but for others (e.g., posterior urethral valves), only a single malformation may be present.

Antenatal ultrasonography for anomaly detection should be performed only by highly experienced physicians. Physicians scanning obstetric patients only for fetal viability, multiple gestations, and placental location should explicitly inform their patients that anomaly assessment is not being attempted. Casual reassurance of fetal normalcy should be eschewed. It should further be realized that almost no individual has sufficient experience to calculate his or her own specificities or sensitivities.

FUTURE DIRECTIONS: PREIMPLANTATION DIAGNOSIS

Despite the advantage CVS offers for first-trimester prenatal diagnosis, even earlier diagnosis may be desirable. One reason is that one can envision certain treatment regimens (metabolic, gene insertion). A second reason is that some couples at risk for affected offspring may undergo repeated prenatal diagnosis and termination. Other couples strongly wish to avoid clinical terminations.

These disadvantages can be addressed by preimplantation genetic diagnosis, utilizing access to gametes (oocytes) or embryos before 6 days, the time at which implantation occurs. Potential approaches include (1) polar body biopsy, (2) aspiration of one to two cells from the six- to eight-cell embryo at 2 to 3 days, and (3) trophectoderm biopsy of the 5- to 6-day blastocyst.

Obtaining Cells for Preimplantation Genetic Diagnosis

Preimplantation genetic diagnosis requires access to gametes (oocytes) or embryos by 6 days after conception or less, the time when implantation occurs. There are three potential approaches: (1) polar body biopsy, (2) blastomere biopsy or aspiration of one to two blastomeres from the six to eight-cell embryo (2 to 3 days), and (3) trophectoderm biopsy from the 5- to 6-day blastocyst. The first two are most widely applied.

Blastomere (Six to Eight Cells) Biopsy

Blastomere biopsy involves aspirating one to two of the six to eight cells contained within the zona pellucida. This can be accomplished by mechanical (razor), laser, or chemical (pronase, ethylenediaminetetraacetic acid [EDTA]) means, followed by aspiration with a second pipette. The sentinel work in this area was conducted by Handyside and colleagues over a decade ago.^[99], ^[99]

In the initial work of Handyside et al.,^[99] a single cell was removed through a hole made in the zona pellucida by a drilling pipette (10 to 20 mm in diameter) containing acid Tyrode's solution. Removal of one or two cells did not affect glucose or pyruvate uptake or delay spontaneous hatching of blastocysts, the traditional indicator of normal embryonic development.^[100]

Polar Body Biopsy

A second approach is to remove either the first or second polar biopsy, or both.^[101] Literally, this is preconceptional rather than preimplantation diagnosis. If a

woman and her mate were heterozygous for an autosomal recessive disorder, a polar body showing the mutant allele should be complemented by a primary oocyte having the normal allele. The normal oocyte could thus be allowed to fertilize in vitro and then transferred for potential implantation. Conversely, if the polar body were normal, fertilization would not be allowed to proceed because the oocyte would be deduced to contain the mutant allele. Similarly, a polar body containing only one chromosome 21 (as determined by FISH with a chromosome-specific probe) should be complemented by a primary oocyte also containing a single chromosome 21. If the first polar body failed to show a chromosome 21, however, the oocyte can be presumed to have two 21 chromosomes. This would lead to a trisomic zygote.

Polar body biopsy has the theoretical advantage of no reduction in cell number following biopsy. There should also be less likelihood of contamination with sperm. Disadvantages include inability to assess the paternal genotype, precluding application if a father has an autosomal dominant disorder. Lacking information about paternal transmission is also less efficient reproductively. Deducing a mutant autosomal recessive allele in the oocyte (by its absence in the polar body) precludes permitting an oocyte to be fertilized, whereas any resulting embryo would actually be affected only if the fertilizing sperm contained the same mutant allele.

A major potential disadvantage is recombination, that meiotic phenomenon occurring routinely between homologous chromosomes. If crossing over involves the region containing the gene in question, the single chromosome in the primary oocyte would contain DNA sequences encoding both alleles. That is, the two chromatids of the single chromosome would differ in genotype (heterozygosity). Genotype of the secondary oocyte could thus not be predicted without either biopsy of the second polar body or biopsy of the embryo per se (blastomere or blastocyst biopsy). Recombination can be addressed by performing biopsy on both the first and second polar bodies.^[102] Actually, the "problem" of recombination then actually can be beneficial because presence of two alleles at the first polar body excludes allele dropout (failure of one allele to amplify) at that stage. Thus, one could be confident of the accuracy of a second polar body biopsy showing only one allele.

Technical Considerations in Diagnosing Chromosomal Abnormalities

Cytogenetic analysis in preimplantation genetic diagnosis would be useful for a variety of reasons. Sex determination (XX or XY) may be desirable for couples at risk for an X-linked recessive trait, in which an exact diagnosis is not possible. Detection of aneuploidy is also possible. Translocations and other chromosomal rearrangements are also detectable by FISH, using specifically selected break-point-specific or a combination of telomeric and centromeric FISH probes.^[103] FISH accuracy in blastomeres seems at least as high as in amniotic fluid or chorionic villus cells.

Experience from individual preimplantation genetic diagnosis (PGD) centers is still limited, but anomaly rates and spontaneous abortion rates following PGD appear to be similar to those in conventional ART without embryo biopsy.^[104] As of June 2000, there are approximately 2,500 PGD cycles worldwide, with a pregnancy rate of 20 to 25 percent.^[104] The anomaly rates do not seem to be increased over that in the general population.^[101], ^[104], ^[105]

Diagnostic accuracy is also achievable for mendelian traits, but single-cell diagnosis requires specialized technology (nested primer or fluorescent PCR; heteroduplex analysis). It cannot be assumed that a routine genetics or diagnostic laboratory can perform single-cell PCR just because they perform the techniques on samples containing many cells.

A major worry is the risk of contamination from ambient cells. Failed PCR also occurs, but this is less catastrophic than contamination, for only the latter would ordinarily lead to a false-negative diagnosis. If in an autosomal recessive disorder the embryo were a heterozygote, failure to amplify the normal allele would erroneously indicate the embryo to be affected; therefore, no transfer would occur. The clinical consequence would be limited to a missed opportunity to achieve a pregnancy. Conversely, failing to amplify the abnormal allele would result in transfer of an embryo assumed erroneously to be homozygously normal but actually heterozygous. In either cases, allele-specific PCR failure would not result in a clinically significant error (i.e., false-negative diagnosis). These problems are especially

acute when attempting to diagnose compound heterozygosity.

A promising new use of PGD is to increase pregnancy in assisted reproductive technology by training on euploid embryos. This is most helpful in women 37 years or older or with prior history of ART failure. [\[106\]](#)

FUTURE DIRECTIONS: FETAL CELLS IN MATERNAL BLOOD

Fetal cells circulate in the maternal blood during pregnancy, and their analysis represents a new approach to noninvasive prenatal genetic diagnosis. Consensus has already developed that detection is possible for fetal aneuploidy and for selected mendelian disorders. The issue is sensitivity compared to other noninvasive approaches.

Using nested primer PCR for Y-specific DNA, signals

can be detected early in pregnancy in the peripheral blood of pregnant women carrying male fetuses. Y-specific signals were detected by 33 days' gestation by Thomas and colleagues.^[107] By 6 weeks' gestation, all pregnancies having a male fetus show a Y-specific signals in maternal blood.

Diagnosis of chromosomal abnormalities requires fetal interphase cell analysis by FISH with chromosome-specific probes. Given the rarity of fetal cells in maternal blood ($1:10^7$), one must enrich for the rare fetal cells. This requires targeting a specific fetal cell type. Targets include fetal trophoblasts, lymphocytes, granulocytes, and nucleated red blood cells (NRBCs). The latter is generally considered to be the most attractive cell type because these cells (NRBCs) comprise about 10 percent of red cells in the 11-week fetus and 0.5 percent in the 19-week fetus. Nucleated red blood cells persist no longer than perhaps 5 days in the adult, and are rare in peripheral adult blood.

One concern is that fetal cells from a prior pregnancy could persist in the maternal circulation and, hence, lead to diagnostic error. This would especially be troublesome if aneuploid cells were to persist after a chromosomally abnormal liveborn offspring or a chromosomally abnormal spontaneous abortion. However, fetal cells usually disappear rapidly after delivery. Using the usual selection criteria, cells from prior pregnancies do not appear to be a major confounder.

Our group was the first to detect fetal aneuploidy by maternal blood analysis. Analyzing interphase cells by FISH with chromosome-specific probes we detected first trisomy 18^[108] and then trisomy 21^[109] in 1992. At present, the detection rate for aneuploidy using fetal cells recovered from maternal blood is estimated to be 40 to 59 percent, on the basis of an ongoing NICHD collaborative study.^[110] Diagnosis is usually made on the basis of one to three trisomic (and, hence, fetal) cells recovered from a 20- to 30-ml specimen. Given that 1 ml of maternal blood is estimated to contain one fetal cell, many fetal cells must be lost. Improved sensitivity would be expected with increased fetal cell recovery and especially better cell separated selection criteria. Active collaborative work is in progress.

Detection of fetal mendelian disorders by analysis of fetal cells in maternal blood does not necessarily require enrichment and, thus, does not necessitate targeting for any specific fetal cell type. PCR-based technology alone may suffice, since the DNA may be derived from any type of fetal cell. Diagnosis can also be made from analysis of plasma, which contains fetal DNA.

In several situations, fetal cell analysis might be useful. First, determining fetal sex is useful in couples at risk for X-linked recessive traits. Second, certain point mutations (mendelian disorders) can be detected. One useful circumstance arises when the father is heterozygous (Aa) and the mother homozygously abnormal (aa) for an autosomal recessive trait. The normal allele may or may not be transmitted by the heterozygous father; but if it is, detection by PCR should be possible. If blood from the homozygous mother reveals the normal paternal allele (A), the fetus can be deduced to be heterozygous. Particularly applicable for obstetricians is diagnosis of fetal rhesus (D) through PCR of maternal blood. The molecular basis of Rh(D) negativity (dd) is usually a gene deletion, a representing lack of the DNA sequence that if present encodes *D*. This makes distinguishing Rh(D)-positive (DD or Dd) from Rh(D)-negative (dd) simple by molecular techniques. If the mother is Rh-negative and the father homozygous for Rh(D) (Rh-positive), all fetuses must be heterozygous (Dd); every pregnancy would then be at risk for RhD-isoimmunization. If the father is heterozygous, however, the likelihood is only 50 percent that the fetus would inherit his RhD gene and, hence, be affected; the other 50 percent of pregnancies would not be at risk for Rh-isoimmunization. If Rh(D) sequences are found in a pregnant Rh-negative woman (dd), their origin must be fetal; thus, the fetus is Dd.

The inconvenience of working with rare fetal cells could be overcome if these fetal cells could be cultured in vitro from a maternal blood sample. Given that maternal stem cells are also present in maternal blood, techniques designed to stimulate fetal cells differentially would be desirable. Several groups have reported the successful fetal cells in culture.^[111]

Key Points

The frequency of major birth defects is 2 to 3 percent. Major etiologic categories include chromosomal abnormalities (1 per 160 live births), single-gene or mendelian disorders, polygenic/multifactorial disorders, and teratogenic disorders. Of the chromosomal abnormalities, approximately half represent autosomal trisomy and half sex chromosomal abnormalities.

Principles of genetic counseling include adequate communication, appreciation of psychological defenses, and philosophy of nondirective counseling.

Genetic screening for heterozygote detection in the nonpregnant and, if not already evaluated, pregnant population is appropriate for only selected autosomal recessive disorders: Tay-Sachs disease in Jewish populations, -thalassemia in Asians, -thalassemia in Mediterranean peoples

216

(Greek and Italian), sickle cell in African-American blacks.

The ACOG and major genetic organizations have recently recommended that screening for cystic fibrosis be offered to Caucasian and Ashkenazi Jewish individuals, and made available to other ethnic populations. Detection rates are 80 to 95 percent in the two former groups, and 70 percent in African-Americans, Hispanics, and Asians. Screening for a defined panel of alleles is considered the minimal standard.

In all pregnancies, genetic screening should be performed for chromosomal abnormalities and NTDs. All women aged 35 years and above at delivery should be offered prenatal cytogenetic diagnosis. For younger women, maternal serum screening should be offered to detect autosomal trisomies. The profile of decreased MSAFP, elevated hCG, and decreased unconjugated serum estriol favors Down syndrome. Maternal serum analyte screening in combination with maternal age can detect 60 percent of Down syndrome cases, but the frequency varies according to maternal age (90 percent over age 35 but about 25 percent in the early third decade). Screening for NTDs involves elevated MSAFP followed by amniotic fluid analysis; approximately 80 to 90 percent of NTDs can be detected at a cost of 5 percent amniocentesis.

All invasive procedures carry risks. Amniocentesis at 15 weeks and above carries a procedure-related risk of perhaps 0.2 to 0.5 percent loss. Amniocentesis before 14 to 15 weeks has been subjected to rigorous trials to determine safety, and use before 13 weeks is not recommended because of the unacceptable 1 to 2 percent risk of clubfoot. CVS is considered, in experienced hands, equal to amniocentesis in terms of loss rates and diagnostic accuracy. Transcervical and transabdominal CVS are equivalent in safety.

Controversy exists concerning LRDs associated with CVS. If a risk exists, it appears to be greatest below 10 weeks' gestation, for which reason, in general, the procedure should generally be available at 10 weeks and beyond. A maximum limb reduction risk of 1 in 3,000 has been reported, and many believe that the risk is not greater than that of the general population.

The complication rate associated with fetal blood sampling is uncertain, but appears to be 1 to 2 percent. The rate varies according to the diagnosis being assessed. No studies have directly compared loss rates in control and tested pregnancies.

Many single-gene disorders are detectable. Some can be detected by enzymatic analysis, whereas others can be recognized best or only through molecular methodologies.

Two principal types of molecular analysis are employed. Direct analysis is possible if the gene sequence is known. Linkage analysis is necessary if the gene has been localized but not yet sequenced. Linkage analysis takes advantage of markers lying close to the gene in question; accuracy is not 100 percent because recombination can occur between the marker and the mutant gene.

Preimplantation genetic diagnosis has been performed in approximately 2,500 cycles, principally by removing a single cell (blastomere) from the eight-cell embryo. Diagnosis requires special molecular techniques for mendelian disorders or FISH for chromosomal abnormalities (trisomy). Accuracy is near 100 percent, and safety does not seem to be a major concern.

Fetal cells have been recovered from maternal blood and fetal trisomies detected, with detection rates for autosomal trisomy of about 40 to 50 percent. Improving sensitivity compared with other noninvasive methods (e.g., maternal serum screening) is underway.

Chapter 9 - Drugs in Pregnancy and Lactation

Jennifer R. Niebyl

Caution with regard to drug ingestion during pregnancy is usually advised. Until recently, the fetus was thought to rest in a privileged site with little exposure to the environment experienced by the mother. The term *placental barrier* has been in widespread use but is truly a contradiction, as the placenta allows the transfer of many drugs and dietary substances.

Lipid-soluble compounds readily cross the placenta, and water-soluble substances pass less well the greater their molecular weight. The degree to which a drug is bound to plasma protein also influences the amount of drug that is free to cross the placenta. Virtually all drugs cross the placenta to some degree, with the exception of large organic ions such as heparin and insulin.

Developmental defects in humans may be from genetic, environmental, or unknown causes. Approximately 25 percent are known to be genetic in origin; drug exposure accounts for only 2 to 3 percent of birth defects. Approximately 65 percent of defects are of unknown etiology but may be from combinations of genetic and environmental factors ([see Chapter 8](#)).

The incidence of major malformations in the general population is usually quoted as 2 to 3 percent. ^[1] A major malformation is defined as one that is incompatible with survival, such as anencephaly, or one requiring major surgery for correction, such as cleft palate or congenital heart disease, or one producing major dysfunction (e.g., mental retardation). If minor malformations are also included, such as ear tags or extra digits, the rate may be as high as 7 to 10 percent. The risk of malformation after exposure to a drug must be compared with this background rate.

There is a marked species specificity in drug teratogenesis. ^[2] For example, thalidomide was not found to be teratogenic in rats and mice but is a potent human teratogen. On the contrary, in certain strains of mice, corticosteroids produce a high percentage of offspring with cleft lip, although no studies have shown these drugs to be teratogenic in humans. The Food and Drug Administration (FDA) lists five categories of labeling for drug use in pregnancy:

- A. Controlled studies in women fail to demonstrate a risk to the fetus in the first trimester, and the possibility of fetal harm appears remote.
- B. Animal studies do not indicate a risk to the fetus; there are no controlled human studies, or animal studies do show an adverse effect on the fetus, but well-controlled studies in pregnant women have failed to demonstrate a risk to the fetus.
- C. Studies have shown the drug to have animal teratogenic or embryocidal effects, but no controlled studies are available in women, or no studies are available in either animals or women.
- D. Positive evidence of human fetal risk exists, but benefits in certain situations (e.g., life-threatening situations or serious diseases for which safer drugs cannot be used or are ineffective) may make use of the drug acceptable despite its risks.
- E. Studies in animals or humans have demonstrated fetal abnormalities, or evidence demonstrates fetal risk based on human experience, or both, and the risk clearly outweighs any possible benefit.

The classic teratogenic period is from day 31 after the last menstrual period in a 28-day cycle to 71 days from the last period ([Fig. 9-1](#)). During this critical period, organs are forming, and teratogens may cause malformations that are usually overt at birth. The timing of exposure is important. Administration of drugs early in the period of organogenesis will affect the organs developing at that time, such as the heart or neural tube. Closer to the end of the classic teratogenic

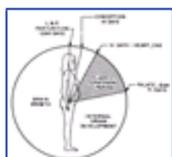

Figure 9-1 Gestational clock showing the classic teratogenic period. (From Blake DA, Niebyl JR: *Requirements and limitations in reproductive and teratogenic risk assessment*. In Niebyl JR (eds): *Drug Use in Pregnancy*, 2nd ed. Philadelphia, Lea & Febiger, 1988, p 1, with permission.)

period, the ear and palate are forming and may be affected by a teratogen.

Before day 31, exposure to a teratogen produces an all-or-none effect. With exposure around conception, the conceptus usually either does not survive or survives without anomalies. Because so few cells exist in the early stages, irreparable damage to some may be lethal to the entire organism. If the organism remains viable, however, organ-specific anomalies are not manifested, because either repair or replacement will occur to permit normal development. A similar insult at a later stage may produce organ-specific defects.

Patients should be educated about avenues other than the use of drugs to cope with tension, aches and pains,

and viral illnesses during pregnancy. Drugs should be used only when necessary. The risk/benefit ratio should justify the use of a particular drug, and the minimum effective dose should be employed. As long-term effects of drug exposure in utero may not be revealed for many years, caution with regard to the use of any drug in pregnancy is warranted.

EMBRYOLOGY

During the first 3 days after ovulation, development takes place in the fallopian tube. At the time of fertilization, a pronuclear stage exists during which the nuclei from the egg and the sperm retain their integrity within the egg cytoplasm. After the pronuclei fuse, the fertilized egg begins a series of mitotic cell divisions (cleavage). The two-cell stage is reached about 30 hours

223

after fertilization. With continued division, the cells develop into a solid ball of cells (morula), which reaches the endometrial cavity about 3 days after fertilization. Thereafter, a fluid-filled cavity forms within the cell mass, at which time the conceptus is called a *blastocyst*. The number of cells increases from approximately 12 to 32 by the end of the third day to 250 by the sixth day.

Until approximately 3 days after conception, any cell is thought to be totipotent, that is, capable of initiating development of any organ system. For example, separation of cells during this period can give rise to monozygotic twins, each normal. At the blastocyst stage, cells first begin to differentiate. The blastocyst is located in the uterus, where implantation occurs 6 to 9 days after conception.

One group of cells forms the inner cell mass that will ultimately develop into the fetus. Different tissues will arise from each of the three cell layers. The brain, nerves, and skin will develop from the ectoderm; the lining of the digestive tract, respiratory tract, and part of the bladder, as well as the liver and pancreas from the endoderm, and connective tissue, cartilage, muscle, blood vessels, the heart, kidneys, and gonads develop from the mesoderm. The group of cells forming the periphery of the blastocyst is termed the *trophoblast*. The placenta and the fetal membranes will develop from this outer cell layer.

The trophoblast continues to grow, and lacunae form within the previously solid syncytiotrophoblast. The lacunae are the precursors of the intervillous spaces of the placenta, and by 2 weeks after conception maternal blood is found within them. Meanwhile, the cytotrophoblast is forming cell masses that will become chorionic villi.

From the third to the eighth week after conception, the embryonic disk undergoes major developments that lay the foundation for all organ systems. By 4 weeks after conception, the fertilized ovum has progressed from one cell to millions of cells. The rudiments of all major systems have differentiated, and the blueprints are set for developmental refinements. The embryo has been transformed into a curved tube approximately 6 mm long and isolated from the extraembryonic membranes.

At 5 weeks after conception, the embryo first begins to assume features of human appearance. The face is recognizable, with the formation of discernible eyes, nose, and ears. Limbs emerge from protruding buds; digits, cartilage, and muscles develop. The cerebral hemispheres begin to fill the brain area, and the optic stalk becomes apparent. Nerve connections are established between the retina and the brain. The digestive tract rotates from its prior tubular structure, and the liver starts to produce blood cells and bile. Two tubes emerge from the pharynx to become bronchi, and the lungs have lobes and bronchioles. The heart is beating at 5 weeks and is almost completely developed by 8 weeks after conception. The diaphragm begins to divide the heart and lungs from the abdominal cavity. The kidneys approach their final form at this time. The urogenital and rectal passages separate, and germ cells migrate toward the genital ridges for future transformation into ovaries or testes. Differentiation of internal ducts begins, with persistence of either müllerian or wolffian ducts. Virilization of external genitalia occurs in males. The embryo increases from approximately 6 to 33 mm in length and increases 50 times in weight.

Structurally, the fetus has become straighter, and the tubular neural canal along which the spinal cord develops becomes filled with nerve cells. Ears remain low on the sides of the head. Teeth are forming, and the two bony plates of the palate fuse in the midline. Disruptions during the latter part of the embryonic period lead to various forms of cleft lip and palate. By 10 weeks after the last menstrual period, all major organ systems have become established and integrated.

Development of other organs continues in the second and third trimesters of pregnancy. Therefore, we need to be concerned about drug use at this time in pregnancy, although the effects may not be recognized until later in life. Some of the uterine anomalies resulting from diethylstilbestrol (DES) occurred with exposure as late as 20 weeks but were not recognized until after puberty. The brain continues to develop throughout pregnancy and the neonatal period. Fetal alcohol syndrome may occur with chronic exposure to alcohol in the later stages of pregnancy.

EFFECTS OF SPECIFIC DRUGS

Estrogens and Progestins

Oral contraceptives and progestins given in the first trimester have been blamed in the past for a variety of birth defects, but recent studies have not confirmed any teratogenic risk for these drugs.

Data from the Collaborative Perinatal Project, a prospective study of 50,282 pregnancies between 1958 and 1965, initially supported the possibility of a risk of cardiac defects after first-trimester exposure to female hormones and oral contraceptives.^[3] However, a reevaluation of these data has questioned this result.^[4] Careful review of the records indicated that some patients had taken the medication too early or too late to affect the cardiovascular system. When infants with Down syndrome were excluded, no significant difference in the risk of cardiovascular anomalies remained. Another study of 2,754 infants born to mothers after bleeding

224

in the first trimester suggested no increased risk associated with first-trimester exposure to progestogens.^[5] A meta-analysis of first-trimester sex hormone exposure revealed no association between exposure and fetal genital malformations.^[6] However, because of the medicolegal climate and the conflicting literature, it is wise to do a sensitive pregnancy test before refilling a prescription for pills or giving progestins to an amenorrheic patient.

Androgenic Steroids

Androgens may masculinize a developing female fetus. Progestational agents, most often the synthetic testosterone derivatives, may cause clitoromegaly and labial fusion if given before 13 weeks of pregnancy.^[7] Danazol (Danocrine) has been reported to produce mild clitoral enlargement and labial fusion when given inadvertently for the first 10 to 12 weeks after conception (Fig. 9-2).^[8] The abnormality was correctable by surgery.

Spermicides

A reported increased risk of abnormal offspring in mothers who had used spermicides for contraception

Figure 9-2 Perineum of a female fetus exposed to danazol in utero. (From Duck SC, Katayama KP: *Danazol may cause female pseudohermaphroditism*. *Fertil Steril* 35:230, 1981, with permission.)

has not been confirmed. In the Collaborative Perinatal Project data,^[9] 462 women reported spermicide use in the first 4 lunar months, with 438 also describing use during the month preceding the last menstrual period. The exposed women had 23 infants with anomalies (5 percent) compared with 4.5 percent in the nonexposed controls, not a significant difference.

In the study of Mills et al.,^[10] the malformation rate in women using spermicides after their last menstrual period was 4.8 in 1,000 compared with 6.4 in 1,000 in the controls, not significantly different. The risk of preterm delivery, a low-birth-weight infant, and spontaneous abortion was no higher in the spermicide-exposed group. The study of Linn et al.^[11] of 12,440 women found no relationship between contraceptive method and the occurrence of malformations.

Anticonvulsants

Epileptic women taking anticonvulsants during pregnancy have approximately double the general population risk of malformations. Compared with the general risk of 2 to 3 percent, the risk of major malformations in epileptic women on anticonvulsants is about 5 percent, especially cleft lip with or without cleft palate and congenital heart disease. Valproic acid (Depakene) and carbamazepine (Tegretol) each carry approximately a 1 percent risk of neural tube defects and possibly other anomalies.^[12], ^[13] In addition, the offspring of epileptic women have a 2 to 3 percent incidence of epilepsy, five times that in the general population.

Whenever a drug is claimed to be a teratogen, one always can raise the issue of whether the drug actually is a teratogen or the disease for which the drug was prescribed in some way contributed to the defect. Even when they take no anticonvulsant drug, women with a convulsive disorder have an increased risk of delivering infants with malformations; this information supports a role for the epilepsy itself rather than the anticonvulsant drug as a contributor to the birth defect.^[14] Of infants born to 305 epileptic women on medication in the Collaborative Perinatal Project, 10.5 percent had a birth defect. Of the offspring of women who had a convulsive disorder and who had taken no phenytoin at all, 11.3 percent had a malformation. In contrast, the total malformation rate was 6.4 percent for the control group of women who did not have a convulsive disorder and who therefore did not take any antiepileptic drugs. The issue remains unresolved, as patients who take more drugs during pregnancy usually have more severe convulsive disorders than do those who do not take any anticonvulsants. A combination of more than three drugs or a high daily dose increases the chance of malformations.^[15]

Possible causes of anomalies in epileptic women on anticonvulsants include the disease itself, a genetic predisposition

225

to both epilepsy and malformations, genetic differences in drug metabolism, the specific drugs themselves, and deficiency states induced by drugs such as decreased serum folate. Phenytoin (Dilantin) decreases folate absorption and lowers the serum folate, which has been implicated in birth defects.^[16] Therefore, folic acid supplementation should be given to these mothers, but may require adjustment of the anticonvulsant dose. Although epileptic women were not included in the Medical Research Council study, most authorities would recommend 4 mg/day folic acid for high-risk women^[16] (see Chapter 6). One study suggested that folic acid at doses of 2.5 to 5 mg daily could reduce birth defects in women on anticonvulsant drugs.^[17]

Fewer than 10 percent of offspring show the fetal hydantoin syndrome, ^[18] which consists of microcephaly, growth deficiency, developmental delays, mental retardation, and dysmorphic craniofacial features (Fig. 9-3). In fact, the risk may be as low as 1 to 2 percent. ^[19] While several of these features are also found in other syndromes, such as fetal alcohol syndrome, more common in the fetal hydantoin syndrome are hypoplasia of the nails and distal phalanges (Fig. 9-4), and hypertelorism. Carbamazepine (Tegretol) is also associated with an increased risk of a dysmorphic syndrome. ^[20]

A genetic metabolic defect in arene oxide detoxification in the infant may increase the risk of a major birth defect. ^[21] Epoxide hydrolase deficiency may indicate susceptibility to fetal hydantoin syndrome. ^[22]

Figure 9-3 Facial features of the fetal hydantoin syndrome. Note broad, flat nasal ridge, epicanthic folds, mild hypertelorism, and wide mouth with prominent upper lip. (Courtesy of Dr. Thaddeus Kelly, Charlottesville, VA.)

Figure 9-4 Hypoplasia of toenails and distal phalanges. (From Hanson JWM: *Fetal hydantoin syndrome*. *Teratology* 13:186, 1976, with permission.)

In a follow-up study of long-term effects of antenatal exposure to phenobarbital and carbamazepine, anomalies were not related to specific maternal medication exposure. There were no neurologic or behavioral differences between the two groups. ^[23] However, children exposed in utero to phenytoin scored 10 points lower on IQ tests than children exposed to carbamazepine or nonexposed controls. ^[24] Also, prenatal exposure to phenobarbital decreased verbal IQ scores in adult men. ^[25]

Newer Antiepileptic Drugs

Lamotrigine (Lamictal) has been studied in a registry ^[26] established by the manufacturer, Glaxo Wellcome. Eight of 123 infants (6.5 percent; 95 percent confidence interval [CI] 3.1 to 12.8 percent) born to women treated with lamotrigine during the first trimester and followed prospectively to birth were found to have congenital anomalies. ^[26] All of the mothers of children with malformations had a seizure disorder and some took at least one other medication during the pregnancy.

Lamotrigine is an inhibitor of dihydrofolate reductase and decreases embryonic folate levels in experimental animals, so it is theoretically possible that this drug would be associated with an increased malformation risk like the other antiepileptic drugs. ^[27] The limited human data to date do not appear to indicate a major risk for congenital malformations or fetal loss following first-trimester exposure to lamotrigine.

There are no epidemiologic studies of congenital anomalies among children born to women treated with felbamate, gabapentin, oxcarbazepine, tiagabine, topiramate, or vigabatrin. ^[28]

Some women may have taken anticonvulsant drugs for a long period without reevaluation of the need for continuation of the drugs. For patients with idiopathic epilepsy who have been seizure free for 2 years and

who have a normal electroencephalogram (EEG), it may be safe to attempt a trial of withdrawal of the drug before pregnancy. ^[29]

Most authorities agree that the benefits of anticonvulsant therapy during pregnancy outweigh the risks of discontinuation of the drug if the patient is first seen during pregnancy. The blood level of drug should be monitored to ensure a therapeutic level but minimize the dosage. If the patient has not been taking her drug regularly, a low blood level may demonstrate her lack of compliance and she may not need the drug. Because the albumin concentration falls in pregnancy, the total amount of phenytoin measured is decreased, as it is highly protein bound. However, the level of free phenytoin, which is the pharmacologically active portion, is unchanged. Neonatologists need to be notified when a patient is on anticonvulsants, because this therapy can affect vitamin K-dependent clotting factors in the newborn. Vitamin K supplementation at 10 mg daily for these mothers has been recommended for the last month of pregnancy. ^[30]

Isotretinoin

Isotretinoin (Accutane) is a significant human teratogen. This drug is marketed for treatment of cystic acne and unfortunately has been taken inadvertently by women who were not planning pregnancy. ^[31] It is labeled as contraindicated in pregnancy (FDA category X) with appropriate warnings that a negative pregnancy test is required before therapy. Of 154 exposed human pregnancies to date, there have been 21 reported cases of birth defects, 12 spontaneous abortions, 95 elective abortions, and 26 normal infants in women who took isotretinoin during early pregnancy. The risk of structural anomalies in patients studied prospectively is now estimated to be about 25 percent. An additional 25 percent have mental retardation alone. ^[32] The malformed infants have a characteristic pattern of craniofacial, cardiac, thymic, and central nervous system anomalies. They include microtia/antia (small/absent ears) (Fig. 9-5), micrognathia, cleft palate, heart defects, thymic defects, retinal or optic nerve anomalies, and central nervous system malformations including hydrocephalus. ^[31] Microtia is rare as an isolated anomaly yet appears commonly as part of the retinoic acid embryopathy. Cardiovascular defects include great vessel transposition and ventricular septal defects.

Unlike vitamin A, isotretinoin is not stored in tissue. Therefore, a pregnancy after discontinuation of isotretinoin is not at risk, as the drug is no longer detectable in serum 5 days after its ingestion. In 88 pregnancies prospectively ascertained after discontinuation of isotretinoin, no increased risk of anomalies was noted, in contrast to etretinate (see below). ^[33] Topical tretinoin (Retin-A) has not been associated with any teratogenic risk. ^[34]

Etretinate (Tegison)

This drug is marketed for use in psoriasis and may well have a teratogenic risk similar to that of isotretinoin. Case reports of malformation, especially central nervous system, ^[35] have appeared, but the absolute risk is

Figure 9-5 Infant exposed to Accutane in utero. Note high forehead, hypoplastic nasal bridge, and abnormal ears. (From Lot IT, Bocian M, Pribam HW, Leitner M: *Fetal hydrocephalus and ear anomalies associated with use of isotretinoin*. *J Pediatr* 105:598, 1984, with permission.)

unknown. The half-life of several months makes levels cumulative, and the drug carries a warning to avoid pregnancy within 6 months of use.

Vitamin A

There is no evidence that vitamin A itself in normal doses is teratogenic, nor is betacarotene. The levels in prenatal vitamins (5,000 IU/day orally) have not been associated with any documented risk. Eighteen cases of birth defects have been reported after exposure to levels of 25,000 IU of vitamin A or greater during pregnancy. Vitamin A in doses greater than 10,000 IU/day was shown to increase the risk of malformations in one study,^[35] but not in another.^[36]

Psychoactive Drugs

There is no clear risk documented for most psychoactive drugs with respect to overt birth defects. However, effects of chronic use of these agents on the developing brain in humans is difficult to study, and so a conservative attitude is appropriate. Lack of overt defects does not exclude the possibility of behavioral teratology.

Tranquilizers

Conflicting reports of the possible teratogenicity of the various tranquilizers, including meprobamate (Miltown) and chlordiazepoxide (Librium), have appeared, but in prospective studies no risk of anomalies has been confirmed.^[37] In most clinical situations, the risk/benefit ratio does not justify the use of benzodiazepines in pregnancy.

A fetal benzodiazepine syndrome has been reported in 7 infants of 36 mothers who regularly took benzodiazepines during pregnancy.^[38] However, the high rate of abnormality occurred with concomitant alcohol and substance abuse and may not be caused by the benzodiazepine exposure.^[39] Perinatal use of diazepam (Valium) has been associated with hypotonia, hypothermia, and respiratory depression.

Lithium (Eskalith, Lithobid)

In the International Register of Lithium Babies,^[40] 217 infants are listed as exposed at least during the first trimester of pregnancy, and 25 (11.5 percent) were malformed. Eighteen had cardiovascular anomalies, including six cases of the rare Ebstein's anomaly, which occurs in only 1 in 20,000 in the nonexposed population. Of 60 unaffected infants who were followed to age 5 years, no increased mental or physical abnormalities were noted compared with unexposed siblings.^[41]

However, two other reports suggest that there was a bias of ascertainment in the registry and that the risk of anomalies is much lower than previously thought. A case-control study of 59 patients with Ebstein's anomaly showed no difference in the rate of lithium exposure in pregnancy from a control group of 168 children with neuroblastoma.^[42] A prospective study of 148 women exposed to lithium in the first trimester showed no difference in the incidence of major anomalies compared with controls.^[43] One fetus in the lithium-exposed group had Ebstein's anomaly, and one infant in the control group had a ventricular septal defect. The authors concluded that lithium is not a major human teratogen. Nevertheless, we do recommend that women exposed to lithium be offered ultrasound and fetal echocardiography.

Lithium is excreted more rapidly during pregnancy; thus, serum lithium levels should be monitored. Perinatal effects of lithium have been noted, including hypotonia, lethargy, and poor feeding in the infant. Also, complications similar to those seen in adults on lithium have been noted in newborns, including goiter and hypothyroidism.

Two cases of polyhydramnios associated with maternal lithium treatment have been reported.^[44] Because nephrogenic diabetes insipidus has been reported in adults taking lithium, the presumed mechanism of this polyhydramnios is fetal diabetes insipidus. Polyhydramnios may be a sign of fetal lithium toxicity.

It is usually recommended that drug therapy be changed in pregnant women on lithium to avoid fetal drug exposure. Tapering over 10 days will delay the risk of relapse.^[45] However, discontinuing lithium is associated with a 70 percent change of relapse of the affective disorder in 1 year as opposed to 20 percent in those who remain on lithium. Discontinuation of lithium may pose an unacceptable risk of increased morbidity in women who have had multiple episodes of affective instability. These women should be offered appropriate prenatal diagnosis with ultrasound, including fetal echocardiography.

Antidepressants

Imipramine (Tofranil) was the original tricyclic antidepressant claimed to be associated with cardiovascular defects, but the number of patients studied remains small. Of 75 newborns exposed in the first trimester, 6 major defects were observed, 3 being cardiovascular.^[47]

Amitriptyline (Elavil) has been more widely used. Although occasional reports have associated the use of this drug with birth defects, the majority of the evidence supports its safety. In the Michigan Medicaid study, 467 newborns had been exposed during the first trimester, with no increased risk of birth defects.^[48]

Fluoxetine (Prozac) is being used with increasing frequency as an antidepressant. No increased risk of

major malformations has been found after first-trimester exposure to fluoxetine in over 500 pregnancies.^[49] ^[50]

Nulman and colleagues^[51] evaluated the neurobehavioral effects of long-term fluoxetine exposure during pregnancy and found no abnormalities among 228 children aged 16 to 86 months (average age, 3 years). Theoretically, some psychiatric or neurobehavioral abnormality might occur as a result of exposure, but it would be very difficult to ascertain because of all of the confounding variables. In mice, some behavioral effects have been observed.^[52]

Chambers and associates^[53] found more minor malformations and perinatal complications among infants exposed to fluoxetine throughout pregnancy, but this study is difficult to interpret because the authors did not control for depression. When a group whose mothers received tricyclic agents was used as a control for depression, infants exposed to fluoxetine in utero did not appear to have more minor malformations or perinatal complications.^[49]

The newer selective serotonin reuptake inhibitors fluvoxamine, paroxetine, and sertraline were also studied during the first trimester in 267 women; there was no increased risk of birth defects.^[54]

Anticoagulants

Warfarin (Coumadin) has been associated with chondrodysplasia punctata, which is similar to the genetic Conradi-Hünemann syndrome. This syndrome, occurring in about 5 percent of exposed pregnancies, includes nasal hypoplasia, bone stippling seen on radiologic examination, ophthalmologic abnormalities including bilateral optic atrophy, and mental retardation (Fig. 9-6). The ophthalmologic abnormalities and mental retardation may occur,^[55] even with use only beyond the first trimester. Fetal and maternal hemorrhage have also been reported in pregnant women on warfarin, although the incidence can be lowered with careful control of the prothrombin time.

The alternative drug, heparin, does not cross the placenta, as it is a large molecule with a strong negative charge. Because heparin does not have an adverse effect on the fetus when given in pregnancy, it should be the drug of choice for patients requiring anticoagulation. In one study, heparin treatment was associated with more thromboembolic complications and more bleeding complications than warfarin therapy.^[56] Therapy with 20,000 units/day for greater than 20 weeks has also been associated with bone demineralization.^[57] Thirty-six percent of patients had more than a 10 percent decrease from baseline bone density to postpartum values.^[58] The risk of spine fractures was 0.7 percent with low-dose heparin and 3 percent with a high-dose regimen.^[59] Heparin can also cause thrombocytopenia.

Low-molecular-weight heparins may have substantial benefits over standard unfractionated heparin.^[60] The molecules are still relatively large, and do not cross the placenta.^[61] The half-life is longer, allowing for once-daily

Figure 9-6 Warfarin embryopathy. Note small nose with hypoplastic bridge. (From Shaul W, Hall JG: Multiple congenital anomalies associated with oral anticoagulants. *Am J Obstet Gynecol* 127:191, 1977, with permission.)

administration. However, enoxaparin is cleared more rapidly during pregnancy, and so twice-daily dosing may be advised. They have a much more predictable dose-response relationship, obviating the need for monitoring. There is less risk of heparin-induced thrombocytopenia and clinical bleeding at delivery, but studies suggesting less risk of osteoporosis are preliminary. The cost is substantially higher than standard heparin. [62], [63]

The risks of heparin during pregnancy may not be justified in patients with only a single episode of thrombosis in the past. [64], [65] Certainly, conservative measures should be recommended, such as elastic stockings and avoidance of prolonged sitting or standing.

In patients with cardiac valve prostheses, full anticoagulation is necessary, as low-dose heparin resulted in three valve thromboses (two fatal) in 35 mothers so treated. [66]

Thyroid and Antithyroid Drugs

Propylthiouracil (PTU) and methimazole (Tapazole) both cross the placenta and may cause some degree of fetal goiter. In contrast, the thyroid hormones triiodothyronine (T_3) and thyroxine (T_4) cross the placenta poorly, so that fetal hypothyroidism produced by antithyroid drugs cannot be corrected satisfactorily by administration of thyroid hormone to the mother. Thus, the goal of such therapy during pregnancy is to keep the mother slightly hyperthyroid to minimize fetal drug exposure. Methimazole has been associated with scalp defects in infants; [67] as well as a higher incidence of maternal side effects. However, PTU and methimazole are equally effective and safe for therapy of hyperthyroidism. [68]

Radioactive iodine (^{131}I or ^{125}I) administered for thyroid ablation or for diagnostic studies is not concentrated by the fetal thyroid until after 12 weeks of pregnancy. [69] Thus, with inadvertent exposure, usually around the time of missed menses, there is no specific risk to the fetal thyroid from ^{131}I or ^{125}I administration.

The need for thyroxine increases in many women with primary hypothyroidism when they are pregnant, as reflected by an increase in serum thyroid-stimulating hormone (TSH) concentrations. [70] In one study, the mean thyroxine dose before pregnancy was 0.10 mg/day; it was increased to a mean dose of 0.15 mg/day during pregnancy. [70] As hypothyroidism in pregnancy may adversely affect the fetus, [71] it is prudent to monitor thyroid function throughout pregnancy and to adjust the thyroid dose to maintain a normal TSH level. Topical iodine preparations are readily absorbed through the vagina during pregnancy, and transient hypothyroidism has been demonstrated in the newborn after exposure during labor. [72]

Digoxin (Lanoxin)

In 52 exposures, no teratogenicity of digoxin was noted. [73] Blood levels should be monitored in pregnancy to ensure adequate therapeutic maternal levels.

Digoxin-like immunoreactive substances may be mistaken in assays for fetal concentrations of digoxin. In one study of fetuses with cardiac anomalies, [74] there was no difference in the immunoreactive digoxin levels whether or not the mother had received digoxin. In hydropic fetuses, digoxin may not easily cross the placenta. [75]

Antihypertensive Drugs

-Methyldopa (Aldomet) has been widely used for the treatment of chronic hypertension in pregnancy. Although postural hypotension may occur, no unusual fetal effects have been noted. Hydralazine (Apresoline) has also had widespread use in pregnancy, and no teratogenic effect has been observed (see also Chapter 28).

Sympathetic Blocking Agents

Propranolol (Inderal) is a β -adrenergic blocking agent in widespread use for a variety of indications. Theoretically, propranolol might increase uterine contractility. However, this has not been reported, presumably because the drug is not specific for β_2 -receptors in the uterine wall. No evidence of teratogenicity has been found. Bradycardia has been reported in the newborn as a direct effect of a dose of the drug given to the mother within 2 hours of delivery of the infant. [76]

Several studies of propranolol use in pregnancy show an increased risk of intrauterine growth restriction or at least a skewing of the birth weight distribution toward the lower range. [77] Ultrasound monitoring of patients on this drug is prudent. Studies from Scotland suggest improved outcome with the use of atenolol (Tenormin) to treat chronic hypertension during pregnancy. [78]

Angiotensin-Converting Enzyme Inhibitors

Angiotensin-converting enzyme inhibitors (e.g., enalapril [Vasotec], captopril [Capoten]) can cause fetal renal tubular dysplasia in the second and third trimesters, leading to oligohydramnios, fetal limb contractures, craniofacial deformities, and hypoplastic lung development. [79] Fetal skull ossification defects have also been described. [80] For these reasons, pregnant women on these medications should be switched to other agents.

Antineoplastic Drugs and Immunosuppressants

Methotrexate, a folic acid antagonist, appears to be a human teratogen, although experience with it is limited. Infants

of three women known to receive methotrexate in the first trimester of pregnancy had multiple congenital anomalies, including cranial defects and malformed extremities. Eight normal infants were delivered to seven women treated with methotrexate in combination with other agents after the first trimester. When low-dose oral methotrexate (7.5 mg/week) was used for rheumatoid disease in the first trimester, five full-term infants were normal, and three patients experienced spontaneous abortions. [81]

Azathioprine (Imuran) has been used by patients with renal transplants or systemic lupus erythematosus. The frequency of anomalies in 80 women treated in the first trimester was not increased. [82] Two infants had leukopenia, one was small for gestational age, and the others were normal.

No increased risk of anomalies in fetuses exposed to cyclosporine (Sandimmune) in utero has been reported. [83] An increased rate of prematurity and growth restriction has also been noted, but it is difficult to separate the contributions of the underlying disease and the drugs given to these transplant patients. The B-cell line may be depleted more than the T-cell line, [84] and one author recommends that infants exposed to immunosuppressive agents be followed for possible immunodeficiency. [84]

Eight malformed infants have resulted from first-trimester exposure to cyclophosphamide (Cytoxan), but these infants were also exposed to other drugs or radiation. [85] Low birth weight may be associated with use after the first trimester, but this may also reflect the underlying medical problem.

Chloroquine (Aralen) is safe in doses used for malarial prophylaxis, and there was no increased incidence of birth defects among 169 infants exposed to 300 mg once

weekly.^[86] However, after exposure to larger anti-inflammatory doses (250 to 500 mg/day), two cases of cochleovestibular paresis were reported.^[87] No abnormalities were noted in an additional 14 infants.^[88]

When cancer chemotherapy is used during embryogenesis there is an increased rate of spontaneous abortion and major birth defects. Later in pregnancy there is a greater risk of stillbirth and intrauterine growth restriction, and myelosuppression is often present in the infant.^[89]

Antiasthmatics

Theophylline (Theo-Dur, Slo-Bid) and Aminophylline

Both theophylline and aminophylline are safe for the treatment of asthma in pregnancy. No evidence of teratogenic risk was found in 76 exposures in the Collaborative Perinatal Project.^[73] Because of increased renal clearance in pregnancy, dosages may need to be increased.

Epinephrine (Adrenalin)

Minor malformations have been reported with sympathomimetic amines as a group in 3,082 exposures in the first trimester, usually in commercial preparations used to treat upper respiratory infections.^[73]

Terbutaline (Brethine)

Terbutaline has been widely used in the treatment of preterm labor (see Chapter 23). It is more rapid in onset and has a longer duration of action than epinephrine and is preferred for asthma in the pregnant patient. No risk of birth defects has been reported. Long-term use has been associated with an increased risk of glucose intolerance.^[90]

Cromolyn Sodium (Intal)

Cromolyn sodium may be administered in pregnancy, and the systemic absorption is minimal. Teratogenicity has not been reported in humans.

Isoproterenol (Isuprel) and Metaproterenol (Alupent)

When isoproterenol and metaproterenol are given as topical aerosols for the treatment of asthma, the total dose absorbed is usually not significant. With oral or intravenous doses, however, the cardiovascular effects of the agents may result in decreased uterine blood flow. For this reason, they should be used with caution. No teratogenicity has been reported.^[73]

Corticosteroids

All steroids cross the placenta to some degree, but prednisone (Deltasone) and prednisolone are inactivated by the placenta. When prednisone or prednisolone are maternally administered, the concentration of active compound in the fetus is less than 10 percent of that in the mother. Therefore, these agents are the drugs of choice for treating medical diseases such as asthma. Inhaled corticosteroids are also effective therapy, and very little drug is absorbed. When steroid effects are desired in the fetus, for example, to accelerate lung maturity, betamethasone (Celestone) and dexamethasone (Decadron) are preferred, as these are minimally inactivated by the placenta. In several hundred infants exposed to corticosteroids in the first trimester, no increase in abnormalities was noted.^[73], ^[82]

Iodide

Iodide such as is found in a saturated solution of potassium iodide (SSKI) expectorant crosses the placenta and may produce a large fetal goiter, enough to produce respiratory obstruction in the newborn (Fig. 9-7).^[69] Before a patient is advised to take a cough medicine, one should be sure to ascertain that it does not contain iodide.

Antiemetics

Remedies suggested to help nausea and vomiting in pregnancy without pharmacologic intervention include taking crackers at the bedside upon first awakening in the morning before getting out of bed, getting up very slowly, omitting the use of iron tablets, consuming frequent small meals, and eating protein snacks at night. Faced with a self-limited condition occurring at the time of organogenesis, the clinician is well advised to avoid the use of medications whenever possible and to encourage these supportive measures initially.

Vitamin B₆

Vitamin B₆ (pyridoxine) 25 mg three times a day has been reported in two randomized placebo controlled trials to be effective for treating the nausea and vomiting of pregnancy.^[91], ^[92] In several other controlled trials there was no evidence of teratogenicity.

Doxylamine

Doxylamine (Unisom) is an effective antihistamine for nausea in pregnancy and can be combined with vitamin B₆ to produce a therapy similar to the former preparation Bendectin. Vitamin B₆ (25 mg) and Unisom (25 mg) at bedtime, and one half of each in the morning and afternoon, is an effective combination.

Ginger

Ginger has been used with success for treating hyperemesis,^[93] when defined as vomiting during pregnancy that was severe enough to require hospital admission. A significantly greater relief of symptoms was found after ginger treatment than with placebo. Patients took 250-mg capsules containing ginger as powdered root four times a day. Although there are no teratogenic effects known for other antiemetics, much less information is available.

Meclizine (Bonine)

In one randomized, placebo-controlled study, meclizine gave significantly better results than placebo.^[94] Prospective

Figure 9-7 Iodide-induced neonatal goiter. A, Appearance on the first day of life. E, Appearance at 2 months of age. (From Senior B, Chernoff HL: Iodide goiter in the newborn. *Pediatrics* 47:510, 1971, with permission.)

clinical studies have provided no evidence that meclizine is teratogenic in humans. In 1,014 patients in the Collaborative Perinatal Project ^[73] and an additional 613 patients from the Kaiser Health Plan, ^[95] no teratogenic risk was found.

Dimenhydrinate (Dramamine)

No teratogenicity has been noted with dimenhydrinate, but a 29 percent failure rate and a significant incidence of side effects, especially drowsiness, has been reported. ^[96]

Diphenhydramine (Benadryl)

In 595 patients treated in the Collaborative Perinatal Project, no teratogenicity was noted with diphenhydramine. ^[73] Drowsiness can be a problem.

Trimethobenzamide (Tigan)

Trimethobenzamide, an antiemetic not classified as either an antihistamine or a phenothiazine, has been used for nausea and vomiting in pregnancy. The data collected from a small number of patients are conflicting. In 193 patients in the Kaiser Health Plan study ^[95] exposed to trimethobenzamide, there was a suggestion of increased congenital anomalies ($p < 0.05$); no concentration of specific anomalies was observed in these children, however, and some of the mothers took other drugs as well. In 340 patients in the Collaborative Perinatal Project, ^[73] no evidence for an association between this drug and malformations was found.

Phenothiazines

Because of the potential for severe side effects, the phenothiazines have not been used routinely in the treatment of mild or moderate nausea and vomiting, but have been reserved for the treatment of hyperemesis gravidarum. Chlorpromazine (Thorazine) has been shown to be effective in hyperemesis gravidarum, with the most important side effect being drowsiness.

Teratogenicity does not appear to be a problem with the phenothiazines when evaluated as a group. In the Kaiser Health Plan Study, ^[95] 976 patients were treated, and in the Collaborative Perinatal Project ^[73] 1,309 patients were treated; no evidence of association between these drugs and malformations was noted. Suspicion of an association between phenothiazines and cardiovascular malformations was observed, however, but this was considered of borderline significance and, in the context of multiple comparisons, of doubtful import. In one study, ^[97] chlorpromazine seemed to be associated with an increased risk of malformations in 141 exposed mothers. In 58 mothers treated with promethazine (Phenergan) and in 48 mothers given prochlorperazine (Compazine), no increased risk of malformations was found.

Ondansetron (Zofran)

Ondansetron is no more effective than promethazine (Phenergan), has not been evaluated for teratogenicity, and is considerably more costly. ^[98]

Methylprednisolone

Forty patients with hyperemesis admitted to the hospital were randomized to oral methylprednisolone or oral promethazine, and methylprednisolone was more effective. ^[99] Corticosteroids may act centrally in the brain stem to exert an antiemetic effect.

Acid-Suppressing Drugs

The use of cimetidine, omeprazole, and ranitidine has not been found to be associated with any teratogenic risk in 2,261 exposures. ^[100]

Antihistamines and Decongestants

No increased risk of anomalies has been associated with most of the commonly used antihistamines, such as chlorpheniramine (Chlor-Trimeton). However, in the Collaborative Perinatal Project, ^[73] the risk of malformations increased after exposure to brompheniramine (Dimetane) (10 of 65 infants), an effect that was not found for other antihistamines.

Terfenadine (Seldane) has been associated in one study with an increased risk of polydactyly. ^[101] Astemizole (Hismanal) did not increase the risk of birth defects in 114 infants exposed in the first trimester. ^[102]

An association between exposure to antihistamines during the last 2 weeks of pregnancy in general and retrolental fibroplasia in premature infants has been reported. ^[103]

In the Collaborative Perinatal Project, ^[73] an increased risk of birth defects was noted with phenylpropanolamine (Entex LA) exposure in the first trimester. In one retrospective study, an increased risk of gastroschisis was associated with first-trimester pseudoephedrine (Sudafed) use. ^[104] Although these findings have not been confirmed, use of these drugs for trivial indications should be discouraged, as long-term effects are unknown. If decongestion is necessary, topical nasal sprays will result in a lower dose to the fetus than systemic medication.

Patients should be educated that antihistamines and decongestants are only symptomatic therapy for the

common cold and have no influence on the course of the disease. Other remedies should be recommended, such as use of a humidifier, rest, and fluids. If medications are necessary, combinations with two drugs should not be used if only one drug is necessary. If the situation is truly an allergy, an antihistamine alone will suffice.

Antibiotics and Anti-infective Agents

As pregnant patients are particularly susceptible to vaginal yeast infections, antibiotics should only be used when clearly indicated. Therapy with antifungal agents may be necessary during or after the course of therapy.

Penicillins

Penicillin, ampicillin, and amoxicillin (Amoxil) are safe in pregnancy. In the Collaborative Perinatal Project, ^[73] 3,546 mothers took penicillin derivatives in the first trimester of pregnancy, with no increased risk of anomalies. There is little experience in pregnancy with the newer penicillins such as piperacillin (Pipracil) and mezlocillin (Mezlin). These drugs, therefore, should be used in pregnancy only when another better-studied antibiotic is not effective.

Most penicillins are primarily excreted unchanged in the urine, with only small amounts being inactivated in the liver. Patients with impaired renal function require a reduction in dosage.

Serum levels of the penicillins are lower and their renal clearance is higher throughout pregnancy than in the nonpregnant state. ^[105] The increase in renal blood flow and glomerular filtration rate results in increased excretion of these drugs. The expansion of the maternal intravascular volume during the late stages of pregnancy is

another factor that affects antibiotic therapy. If the same dose of penicillin or ampicillin is given to both nonpregnant and pregnant women, lower serum levels are attained during pregnancy as a result of the distribution of the drug in a larger intravascular volume.

Transplacental passage of penicillin is by simple diffusion. The free circulating portion of the antibiotic crosses the placenta, resulting in a lower maternal serum level of the unbound portion of the drug. Administration of penicillins with high protein binding (e.g., oxacillin, cloxacillin [Cloxapen], dicloxacillin [Pathocil], and nafcillin [Unipen]) to a pregnant woman leads to lower fetal tissue and amniotic fluid levels than the administration of poorly bound penicillins (e.g., penicillin G and ampicillin).

The antibiotic is ultimately excreted in the fetal urine and thus into the amniotic fluid. The delay in appearance of different types of penicillins in the amniotic fluid depends primarily on the rate of transplacental diffusion, the amount of protein binding in fetal serum, and the adequacy of fetal enzymatic and renal function. A time delay may occur before effective levels of the antibiotic appear in the amniotic fluid.

Cephalosporins

In a study of 5,000 Michigan Medicaid recipients, there was a suggestion of possible teratogenicity (25 percent increased birth defects) with cefaclor, cephalexin, and cephadrine, but not other cephalosporins.^[106] Because other antibiotics that have been used extensively (e.g., penicillin, ampicillin, amoxicillin, erythromycin) have not been associated with an increased risk of congenital defects, they should be first-line therapy when such treatment is needed in the first trimester.

Maternal serum levels of cephalosporins are lower than in nonpregnant patients receiving equivalent dosages due to a shorter half-life in pregnancy, an increased volume of distribution, and increased renal elimination. They readily cross the placenta to the fetal bloodstream and ultimately the amniotic fluid.

Sulfonamides

Among 1,455 human infants exposed to sulfonamides during the first trimester, no teratogenic effects were noted.^[73] However, the administration of sulfonamides should be avoided in women deficient in glucose-6-phosphate dehydrogenase (G6PD), as a dose-related toxic reaction may occur, resulting in red cell hemolysis.

Sulfonamides cause no known damage to the fetus in utero, as the fetus can clear free bilirubin through the placenta. These drugs might theoretically have deleterious effects if present in the blood of the neonate after birth, however. Sulfonamides compete with bilirubin for binding sites on albumin, thus raising the levels of free bilirubin in the serum and increasing the risk of hyperbilirubinemia in the neonate. Although this toxicity occurs with direct administration to the neonate, kernicterus in the newborn following in utero exposure has not been reported.^[107] The sulfonamides are easily absorbed orally, and readily cross the placenta, achieving fetal plasma levels 50 to 90 percent of those attained in the mother.^[108]

Sulfasalazine (Azulfidine)

Sulfasalazine is used for treatment of ulcerative colitis and Crohn's disease because of its relatively poor oral absorption. However, it does cross the placenta, leading to fetal drug concentrations approximately the same as those of the mother, although both are low. Neither

kernicterus nor severe neonatal jaundice have been reported following maternal use of sulfasalazine even when the drug was given up to the time of delivery.^[109]

Sulfamethoxazole with Trimethoprim (Bactrim, Septra)

Trimethoprim is often given with sulfa to treat urinary tract infections. Two published trials including 131 women failed to show any increased risk of birth defects after first-trimester exposure to trimethoprim.^[110],^[111] However, one unpublished study of 2,296 Michigan Medicaid recipients suggested an increased risk of cardiovascular defects after exposure in the first trimester.^[112] In a retrospective study of trimethoprim with sulfamethoxazole, the odds ratio for birth defects was 2.3.^[113]

Nitrofurantoin (Macrochantin)

Nitrofurantoin is used in the treatment of acute uncomplicated lower urinary tract infections as well as for long-term suppression in patients with chronic bacteriuria. Nitrofurantoin is capable of inducing hemolytic anemia in patients deficient in G6PD. However, hemolytic anemia in the newborn as a result of in utero exposure to nitrofurantoin has not been reported.

No reports have linked the use of nitrofurantoin with congenital defects. In the Collaborative Perinatal Project,^[73] 590 infants were exposed, 83 in the first trimester, with no increased risk of adverse effects. More recent studies have confirmed these findings.^[114],^[115]

Nitrofurantoin absorption from the gastrointestinal tract varies with the form administered. The macrocrystalline form is absorbed more slowly than the crystalline and is associated with less gastrointestinal intolerance. Because of rapid elimination, the serum half-life is 20 to 60 minutes. Therapeutic serum levels are not achieved, and therefore this drug is not indicated when there is a possibility of bacteremia. Approximately one third of an oral dose appears in the active form in the urine.

Tetracyclines

The tetracyclines readily cross the placenta and are firmly bound by chelation to calcium in developing bone and tooth structures. This produces brown discoloration of the deciduous teeth, hypoplasia of the enamel, and inhibition of bone growth.^[116] The staining of the teeth takes place in the second or third trimesters of pregnancy, while bone incorporation can occur earlier. Depression of skeletal growth was particularly common among premature infants treated with tetracycline. First-trimester exposure to doxycycline is not known to carry any risk.^[117] Alternate antibiotics are currently recommended during pregnancy.

Hepatotoxicity has been reported in pregnant women treated with tetracyclines in large doses, usually with intravenous administration for pyelonephritis. First-trimester exposure to tetracyclines has not been found to have any teratogenic risk in 341 women in the Collaborative Perinatal Project^[73] or in 174 women in another study.^[118]

Aminoglycosides

Streptomycin and kanamycin have been associated with congenital deafness in the offspring of mothers who took these drugs during pregnancy. Ototoxicity was reported with doses as low as 1 g of streptomycin biweekly for 8 weeks during the first trimester.^[119] Of 391 mothers who had received 50 mg/kg of kanamycin for prolonged periods during pregnancy, nine children (2.3 percent) were found to have hearing loss.^[120]

Nephrotoxicity may be greater when aminoglycosides are combined with cephalosporins. Neuromuscular blockade may be potentiated by the combined use of aminoglycosides and curariform drugs; therefore, the dosages should be reduced appropriately. Potentiation of magnesium sulfate-induced neuromuscular weakness has also been reported in a neonate exposed to magnesium sulfate and gentamicin (Garamycin).^[121]

No known teratogenic effect other than ototoxicity has been associated with the use of aminoglycosides in the first trimester. In 135 infants exposed to streptomycin in the Collaborative Perinatal Project,^[73] no teratogenic effects were observed. In a group of 1,619 newborns whose mothers were treated for tuberculosis with multiple drugs, including streptomycin, the incidence of congenital defects was the same as in a healthy control group.^[122]

Aminoglycosides are poorly absorbed after oral administration and are rapidly excreted by the normal kidney. Because the rate of clearance is related to the glomerular filtration rate, dosage must be reduced in the face of abnormal renal function. The serum aminoglycoside levels are usually lower in pregnant than in nonpregnant patients receiving equivalent doses because of more rapid elimination.^[123] Thus, it is important to monitor levels to prevent subtherapeutic dosing.

Once-a-day dosing with gentamicin at 4 mg/kg, in treatment of puerperal infections, increases efficacy and decreases toxicity and cost. ^[124]

Antituberculosis Drugs

There is no evidence of any teratogenic effect of isoniazid (INH), para-aminosalicylic acid (PAS), rifampin (Rifadin), or ethambutol (Myambutol).

235

Erythromycin

No teratogenic risk of erythromycin has been reported. In 79 patients in the Collaborative Perinatal Project ^[73] and 260 in another study, ^[119] no increase in birth defects was noted.

Erythromycin is not consistently absorbed from the gastrointestinal tract of pregnant women, and the transplacental passage is unpredictable. Both maternal and fetal plasma levels achieved after the administration of the drug in pregnancy are low and vary considerably, with fetal plasma concentrations being 5 to 20 percent of those in maternal plasma. ^[125] Thus, some authors have recommended that penicillin be administered to every newborn whose mother received erythromycin for the treatment of syphilis. ^[126] Fetal tissue levels increase after multiple doses. ^[125] The usual oral dose is 250 to 500 mg every 6 hours, but the higher dose may not be well tolerated in pregnant women who are susceptible to nausea and gastrointestinal symptoms.

Clarithromycin

Of 122 first-trimester exposures, there was no significant risk of birth defects. ^[127]

Clindamycin (Cleocin)

Of 647 infants exposed to clindamycin in the first trimester, no increased risk of birth defects was noted. ^[128] Clindamycin is nearly completely absorbed after oral administration; a small percentage is absorbed after topical application. The drug crosses the placenta, achieving maximum cord serum levels of about 50 percent of the maternal serum. ^[125] Clindamycin is 90 percent bound to serum protein, and fetal tissue levels increase following multiple dosing. ^[125] Maternal serum levels after dosing at various stages of pregnancy are similar to those of nonpregnant patients.

Quinolones

The quinolones (e.g., ciprofloxacin [Cipro], norfloxacin [Noraxin]) have a high affinity for bone tissue and cartilage and may cause arthralgia in children. However, no malformations or musculoskeletal problems were noted in 38 infants exposed in utero in the first trimester. ^[129] Of 132 newborns exposed in the first trimester in the Michigan Medicaid data, no increased risk of birth defects was noted. ^[130] The manufacturer recommends against use in pregnancy and in children.

Metronidazole (Flagyl)

Studies have failed to show any increase in the incidence of congenital defects among the newborns of mothers treated with metronidazole during early or late gestation. In a study of 1,387 prescriptions filled, no risk of birth defects could be determined. ^[131] A recent meta-analysis confirmed no teratogenic risk. ^[132]

Controversy regarding the use of metronidazole during pregnancy was stirred when metronidazole was shown to be mutagenic in bacteria by the Ames test, which correlates with carcinogenicity in animals. However, the doses used were much higher than those used clinically, and carcinogenicity in humans has not been confirmed. ^[133] As some have recommended against its use in pregnancy, metronidazole should still be given only for clear-cut indications and its use deferred until after the first trimester if possible.

Acyclovir (Zovirax)

The Acyclovir Registry has recorded 581 first-trimester exposures during pregnancy, with no increased risk of abnormalities in the infants. ^[26] The Centers for Disease Control and Prevention recommends that pregnant women with disseminated infection (e.g., herpetic encephalitis or hepatitis or varicella pneumonia) be treated with acyclovir. ^[134]

Lindane (Kwell)

After application of lindane to the skin, about 10 percent of the dose used can be recovered in the urine. Toxicity in humans after use of topical 1 percent lindane has been observed almost exclusively after misuse and overexposure to the agent. Although no evidence of specific fetal damage is attributable to lindane, the agent is a potent neurotoxin, and its use during pregnancy should be limited. Pregnant women should be cautioned about shampooing their children's hair, as absorption could easily occur across the skin of the hands of the mother. An alternate drug for lice is usually recommended, such as pyrethrins with piperonyl butoxide (RID).

Antifungal Agents

Nystatin (Mycostatin) is poorly absorbed from intact skin and mucous membranes, and topical use has not been associated with teratogenesis. ^[119] The imidazoles are absorbed in only small amounts from the vagina. Clotrimazole (Lotrimin) or miconazole (Monistat) in pregnancy is not known to be associated with congenital malformations. However, in one study a statistically significantly increased risk of first-trimester abortion was noted after use of these drugs, but these findings were considered not to be definitive evidence of risk. ^[135] Of 7,266 newborns exposed in the first trimester in the Michigan Medicaid data, there was no increased risk of anomalies. ^[136]

236

An increased risk of limb deformities was reported in fetuses exposed to 400 to 800 mg/day of fluconazole in the first trimester. ^[137] In 460 who received a single 150-mg dose of fluconazole, no increased risk of defects was observed. ^[138], ^[139]

Drugs for Induction of Ovulation

In more than 2,000 exposures, no evidence of teratogenic risk of clomiphene (Clomid) has been noted, ^[140] and the percentage of spontaneous abortions is close to the expected rate. Although infants are often exposed to bromocriptine (Parlodel) in early pregnancy, no teratogenic effects have been observed in more than 1,400 pregnancies. ^[141]

Mild Analgesics

Few pains during pregnancy justify the use of a mild analgesic. Pregnant patients should be encouraged to use nonpharmacologic remedies, such as local heat and rest.

Aspirin

There is no evidence of any teratogenic effect of aspirin taken in the first trimester. ^[73], ^[142] Aspirin does have significant perinatal effects, however, as it inhibits prostaglandin synthesis. Uterine contractility is decreased, and patients taking aspirin in analgesic doses have delayed onset of labor, longer duration of labor, and an

increased risk of a prolonged pregnancy. ^[143]

Aspirin also decreases platelet aggregation, which can increase the risk of bleeding before as well as at delivery. Platelet dysfunction has been described in newborns within 5 days of ingestion of aspirin by the mother. ^[144] Because aspirin causes permanent inhibition of prostaglandin synthetase in platelets, the only way for adequate clotting to occur is for more platelets to be produced.

Multiple organs may be affected by chronic aspirin use. Of note, prostaglandins mediate the neonatal closure of the ductus arteriosus. In one case report, maternal ingestion of aspirin close to the time of delivery was related to closure of the ductus arteriosus in utero. ^[145]

Low-dose aspirin (80 mg/day) may ultimately prove of benefit in prevention of fetal wastage associated with autoimmune diseases. Lubbe et al. ^[146] treated patients with lupus anticoagulant and fetal wastage with prednisone 40 to 60 mg/day and low-dose aspirin (75 mg/day) with improved fetal outcome (see Chapter 22). Cowchock et al. ^[147] have reported that in patients with antiphospholipid-associated fetal wastage, heparin is preferable to prednisone in combination with low-dose aspirin.

Although preliminary small studies suggested that low-dose aspirin might prevent preeclampsia, a large randomized trial has not shown any benefit. ^[148] Aspirin 60 mg/day did not prevent preeclampsia in women with twins, chronic hypertension, insulin-dependent diabetes, or a history of preeclampsia in a previous pregnancy. ^[149]

Acetaminophen (Tylenol, Datril)

Acetaminophen has also shown no evidence of teratogenicity. ^[150] With acetaminophen, inhibition of prostaglandin synthesis is reversible so that, once the drug has cleared, platelet aggregation returns to normal. The bleeding time is not prolonged with acetaminophen in contrast to aspirin, ^[151] and the drug is not toxic to the newborn. Thus, if a mild analgesic or antipyretic is indicated, acetaminophen is preferred over aspirin. Absorption and disposition of acetaminophen in normal doses is not altered by pregnancy. ^[152]

Other Nonsteroidal Anti-inflammatory Agents

No evidence of teratogenicity has been reported for other nonsteroidal anti-inflammatory drugs (e.g., ibuprofen ^[153] [Motrin, Advil], naproxen ^[154] [Naprosyn]), but limited information is available. Chronic use may lead to oligohydramnios, and constriction of the fetal ductus arteriosus or neonatal pulmonary hypertension as has been reported with indomethacin might occur.

Propoxyphene (Darvon)

Propoxyphene is an acceptable alternative mild analgesic with no known teratogenicity. ^[73] However, it should not be used for trivial indications, as it carries potential for narcotic addiction. Evidence of risk in late pregnancy comes from case reports of infants of mothers who were addicted to propoxyphene and had typical narcotic withdrawal in the neonatal period. ^[155]

Codeine

In the Collaborative Perinatal Project, no increased relative risk of malformations was observed in 563 codeine user. ^[73] Codeine can cause addiction and newborn withdrawal symptoms if used to excess perinatally.

Sumatriptan

Of 183 exposures in the first trimester, ^[26] seven infants (3.8 percent) had birth defects, not significantly different from the nonexposed population.

Smoking

Smoking has been associated with a fourfold increase in small size for gestational age as well as an increased prematurity rate. ^[156] The spontaneous abortion rate is

up to twice that of nonsmokers. Abortions associated with maternal smoking tend to have a higher percentage of normal karyotypes and occur later than those with chromosomal aberrations ^[157] (see Chapter 22). The higher perinatal mortality rate associated with smoking is attributable to an increased risk of abruptio placentae, placenta previa, premature and prolonged rupture of membranes, and intrauterine growth restriction. The risks of complications and of the associated perinatal loss rise with the number of cigarettes smoked. Discontinuation of smoking during pregnancy can reduce the risk of both pregnancy complications and perinatal mortality, especially in women at high risk for other reasons. ^[158] Maternal passive smoking was also associated with a twofold risk of low birth weight at term in one study. ^[159]

There is also a positive association between smoking and sudden infant death syndrome (SIDS) and increased respiratory illnesses in children. In such reports, it is not possible to distinguish between apparent effects of maternal smoking during pregnancy and smoking after pregnancy, but both may play a role.

Smoking Cessation during Pregnancy

Tobacco smoke contains nicotine, carbon monoxide, and thousands of other compounds. Although nicotine is the mechanism of addiction to cigarettes, other chemicals may contribute to adverse pregnancy outcome. For example, carbon monoxide decreases oxygen delivery to the fetus, whereas nicotine decreases uterine blood flow.

Nicotine withdrawal may first be attempted with nicotine fading, switching to brands of cigarettes with progressively less nicotine over a 3-week period. Exercise may also improve quitting success rates. ^[160] Nicotine medications are indicated for patients with nicotine dependence. This is defined as greater than one pack per day smoking, smoking within 30 minutes of getting up in the morning, or prior withdrawal symptoms. ^[161] Nicotine medications are available as patches, gum, or inhalers. Although one might question the propriety of prescribing nicotine during pregnancy, if the patient can stop smoking she eliminates many other toxins, including carbon monoxide, and nicotine blood levels are similar to that of smokers. ^[162] There are no studies of bupropion (Zyban) in human pregnancy for smoking cessation.

Alcohol

The fetal alcohol syndrome (FAS) has been reported in the offspring of alcoholic mothers and includes the features of gross physical retardation with onset prenatally and continuing after birth (Fig. 9-8). ^[163]

In 1980, the Fetal Alcohol Study Group of the Research Society on Alcoholism proposed strict criteria for the diagnosis of FAS. ^[164] At least one characteristic from each of the following three categories had to be present for a valid diagnosis of the syndrome:

1. Growth retardation before and/or after birth
2. Facial anomalies, including small palpebral fissures, indistinct or absent philtrum, epicanthic folds, flattened nasal bridge, short length of nose, thin upper lip, low-set, unparallel ears, and retarded midfacial development
3. Central nervous system dysfunction including microcephaly, varying degrees of mental retardation, or other evidence of abnormal neurobehavioral development, such as attention deficit disorder with hyperactivity.

Figure 9-8 Fetal alcohol syndrome. Patient photographed at (A) birth, (B) 5 years, and (C) 8 years. Note short palpebral fissures, short nose, hypoplastic philtrum, thinned upper lip vermilion, and flattened midface. (From Streissguth AP: *CIBA Foundation Monograph 105*. London, Pitman, 1984, with permission.)

None of these features is individually pathognomonic for fetal alcohol exposure. Confirmatory evidence for this diagnosis is a history of heavy maternal drinking during pregnancy.

In the study of Jones et al.,^[169] 23 chronically alcoholic women were matched with 46 controls and the pregnancy outcomes of the two groups compared. Among the alcoholic mothers, perinatal deaths were about eight times more frequent. Growth restriction, microcephaly, and IQ below 80 were considerably more frequent than among the controls. Overall outcome was abnormal in 43 percent of the offspring of the alcoholic mothers compared with 2 percent of the controls.

Ouellette et al.^[166] addressed the risks of smaller amounts of alcohol. Nine percent of infants of abstinent or rare drinkers and 14 percent of infants of moderate drinkers were abnormal, not a significant difference. In heavy drinkers (average daily intake of 3 oz of 100-proof liquor or more), 32 percent of the infants had anomalies. Overall, including anomalies, growth restriction, and an abnormal neurologic examination, 71 percent of the children of heavy drinkers were affected, twice the frequency of abnormality found in the moderate and rarely drinking groups. In this study, an increased frequency of abnormality was not found until 45 ml of ethanol (equivalent to three drinks) daily were exceeded. The study of Mills and Graubard^[167] also showed that total malformation rates were not significantly higher among offspring of women who had an average of less than one drink per day (77.3 in 1,000) or one to two drinks per day (83.2 in 1,000) than among nondrinkers (78.1 in 1,000). Genitourinary malformations increased with increasing alcohol consumption, however, so the possibility remains that for some malformations no safe drinking level exists.

Heavy drinking remains a major risk to the fetus, and reduction even in midpregnancy can benefit the infant. An occasional drink during pregnancy carries no known risk, but no level of drinking is known to be safe.

Sokol et al.^[169] have addressed history taking for prenatal detection of risk drinking. Four questions help differentiate patients drinking sufficiently to potentially damage the fetus (Table 9-2). The patient is considered at risk if more than two drinks are required to make her feel "high." The probability of "risk drinking" increases to 63 percent for those responding positively to all four questions.

Marihuana

No teratogenic effect of marihuana has been documented. In a prospective study of 35 pregnancies,^[169] infants born to marihuana users exhibited significantly more meconium staining (57 percent vs. 25 percent in

TABLE 9-2 -- THE T-ACE QUESTIONS FOUND TO IDENTIFY WOMEN DRINKING SUFFICIENTLY TO POTENTIALLY DAMAGE THE FETUS*

T	How many drinks does it take to make you feel high (can you hold) (<i>tolerance</i>)?
A	Have people <i>annoyed</i> you by criticizing your drinking?
C	Have you felt you ought to <i>cut down</i> on your drinking?
E	Have you ever had to drink first thing in the morning to steady your nerves or to get rid of a hangover (<i>eye-opener</i>)?

From Sokol RJ, Martier SS, Ager JW: *The T-ACE questions: practical prenatal detection of risk-drinking*. *Am J Obstet Gynecol* 160:863, 1989, with permission.

* Two points are scored as a positive answer to the tolerance question and one each for the other three. A score of 2 or more correctly identified 69 percent of risk drinkers.

nonusers). However, users tended to come from lower socioeconomic backgrounds. Most adverse outcomes of pregnancy were too infrequent to permit reliable comparisons between the groups. Marihuana users had an increased incidence of precipitate labor (<3 hours total), 29 percent compared with 3 percent in the control group.^[169]

In another population in which the users and nonusers of marihuana were similar in general health, ethnic background, nutritional habits, and use of tobacco, these differences were not confirmed (19 patients in each group).^[170] In this same small group of patients, average use of marihuana six or more times per week during pregnancy was associated with a reduction of 0.8 weeks in the length of gestation, although no reduction in birth weight was noted. One study suggested a mean 73-g decrease in birth weight associated with marihuana use, when urine assays were performed rather than relying on self-reporting.^[171]

Cocaine

A serious difficulty in determining the effects of cocaine on the infant is the frequent presence of many confounding variables in the population using cocaine. These mothers often abuse other drugs, smoke, have poor nutrition, fail to seek prenatal care, and live under poor socioeconomic conditions. These factors are difficult to take into account in comparison groups. Another difficulty is the choice of outcome measures for infants exposed in utero. The neural systems likely to be affected by cocaine are involved in neurologic and behavioral functions that are not easily quantitated by standard infant development tests.

Cocaine-using women have a higher rate of spontaneous abortion than controls.^[172] Three studies have suggested an increased risk of congenital anomalies after first-trimester cocaine use,^{[173] [174] [175]} most frequently

cardiac and central nervous system. In the study of Bingol et al.,^[174] the malformation rate was 10 percent in cocaine users, 4.5 percent in polydrug users, and 2 percent in controls. MacGregor et al.^[175] reported a 6 percent anomaly rate compared with 1 percent for controls.

Cocaine is a central nervous system stimulant and has local anesthetic and marked vasoconstrictive effects. Abruptio placentae has been reported to occur immediately after nasal or intravenous administration.^[172] Several studies have also noted increased stillbirths, preterm labor, premature birth, and small-for-gestational-age infants with cocaine use.^{[171] [172] [173] , [176] , [177]}

The impairment of intrauterine brain growth as manifested by microcephaly is the most common brain abnormality in infants exposed to cocaine in utero.^[178] In one study, 16 percent of newborns had microcephaly compared with 6 percent of controls.^[179] Somatic growth is also impaired, and so the growth restriction may be symmetric or characterized by a relatively low head circumference/abdominal circumference ratio.^[180] Multiple other neurologic problems have been reported after cocaine exposure, as well as dysmorphic features and neurobehavioral abnormalities.^[177]

Aside from causing congenital anomalies in the first trimester, cocaine has been reported to cause fetal disruption^[181] presumably due to interruption of blood flow to various organs. Bowel infarction has been noted with unusual ileal atresia and bowel perforation. Limb infarction has resulted in missing fingers in a distribution different from the usual congenital limb anomalies. Central nervous system bleeding in utero may result in porencephalic cysts.

Narcotics

Menstrual abnormalities, especially amenorrhea, are common in heroin abusers, although they are not associated with the use of methadone. The goal of methadone

maintenance is to bring the patient to a level of approximately 20 to 40 mg/day. The dose should be individualized at a level sufficient to minimize the use of supplemental illicit drugs, since they represent a greater risk to the fetus than do the higher doses of methadone required by some patients. Manipulation of the dose in women maintained on methadone should be avoided in the last trimester because of an association with increased fetal complications and in utero deaths attributed to fetal withdrawal in utero.^[182] As management of narcotic addiction during pregnancy requires a host of social, nutritional, educational, and psychiatric interventions, these patients are best managed in specialized programs.

The infant of the narcotic addict is at increased risk of abortion, prematurity, and growth restriction. Withdrawal should be watched for carefully in the neonatal period.

Caffeine

There is no evidence of teratogenic effects of caffeine in humans. The Collaborative Perinatal Project^[73] showed no increased incidence of congenital defects in 5,773 women taking caffeine in pregnancy, usually in a fixed-dose analgesic medication. There is still some conflicting evidence concerning the association between heavy ingestion of caffeine and increased pregnancy complications. Early studies suggested that the intake of greater than seven to eight cups of coffee per day (a cup of coffee contains about 100 mg of caffeine) was associated with low-birth-weight infants, spontaneous abortions, prematurity, and stillbirths.^[183] However, these studies were not controlled for the concomitant use of tobacco and alcohol. In one report controlled for smoking, other habits, demographic characteristics, and medical history, no relationship was found between either low birth weight or short gestation and heavy coffee consumption.^[184] Also, there was no excess of malformations among coffee drinkers. When pregnant women consumed over 300 mg of caffeine per day, one study suggested an increase in term low-birth-weight infants,^[185] less than 2,500 g at greater than 36 weeks.

Concomitant consumption of caffeine with cigarette smoking may increase the risk of low birth weight.^[186] Maternal coffee intake decreases iron absorption and may contribute to maternal anemia.^[187]

Two other studies have shown conflicting results. One retrospective investigation reporting a higher risk of fetal loss was biased by ascertainment of the patients at the time of fetal loss, as these patients typically have less nausea and would be expected to drink more coffee.^[188] A prospective cohort study found no evidence that moderate caffeine use increased the risk of spontaneous abortion or growth retardation.^[189] Measurement of serum paraxanthine, a caffeine metabolite, revealed that only extremely high levels are associated with spontaneous abortions.^[190]

Aspartame (NutraSweet)

The major metabolite of aspartame is phenylalanine,^[191] which is concentrated in the fetus by active placental transport. Sustained high blood levels of phenylalanine in the fetus as seen in maternal phenylketonuria (PKU) are associated with mental retardation in the infant. Within the usual range of aspartame ingestion, peak phenylalanine levels do not exceed normal postprandial levels, and even with high doses phenylalanine concentrations are still very far below those associated with mental retardation. These responses have also been studied in women known to be carriers of PKU, and

the levels are still normal. Thus, it seems unlikely that use of aspartame in pregnancy would cause any fetal toxicity.

Drugs in Breast Milk

Many drugs can be detected in breast milk at low levels that are not usually of clinical significance to the infant. The rate of transfer into milk depends on the lipid solubility, molecular weight, degree of protein binding, degree of ionization of the drug, and the presence or absence of active secretion. Nonionized molecules of low molecular weight such as ethanol cross easily.^[192] If the mother has unusually high blood concentrations such as with increased dosage or decreased renal function, drugs may appear in higher concentrations in the milk.

The amount of drug in breast milk is a variable fraction of the maternal blood level, which itself is proportional to the maternal oral dose. Thus, the dose to the infant is usually subtherapeutic, approximately 1 to 2 percent of the maternal dose on the average. This amount is usually so trivial that no adverse effects are noted. In the case of toxic drugs, however, any exposure may be inappropriate. Allergy may also be possible. Long-term effects of even small doses of drugs may yet be discovered. Also, drugs are eliminated more slowly in the infant with immature enzyme systems. Short-term effects of most maternal medications on breast-fed infants are mild and pose little risk to the infants. As the benefits of breast-feeding are well known, the risk of drug exposure must be weighed against these benefits.

With respect to drug administration in the immediate few days postpartum before lactation is fully established, the infant receives only a small volume of colostrum, and thus little drug is excreted into the milk at this time. It is helpful to allay fears of patients undergoing cesarean deliveries that analgesics or other drugs administered at this time will have no known adverse effects on the infant. For drugs requiring daily dosing during lactation, knowledge of pharmacokinetics in breast milk may minimize the dose to the infant. For example, dosing after nursing will decrease the exposure, as the blood level will be lowest before the next dose.

The short-term effects, if any, of most maternal medications on breast-fed infants are mild and pose little risk to the infants.^[193] Of 838 breast-feeding women, 11.2 percent reported minor infant adverse reactions in the infants, but these did not require medical attention. In 19 percent antibiotics caused diarrhea; in 11 percent narcotics caused drowsiness; in 9 percent antihistamines caused irritability; and in 10 percent sedatives, antidepressants, or antiepileptics caused drowsiness.^[193]

The American Academy of Pediatrics has reviewed drugs in lactation^[194] and categorized the drugs as listed below.

Drugs Commonly Listed as Contraindicated during Breast-Feeding

Cytotoxic Agents

Cyclosporine (Sandimmune), doxorubicin (Adriamycin), and cyclophosphamide (Cytoxan) might cause immune suppression in the infant, although data are limited with respect to these and other cytotoxic agents. In general, the potential risks of these drugs would outweigh the benefits of continuing nursing if these were required.

After oral administration to a lactating patient with choriocarcinoma, methotrexate was found in milk in low but detectable levels (0.26 g/dl). Most individuals would elect to avoid any exposure of the infant to this drug. However, in environments in which bottle feeding is rarely practiced and presents practical and cultural difficulties, therapy with this drug would not in itself appear to constitute a contraindication to breast-feeding.^[195] Busulphan (Myleran) has been reported to cause no adverse effect in nursing infants.^[196]

Bromocriptine (Parlodel)

This agent is an ergot alkaloid derivative that has an inhibitory effect on lactation. However, in one report, a mother taking 5 mg/day for a pituitary tumor was able to nurse her infant.^[197]

Ergotamine (Ergomar)

This medication has been reported to be associated with vomiting, diarrhea, and convulsions in the infant in doses used in migraine medications. However, short-term ergot therapy in the postpartum period for uterine atony is not a contraindication to lactation.

Lithium (Eskalith, Lithobid)

Lithium reaches one third to one half the therapeutic blood concentration in infants, who might develop lithium toxicity, with hypotonia and lethargy.^[198]

Amphetamines

One report of 103 cases of exposure to amphetamines in breast milk noted no insomnia or stimulation in the infants.^[195] However, amphetamines are concentrated in breast milk.

241

Radioactive Compounds That Require Temporary Cessation of Breast-Feeding

Radiopharmaceuticals require variable intervals of interruption of nursing to ensure that no radioactivity is detectable in the milk. Intervals generally quoted are, for ^[67] Ga, 2 weeks; ^[133] I, 5 days; radioactive sodium, 4 days; and ^[99] Tc, 24 hours. For reassurance, the milk may be counted for radioactivity before nursing is resumed.^[200]

Drugs Whose Effects on Nursing Infants Are Unknown but May Be of Concern

Psychotropic drugs such as antianxiety, antidepressant, and antipsychotic agents are sometimes given to nursing mothers for long periods. Although there are no data about adverse effects in infants exposed to these drugs via breast milk, they could theoretically alter central nervous system function.^[194] Fluoxetine (Prozac) is excreted in breast milk at low levels, so the infant receives approximately 6.7 percent of the maternal dose.^[201] The level in the breast-fed newborn is certainly lower than the level during pregnancy.^[202]

Sertraline causes a decline in 5-hydroxytryptamine levels in mothers, but not in their breast-fed infants.^[203] This implies that the small amount of drug the infant ingests in breast milk is not enough to have a pharmacologic effect (Fig. 9-9) (Figure Not Available).

Temporary cessation of breast-feeding after a single dose of metronidazole (Flagyl) may be considered. Its half-life is such that interruption of lactation for 12 to 24 hours after single-dose therapy usually results in negligible exposure to the infant. It is excreted into breast milk with a milk/plasma ratio of about 1:0. Therefore, even if a woman continued to nurse, the infant would get a trivial dose.

Drugs Usually Compatible with Breast-Feeding

Narcotics, Sedatives, and Anticonvulsants

In general, no evidence of adverse effect is noted with most of the sedatives, narcotic analgesics, and anticonvulsants. Patients may be reassured that, in normal doses, carbamazepine (Tegretol),^[204] phenytoin (Dilantin), magnesium sulfate, codeine, morphine, and meperidine (Demerol) do not cause any obvious adverse effects in the infants,^[205] since the dose detectable in the breast milk is approximately 1 to 2 percent of the mother's dose, which is sufficiently low to have no significant pharmacologic activity.

With diazepam (Valium), the milk/plasma ratio at peak dose is 0.68, with only small amounts detected in

Figure 9-9 (Figure Not Available) Effect of sertraline on platelet 5-hydroxytryptamine levels in four breast-fed infants and their mothers. (From Epperson CN, Anderson GM, McDougale CJ: Sertraline and breast-feeding. *N Engl J Med* 336:1189, 1997. Copyright 1997 Massachusetts Medical Society, with permission.)

the breast milk.^[206] In two patients who took carbamazepine (Tegretol) while nursing, the concentration of the drug in breast milk at 4 and 5 weeks postpartum was similar, about 60 percent of the maternal serum level. Accumulation does not seem to occur, and no adverse effects were noted in either infant.^[207]

In studies in which phenobarbital^[208] and phenytoin (Dilantin) levels were measured, only small amounts of these drugs were detected in breast milk. Phenobarbital and diazepam (Valium) are slowly eliminated by the infant, however, and so accumulation may occur. Women consuming barbiturates or benzodiazepines should observe the infants for sedation.

In 10 preeclamptic patients receiving magnesium sulfate 1 g/h intravenously for 24 hours after delivery, magnesium levels in breast milk were 64 g/ml compared with 48 g/ml in controls.^[209] Breast milk calcium levels were not affected by magnesium sulfate therapy.

Analgesics

Aspirin is transferred into breast milk in small amounts. Since acids exist primarily in the ionized form, salicylate transport from plasma into milk is not favored. The risk is related to high dosages (e.g., > 16 300-mg tablets per day in the mother, when the infant may get sufficiently high serum levels to affect platelet aggregation or even cause metabolic acidosis). No

242

harmful effects of acetaminophen (Tylenol, Datril) have been noted. In one patient taking propoxyphene (Darvon) in a suicide attempt, the level in breast milk was half that of the serum. A breast-feeding infant could theoretically receive up to 1 mg of propoxyphene a day if the mother were to consume the maximum dose continually.^[210] One infant was reported to have poor muscle tone when the mother was taking propoxyphene every 4 hours.

Antihistamines and Decongestants

Although studies are not extensive, no harmful effects have been noted from antihistamines or decongestants. Less than 1 percent of a pseudoephedrine dose or tripolidine dose ingested by the mother is excreted in the breast milk.^[211]

Aminophylline

Maximum milk concentrations of aminophylline are achieved between 1 and 3 hours after an oral dose. The nursing infant has been calculated to receive less than 1 percent of the maternal dose with no noted adverse effects. To minimize neonatal drug exposure, however, a nursing mother should try to breast-feed her infant immediately before her doses of the drug.^[212]

Antihypertensives

THIAZIDES.

After a single 500-mg oral dose of chlorothiazide (Diuril), no drug was detected in breast milk at a sensitivity of 1 g/ml.^[213] In one mother taking 50 mg of hydrochlorothiazide (Hydrodiuril) daily, peak milk levels were about 25 percent of maternal blood levels. The drug was not detectable in the nursing infant's serum, and the infant's electrolytes were normal.^[214] Thiazide diuretics may decrease milk production in the first month of lactation.^[194]

-BLOCKERS.

Propranolol (Inderal) is excreted in breast milk, with milk concentrations after a single 40-mg dose less than 40 percent of peak plasma concentrations. In one patient on a continuous dosage of 40 mg four times daily,^[215] plasma and breast milk concentrations peaked 3 hours after dosing and the peak breast milk concentration of 42 ng/ml was 64 percent of the corresponding plasma concentration. After a 30-day regimen of 240 mg/day of propranolol, the predose and 3-hour postdose propranolol

concentrations in breast milk were 26 and 64 ng/ml, respectively. Thus, an infant consuming 500 ml/day of milk would ingest a maximum of 21 g in 24 hours at a maternal dose of 160 mg/day and a maximum of 32 g in 24 hours at a maternal dose of 240 mg/day. This amount represents approximately 1 percent of a therapeutic dose, which is unlikely to cause any adverse effect. ^[216]

Atenolol (Tenormin) is concentrated in breast milk to about three times the plasma level. ^[217] One case has been reported in which a 5-day-old term infant had signs of -adrenergic blockade with bradycardia (80 bpm) with the breast milk dose calculated to be 9 percent of the maternal dose. ^[218] Adverse effects in other infants have not been reported. As milk accumulation occurs with atenolol, infants must be monitored closely for bradycardia. Propranolol is a safer alternative. ^[219]

Clonidine (Catapres) concentrations in milk are almost twice maternal serum levels. ^[220] Neurologic and laboratory parameters in the infants of treated mothers are similar to those of controls.

ACE INHIBITORS.

Captopril (Capoten) is excreted into breast milk in low levels, and no effects on nursing infants have been observed. ^[221]

CALCIUM CHANNEL BLOCKERS.

Nifedipine is excreted into breast milk at a concentration of less than 5 percent of the maternal dose, ^[222] and verapamil at an even lower level. Neither have caused adverse effects in the infant.

Anticoagulants

Most mothers requiring anticoagulation may continue to nurse their infants with no problems. Heparin does not cross into milk and is not active orally.

At a maternal dose of warfarin (Coumadin) of 5 to 12 mg/day in seven patients with maternal plasma concentrations of 0.5 to 2.6 g/ml, no warfarin was detected in infant breast milk or plasma at a sensitivity of 0.025 g/ml. This low concentration is probably because warfarin is 98 percent protein bound. Thus, 1 L of milk would contain 20 g of the drug at maximum, an insignificant amount to have an anticoagulant effect. ^[223] Another report confirms that warfarin appears only in insignificant quantities in breast milk. ^[224] The oral anticoagulant bishydroxycoumarin (dicumarol) has been given to 125 nursing mothers with no effect on the infants' prothrombin times and no hemorrhages. ^[225] Thus, with careful monitoring of maternal prothrombin time so that the dosage is minimized and of neonatal prothrombin times to ensure lack of drug accumulation, warfarin may be safely administered to nursing mothers.

This safety does not apply to all oral anticoagulant drugs, however. Phenindione, ^[226] a drug not used in the United States, has caused infant bleeding.

Corticosteroids

In one patient requiring corticosteroids, breast milk was obtained 2 hours after an oral dose of 10 mg of prednisone

(Deltasone). The levels in the milk were 0.1 g/dl of prednisolone and 2.67 g/dl of prednisone. Thus, an infant taking 1 L of milk would obtain 28.3 g of the two steroids, an amount not likely to have any deleterious effect. ^[227] In another study of seven patients, ^[228] 0.14 percent of a sample was secreted in the milk in the subsequent 60 hours, a negligible quantity. Thus, breast-feeding is allowed in mothers taking corticosteroids. Even at 80 mg/day, the nursing infant would ingest less than 0.1 percent of the dose, less than 10 percent of its endogenous cortisol. ^[229]

Digoxin (Lanoxin)

After a maternal dose of 0.25 mg, peak breast milk levels of 0.6 to 1 ng/ml occur, and the milk/plasma ratio at the 4-hour peak is 0.8 to 0.9. This represents a small amount due to significant maternal protein binding. In 24 hours, an infant would receive about 1 percent of the maternal dose. ^[230] No adverse effects in nursing infants have been reported.

Antibiotics

Penicillin derivatives are safe in nursing mothers. In the usual therapeutic doses of penicillin or ampicillin (Amoxil), the mother's milk/plasma ratios are only up to 0.2, and no adverse effects are noted in the infants. In susceptible individuals or with prolonged therapy, diarrhea and candidiasis are theoretical concerns.

Dicloxacillin (Pathocil) is 98 percent protein bound. If this drug is used to treat breast infections, very little will get into the breast milk, and nursing may be continued.

Cephalosporins appear only in trace amounts in milk. In one study after cefazolin 500 mg intramuscularly three times a day (Ancef, Kefzol), no drug was detected in breast milk. ^[231] After 2 g of cefazolin intravenously, 1.51 g/ml was detected, for a milk/plasma ratio of 0.023 at the 3-hour peak level. Thus, the infant was exposed less than 1 percent of the maternal dose.

Tooth staining or delayed bone growth from tetracyclines have not been reported after the drug was taken by a breast-feeding mother. This finding is probably because of the high binding of the drug to calcium and protein, limiting its absorption from the milk. The amount in the milk is about half the level in the mother's plasma. Therefore, the amount of free tetracycline available is too small to be significant.

Sulfonamides only appear in small amounts in breast milk and are ordinarily not contraindicated during nursing. However, the drug is best avoided in premature infants or ill or stressed infants when hyperbilirubinemia may be a problem, as the drug may displace bilirubin from binding sites on albumin. In one study of sulfapyridine, the drug and its metabolites were detected in plasma and milk at levels of 4 to 7 g/ml. Thus, the infant would receive less than 1 percent of the maternal dose. When a mother took sulfasalazine (Azulfidine) 500 mg every 6 hours, the drug was undetectable in all milk samples.

Gentamicin (Garamycin) is transferred into breast milk, and half of nursing newborn infants have the drug detectable in their serum. The low levels detected would not be expected to cause clinical effects. ^[232]

Nitrofurantoin (Macrochantin) is excreted into breast milk in very low concentrations. In one study the drug could not be detected in 20 samples from mothers receiving 100 mg four times a day. ^[233]

Erythromycin is excreted into breast milk in small amounts, with milk/plasma ratios of about 0.5. No reports of adverse effects on infants exposed to erythromycin in breast milk have been noted. Azithromycin (Zithromax) also appears in breast milk in low concentrations. ^[234] Clindamycin (Cleocin) is excreted into breast milk in low levels, and nursing is usually continued during administration of this drug.

There are no reported adverse effects on the infant of isoniazid (INH) administered to nursing mothers, and its use is considered compatible with breast-feeding. ^[194]

Acyclovir

Acyclovir is concentrated in breast milk with the average ratio of milk to serum 3.24. ^[235] The amount to which the infant would be exposed through breast milk will be less than 1 mg/day if the mother is taking 1,000 mg/day, which seems of low theoretical risk, provided the infant has normal renal function.

Antifungal Agents

No data are available with nystatin, miconazole, or clotrimazole in breast milk, but as only small amounts are absorbed vaginally, this would not be expected to be a problem.

Infant exposure to ketoconazole in human milk was 0.4 percent of the therapeutic dose, unlikely to cause adverse effects. ^[236]

Oral Contraceptives

Estrogen and progestin combination oral contraceptives cause a dose-related suppression of the quantity of milk produced. The use of oral contraceptives containing 50 µg and more of estrogen during lactation has been associated with shortened duration of lactation, decreased milk production, decreased infant weight gain, and decreased composition of nitrogen and protein content of the milk. However, the composition and volume of breast milk may vary considerably even in the absence of birth control pills. Lactation is inhibited to a

244

lesser degree if the pill is started about 3 weeks postpartum and with lower doses of estrogen than 50 µg. Although the magnitude of the changes is low, the changes may be of nutritional importance, particularly in malnourished mothers. However, if the patient persists in taking birth control pills while nursing, there is no documented adverse effect of this practice.

An infant consuming 600 ml of breast milk daily from a mother using an oral contraceptive containing 50 µg of the ethinylestradiol receives a daily dose in the range of 10 ng of the estrogen. ^[237] The amount of natural estradiol received by infants who consume a similar volume of milk from mothers not using oral contraceptives is estimated at 3 to 6 ng during anovulatory cycles and 6 to 12 ng during ovulatory cycles. No consistent long-term adverse effects on children's growth and development have been described.

Evidence indicates that norgestrel (Ovrette) is metabolized rather than accumulated by the infants and, to date, no adverse effects have been identified as a result of progestational agents taken by the mother. Progestin-only contraceptives do not cause alteration of breast milk composition or volume, ^[238] making them ideal in the breast-feeding mother. When the infant is weaned, the mother should be switched to combined oral contraceptives for maximum contraceptive efficacy.

Alcohol

Alcohol levels in breast milk are similar to those in maternal blood. If a moderate social drinker had two cocktails and had a blood alcohol concentration of 50 mg/1 dl, the nursing infant would receive about 82 mg of alcohol, which would produce insignificant blood concentrations. ^[192] There is no evidence that occasional ingestion of alcohol by a mother is harmful to the infant. However, one study showed that ethanol ingested chronically through breast milk might have a detrimental effect on motor development, but not mental development, in the infant. ^[239] Also, alcohol in breast milk has an immediate effect on the odor of the milk, and this may decrease the amount of milk the infant consumes. ^[240]

Propylthiouracil

PTU is found in breast milk in small amounts. ^[241] If the mother takes 200 mg PTU three times a day, the child would receive 149 µg daily, or the equivalent of a 70-kg adult receiving 3 mg/day. Several infants have been studied up to 5 months of age with no changes in thyroid parameters, including TSH. Lactating mothers on PTU can continue nursing with close supervision of the infant. ^[241], ^[242] PTU is preferred over methimazole (Tapazole) due to its high protein binding (80 percent) and lower breast milk concentrations. ^[243]

H₂-Receptor Blockers

In theory, H₂-receptor antagonists (e.g., ranitidine, cimetidine) might suppress gastric acidity and/or cause central nervous system stimulation in the infant, but these effects have not been confirmed in published studies. The American Academy of Pediatrics now considers H₂-receptor antagonists to be compatible with breast-feeding. ^[194] Famotidine, nizatidine, and roxatidine are less concentrated in breast milk and may be preferable in nursing mothers. ^[244]

Caffeine

Caffeine has been reported to have no adverse effects on the nursing infant, even after the mother consumes several cups of strong coffee. ^[243] In one study, the milk level contained 1 percent of the total dose 6 hours after coffee ingestion, which is not enough to affect the infant. In another report, no significant difference in 24-hour heart rate or sleep time was observed in nursing infants when their mothers drank coffee for 5 days or abstained for 5 days. ^[245]

Smoking

Nicotine and its metabolite cotinine enter breast milk. Infants of smoking mothers achieve significant serum concentrations of nicotine even if they are not exposed to passive smoking, and exposure to passive smoking further raises the levels of nicotine. ^[246] Women who smoke should be encouraged to stop smoking during lactation as well as during pregnancy. ^[247]

Conclusions

Many medical conditions during pregnancy and lactation are best treated initially with nonpharmacologic remedies. Before a drug is administered in pregnancy, the indications should be clear and the risk/benefit ratio should justify drug use. If possible, therapy should be postponed until after the first trimester. In addition, patients should be cautioned about the risks of social drug use such as smoking, alcohol, and cocaine during pregnancy. Most drug therapy does not require cessation of lactation, as the amount excreted into breast milk is sufficiently small to be pharmacologically insignificant.

Key Points

Infants of epileptic women taking anticonvulsants have double the rate of malformations of

245

unexposed infants; the risk of fetal hydantoin syndrome is less than 10 percent.

The risk of malformations after in utero exposure to isotretinoin is 25 percent, and an additional 25 percent of infants have mental retardation.

Heparin is the drug of choice for anticoagulation during pregnancy, although there is some risk of osteoporosis from its use.

Angiotensin-converting enzyme inhibitors can cause fetal renal failure in the second and third trimesters, leading to oligohydramnios and hypoplastic lungs.

Vitamin B₆ 25 mg three times a day is a safe and effective therapy for first-trimester nausea and vomiting; doxylamine (Unisom) 12.5 mg three times a day is also effective in combination with B₆.

Most antibiotics are generally safe in pregnancy. Cephalosporins and trimethoprim may carry an increased risk in the first trimester, and tetracyclines cause tooth discoloration in the second and third trimesters. Aminoglycosides can cause fetal ototoxicity.

Aspirin in analgesic doses inhibits platelet function and prolongs bleeding time; thus, alternate analgesics are preferred in pregnancy.

Fetal alcohol syndrome occurs in infants of mothers drinking heavily during pregnancy. A safe level of alcohol intake during pregnancy has not been determined.

Cocaine has been associated with increased risk of spontaneous abortions, abruptio placentae, and congenital malformations, in particular, microcephaly.

Most drugs are safe during lactation, as subtherapeutic amounts appear in breast milk, approximately 1 to 2 percent of the maternal dose.

Chapter 10 - Obstetric Ultrasound: Assessment of Fetal Growth and Anatomy

Frank A. Chervenak
Steven G. Gabbe

Diagnostic ultrasound has emerged as an important tool for antepartum fetal surveillance. This technology has permitted the most accurate assessment of gestational age and has enabled the obstetrician to follow fetal growth serially and to detect fetal growth disorders. In addition, ultrasound has become an essential aid in the safe performance of a variety of diagnostic procedures, including amniocentesis, chorionic villus sampling, and cordocentesis. Finally, the use of real-time ultrasound has permitted the obstetrician to assess fetal well-being through the evaluation of fetal movements, breathing activity, tone, and the volume of amniotic fluid.

Gabbe: Obstetrics - Normal and Problem Pregnancies, 4th ed. , Copyright © 2002 Churchill Livingstone, Inc.

BIOPHYSICS OF ULTRASOUND

To use ultrasound most effectively, the obstetrician should understand the basic biophysics of the technique. ¹ Sound is a waveform of energy that causes small particles in a medium to oscillate. The frequency of sound refers to the number of peaks or waves that traverse a given point per unit of time and is expressed in hertz. Sound with a frequency of one cycle or one peak per second would have a frequency of 1 Hz. Ultrasound applies to high-frequency sound waves exceeding 20,000 Hz. Diagnostic ultrasound instruments operate in a higher range of frequencies, varying from 2 to 10 million Hz, or 2 to 10 MHz.

Ultrasound energy is produced by a transducer containing crystal structures that convert electrical energy to ultrasound waves and the returning echoes to electrical energy. Therefore, each crystal in the transducer acts as both a transmitter and a receiver. The power of ultrasound refers to the amount of work being done by the ultrasound field as it interacts with the medium in which the sound waves are propagating and is expressed in terms of watts. Most therapeutic equipment operates in the range of 1 to 50 W, whereas diagnostic and monitoring units use 0.1 to 100 mW. The standard unit used to define the power of ultrasound equipment is watts per square centimeter, which describes the amount of energy delivered per given surface area.

Diagnostic ultrasound equipment generates a sound pulse every 1 msec, and the duration of the pulse is 1 sec. The time the sound pulse is off is 1,000 times greater than the time it is on. Therefore, the duty factor of diagnostic ultrasound, defined as the ratio between the emission of a sound wave and the reception of the sound wave, is 1:1,000 or 0.001. During a 15-minute diagnostic evaluation, the fetus is exposed to only 1 second of ultrasound energy. The safety of diagnostic ultrasound is discussed later in more detail.

PRINCIPLES OF IMAGING

A two-dimensional picture is created when the returning ultrasound echoes are displayed on an oscilloscope screen. ^[1] The ultrasound signal returning to the transducer is converted to an electrical impulse, and the strength of that electrical impulse is directly proportional to the strength of the returning echo. The density of the medium into which the sound wave has been transmitted and through which it is reflected will determine the strength of the signal. The velocity of the reflected sound wave will be faster and its signal on the oscilloscope brighter after reflection off bone than off tissues that are less dense, such as muscle, fat, brain, or water. Air greatly decreases the transmission of sound

waves. For this reason, a coupling medium or gel is applied between the surface of the transducer and the skin or vaginal mucosa.

Ultrasound can be used to produce diagnostic images in several ways. With M mode (motion mode), the reflected echo is displayed as a spot that generates a horizontal line on a moving display. In this way, one can examine the motion of structures against time. This technique has been widely applied in the assessment of cardiac anatomy, including the dimensions of the cardiac chambers, ventricular wall thickness, and valvular motion. B mode (brightness modulation) converts the strength of the returning echoes into signals of varying brightness that are proportional to the amplitude of the returning echoes. A storage oscilloscope is used to create a compounded image of the target and, in this way, produce a two-dimensional picture. Real-time array transducer systems create these images within a fraction of a second. When the image of the fetus is compounded at a rate faster than the flicker fusion rate of the eye, the fetus will appear to be moving in real time. In a linear array transducer, a series of crystals are aligned along the transducer. The standard transducer used in these systems is 3.5 MHz. The higher the frequency of the sound the better the reproduction and resolution, but the shallower the depth of penetration. Sector scanning uses a moving transducer head containing the crystals or a wheel containing multiple transducers that moves through a prescribed sector. Sector scanning facilitates the visualization of structures behind the symphysis pubis. The obstetrician will often use a curvilinear transducer, incorporating the advantages of both the linear array and the sector transducers. Recently, three-dimensional ultrasound has been used to better define surface rendering of normal fetal anatomy and fetal anomalies. Its role in clinical practice is uncertain at this time. ^[2] , ^[3]

Doppler ultrasound differs significantly from the imaging techniques that have been described. In this application of ultrasound, used in Doppler velocimetry (see [Chapter 12](#)) and antepartum and intrapartum fetal heart rate monitoring (see [Chapter 12](#) and [Chapter 14](#)), the receiver detects shifts in the frequency of the returning sound waves rather than in the amplitude of these reflected echoes. Targets moving toward the receiving transducer produce an increase in the frequency of the echo, whereas objects moving away decrease the frequency. Doppler ultrasound uses a continuous beam of sound rather than intermittent transmission, which characterizes real-time ultrasound.

SAFETY OF ULTRASOUND

Concern has been expressed by basic scientists, physicians, and consumers about the safety of diagnostic ultrasound.^[4]^[5]^[6] The dissipation of energy from ultrasound can produce heating of the exposed tissues.^[7]^[8] Ultrasound may also create cavitation or the formation of bubbles and microstreaming, the flow of liquid around these oscillating bubbles. In experimental systems, exposure to high-intensity ultrasound has been associated with alterations in immune response, increases in sister chromatid exchange frequencies,^[9] fetal malformations, and growth restriction. However, these effects have *not* been seen with diagnostic ultrasound.

The total ultrasound exposure for a fetus will depend on the number of ultrasound examinations performed, the type of equipment used, and the amount of energy received, which is dependent on the duration of the examination. It has been recommended that the length of each ultrasound study and the type of equipment used be recorded.^[5]

The amount of ultrasound energy received by the fetus varies directly with the intensity of the ultrasound signal and is inversely related to the square of its distance from the emitting source. If one is using a 3.5-MHz transducer, which focuses at approximately 8 cm, exposed tissues will receive only 1/64th of the energy originally emitted from the transducer. Thus far, the safe level of ultrasound intensity has been defined as less than 100 mW/cm² for unfocused ultrasound and below 1 W/cm² for focused ultrasound. Most instruments in use today produce maximum power levels less than 50 mW/cm² in a standard scan mode.^[10]

Studies of clinical outcomes of infants exposed to ultrasound have failed to demonstrate any significant effects. No effect on neurologic function, including speech, hearing, and vision, or on school performance, or on the incidence of childhood leukemia has been observed.^[11]^[12]^[13] In 1993, the American Institute of Ultrasound in Medicine (AIUM) Bioeffects Committee concluded^[10]

Diagnostic ultrasound has been in use since the late 1950s. Given its known benefits and recognized efficacy for medical diagnosis, including use during human pregnancy, the American Institute of Ultrasound in Medicine (AIUM) herein addresses the clinical safety of such use:

No confirmed biological effects on patients or instrument operators caused by exposure at intensities typical of the present diagnostic ultrasound instruments have ever been reported. Although the possibility exists that such biological effects may be identified in the future, current data indicate that the benefits to patients of the prudent use of diagnostic ultrasound outweigh the risks, if any, that may be present.

In considering the safety of any diagnostic procedure, one must also consider the skill with which the examination is conducted and the way in which the results are interpreted and utilized. False-positive and false-negative diagnoses appear to be the greatest risk for the patient undergoing an obstetric ultrasound examination. What guidelines should be followed to ensure that

an obstetrician is adequately trained in the application of ultrasound? The AIUM has published guidelines for training in diagnostic ultrasound.^[14] These recommendations call for completion of an approved residency program, fellowship, or postgraduate training with a minimum of 3 months' supervised experience. The guidelines also specify involvement in the evaluation and interpretation of at least 500 diagnostic ultrasound examinations. Most recently, AIUM has broadened these guidelines to accredit ultrasound laboratories or practices including the experience of the sonographers, quality and maintenance of the equipment, record keeping, facilities, and quality assurance. Many managed care plans now require these or similar accreditation standards be met by their providers.

TRANSVAGINAL ULTRASOUND

Transvaginal ultrasound, with its ability to use higher frequency transducers, can result in better visualization of the early pregnancy. ^{[15] [16] [17]} The gestational sac, yolk sac, and embryo can be seen earlier and with more detail than transabdominal ultrasound. Extrauterine pathology, such as an ectopic pregnancy or an ovarian mass, can be better evaluated. This enhanced visualization with vaginal ultrasound is especially important in the obese patient and when there is a retroverted or myomatous uterus.

A gestational sac can be seen with transvaginal ultrasound as early as 4.5 menstrual weeks ^[18] This sac is surrounded by an echogenic ring that represents trophoblastic tissue. The normal gestational sac is located in the upper uterine body and has a smooth contour and a round shape. Once seen, the gestational sac grows at a fairly constant rate of 1 mm in mean diameter per day. ^[19]

The yolk sac is visualized when the gestational sac is 10 mm or larger. Visualization of a yolk sac documents that an anechoic area in the uterus represents a true gestational sac and not the pseudogestational sac seen in ectopic pregnancy. Between the 7th and the 13th menstrual weeks, the yolk sac gradually increases in diameter from about 3 mm to 6 mm ^(Fig. 10-1) and ^(Fig. 10-2) . ^{[20] , [21]}

The amnion develops about the same time as the yolk sac but, because it is thinner, the amnion is more difficult to visualize. It surrounds the embryo and is opposite the yolk sac. The amnion grows rapidly during early pregnancy, and fusion with the chorion is usually complete by the 16th week. At that time, the extraembryonic coelom is obliterated.

Cardiac activity is usually the first manifestation of the embryo at about 6 menstrual weeks. Once the embryo is 5 mm, cardiac activity should be present; its absence is indicative of early demise. ^{[22] [23] [24]} If cardiac activity is absent and the embryo is less than 5 mm, the findings are not conclusive. At a gestational age of about 6.2 weeks, the normal heart rate is about 100 bpm, and at 6.3 to 7.0 weeks, about 120 bpm. A slow fetal heart rate is associated with a 35 to 50 percent rate of fetal loss. However, a slow fetal heart

Figure 10-1 Sonogram demonstrating crown-rump length (between crosses) of 8-week fetus. Yolk sac is in the near field.

254

rate at or before 7 weeks in a pregnancy continuing beyond the first trimester is likely to be associated with a normal outcome. ^[25] Embryonic movements can be seen between 7 and 8 menstrual weeks.

Although the gestational sac can be used to date an early pregnancy, the most accurate sonographic measure is the crown-rump length. ^[23] During the first trimester, this method is accurate to within 4 to 5 days. As this is the single best tool to assess gestational age at any time in pregnancy, it should be considered for patients at risk for growth restriction and other complications of pregnancy.

The embryonic pole, a flat, echogenic structure, can be visualized when it is 2 to 4 mm during the seventh

Figure 10-3 Crosses outline normal midgut herniation in 10-week fetus.

255

menstrual week. During the eighth week, a large head with a posterior cystic space, representing the rhombencephalon, can be visualized, together with the spinal column and the lower and upper extremities. By the 9th week, the falx cerebri and the choroid plexus can be seen, and, by the 11th week, the echogenic choroid plexus fills the prominent ventricles. The cerebellum may not be visualized until after 12 weeks. ^{[15] [16] [17]}

Figure 10-4 A, Sonogram at 11 weeks demonstrating conjoined twins. B, Sonogram showing conjoined twins in near field and normal triplet in far field.

Between the 8th and 12th weeks, there is a normal midgut herniation ^(Fig. 10-3) . This should not be confused with an omphalocele, which can be diagnosed with

certainty after that time. The liver can be seen at 9 to 10 weeks; the stomach, at 10 to 12 weeks; the bladder, at 11 to 13 weeks; and the four chambers of the heart, at about 12 weeks. ^[15] ^[16] ^[17]

Many of the fetal anomalies identified during a trans-abdominal

anatomic survey at 18 to 20 weeks can be diagnosed earlier with transvaginal ultrasound. The anomalies with the most serious disruptions of anatomy, such as anencephaly, holoprosencephaly, cystic hygroma, and conjoined twins, may be detected (Fig. 10-4). ^[15] ^[16] ^[17] However, at this time, first-trimester vaginal ultrasound is not as accurate in detecting anomalies. This is because some structures, such as the brain, are not as well developed and other structures, such as the heart, are too small to be adequately evaluated. Therefore, first-trimester ultrasound should not be used as a substitute for a second-trimester evaluation of anatomy.

An important aspect of first-trimester ultrasound is the evaluation of nuchal translucency (Fig. 10-5) to predict chromosomal aberrations. Nicolaides ^[26] and others have shown that nuchal translucency when combined with maternal age and/or serum analytes such as free -human chorionic gonadotropin and pregnancy-associated plasma protein A have a combined sensitivity exceeding 90 percent in detecting chromosomal abnormalities including Down syndrome. ^[27] ^[28] ^[29] ^[30] It is essential that the nuchal translucency be measured in a standardized manner.

Although the main value of vaginal ultrasound is in early pregnancy, it may be of clinical use later in gestation. Vaginal ultrasound permits direct visualization of the internal cervical os and therefore permits accurate assessment of the location of the placenta and its distance from the internal os. The diagnosis or exclusion of placenta previa is therefore facilitated. ^[31] In addition,

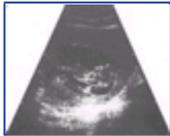

Figure 10-5 Sonogram demonstrating nuchal translucency (arrow) greater than 3 mm in 10-week embryo.

because the cervix can be accurately visualized, vaginal ultrasound may identify early signs of preterm labor or incompetent cervix, such as funneling or shortening of the cervical length, ^[32] ^[33] and thereby directly aid in patient care (see Chapter 23). Lastly, vaginal ultrasound can improve visualization of intracranial anatomy when the head is engaged and permits enhanced views of cranial structures in coronal and sagittal planes.

SECOND TRIMESTER

Assessment of Gestational Age

When performed during the first trimester, ultrasound permits an extremely accurate assessment of gestational age. The early studies of Robinson and Fleming^[34] demonstrated that a fetal crown-rump length, a measurement from the top of the fetal head to its rump, could define gestational ages between 6 and 10 weeks with an error of ± 3 to 5 days (Table 10-1).^[35] In general, the gestational age of the pregnancy in weeks is equal to 6.5 plus the crown-rump length of the fetus in centimeters. When performing a crown-rump length measurement, care must be taken to avoid confusing the yolk sac with the fetal head. Beyond 12 weeks, the fetus begins to curve and the crown-rump length loses its accuracy.

257

TABLE 10-1 -- ULTRASONOGRAPHIC ASSESSMENT OF FETAL AGE

Measurement	Gestational Age (Menstrual Weeks)	Range (Days)
Crown-rump length	512	± 3
Biparietal diameter	1220	± 8
	2024	± 12
	2432	± 15
	>32	± 21
Femur length	1220	± 7
	2036	± 11
	>36	± 16

From Gabbe SG, Iams JD: Intrauterine growth retardation. In Iams JD, Zuspan FP (eds): Manual of Obstetrics and Gynecology. St. Louis, CV Mosby, 1990, p 169.

The biparietal diameter (BPD) is the measurement most often used for establishing fetal gestational age. Campbell et al.^[36] found the BPD to be the most accurate predictor of the estimated date of confinement (EDC) when performed between 12 and 18 weeks' gestation. The transaxial or transverse BPD is best obtained at the level of the thalami and cavum septum pellucidum (Fig. 10-6). The BPD measurement is made from the outer edge of the skull to the inner edge of the opposite side.

Assessment of gestational age in the second trimester is especially important because a routine obstetric ultrasound examination is commonly performed at this time. Gestational age assessment by ultrasound has recently been assessed in populations of patients with

Figure 10-6 A determination of the BPD at the level of the thalami (T) and cavum septum pellucidum (C). The BPD measurement is made from the outer edge of the skull to the opposite inner edge (D1) and on a line perpendicular to the midline. The occipitofrontal diameter (D2) is also shown. The electronic calipers (dots) have been placed to obtain a measurement of the HC.

precisely dated pregnancies that resulted from in vitro fertilization (IVF).^{[37], [38]} Head circumference improved the accuracy of the dating equation (random error, 3.35 days). Most dating formulas had systematic errors of less than 1 week. The systematic error was -0.32 day when using the average singleton-based prediction for twins and -1.26 days for triplets.^[37] The clinical practice in many units has been that, when gestational age by last menstrual period disagrees by more than 10 or 14 days from that derived from fetal biometry in the second trimester, the last menstrual period is superseded by fetal biometry. These data derived from an IVF population suggest that, in the face of a discrepancy of more than 7 days (2 SD), the sonographic biometric prediction should be given preference, provided there is no anomaly or severe growth delay. Other authorities would recommend that the biometric prediction should be given preference in every case.^{[38], [39]}

From 12 to 28 weeks' gestation, the relationship between BPD and gestational age is linear.^[40] The error when measuring the BPD using a 3.5-MHz transducer is ± 1 to 1.5 mm. This error will be least significant early in gestation when the fetal head is growing rapidly (Table 10-1). However, late in gestation, growth of the fetal head slows, and errors of several weeks may be made in estimating gestational age. In addition, later in gestation, the fetal head becomes more elongated in its anterior posterior plane. Such dolichocephaly may be assessed by measuring the cephalic index, the ratio of the BPD divided by the occipital frontal diameter. This ratio should normally be 0.75 to 0.85. If the ratio falls outside this range, the BPD should not be used to estimate gestational age. Femur length may be applied in such cases.

258

Assessment of Fetal Viability

Real-time ultrasound can be used to confirm the presence of fetal death in utero. The absence of fetal cardiac motion as well as the presence of fetal scalp edema and overlapping of the fetal cranial bones confirms fetal death.

THIRD TRIMESTER

Evaluation of Fetal Growth

When establishing gestational age and evaluating fetal growth, it is best to evaluate a variety of parameters, including the BPD, long bones, especially the femur and humerus, as well as the abdominal circumference (AC) (Fig. 10-7), outer and inner orbital diameters, and transcerebellar diameter. The uniformity of fetal growth that characterizes early gestation is lost after 20 weeks. Therefore, a single ultrasound study performed late in pregnancy cannot accurately establish gestational age (Table 10-1). The fetal AC or perimeter measured at the level of the umbilical vein has been used not only to assess gestational age, but to detect the presence of intrauterine growth restriction (IUGR) and macrosomia (Fig. 10-7). Composite tables estimating fetal weight have been constructed by several authors and are usually based on a combination of (1) head size, as measured by BPD or head circumference (HC); (2) femur length (FL); and (3) AC. [41] Tables by Hadlock et al. [42] and Shepard et al. [43] are currently in most common use. Shepard et al. demonstrated that the BPD and fetal AC may be combined to calculate estimates of fetal weight that are likely to be within 10 percent of actual weight.

Abnormal Fetal Growth

Fetal growth restriction is discussed [in Chapter 25](#).

Fetal Macrosomia (see Chapter 16) and (Chapter 27)

Macrosomia has been defined by some investigators as a birth weight in excess of 4,000 to 4,500 g. [44] Other studies, using population-specific growth curves, categorize infants with a birth weight above the 90th percentile as large for gestational age (LGA). Excessive fetal growth resulting in macrosomia has long been recognized as an important cause of perinatal morbidity and mortality, especially in the pregnancy complicated by diabetes mellitus. At delivery, the macrosomic fetus is more likely to suffer shoulder dystocia, traumatic injury, and asphyxia.

Macrosomia in the infant of the diabetic mother (IDM) is characterized by selected organomegaly, with increases in both fat and muscle mass resulting in a disproportionate increase in the size of the abdomen and shoulders. However, brain growth is not altered, and, therefore, the HC is usually normal. Thus, the macrosomia of the IDM is asymmetric. The macrosomic infant of an obese woman without glucose intolerance

Figure 10-7 Transverse or axial view of the abdomen demonstrates the fetal stomach (S) and umbilical vein (UV). Note that the abdomen is round and the umbilical vein is well within the substance of the liver. This is the proper level for determination of the fetal AC; electronic calipers (dots) have been placed to make this measurement. The AC may also be calculated using measurements of the anteroposterior (D1) and transverse (D2) abdominal diameters using the following formula: $AC = D1 + D2 \times 1.57$.

will demonstrate excessive growth of *both* the AC and HC, or symmetric macrosomia.

Antenatal sonographic detection of the LGA fetus could allow optimal selection of the route of delivery to reduce the likelihood of birth trauma. Unfortunately, our clinical ability to evaluate fetal size at term remains poor, with only 35 percent of large infants being identified by excessive symphysis-fundal height measurements. [45]

Sonographic estimation of fetal weight has been used to improve the detection of excessive growth. Using Shepard's formula, Ott and Doyle [46] determined fetal weight in 595 patients undergoing real-time ultrasound estimation within 72 hours of delivery. Overall, almost 75 percent of LGA infants were detected using an estimated fetal weight (EFW) above the 90th percentile as the cut-off for diagnosis. There were a significant number of false-positives, as the predictive value of a positive test was only 63.2 percent. An EFW below the 90th percentile predicted a normally grown fetus in 96 percent of cases, emphasizing the high negative predictive value of ultrasound.

Several studies have emphasized the limited predictive value of ultrasound to identify the macrosomic fetus and the unnecessary interventions that may be undertaken for suspected macrosomia. [47] [48] [49] [50] [51] Overall, both the sensitivity and positive predictive value in these reports range between 50 and 60 percent. It must be remembered that formulas for estimation of fetal weight are associated with a 95 percent confidence range of at least 10 to 15 percent. [42] Thus, the predicted weight using ultrasonography would have to exceed 4,700 g for all fetuses with weights in excess of 4,000 g to be accurately identified!

Measurement of the AC is probably the most reliable sonographic parameter for the detection of macrosomia. Using an AC above the 90th percentile obtained within 2 weeks of delivery, Tamura et al. [47] correctly identified 78 percent of LGA fetuses. When both the AC and EFW exceeded the 90th percentile, an LGA infant was correctly diagnosed in 88.8 percent of cases. Bochner et al. [52] used early third-trimester ultrasound measurements of the AC to determine the risk for both macrosomia and birth trauma at term. In a series of 201 women with gestational diabetes mellitus, 36 of 41 cases of macrosomia were identified by the presence of an AC above the 90th percentile at 30 to 33 weeks' gestation. The false-positive rate was high, with 28 normally grown fetuses having large AC measurements. Of note, the risk for shoulder dystocia was 9.3 percent in the suspected LGA group versus 0.8 percent in the group with a normal AC measurement at 30 to 33 weeks.

The HC/AC ratio has been used for the detection of asymmetric macrosomia. The HC/AC ratio should be reduced in cases of asymmetric macrosomia seen in diabetes mellitus, since abdominal size is disproportionately large compared with head growth (Fig. 10-8). [53] The HC/AC ratio does require an accurate knowledge of gestational age, since the ratio varies throughout pregnancy. Using a similar approach, Cohen has reported that when the difference between the abdominal diameter and BPD is 2.6 cm or more in IDMs weighing 3,800 to 4,200 g, the risk of significant shoulder dystocia is 30 percent. [54]

In summary, detection of the macrosomic infant using both clinical *and* ultrasonographic techniques remains challenging. In patients at risk for fetal macrosomia women who have diabetes mellitus, are obese, or whose pregnancies go beyond 41 weeks a "growth profile" including ultrasound measurements of estimated fetal weight and the HC/AC ratio may improve the identification of excessive fetal growth. [55] In patients at low risk for macrosomia, a fundal height

measurement of 4 cm or more than expected for gestational age should signal the need for an ultrasound study.

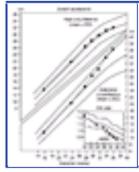

Figure 10-8 Growth chart in a case of asymmetric macrosomia. While HC growth is preserved, AC growth is accelerated in the third trimester. For this reason, the HC/AC or H/A ratio shown in the lower right corner of the graph is reduced. This growth pattern is characteristic of the accelerated growth of the fetus of the diabetic mother. (From Chudleigh P, Pearce JM [eds]: *Obstetric Ultrasound*. Edinburgh, Churchill Livingstone, 1986.)

Assessment of Amniotic Fluid Volume

Ultrasound has proved valuable in the evaluation of amniotic fluid volume. Early application of this technology included measurements of the largest vertical pocket of fluid. Oligohydramnios, a reduction in amniotic fluid volume, was diagnosed when the largest pocket of amniotic fluid measured in two perpendicular planes was less than 1 cm. Chamberlain et al.^[56] reported this degree of oligohydramnios in 0.85 percent of more than 7,500 patients evaluated. When defined in this way, oligohydramnios was associated with a 40-fold increase in perinatal mortality (187.5 per 1,000); a 17-fold increase in lethal congenital anomalies such as renal agenesis, polycystic kidney disease, or complete obstruction of the genitourinary system (9.4 percent); and an eight-fold increase in growth restriction (39 percent). Hydramnios or excessive amniotic fluid was diagnosed when the largest pocket of amniotic fluid exceeded 8 cm in two perpendicular planes^[57] (see Table 1-2).

Several investigators have questioned the diagnostic accuracy of the largest or maximum vertical pocket concept as an index of overall amniotic fluid volume and perinatal outcome. Bottoms et al.^[58] reported that subjective assessment of amniotic fluid volume was as valuable as measurements of the maximum vertical pocket. They did note that suspected fetal growth restriction and suspected postterm gestation were negatively correlated with the maximum vertical pocket, whereas suspected fetal growth acceleration and increasing birth weight were positively correlated. Hoddick et al.^[59] reported poor sensitivity when applying the 1-cm vertical pocket as an index of oligohydramnios for the detection of IUGR.

In an effort to find a more reproducible and quantitative technique to assess amniotic fluid volume, Phelan and colleagues^[60],^[61] developed the amniotic fluid index (AFI). The AFI measurement is performed with the patient in the supine or semi-Fowler's positive position. The maternal abdomen is divided into quadrants (Fig. 10-9) and (Fig. 10-10). The umbilicus is used as one reference point to divide the uterus into upper and lower halves, and the linea nigra is used as the midline to divide the uterus into right and left halves. The ultrasound transducer head is then placed on the maternal abdomen along the longitudinal axis. The transducer head is maintained perpendicular to the floor, and the vertical diameter of the largest amniotic fluid pocket in each quadrant is identified and measured. The total of each of these measurements is summed to obtain the AFI in centimeters. If a fetal extremity or portion of the umbilical cord is observed in the quadrant to be measured, the transducer head is moved slightly to exclude these structures. A linear array, sector, or curvilinear transducer may be used to determine the AFI.^[52] Care

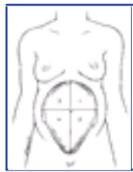

Figure 10-9 The AFI measurement utilizes ultrasound to assess the depth of fluid pockets in each quadrant of the uterus. Note that the umbilicus divides the uterus into upper and lower halves, and the linea nigra divides the uterus into right and left halves.

must be taken to avoid excessive pressure on the transducer, as this might decrease the AFI.^[63] Moore and Cayle^[64] have modified this approach by measuring only those amniotic fluid pockets completely clear of cord or extremities. The technique is extremely reproducible, with intraobserver and interobserver variations averaging 1.0 and 2.0 cm, respectively.^[64]^[65]^[66] When the AFI is determined in a patient at 20 weeks' gestation or lower, the uterus is divided into halves using the linea nigra, and the largest pocket identified in each half is added to produce an AFI.

Using this technique, Phelan et al.^[60] found that the mean AFI in over 350 pregnancies at 36 to 42 weeks was 12.9 ± 4.6 cm. Patients with an AFI less than 5.0 cm at term were considered to have oligohydramnios, and those with an AFI of 20 cm or greater were considered to have polyhydramnios. When the AFI fell below 5 cm, Rutherford et al.^[65] noted that the frequency of nonreactive nonstress tests, fetal heart rate decelerations, meconium staining, cesarean sections for fetal distress, and low Apgar scores increased. Based on a maximum vertical pocket of 8 cm or more to define polyhydramnios, fetal structural anomalies have been observed in 36 to 63 percent of cases with polyhydramnios.^[67],^[68]

Moore and his colleagues have demonstrated the validity of the AFI and established normative values for this measurement. In a pregnant sheep model, Moore and Brace^[69] first found that the AFI demonstrated a

Figure 10-10 Ultrasound determination of the AFI at 29 weeks' gestation. The numbers in the corner of each ultrasound section correspond to those in Figure 10-9. The AFI was 15.6 cm, which is normal at this gestational age (see Table 10-2)

close linear relationship to the actual amount of amniotic fluid and was 88 percent accurate in quantitating amniotic fluid volume. Moore and Cayle^[64] next studied 791 uncomplicated pregnancies prospectively to establish normal values for the AFI (Table 10-2). At term, the mean AFI was 11.5 cm, and the 5th and 95th percentiles were 6.8 and 19.6 cm, respectively. These values are similar to those reported by Phelan and coworkers. Moore^[70] has also demonstrated the superiority of the AFI over the maximum vertical pocket in detecting abnormalities of amniotic fluid volume. In this study of 1,178 high-risk patients, oligohydramnios was defined as an AFI less than the 5th percentile for gestational age, whereas hydramnios was defined as an AFI greater than the 95th percentile for gestational age. The ability of a maximum vertical pocket of 3 cm or less to

From Moore TR, Cayle JE: The amniotic fluid index in normal human pregnancy. *Am J Obstet Gynecol* 162:1168, 1990, with permission.

identify cases with oligohydramnios by AFI was poor, with a sensitivity of only 42 percent and a positive predictive value of 51 percent. Moore ⁶³ noted that 58 percent of cases with oligohydramnios by AFI had normal values when using the largest vertical pocket technique. The detection of polyhydramnios, defined as a maximum vertical pocket of 8.0 cm or greater, was also limited in cases identified to have excessive amniotic fluid by this method.

In summary, whereas there is reasonably good correlation between quantitation of amniotic fluid volume using subjective assessment of amniotic fluid volume, measurements of the maximum vertical pocket, and AFI, the AFI appears to have significant advantages. This index appears highly reproducible and may, therefore, be more uniformly used by a number of different examiners. Furthermore, the AFI may be applied with greater reliability at each gestational age using the normative values that have been developed by Moore and Cayle. ⁶⁴ Finally, the AFI has greater sensitivity and predictive value in evaluating the pregnancy at risk for oligohydramnios and polyhydramnios.

SONOGRAPHIC EVALUATION OF FETAL AND PLACENTAL ANATOMY

Evaluation of fetal and placental anatomy is an integral part of ultrasound examinations during the second and third trimesters. A basic ultrasound examination that documents fetal life, fetal number, fetal presentation, gestational age and growth, amniotic fluid volume, and placental localization without an evaluation of fetal anatomy, therefore, should be considered incomplete. The following is meant to represent the examination of fetal anatomy that should be part of the basic study. A comprehensive sonographic examination of fetal anatomy is often more detailed when it is targeted to look for a certain anomaly. ^[72] ^[73] ^[74]

The fetal skull should be elliptical, with the cranium ossified and intact. The ventricular system should be evaluated by assessment of the width of the atrium (Fig. 10-11), and the cerebellum should be visualized (Fig. 10-12) and nuchal thickness measured. An attempt should be made to visualize the face, especially

263

Figure 10-11 Transverse sonogram of fetal skull demonstrating normal ovoid contour. Arrows define width of the atrium of the lateral ventricle. C, choroid plexus.

to rule out a facial cleft (Fig. 10-13). The spine is easier to evaluate in its entirety in the second trimester than in the third. A sagittal sonogram should be complemented by a series of transverse sonograms to identify normal anterior and normal posterior ossification elements (Fig. 10-14 and Fig. 10-15). A four-chambered view of the heart should be obtained. ^[75] Ventricles and atria of equal and appropriate sizes and an intact ventricular septum should be observed (Fig. 10-16). Evaluation of outflow tracts should be attempted (Fig. 10-17). The fetal bladder (Fig. 10-18), stomach (Fig. 10-19), and kidneys (Fig. 10-20) should be visualized. The abdominal wall should be intact (Fig. 10-21). The long bones of at least the lower extremities should be visualized (Fig. 10-22 and Fig. 10-23). Although fetal gender often may be identified in the second and third trimesters, this should not be considered an integral part of the examination (Fig. 10-24 and Fig. 10-25).

In addition to the assessment of placental location, ultrasound can provide an evaluation of placental anatomy ^[76], ^[77] (Fig. 10-26; see also Fig. 1-5). Although difficult during the first trimester, the location of the placenta can be clearly established by the second trimester. Early in gestation, the placental substance is homogeneous but, as pregnancy advances, echospared areas corresponding to flow of blood from the maternal spiral arterioles and calcium deposition can be seen. The chorionic plate, the fetal surface of the placenta, is initially straight and well defined, but develops indentations as gestation progresses. The basal layer of the placenta is characterized by a hypoechoic area representing venous blood flow. As gestation advances, the basal layer reveals more calcifications. A system of placental grading based on the characteristics of the chorionic plate, placental substance, and basal layer has been used in the past to predict fetal pulmonary maturity (see Chapter 12).

Placental thickness can be directly related to gestational age, with the thickness of the placenta in millimeters corresponding approximately to the weeks of gestation. For example, at 20 weeks' gestation, the placenta will be approximately 20 mm thick. Placentomegaly, a placenta of greater than normal thickness, has been associated with maternal diabetes mellitus, fetal hydrops, placental hemorrhage, intrauterine infection including syphilis, chromosomal abnormalities, and hydatidiform mole (Fig. 10-27), or a placental chorioangioma (Fig. 10-28).

Currently, placenta accreta can be suspected with ultrasound and may be of value in high-risk patients who have a placenta previa in conjunction with a prior cesarean delivery (see Fig. 17-8). However, a normal ultrasound examination does not exclude the possibility of an accreta, as sonographic diagnosis is imperfect. ^[78], ^[79]

ULTRASOUND DIAGNOSIS OF FETAL ANOMALIES

Antenatal ultrasound scanning at about 18 to 20 weeks of gestation permits the detection of most major fetal structural anomalies.^{[80] [81] [82]} It is important to appreciate, however, that even a thorough ultrasound evaluation during the second trimester will not detect all structural malformations. Anomalies such as hydrocephalus caused by aqueductal stenosis, duodenal atresia, microcephaly, achondroplasia, and polycystic kidneys may not manifest until the third trimester, when the degree of anatomic distortion is sufficient to be sonographically detectable.

What fetal malformations should be identified during a basic ultrasound examination? Nelson et al.^[83] surveyed 27 radiologists and 15 obstetricians with expertise in this field who were told that the patient was referred for a dating scan between 20 and 24 weeks' gestation and had no complicating obstetric problems. The anomalies believed to be observable in the majority of cases included anencephaly, hydranencephaly, ventriculomegaly of greater than 15 mm, alobar holoprosencephaly, open spina bifida, a large amount of ascites, bilateral hydronephrosis greater than 20 mm, omphalocele, gastroschisis, and hydrothorax with a mediastinal shift. A useful classification of fetal anomalies is based on the nature of the dysmorphology that permits sonographic detection.

Absence of a Normally Present Structure

A dramatic example of the absence of a structure normally detected by ultrasound is anencephaly, the absence of calvaria and forebrain (Fig. 10-29). Ultrasound clearly reveals the absence of echogenic skull bones and the presence of a heterogeneous mass of cystic tissue, called the area cerebrovasculosa, which replaces well-defined cerebral structures. In 1972, anencephaly was the first fetal anomaly to be diagnosed with sufficient certainty to support a decision to terminate a pregnancy.^[84]

Alobar holoprosencephaly is the absence of midline cerebral structures, resulting from incomplete cleavage

Figure 10-16 Four-chamber view of the heart. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

266

Figure 10-17 Sonogram demonstrating outflow tract (AO), left ventricle (LV), left atrium (LA), and right ventricle (RV). The anterior wall of the aortic outflow tract is contiguous with the interventricular septum (IVS).

of the primitive forebrain. The "midline echo" of the fetal head, normally generated by acoustic interfaces in the area of the interhemispheric fissure, is absent. However, absence of a midline echo is not specific to alobar holoprosencephaly; an additional sonographic sign should be sought to confirm a diagnosis, which may include hypotelorism, nasal anomalies, and facial clefts. The detection of the facial aberration helps to confirm the diagnosis of alobar holoprosencephaly (Fig. 10-30).^[85]

The kidneys are normally visualized as bilateral, ovoid, paraspinal masses with echospared renal pelves. When not visualized, the diagnosis of renal agenesis should be suspected. Severe oligohydramnios and the inability to visualize the bladder support the diagnosis of renal agenesis. Although antenatal diagnosis of renal agenesis is possible, false-positive and false-negative diagnoses occur from inadequate visualization because of the presence of oligohydramnios and simulation of the sonographic appearance of kidneys by the ovoid-shaped adrenal glands.^[86]

Presence of an Additional Structure

Masses that distort normal fetal anatomy can be readily identified with ultrasound. Teratomas are the most common neoplasms of fetuses. They are derived from pluripotent cells and are composed of a diversity of tissue foreign to the anatomic site from which they arise. They may be visualized as distortions of fetal contour, often in the sacrococcygeal area or along the fetal midline. The internal sonographic appearance, characterized by irregular cystic and solid areas and occasional calcifications, helps to identify the lesion (Fig. 10-31).^[87]

Fetal cystic hygromas are fluid-filled masses of the fetal neck that arise from abnormal lymphatic development. They are generally anechoic, with scattered septations and the presence of a midline septum arising from the nuchal ligament. If the lymphatic disorder causing the hygromas is widespread, it may produce fetal hydrops and intrauterine death^{[88] , [89]} (Fig. 10-32).

Fetal hydrops or fetal anasarca may be identified by the distortion of the normal fetal surface by skin edema. Ascites, pleural effusions, and pericardial effusions also may be identified. The etiologies of fetal hydrops are many and varied^{[90] [91] [92]} (Fig. 10-33).

Herniation Through Structural Defects

A common theme in the development of the fetus is the formation of compartments containing vital structures by folding and midline fusion. Incomplete fusion in a

variety of locations can lead to defects and herniations of contained structures. ^[93]

The neural tube and overlying mesoderm begin their closure in the region of the fourth somite, with fusion extending both rostrally and caudally during the fourth week of fetal life. ^[93] Incomplete closure at the rostral end produces cephaloceles, with herniations of meninges and, frequently, of brain substance through a defect in the cranium (Fig. 10-34). ^[94] Failed fusion at the caudal end produces spina bifida with protruding meningoceles and meningomyeloceles (Fig. 10-35). Sonographic diagnosis of each of these anomalies depends on the

Figure 10-24 Sonogram demonstrating male genitalia. P, penis; S, scrotum.

demonstration of a defect in the normal structure of the cranium or spine and of a protruding sac, often containing tissue. ^[95], ^[96]

The Arnold-Chiari malformation is an anomaly of the hindbrain that has two components. The first is a variable displacement of a tongue of spinal canal. The second is a similar caudal dislocation of the medulla

Figure 10-25 Sonogram demonstrating female genitalia. L, labia.

layer (B).

and fourth ventricle. Most, if not all, cases of spina bifida are complicated by the Arnold-Chiari malformation. [97] The Arnold-Chiari malformation can serve, therefore, as an important marker for spina bifida. Two characteristic sonographic signs (the "lemon" and the "banana") of the Arnold-Chiari malformation have been described. [98] A scalloping of the frontal bones can give a lemon-like configuration, in axial section, to the skull of an affected fetus during the second trimester. The caudal displacement of the cranial contents within a pliable skull is thought to produce this scalloping effect. Similarly, as the cerebellar hemispheres are displaced into the cervical canal, they are flattened rostrocaudally, and the cisterna magna is obliterated, thus producing a flattened, centrally curved, banana-like sonographic appearance. In extreme instances, the cerebellar hemispheres may be absent from view during fetal head scanning. These characteristic cranial signs are valuable adjuncts to the sonographer in the search for spina bifida (Fig. 10-36). [99]

American College of Obstetricians and Gynecologists, with permission.)

Omphaloceles result from failure of the intestines to retract from their temporary location in the umbilical cord and the subsequent herniation of other abdominal contents, including both hollow and solid structures contained within a peritoneal sac. Insertion of the umbilical cord into the sac helps to differentiate an omphalocele from gastroschisis, which has no covering membrane. Nonetheless, distinguishing these two entities may be difficult [99] (Fig. 10-37) and (Fig. 10-38) .

The diaphragm forms from four separate structures

that fuse to separate the pleural and peritoneal cavities. When a diaphragmatic hernia is present, abdominal contents may be visualized within the chest on transverse sonographic scanning. A disruption in this development of the diaphragm may be seen in the sagittal plane. [100] , [101]

Dilatation Behind an Obstruction

In this class of anomalies, the structural defect itself is rarely seen. Rather, what is observed is the distention of structures behind a defect. Such dilatation is caused by obstruction to the normal flow of cerebrospinal fluid, urine, or swallowed amniotic fluid.

Hydrocephalus is characterized by a relative enlargement of the cerebroventricular system with an accompanying increase of pressure of the cerebrospinal fluid within the fetal head. Hydrocephalus is suggested by a lateral ventricular atrial width greater than 1 cm, [102] [103] [104] a dangling choroid plexus, [105] and an asymmetric

appearance of the choroid plexus.^[104],^[105] The location of the obstruction may be determined by observing which portions of the ventricular system are enlarged (Fig. 10-39). There is a frequent association of fetal hydrocephalus with other anomalies, especially spina bifida.^[106]

Fetal small bowel obstruction may cause dilatation proximal to the area of obstruction. Duodenal atresia has been observed to produce its characteristic "double-bubble" sign, consisting of enlarged duodenum and stomach with narrowing at the pylorus and duodenum and is commonly associated with Down syndrome^[107],^[108] (Fig. 10-40). Obstruction in the lower gastrointestinal tract (e.g., imperforate anus) is generally not detected on antenatal ultrasound unless there is an associated lesion.

Obstructions to urinary flow with proximal dilatation can occur at the uteropelvic and uterovesicular junctions (Fig. 10-41). These are commonly unilateral defects, whereas obstruction at the urethra from posterior urethral valves characteristically produces bilateral dilatation of the ureters and renal pelves.^[109]^[110]^[111] When a posterior urethral valve produces a complete obstruction, renal dysplasia and pulmonary hypoplasia may result (see Chapter 11).

Abnormal Fetal Biometry

Several fetal anomalies are best diagnosed not by observing alterations in shape or consistency, but by determining abnormalities in size. The science of fetal biometry has generated many nomograms defining normal values for parts of the fetal anatomy at various gestational ages.^[109]

Fetal microcephaly is usually the result of an underdeveloped brain. Although commonly associated with cerebral structural malformations, microcephaly may be produced by a brain that is normal in configuration but merely small. The accurate diagnosis of microcephaly has proved challenging because compressive forces within the uterus may distort the shape of the fetal head. The best correlation between microcephaly diagnosed in utero and neonatal microcephaly is made when multiple parameters are measured and suggest a small head.^[112],^[113]

A variety of skeletal dysplasias may affect the growth of long bones. Measurement may suggest a particular skeletal dysplasia, depending on which bones are foreshortened. The shape of these bones, their density, the presence of fractures, or the absence of specific bones may aid in differentiating the various bony abnormalities.^[114]

When interorbital distances are inconsistent with gestational age, hypotelorism or hypertelorism may be suggested. Abnormal distance between the orbits may serve as a clue to several malformation syndromes (e.g., alobar holoprosencephaly^[62] and median cleft face syndrome^[115]) (Fig. 10-42).

The internal architecture of the kidneys may be difficult to assess in the presence of oligohydramnios. The diagnosis of polycystic kidneys thus is aided by renal measurement. In addition to being echogenic, polycystic kidneys usually are enlarged and display an abnormally

increased kidney circumference/abdominal circumference ratio.^[116],^[117]

Absent or Abnormal Fetal Motion

Abnormalities in fetal motion may suggest a malformation that cannot itself be seen. Although the fetus normally can assume contorted positions in utero, the

persistence of such an unusual posture over time may suggest an orthopedic or neurologic anomaly such as clubfoot (Fig. 10-43)^[118] or arthrogryposis.^[119]

The fetal heart is the most conspicuously dynamic part of the fetus. Real-time ultrasound is invaluable in diagnosing most fetal cardiac anomalies (Fig. 10-44). An attempt should be made to obtain a four-chamber view of the heart in any obstetric ultrasound examination in which fetal anatomy is surveyed.^[79] Examination of the fetal outflow tracts increases the detection of heart anomalies. In cases of a suspected fetal arrhythmia, atrial and ventricular rates can be determined.^[120],^[121]

Ultrasound Detection of Chromosomal Abnormalities in the Second Trimester

Ultrasound examination can suggest a chromosomal aberration. Sonographic markers for the most serious karyotype abnormalities are often present. Holoprosencephaly,

278

facial clefts, hypotelorism, omphalocele, polydactyly, and heart defects are associated with trisomy 13, whereas growth restriction, micrognathus, overlapping fingers, omphalocele, horseshoe kidney, and heart defects are associated with trisomy 18 (see Chapter 8). Early-onset severe growth restriction, large head, syndactyly, and heart defects suggest triploidy. Turner's syndrome (45,X) is classically associated with nuchal cystic hygroma, but this ultrasound finding can occur in a wide variety of genetic disorders.^[122]

Major structural malformations, including hydrops, duodenal atresia, and heart defects, are associated with

Figure 10-38 A, Loops of bowel (B) without a surrounding membrane are characteristic of gastroschisis. The arrow points to the insertion of the umbilical cord. Note the absence of a surrounding membrane. As in the ultrasound, the abdominal contents are seen to the right of the umbilical cord. (Courtesy of Dr. Harbhajan Chawla.)

trisomy 21 but are detected sonographically in only about 30 percent of cases.^[123],^[124] Nuchal skin thickness, defined as 6 mm or more, is a useful screening tool for trisomy 21 and other chromosomal malformations (Fig. 10-45).^[121],^[125],^[126] Other sonographic signs used to screen for Down syndrome include short femur, short humerus, pyelectasis, mild cerebral ventriculomegaly, clinodactyly with hypoplastic middle phalanx of the fifth digit, widely spaced first and second toes, low-set ears, echogenic bowel, and a single palmar crease.^[123],^[124],^[127] Scoring systems have been developed to include these sonographic markers, maternal age, and

279

Figure 10-39 A, Common sites of obstruction of cerebrospinal fluid flow resulting in ventriculomegaly. B, Transverse sonogram of fetal head demonstrating hydrocephalus. LV, dilated lateral ventricle; arrow points to dangling choroid plexus.

serum markers to achieve a reported sensitivity of 90 percent.^[128]^[129]^[130]^[131]

Choroid plexus cysts can occur in about 1 percent of fetuses and, although most are closely associated with trisomy 18, can be a marker for other chromosomal abnormalities^[132],^[133] (Fig. 10-46). The need for a karyotype determination when the only structural abnormality seen is a choroid plexus cyst remains controversial.^[134],^[135] Benaceraff et al.^[136] have calculated that the performance of amniocentesis for choroid plexus cysts would result in more fetal loss than in detection of unsuspected chromosomal aberrations. In a study of over 30,000 patients, Boyd et al. found that the use of so-called soft markers for aneuploidy such as choroid

280

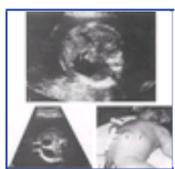

Figure 10-40 A, Sonogram demonstrating normal duodenum (arrow). B, Sonogram illustrating classic "double bubble" sign. The two echo-free areas (arrows) represent the stomach and proximal duodenum. C, Infant with "double bubble" sign (arrows) and duodenal atresia.

plexus cyst(s), echogenic bowel, and nuchal thickening led to a small increase in the detection rate for the abnormal fetus but increased the false-positive rate 12-fold!^[136]

In summary, if a major structural malformation is detected with ultrasound, karyotype determination should be considered by the pregnant woman. At the present time, nuchal thickness is a most clinically useful ultrasound marker for trisomy, with the relative value of other ultrasound markers under investigation.

MANAGEMENT OF A PREGNANCY COMPLICATED BY AN ULTRASONICALLY DIAGNOSED FETAL ANOMALY

If a fetal anomaly is diagnosed by obstetric ultrasound, the fetus should be carefully evaluated for other anomalies before management options can be considered. Echocardiography

281

Figure 10-41 A, Sonogram demonstrating hydronephrosis with dilated renal pelvis and calyces. B, Sonogram demonstrating dysplastic left kidney with noncommunicating cysts (proximal) and normal right kidney (distal).

and karyotype determination should usually be part of this evaluation. Copel et al. ^[137] have shown that 23 percent of fetuses referred for echocardiography because of an extracardiac anomaly had congenital heart disease. Approximately one third of fetuses with structural anomalies have a chromosomal disorder. ^{[138] [139] [140] [141]} This additional information is invaluable to define fetal prognosis. For example, the prognosis for isolated hydrocephalus is substantially better than that for hydrocephalus associated with alobar holoprosencephaly and trisomy 13.

After the fetal evaluation is completed, the certainties and uncertainties of fetal prognosis should be explained to the pregnant woman and her partner. The disclosure requirements of the informed consent process require the physician to present information about the range of

282

Figure 10-42 A, Transverse scan through orbits of fetus affected with median cleft face syndrome demonstrates hypertelorism. available management options: aggressive management, termination of pregnancy, nonaggressive management, and cephalocentesis. ^[142] These disclosure requirements obligate the physician to be objective when presenting this information. That is, the physician is not justified in withholding information about available management options to which he or she might object for reasons of personal conscience. ^[143]

Aggressive Management (see Chapter 11)

To optimize fetal outcome, there should be an interdisciplinary approach, including specialists in maternal-fetal medicine, neonatology, genetics, pediatric surgery, and pediatric cardiology. ^{[144] [145] [146]} Social work services may provide important support to the family before as well as after birth. Such a team approach is best equipped to address the important questions of where, when, and how the infant should be delivered, as well as the role of invasive fetal therapy.

Most infants with anomalies are best delivered in a referral center with a neonatal intensive care unit experienced in caring for such infants. In such a setting there is immediate access to diagnostic and therapeutic medical and surgical interventions.

Delivery at term is optimal for most fetal anomalies. For some malformations, however, such as hydrocephalus, delivery as soon as fetal lung maturation has occurred may be advisable in order to expedite corrective neonatal surgery. ^[147] Rarely, because of the risk of imminent fetal death, an anomaly such as progressive fetal hydrops may necessitate delivery prior to fetal lung maturity. ^[145]

Most fetuses with anomalies can be delivered vaginally. Cesarean delivery may be necessary to avoid dystocia if conditions such as a sacrococcygeal teratoma or conjoined twins are present. For other anomalies, such as spina bifida, cesarean delivery may be recommended in order to minimize trauma to fetal tissues and preserve neurologic function. ^[148]

Rarely, an invasive approach such as shunt placement may be considered to optimize outcome during the antenatal period. This strategy should only be considered when the natural history of the anomaly diagnosed is dismal and a relatively simple intrauterine correction is possible. The sonographic and karyotypic evaluations described above are especially important

284

before an invasive approach can be considered. The disclosure requirements of the informed consent process necessitate that the experimental nature of invasive fetal therapy and the potential harms to the fetus and the mother be carefully explained. In addition, it is generally agreed that after 32 weeks of gestation such efforts offer no clear advantage over delivery and neonatal treatment. Given the risk of iatrogenic premature delivery as well as the experimental nature of these procedures, a normal coincident twin is considered to be a contraindication to this approach. ^{[144] , [145] , [146]}

The most common form of invasive fetal therapy has been intrauterine shunt placement. The purpose of such a shunt is to drain fluid under high pressure in a fetal

organ to the lower pressure of the amniotic fluid. Such a shunt may have a role in the treatment of a complete bladder outlet obstruction that would be expected to result eventually in renal failure and pulmonary hypoplasia. ^[149] ^[150] ^[151] Analysis of fetal urine after bladder aspiration may help to define which fetuses are candidates for this vesiculoamniotic shunt. ^[151] ^[152] ^[153] Intrauterine aspiration or shunt placement may also be of value in cases of isolated pleural effusions ^[154] ^[155] ^[156] (Fig. 10-47). In fetal hydrocephalus, however, current experience does not demonstrate a clear benefit, and ventriculoamniotic shunt placement should be avoided unless performed under a research protocol. ^[148] ^[157] ^[158]

Harrison and colleagues have pioneered open fetal surgery to manage such conditions as congenital diaphragmatic hernia, sacrococcygeal teratoma with hydrops, cystic adenomatoid malformation of the lung, and spina bifida. In such cases, hysterotomy and exteriorization of the fetus is followed by repair of the abnormality, replacement of the fetus, and continuation of the pregnancy. ^[144] ^[159] More recently, endoscopic procedures have been used to avoid hysterotomy. ^[142] ^[159] ^[160] ^[161] ^[162] ^[163] ^[164] ^[165] ^[166] At this time, it is not possible to make a final judgment concerning the place of this fascinating modality in fetal therapy. More clinical experience is needed to better define the benefits to the fetus and the risks to the mother.

Termination of Pregnancy

Prior to fetal viability, abortion of any pregnancy is a woman's right as established by *Roe v. Wade*.^[167] The option of abortion prior to fetal viability is, therefore, available to a pregnant woman when *any* fetal anomaly is diagnosed by ultrasound. Ethically, this option is supported by an approach that holds that all of obstetric ethics is essentially a function of the pregnant woman's autonomy^[168] ^[169] as well as an approach that holds that autonomous-based obligations to the pregnant woman should be balanced against beneficence-based obligations to her and the fetus she is carrying (see Chapter 41).^[143]

After fetal viability, there is limited legal access in the United States to termination of pregnancy because of a fetal anomaly. Ethically, the option of terminating third-trimester pregnancies complicated by fetal anomalies has been defended when there is (1) certainty of diagnosis and (2) either (a) certainty of death as an outcome of the anomaly diagnosed or (b) short-term survival but certainty of the absence of cognitive developmental capacity as a result of the anomaly diagnosed. Anencephaly is a clear example of a sonographically diagnosed anomaly that meets these criteria. ^[170] Trisomy 21 is a clear example of an anomaly that does *not* meet these criteria. ^[171] ^[172]

Nonaggressive Management

The above-mentioned criteria for termination of pregnancy for fetal anomalies during the third trimester are quite restrictive. In addition, even if ethical criteria for third-trimester termination of pregnancy were met, it may not be possible to perform termination in some situations because of legal concerns. Nonaggressive management is the noninclusion of obstetric interventions to benefit the fetus, such as fetal surveillance, tocolysis, cesarean delivery, or delivery in a referral center.^[173] Ethically, the option of nonaggressive management for third-trimester pregnancies complicated by fetal anomalies has been defended when there is (1) a very high probability of a correct diagnosis and (2) either (a) a very high probability of death as an outcome of the anomaly diagnosed or (b) a very high probability of severe irreversible deficit of cognitive developmental capacity as a result of the anomaly diagnosed.

Cephalocentesis

When a pregnancy is complicated by fetal hydrocephalus with macrocephaly, there may be a role for cephalocentesis, which is the transabdominal or transvaginal aspiration of cerebrospinal fluid to avoid cesarean delivery. Ethical justification for this procedure can be based on an analysis of beneficence-based and autonomy-based obligations to the pregnant woman and the fetus she is carrying. Such an analysis needs to respect the heterogeneity of fetal hydrocephalus: isolated fetal hydrocephalus, hydrocephalus with severe associated anomalies (such as alobar holoprosencephaly), and hydrocephalus with other associated anomalies (such as an arachnoid cyst)^[174] ^[175] (Fig. 10-48).

WHO SHOULD HAVE AN OBSTETRIC ULTRASOUND EXAMINATION?

Routine performance of obstetric ultrasound examinations, the performance of an ultrasound study on every obstetric patient at approximately 18 weeks' gestation, remains controversial. A routine obstetric ultrasound examination describes what the American College of Obstetricians and Gynecologists (ACOG) has called a *basic* ultrasound examination, which would include the following information: fetal number, fetal presentation, documentation of fetal life, placental location, assessment of amniotic fluid volume, assessment of gestational age, survey of fetal anatomy for gross malformations,

286

Figure 10-45 Sonogram demonstrating nuchal skin thickness greater than 6 mm.

Figure 10-46 Sonogram demonstrating choroid plexus cyst outlined by arrows.

and an evaluation for maternal pelvic masses.^[174], ^[176] When the findings of a basic ultrasound examination suggest a fetal abnormality or in patients at greater risk of a fetal abnormality, a comprehensive ultrasound examination may be indicated. As noted by the ACOG, the comprehensive ultrasound study should be conducted by an individual experienced in these evaluations.

At the present time, routine obstetric ultrasound is practiced in many European countries. The Royal College of Obstetricians and Gynaecologists has concluded that a routine obstetric ultrasound examination is justifiable.^[4] Routine obstetric ultrasound has become widely used in the United States. This practice offers at least six advantages: accurate dating of all pregnancies; accurate evaluation of maternal serum levels of -fetoprotein, human chorionic gonadotropin, and unconjugated estriol (triple screening); early detection of multiple pregnancies; placental localization to rule out placenta previa; detection of structural abnormalities of the fetus; and psychological benefit to the parents.^[177], ^[178]

The ideal timing for a routine ultrasound study would appear to be approximately 18 weeks' gestation. At this gestational age, the pregnancy can be accurately dated and fetal anatomy well visualized. Should a fetal abnormality be identified, sufficient time is available to perform a comprehensive ultrasound, obtain a fetal karyotype if necessary, and counsel the patient and her partner.

A large number of clinical studies support the value

287

Figure 10-47 A shunt (arrow) has been placed to drain a pleural effusion (P) in a fetus at 24 weeks' gestation. Note the compressed lung (L).

of routine obstetric ultrasound.^[179] In an investigation of 11,045 women for whom an ultrasound at 16 to 18 weeks was used as the standard for dating a pregnancy, Kramer et al.^[180] found that obstetric dating based on the patient's last menstrual period was most likely to be in error in identifying a preterm or postterm pregnancy. Kramer et al.^[180] concluded that the mistakes made in dating using menstrual gestational age "support the argument for routine gestational dating with an early ultrasound examination," particularly when one considers the clinical consequences of poor dating. Reviewing their experience with maternal serum markers to screen for Down syndrome in over 25,000 women, Haddow et al.^[181] noted that "Universal dating by ultrasonography before screening would greatly lessen the number of women who are wrongly told that their pregnancies are high risk, and it would allow subsequent diagnostic steps to be taken more expeditiously."

Routine ultrasound performed at 18 weeks' gestation will detect nearly all multiple pregnancies.^[182] ^[183] ^[184] Clinical

288

experience gained in Sweden as well as in the United States indicates that earlier identification of a twin gestation can reduce perinatal mortality and morbidity, perhaps by allowing more close observation and intervention.

An ultrasound performed at 18 weeks' gestation will reveal that approximately 10 percent of placentas overlie the cervical os, allowing the obstetrician to exclude placenta previa in the remaining 90 percent of cases. Of patients with a low-lying placenta at 18 weeks, only those women in whom the placenta completely covers the os are at risk for a placenta previa in the third trimester. The risk of placenta previa in this group is 41 percent, and a repeat ultrasound evaluation should be performed in these cases.^[176] ^[177] ^[178] ^[179] ^[180] ^[181] ^[182] ^[183] ^[184] ^[185]

One of the most important benefits of routine ultrasound appears to be the identification of major congenital malformations. Major anomalies occur in 2 to 3 percent of all births, and data from the Centers for Disease Control and Prevention demonstrate that birth defects are a leading cause of infant mortality, accounting for 22 percent of all infant deaths in 1995 (see Chapter 12). Cardiac abnormalities result in one third of infant deaths caused by birth defects, with respiratory, central nervous system, and chromosomal abnormalities each responsible for approximately 15 percent of these losses. Systematic examination of fetal structure as part of the basic ultrasound study outlined by the ACOG can identify a significant proportion of these abnormalities. In six European studies, including 52,295 patients scanned between 1980 and 1991, routine ultrasound had a sensitivity of 52.9 percent and a positive predictive value of 95.9 percent in identifying major structural

anomalies.^[186] The specificity and negative predictive value were 99.9 and 99.2 percent, respectively. Recent data from 61 European obstetric units participating in the Eurofetus study demonstrate a sensitivity of 61.4 percent for the detection of 3,685 malformed fetuses.^[187] Similar sensitivities and predictive values have been reported by experienced groups in this country.^[188], ^[189]

Several investigations have confirmed the psychological benefit of routine ultrasound, revealing that women who have undergone a scan are more likely to follow the recommendations of their health care providers to stop smoking cigarettes and drinking alcohol.^[190], ^[191]

Until recently, the proposed benefits of routine ultrasound had not been evaluated in large, prospective, randomized studies. Six small studies did reveal that routine ultrasound was associated with fewer inductions for suspected prolonged pregnancy, less morbidity in postdate infants, greater birth weight in twins, and fewer cases of unexpected bleeding from placenta previa.^[192] ^[193] ^[194] ^[195] ^[196] ^[197]

To determine the value of an ultrasound scan at the first prenatal visit, Crowther and her colleagues in Australia performed a prospective randomized clinical trial of 648 women presenting at 10 to 11 weeks' gestation.^[198] Women who had no previous ultrasound and no indication for a scan were randomized to have an ultrasound performed at that time or to a control group. The main outcome measures included the number of women who needed adjustment in their dates by 10 days or more when an ultrasound was later performed to assess fetal anatomy at 18 to 20 weeks, as well as the number of women who were scheduled for their fetal anatomy scan or who had maternal serum screening tests at inappropriate gestational ages. Women in both study groups also completed a questionnaire at the first prenatal visit to assess their feelings about the pregnancy.

For those women randomized to receive an ultrasound at the first prenatal visit, 24 percent required a correction in gestational dating by 10 days or more. Among women who said they were certain of the date of their last menstrual period, 18 percent needed adjustment of their dates. As expected, significantly fewer women who had an ultrasound at their first visit needed an adjustment of their due date when an ultrasound was performed at 18 to 20 weeks (9 percent vs. 18 percent). In the control group, 25 percent of women did have a scan before 18 to 20 weeks, most often for vaginal bleeding or uncertain gestational age. No significant differences were observed in the number of control group women who were scheduled inappropriately for their 18- to 20-week scan or the number of repeat maternal serum screening tests required because of incorrect dating, the number of nonviable pregnancies detected, the number of twins diagnosed at an earlier gestational age, or the number of major anomalies detected. Women who had an ultrasound at the first visit were less worried about their pregnancy. These investigators concluded that a routine ultrasound assessment for dating at the first antenatal visit allowed a more accurate estimation of gestational age and decreased the need to adjust dating later in pregnancy.

Saari-Kemppainen et al.^[199] reported the results of a prospective, randomized investigation of routine ultrasonography performed in the early second trimester including 9,000 Finnish women. The study compared routine ultrasound screening between 16 and 20 weeks, with selective screening performed for usual practice standards. Routine ultrasonography was associated with fewer outpatient clinic visits and antenatal hospitalizations, improved early detection of twins, and identification of patients at risk for placenta previa. There were no differences in the number of labor inductions or mean birth weights in the two groups. Perinatal mortality was significantly lower in the screened than in the control group (4.6 per 1,000 vs. 9.0 per 1,000). This reduction by almost one half was due primarily to early detection of major malformations that led to induced

abortion. Additional benefits were correction of the expected date of delivery by 10 or more days in over 11 percent of the screened group and a decrease in the rate of prolonged pregnancy. The authors concluded that their findings justified routine ultrasound screening of all pregnancies at 16 to 20 weeks for the detection of major congenital abnormalities under circumstances in which induced abortion was acceptable.

The Routine Antenatal Diagnostic Imaging with Ultrasound Study (RADIUS) is the largest prospective randomized investigation evaluating the efficacy of routine ultrasound screening.^[200] ^[201] ^[202] To determine if routine ultrasound could improve the detection of congenital malformations, pregnancies with multiple gestations, abnormal fetal growth, placental abnormalities, and errors in the estimation of gestational age and reduce the frequency of adverse perinatal outcomes, Ewigman and his colleagues^[200] studied 15,151 low-risk patients recruited from 92 obstetric and 17 family medicine practices in six states. Ultrasound screening was performed twice in 7,812 study subjects, first at 15 to 22 weeks and again at 31 to 35 weeks, whereas the 7,718 women in the control group had an ultrasound only if medically indicated. The adverse outcomes evaluated included fetal or neonatal deaths, severe morbidity such as the need for mechanical ventilation for more than 48 hours, a stay of more than 30 days in the special care nursery, and moderate morbidity including a brachial plexus injury.

Women in the experimental group had an average of 2.2 ultrasound studies. Forty-five percent of control subjects also had an ultrasound, for an average of 0.6 studies per control patient. No statistically significant difference was noted in the rate of adverse perinatal outcomes in this investigation: 5.0 percent in the experimental group and 4.9 percent for the control subjects.^[200] No difference was observed in the rate of preterm births or in birth weight distribution. Of 187 major anomalies in the infants of ultrasound-screened patients, 65 (34.8 percent) were detected. Of these, 31 (16.6 percent) were identified before 24 weeks' gestation. In the control group, only 18 of 163 major malformations (11 percent) were recognized, 8 (4.9 percent) before 24 weeks' gestation.^[202] When outcomes were examined in subgroups of patients with postdate pregnancies, multiple gestations, or infants with a birth weight below the 10th percentile, no differences were observed. In an analysis of data on maternal management and outcome, LeFevre et al.^[201] noted no significant differences in the rates of induced abortion, amniocentesis, tests of fetal well-being, external version, induction, cesarean delivery, and the distribution of total hospital days. However, the use of tocolytics and the rate of postdate pregnancy were both slightly lower in the screened group. These investigators concluded that screening ultrasonography did not improve perinatal outcome compared with ultrasonography performed only for medical indications.

Although the RADIUS trial is an important study, a number of significant concerns have been raised in applying the results to general obstetric practice.^[186], ^[203] The adverse perinatal outcomes studied were caused primarily by prematurity or birth trauma. Clearly, prematurity cannot be reduced by routine ultrasound, nor will a second ultrasound examination performed as early as 31 to 35 weeks help to identify the macrosomic fetus at risk for birth trauma. As noted by Berkowitz^[203] in an accompanying editorial, the study population was at extremely low risk for perinatal problems. Women who were eligible for the study had to be at least 18 years of age and speak English. Only 13 percent of them smoked, and more than 40 percent of them had graduated from college.^[200] When O'Day et al.^[204] applied these criteria to 1,000 Medicaid patients at the University of Texas, Houston, only 78 women met the eligibility criteria for the RADIUS trial! Accurate dating of all pregnancies has been cited as an advantage of routine ultrasound. Yet, in the RADIUS trial, women had to know their last menstrual period within 1 week. Not surprisingly, gestational age was reassigned in only 11 percent of the study subjects.^[187] Even in those women assigned to the routine ultrasound group, the detection of major anomalies was poor, only 34.8 percent, and of the 65 malformations identified, only 31 were recognized before 24 weeks.

Why do these results differ from the large clinical experiences of many centers? The answer may be that there is nothing "routine" about a routine ultrasound examination. A basic ultrasound study must be carefully performed by an experienced sonographer. Of note, the rate of detection of fetal malformations at tertiary centers in the RADIUS trial was 35 percent (19 of 54), but only 13 percent (8 of 64) in nontertiary centers. Few women in the RADIUS trial who had a fetal malformation identified elected to terminate their pregnancies.^[200] This choice may be based on cultural differences compared with the study in Helsinki,^[199] on the severity of the anomalies recognized, or, perhaps, on lack of confidence in the diagnosis.^[186] Unfortunately, the RADIUS trial did not evaluate the psychological benefits of routine ultrasound screening, which have been recognized in other prospective studies. Clinicians caring for patients in the routine ultrasound arm of the RADIUS trial, although having the results of the ultrasound studies available, did not follow established protocols in their management of pregnancies complicated by growth restriction, prolonged pregnancy, or multiple gestations.^[201] Furthermore, the number of cases in each of these high-risk groups was limited. These short-comings make it difficult to evaluate whether routine ultrasound is useful in the care of such patients. Finally, it is important to point out that ultrasound

screening did not *increase* the risk of adverse perinatal outcomes.

In their discussion of the results of the RADIUS trial, the authors note that the cost of screening more than 4 million pregnant women annually in the United States at \$200 per ultrasound scan would be more than \$1 billion. This figure could be reduced to \$500 million, since only 40 percent of all pregnancies screened were eligible for the study. However, several other factors should be considered in calculating this cost. Barrett and Brinson^[205] found that a routine ultrasound performed at the first prenatal visit was the most cost-effective of all prenatal laboratory assessments performed. DeVore^[206] has examined the cost of detecting a malformed fetus in the RADIUS trial compared with the California MSAFP screening program. For tertiary centers in the RADIUS trial with a detection rate for fetal anomalies of 6.8 per

1,000, the cost was \$29,533 compared with a detection rate of 1.7 per 1,000 and a cost of \$115,575 for nontertiary centers. The detection rate in the California MSAFP program is 1.3 per 1,000, yielding a cost of \$40,338 for each identified malformed fetus. One must compare this expense with those of caring for a severely malformed infant. Vintzileos and his colleagues recently performed a cost-benefit analysis of routine second-trimester sonograms in 1 million American women.^[207] When performed in tertiary care centers, routine studies resulted in a net savings of \$1.35 to \$1.70 for every dollar spent, with an annual net benefit of \$97 to \$189 million. In contrast, the reduced sensitivity observed in the nontertiary sites in the RADIUS trial would lead to expected net losses of \$69 to \$161 million.

In its 1993 Technical Bulletin, the ACOG^[176] offered the following recommendations concerning routine ultrasound:

Routine ultrasonography in early pregnancy can help to reduce the incidence of labor induction for suspected postdatism, and decrease the frequency of undiagnosed major fetal anomalies and undiagnosed twins. However, significant effects on infant outcome are not confirmed by randomized, controlled trials. Although obstetric ultrasound studies are performed routinely in many European countries, in the United States the routine use of ultrasonography cannot be supported from a cost-benefit standpoint.

More recently, in the summary of its Practice Pattern on routine ultrasound in low-risk pregnancy, the ACOG concluded^[208]

The specificity of a fetal anatomic survey in detecting fetal anomalies can be anticipated to exceed 99 percent. The sensitivity of a fetal anatomic survey in detecting fetal anomalies cannot be estimated with precision; rather, it should be acknowledged that sensitivity may vary in different clinical settings and with different levels of skill of professionals performing the examination. It is uncertain whether an improvement in the survival of fetuses with life-threatening anomalies can be expected from routine ultrasound in low-risk pregnancy. In a population of women with low-risk pregnancy, neither a reduction in perinatal morbidity and mortality nor a lower rate of unnecessary interventions can be expected from routine diagnostic ultrasound. Thus ultrasound should be performed for specific indications in low-risk pregnancy.

While the debate concerning routine obstetric ultrasound continues, a reasonable strategy for this dilemma is the concept that prenatal informed consent for sonogram be considered.^[209] Shortly after the pregnancy is diagnosed, the woman should be provided with information about the actual and theoretical benefits and harms of a routine ultrasound examination. Because the sonographic detection of fetal anomalies has been recognized as a benefit of routine ultrasound, withholding this information from the pregnant patient would not appear to be justified. Thus, a routine obstetric ultrasound examination is *offered*, but not necessarily recommended.

CONCLUSION

In summary, studies of routine ultrasound have failed to demonstrate any associated adverse effects on the mother or fetus. Routine ultrasound has a high positive predictive value for conditions known to be associated with poor perinatal outcome such as twins, placenta previa, and congenital malformations. To date, several large, prospective, randomized studies have evaluated the benefits of routine ultrasound in obstetric practice. ^[199] ^[200] ^[201] ^[202] One, performed in Finland, ^[199] demonstrated a reduction in perinatal mortality, resulting from the identification of major fetal anomalies. The RADIUS trial, ^[201] ^[202] performed in the United States, failed to show an improvement in perinatal outcome. Nevertheless, a large clinical experience from centers both in the United States and in Europe has repeatedly found that routine ultrasound screening at 18 weeks can improve gestational dating in approximately 10 to 25 percent of patients, detect nearly all multiple gestations, exclude placenta previa in most patients and recognize those at greatest risk for this condition, detect one third to one half of major fetal malformations, and reduce parental anxiety and increase compliance with the recommendations of health care providers. The cost of routine ultrasound

screening must be compared with the costs created by false-positive diagnoses, which may lead to unnecessary patient anxiety and further intervention, ^[210] and to the cost savings resulting from reduction in the rate of inductions for suspected prolonged pregnancy, a decrease in the rate of preterm delivery for twins, and the identification of a fetus with an anomaly likely to survive but with a poor quality of life. Finally, like any analytic technique, the value of ultrasound screening is dependent on the skill with which the study is performed and the manner in which the results are interpreted and used in clinical care. ^[179]

Key Points

Ultrasound energy is produced by a transducer containing crystal structures that convert electrical energy to ultrasound waves and the returning echoes to electrical energy.

No deleterious effects on the pregnant woman or fetus caused by exposure to ultrasound at the intensities used for imaging have ever been reported.

Although the gestational sac can be used to date an early pregnancy, measurement of the crown-rump length is the single best method to assess gestational age at any time in pregnancy.

From 12 to 28 weeks' gestation, the relationship between the biparietal diameter and gestational age is linear.

Formulas for estimation of fetal weight are associated with a 95 percent confidence range of at least 10 to 15 percent.

Measurement of the fetal abdominal circumference is probably the most reliable sonographic parameter for the detection of macrosomia.

At term, an AFI less than 5.0 cm indicates oligohydramnios and greater than 20 cm polyhydramnios.

The thickness of the placenta in millimeters corresponds to the number of weeks gestation.

The "lemon" and "banana" signs are important cranial markers for spina bifida.

Major structural malformations, including hydrops, duodenal atresia, and cardiac anomalies, are observed in 30 percent of cases of Down syndrome (trisomy 21).

Chapter 11 - Fetal Therapeutic Intervention

Mark I. Evans
Michael R. Harrison
Alan W. Flake
Mark P. Johnson

For close to 30 years, obstetricians have developed a number of approaches to diagnose both structural and functional fetal anomalies. ¹ When such abnormalities are severe or lethal, pregnancy termination may provide a reasonable management option for couples. In less severe cases, obstetric care can be tailored to optimize outcomes and prevent secondary complications. In certain situations, prenatal correction of the underlying problem has become possible. Structural malformations can sometimes be approached surgically, while metabolic disorders may benefit from pharmacologic or genetic therapy. Over the past decade, fetal therapy has evolved into four major areas: open surgical approaches, "closed" endoscopic surgical approaches, pharmacologic therapy, and stem cell/gene therapy. Advances in the field have been characterized by alternating exuberance at dramatic successes, but also periods of intense frustration at technical challenges needing to be overcome to bring new approaches on line.

Perhaps the single most misunderstood issue about fetal therapy is why before and not after birth. There is not one single answer, but rather a series of disorder-specific considerations. If something can be treated well and safely postnatally, then there is no justification for prenatal intervention. However, for the conditions discussed below, profound and irreparable damage occurs before birth, making fetal intervention the best, or sometimes only, way to ameliorate the damage. Some of those procedures have been quite rare. Others are more common, but the expectation is that with improvements and increasing utilization of prenatal diagnosis, more women will chose to avail themselves of opportunities to treat fetuses with discernable problems.

SURGICAL THERAPY

In Utero "Closed" Fetal Surgery

The most efficacious percutaneous in utero fetal surgery has been for the evaluation and treatment of obstructive uropathy. Lower urinary tract obstruction (LUTO) is a heterogeneous entity that affects 1 in 5,000 to 1 in 8,000 newborn males. Posterior urethral valves (PUV) or urethral atresias are the most common causes for LUTO, although other etiologies such as stenosis of the urethral meatus, anterior urethral valves, ectopic insertion of a ureter, and tumors of the bladder have been observed. LUTO can result in massive distention of the bladder with compensatory hypertrophy and hyperplasia of the smooth muscle within the bladder wall, leading to a loss of compliance and elasticity, and poor postnatal function generally requiring surgical reconstruction.^[2] Elevated intravesicular pressures prevent urine inflow from the ureters; distortion of the ureterovesical angles contributes to eventual reflux hydronephrosis. Progressive pyelectasis and calycectasis compress the delicate renal parenchyma within the encasing serosal capsule, leading to functional abnormalities within the medullary and eventually the cortical regions (Fig. 11-1). Focal compressive hypoxia likely contributes to the progressive fibrosis and perturbations in tubular function resulting in the urinary hypertonicity that is observed. Obstructive processes can lead to type IV cystic dysplasia and renal insufficiency.

The effects are not limited to the genitourinary (GU) tract. Progressive oligo-/anhydramnios leads to compressive deformations as seen in Potter sequence, including

298

Figure 11-1 Oligohydramnios and dilated ureters (arrow) in a fetus at 23 weeks with poor electrolytes.

extremity contractures and facial dysmorphism. Absence of normal amniotic fluid volume also interferes with pulmonary growth and development. Constant compressive pressure on the fetal thorax leads to restriction of expansion of the chest through normal physiologic "breathing movements." Babies born with LUTO generally die due to pulmonary complications and not renal failure.

The prenatal sonographic diagnosis of LUTO includes a dilated and thickened wall bladder, hydronephrosis, and oligohydramnios (Fig. 11-2). Urethral strictures or atresia, urethral agenesis, megalourethra, ureteral reflux, and cloacal anomalies may be present and have a very similar appearance on ultrasound. The typical "keyhole sign" of proximal urethral dilation is secondary to urethral obstruction present in PUV or atresia. However, the precise diagnosis can only be made after birth.^[3]

The prenatal evaluation and management of fetuses with the sonographic findings of LUTO is complex. Ruling out other congenital anomalies such as cardiac and neural tube defects is necessary before intervention can be considered. Karyotyping is essential to confirm a normal male chromosomal status, as cases of LUTO

Figure 11-2 Ultrasound image of an obstructed fetal bladder at 15 weeks' gestation with classic keyhole sign (arrow).

299

Figure 11-3 Vesicoamniotic shunt with the proximal portion lying within the fetal bladder (right arrows) while the distal portion lies within the amniotic fluid space (left arrow), allowing diversionary draining of urine into the appropriate space.

have an increased incidence of aneuploidy. Female fetuses almost always represent more complex syndromes of cloacal malformations, which do not benefit from in utero shunt therapy. Because of the presence of oligo-/anhydramnios, we commonly obtain karyotypes by transabdominal chorionic villus sampling. This approach yields reliable results within 5 days, during which the remainder of the prenatal evaluation is underway.

Perhaps the most important, complicated, and poorly understood aspect of the prenatal work-up is the evaluation of underlying renal status in the fetus. We use a multicomponent approach to the analysis of fetal urine that evaluates proximal tubular and possible glomerular status using sodium, chloride, osmolality, calcium, ² -microglobulin, albumin, and total protein concentrations.^[4] We have demonstrated that predictive reliability can be significantly improved by sequential samplings at 48- to 72-hour intervals.^[5] Using such an approach, one can directly correlate the degree of impaired renal function and damage with the extent of urinary hypertonicity and proteinuria. As such, the ability to counsel patients about the renal status of their fetus and the long-term prognosis has been dramatically improved.

The function of the vesicoamniotic catheter is to bypass the urethral obstruction, diverting urine into the amniotic space to allow appropriate drainage of the upper urinary tract and prevention of pulmonary hypoplasia and physical deformations (Fig. 11-3). In fetuses with isolated LUTO, a normal male karyotype, and progressively improving urinary profile that meet threshold parameters (Table 11-1), we have been very successful in salvaging fetuses using percutaneous vesicoamniotic shunt therapy.

Subsequent experience in humans has been widely variable and appears to be related to the extent of prenatal evaluation prior to shunt placement, as well as the etiology of obstruction. Freedman et al. found that prune belly infants without complete urethral obstructions have very good renal outcomes following vesicoamniotic shunt therapy.^[6] They also observed significant improvement in survival and renal function in infants with PUVs treated by shunting; however, many of these children

have mild to moderate renal insufficiency at birth, and several progressed to renal failure, dialysis, and transplantation. The worst outcomes are observed in infants with urethral atresia. In the Wayne State University series, there have been two survivors following early shunt intervention, both with stable mild to moderate renal insufficiency. These findings support animal studies that indicate that early-onset,

Total protein	<20 mg/dl

300

complete obstructions resulted in more severe renal damage than later onset or partial obstructions, and emphasizes the necessity for early diagnosis, evaluation, and intervention in such cases.

Although vesicoamniotic shunting has certainly improved survival and renal function in cases of early obstructive uropathy, complications of this procedure remain unacceptably high. We have found that in 48 percent of our cases the shunts have become physically displaced into the amniotic or intraperitoneal space, or have become obstructed with loss of drainage function, necessitating replacement. Concerns also remain about the physiologic consequences of chronic shunt drainage on the normal development process of the lower urinary tract, given the presence of this foreign body and absence of normal filling and emptying cycles in the bladder.

Because of these concerns we have looked for alternate ways to approach LUTO. Using thin, fiberoptic endoscopes we have recently been able to perform in utero fetal cystoscopy and antegrade urethroscopy using simple needle systems and techniques similar to vesicocentesis.

Early therapeutic removal of a LUTO due to posterior urethral valves should improve physiologic development of the urinary tract. Reestablished patency of the penile urethra should improve the urethral hypoplasia distal to the site of obstruction, which is encountered postnatally at the time of retrograde resection. Normal filling and emptying of the fetal bladder should help in normal bladder development and may eliminate the need for reconstructive procedures postnatally. Also, this may reduce the need for temporary vesicostomy placement postnatally, which carries a high incidence of infectious febrile morbidity and accumulative renal damage. On balance, intervention for LUTO has saved fetuses who would otherwise have surely died. Many have normal to moderately impaired renal function. A carefully balanced approach in counseling is required for patients to determine what is right for them.

Other Shunt Approaches

Originally, shunting was attempted in cases of obstructive hydrocephalus. Attempts in the late 1970s and early 1980s at ventriculoamniotic shunting were nearly uniformly dismal. However, in retrospect, most operated patients were, in fact, poor candidates for intervention. Many had multisystem syndromic disorders, including aneuploidy, and hopeless congenital anomalies such as holoprosencephaly.

Ventriculoamniotic shunts were abandoned in the early 1980s. With better understanding of the poor natural history of the anomaly, ^[9] and more accurate diagnostic techniques, there may now be limited applications for prenatal neurologic shunting in cases of early-onset, isolated, progressive obstructive hydrocephaly.

The other use of percutaneously placed shunts has been for thoracic abnormalities. The macrocystic form of congenital cystic adenomatous malformation can present with a large, dominant macrocyst that causes mediastinal shift with its potential hemodynamic changes, as well as pulmonary compression and risk of lung hypoplasia (Fig. 11-4). Such dominant cysts can be approached using pleuroamniotic shunts to chronically drain these structures, reducing their volume, and diminishing their space-occupying effects.

Isolated pleural effusions can also accumulate, causing mediastinal hemodynamic changes and onset of generalized hydrops as well as pulmonary compression, which interferes with normal lung development, increasing the risk of hypoplasia (Fig. 11-5). Small, unilateral effusions generally do not warrant intervention, but must be followed closely, as they have the potential for rapid progression and initiation of generalized hydrops. ^[9]

Prenatal evaluation prior to intervention is critical for appropriate case selection, as isolated effusions may be the first sign of a cardiac malformation, aneuploidy, anemia, or an infectious process. Thoracoamniotic shunting is effective in carefully evaluated cases when the risk of pulmonary hypoplasia from large effusions early in gestation is present, or early signs of progressive hydrops (unilateral or bilateral effusions, skin or scalp edema, ascites, pericardial effusion) appear. Fetal anemia is not an indication for thoracoamniotic effusion shunting, as hydropic changes will usually resolve with timely fetal transfusion therapy. Also, if one waits

Figure 11-4 Microcystic congenital cystic adenomatous malformation (microcystic) with beginnings of hydrops (rim underskin).

301

Figure 11-5 Sonographic image of a pleural effusion with needle (arrow) entering from top left.

to intervene until the fetus develops significant ascites, the prognosis becomes much poorer despite successful shunt intervention. ^[9] Nevertheless, several cases with suddenly progressive pleural effusions and onset of generalized hydrops (skin and/or scalp edema, pericardial effusion, and moderate ascites) have been treated with complete resolution of all hydropic complications and normal postnatal outcomes.

Positioning of the thoracoamniotic shunt is critical for success, and great care must be taken to avoid mediastinal structures. Shunts have the potential for displacement and obstruction, so continued ultrasound surveillance throughout the remainder of the pregnancy is necessary. ^[9] In most cases, postnatal management involves simple removal of the shunt in the nursery, as most of these cases represent transient chylothorax that require no additional therapy.

OPEN SURGICAL APPROACHES

Open fetal surgery has been performed for a limited number of indications for over 15 years, primarily at the University of California, San Francisco, with later expansion to a few other sites. Its application has been limited by the appropriate concern for maternal risk, rigorous selection criteria, and somewhat frustrating results. During this time, there has been continuing innovation and development of instruments and techniques, motivated by the clinical necessity to improve the feasibility and safety of open fetal surgery for both the fetus and the mother.

The Fetal Operation General Considerations

Opening the Gravid Uterus

Open fetal surgery is performed through a maternal hysterotomy, preferentially performed in the lower uterine segment. The uterine incision must provide optimal exposure of a specific fetal part or region, avoid the placenta, and provide hemostasis with absolute control of the fetal membranes. The consequences of a poorly placed or technically inadequate hysterotomy include technical failure of the fetal procedure, intra- or postoperative fetal demise, postoperative amniotic fluid leak, chorioamnionitis, and associated preterm labor.

For all fetal surgical procedures, exposure of the uterus is facilitated by a large, true transverse, lower abdominal incision with division of the rectus muscle. Exposure is enhanced by placement of a large, circular, fixed retraction system and exteriorization of the uterus. Pre- and intraoperative sonographic assessment is essential for planning the hysterotomy to identify the position and size of the placenta, as well as other potentially disastrous anatomic abnormalities such as a velamentous insertion of the umbilical cord. Complete uterine relaxation facilitates fetal version when necessary and is essential for hysterotomy and the entire period of the fetal operation. Various regimens have proven effective, including a combination of preoperative indomethacin, with intraoperative isoflurane and nitroglycerin, supplemented with intravenous terbutaline or magnesium sulfate as required.

After adequate uterine relaxation is confirmed by palpation, the planned hysterotomy is initiated by placement of full-thickness, monofilament, absorbable traction sutures on large needles, under ultrasound guidance at the anticipated midpoint of the planned hysterotomy. The traction sutures are then used to elevate the uterine wall, which is grasped and compressed to assist in hemostasis. A large metal trocar is inserted under ultrasound guidance through this area into the amniotic space. The myometrium and membranes are then incised over the trocar for a distance of 2 to 4 cm. The full thickness of the uterus and membranes is grasped on each side with broad Allis clamps. This results in a circumferentially controlled, full-thickness puncture site in the uterine wall. A commercially available uterine stapler is then passed through the opening and fired once in each direction. The absorbable staples hemostatically compress and divide the layers of the uterus, including the membranes, with each application.^[13], ^[11]

Fetal Monitoring and Homeostasis

Reliable intraoperative monitoring of the fetus and uterus has been very difficult to achieve. The confined space and small amount of exposed fetal tissue in combination with the poor tissue integrity of the fetus early in gestation make sutured electrodes unsatisfactory. Originally, pulse oximetry was utilized, but the inherent problems and limitations of this technology are amplified in the fetus. Radiotelemetry systems have been developed in cooperation with the National Aeronautics and Space Administration, which allow fetal heart rate, temperature, intra-amniotic pressure, and other parameters such as blood pH and tissue oxygenation to be monitored.^[12] A small radiotelemeter sutured to the fetal skin sends a continuous signal to an outside antenna. This can be left in place postoperatively for monitoring and is more sensitive for detection of uterine contractions than standard tocodynamometry. At this time, however, the use of intraoperative ultrasound remains the most reliable method of assessing fetal status, providing information on fetal heart rate, volume status, and contractility.

Fetal homeostasis is maintained by protection of uteroplacental blood flow through continued uterine relaxation and careful monitoring, and control of maternal volume status and blood pressure. Care is taken to avoid umbilical cord compression, which may occur at the margins of the hysterotomy or if inadequate amniotic fluid surrounds the fetus. Intra-amniotic volume is maintained by exteriorization of only the necessary part of the fetus, and by continuous high-volume perfusion of the amniotic space with warm lactated Ringer's solution. Without such high-volume flow, loss of uterine volume could initiate uterine contractions.

Congenital Diaphragmatic Hernia

The repair of congenital diaphragmatic hernia (CDH) in the fetus has undergone continuous evolution since it was first attempted in 1986.^[13], ^[14] Definitive repair of CDH by reduction of viscera from the chest, diaphragmatic patch placement, and abdominal silo construction to reduce intra-abdominal pressure had unacceptable mortality, particularly when the liver was herniated into the chest. The definitive repair was therefore abandoned as an option for CDH, and in utero tracheal occlusion was utilized. Tracheal occlusion induces lung growth through accumulation of pulmonary secretions, which reduces the herniated viscera from the chest and alleviates lung hypoplasia. The tracheal occlusion procedure is relatively simple, consisting of exposure of the fetal neck in hyperextension, dissection of the trachea circumferentially (Fig. 11-6) taking care to avoid the recurrent laryngeal nerves, and placement of occlusive hemoclips. The fetus is then gently placed back into the uterus, and the uterine incision close, paying careful attention to hemostasis.

Experience with tracheal occlusion likewise proved to have a significant learning curve. Multiple attempts were made to find an appropriate polymer to use as a tracheal plug inserted through the fetal mouth. Experience quickly showed that unless there was 100 percent occlusion, the pulmonary secretions would seep out, thereby defeating the purpose of the plug. Eventually, it was decided that procedures would best be done using an external tracheal clip to make sure the occlusion was complete, and for the past several years, all cases have been done using this method.

A principal divergence in methodology has come between

Figure 11-6 Surgical isolation of the fetal trachea prior to placement of hemoclips in a tracheal occlusion procedure for congenital diaphragmatic hernia.

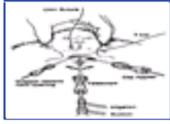

Figure 11-7 Schematic of FETENDO endoscopic approach to tracheal ligation clip for diaphragmatic hernia.

two camps. One favors the open surgical approach to this problem, while the other favors a more technically difficult endoscopic surgical approach to minimize the complications of open fetal surgery (Fig. 11-7). Published data on the two methods so far have been somewhat comparable, although it will take several more years of experience to have a definitive answer as to the best approach.

Congenital Cystic Adenomatoid Malformation

Congenital cystic adenomatoid malformation (CCAM) is a space-occupying congenital cystic lesion of the lung that may grow and induce hydrops by causing mediastinal shift and compromising venous return to the heart. Fetuses with CCAM who develop hydrops have a mortality approaching 100 percent. Fetal resection of CCAM reverses hydrops and has improved survival dramatically.^[19] The fetal operation is performed by exposure of the arm and chest wall on the side of the lesion through the maternal hysterotomy. A large thoracotomy is performed through midthorax of the fetus and the lobe containing the CCAM is exteriorized. The attachments of the lobe to adjacent lung tissue are bluntly divided and the lobar hilum is divided by application of a stapler or a bulk ligature. The thoracotomy is quickly closed. Although a major operative procedure, operative time is short compared to repair of CDH, and blood loss and fetal stress relatively minimal.

Sacroccocygeal Teratoma

Fetal sacroccocygeal teratoma (SCT) arises from the presacral space and may grow to massive proportions. In some fetuses, high-output cardiac failure results from tumor vascular steal. Fetal SCT and high-output failure with associated placentomegaly or hydrops uniformly result in fetal demise. Ligation of vessels to the SCT may reduce the vascular steal and high-output failure. The fetal operation is performed by exteriorization of the fetal buttocks with the attached tumor.^[19] Every attempt is made to keep the head, torso, and lower extremities of the fetus in the uterus. Since the tumor can sometimes be larger than the fetus, significant loss of uterine volume occurs, and the uterus may contract. After exteriorization of the fetus, the anus is identified, and the fetal skin incised posterior to the anorectal sphincter complex to avoid injury to the continence mechanism. A tourniquet is then applied to the base of the tumor and gradually compressed. The vascular pedicle is ligated with suture ligatures or stapled depending on the width of the pedicle. The entire fetal procedure can be performed in less than 15 minutes with minimal blood loss. Because of the increase in afterload following ligation of the low-resistance tumor circuit, fetal hemodynamic status must be monitored by ultrasound closely during and in the immediate period following the ligation.

The EXIT Procedure

The EXIT procedure is a modified fetal delivery and may be used for the delivery of fetuses after surgical procedures such as tracheal ligation, or for fetuses with difficult airway problems such as massive cervical teratomas or cystic hygromas. The most important component of the EXIT procedure is maintenance of uteroplacental perfusion until the fetal airway is secured and ventilation is established. In direct contrast to cesarean section, where uterine contraction for hemostasis is encouraged, uterine relaxation is maintained by active tocolysis. With this approach, clips can be removed, bronchoscopy performed, and stable airway access established in otherwise difficult circumstances. Once the fetus is ready for transport to the nursery or operating suite, the cord is clamped and cut and the cesarean delivery completed.

Meningomyelocele

It has long been appreciated that babies with meningomyeloceles have impaired motor function and loss of bowel and bladder control. A significant percentage develop obstructive hydrocephalus, which requires ventriculoperitoneal shunting which, in and of itself, is fraught with complications. Experience from the 1970s and 1980s has shown that babies with meningomyeloceles delivered atraumatically by cesarean section maintain a better level of motor function for the given level of anatomic defect than those babies delivered through the vaginal canal.^[17] Such data suggest that compression of the cord in the delivery process can have permanent

Figure 11-8 Open repair of fetal meningomyelocele. Uterus is opened over open meningomyelocele. (Courtesy of Dr. N. Scott Adzick.)

long-term sequelae on motor function. It therefore follows that trauma to the spinal cord in utero, either from the uterine wall, or perhaps even the amniotic fluid could be detrimental to the function of the spinal cord. It was generally believed that an abnormally developed spinal cord prevented the normal proper development of the bony spinal column, leading to a meningomyelocele. It is now understood that the primary defect is likely to be the bony spinal column, which exposes a perfectly normal spinal cord, that is then damaged by the trauma of amniotic fluid and the uterine environment. Thus, the rationale was formed for attempts to patch over, or at least to protect the spinal cord in utero to minimize these sequelae.^[18]

Two groups at Vanderbilt and the Children's Hospital of Philadelphia have done considerable work in this area. The two groups have attempted to repair meningomyeloceles in utero (Fig. 11-8 and Fig. 11-9), both as an open surgical procedure and endoscopically.^{[19], [21]} The principal benefit of the surgery is secondary (i.e., significant reduction in the number of babies requiring ventriculoperitoneal shunting for obstructive hydrocephalus has been observed). It is currently too early in the experience to understand whether or not there will be significant improvements in long-term lower motor function. A randomized controlled trial would be the optimal way to answer important questions about the efficacy of this therapy.

Closing the Uterus

The obvious difference between fetal surgery and a cesarean delivery is that the fetus must be returned to the uterus, and remain in utero for several weeks. The primary criteria of an adequate closure are strength, healing, and avoidance of amniotic fluid loss. The described approach has been applied in many cases and has resulted in strong closures that heal well with minimal risk of amniotic fluid leak. The closure is initiated by placement of large, interrupted, full-thickness monofilament retention sutures the length of the wound. This allows elevation of the wound edges during closure to minimize hemorrhage. The staple lines are then cut

Figure 11-9 Same patient as Figure 11-8 after meningomyelocele repair. (Courtesy of Dr. N. Scott Adzick.)

away to freshen the edges and allow apposition of muscle tissue. A fine running monofilament is used to approximate the membranes. A small catheter is left in the amniotic space to reconstitute amniotic fluid and instill antibiotics prior to the completion of the closure. A second running layer of larger monofilament absorbable suture is placed through the myometrium to achieve broad muscular approximation. Finally, the retention sutures are tied to relieve tension on the wound and provide strength. Fibrin glue has been used as an additional sealant but has not been proven to be necessary. Prior to tying the last stitch, the amniotic fluid volume is reconstituted with warm lactated Ringer's solution under ultrasound guidance. Antibiotics are then instilled, and the catheter is removed.

MEDICAL THERAPY

Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia (CAH) was the first example of an inborn error of metabolism treated in utero with the primary goal of preventing malformations. Prenatal diagnosis became possible in the early 1980s by using the accumulation of 17-hydroxyprogesterone in the amniotic fluid as a marker. Later, the diagnosis became possible by linkage analysis, as the CAH gene was known to lie within the human leukocyte antigen (HLA) region of chromosome 6. More recently, the gene has been located, and the diagnosis has been made directly using molecular probes.

The 21-hydroxylase enzyme defect most commonly present in CAH impairs the metabolism of cholesterol to cortisol, generating excessive 17-hydroxyprogesterone. Alternate metabolism of this precursor shifts to androstenedione and other androgens (Fig. 11-10). Consequently, genetic females are exposed to high levels of androgens and can become masculinized. The resulting abnormal differentiation can vary from mild clitoral hypertrophy to formation of a phallus with labial fusion, giving rise to an apparent scrotum and misclassification of the newborn's sex.

The clinical spectrum of disease associated with CAH ranges from a severe salt-wasting variety to milder forms with simple precocious virilization in males or genital ambiguity in females. Since virilization of the female fetus was thought to occur during weeks 10 to 16 of gestation, prenatal in utero therapy aimed at preventing these changes must be started prior to determination of gender or disease status.^[21],^[24] Prenatal treatment for this problem has been aimed at pharmacologically suppressing the fetal adrenal by giving the mother dexamethasone, which readily crosses the placenta.

In the first attempt to prevent this birth defect, Evans and colleagues^[24] administered dexamethasone, a fluorinated steroid, to an at-risk mother, beginning in the 10th week of gestation. Maternal estriol and cortisol values indicated rapid and sustained fetal and maternal adrenal gland suppression. Forrest and David,^[22],^[24] using the same protocol of 0.25 mg of dexamethasone four times a day, but beginning at 9 weeks, reported the successful prevention of masculinization of the external genitalia in several pregnancies at risk for the severe form of 21-hydroxylase deficiency.

Utilization of chorionic villus sampling and molecular markers for the diagnosis of CAH can now assign disease status and gender sooner than amniocentesis, allowing maternal steroid therapy to be discontinued in males or unaffected females, all of whom have to be started on therapy before the diagnosis can be performed. Because masculinization has now been reported in a few cases following the start of therapy at 9 weeks, it is important to begin steroid suppression at 7 weeks, and continue treatment until delivery, or confirmation of an unaffected fetus.

The fundamental principles addressed in attempts to prevent masculinization of the female fetus with CAH are logically extended to other fetal therapies. The concepts of a thorough informed consent for innovative treatments as well as detailed documentation of obstetric management and outcomes have generally been followed by investigators in this field.

Methylmalonic Acidemia

Methylmalonic acidemia is related to a functional vitamin B₁₂ deficiency. Coenzymatically active vitamin B₁₂ is required for the conversion of methylmalonyl-coenzyme A to succinylcoenzyme A. Genetically determined etiologies for methylmalonic acidemia include defects in methylmalonyl-coenzyme A mutase or in the metabolism of vitamin B₁₂ to the coenzymatically active form, adenosylcobalamin by the converting enzyme. Some patients respond to high-dose vitamin B₁₂ therapy, which can enhance the amount of the active holoenzyme (mutase apoenzyme plus adenosylcobalamin). There are at least five complementation groups in this enzymatic classification.

Ampola and colleagues^[25] were the first to attempt prenatal diagnosis and treatment of a vitamin B₁₂-responsive variant of methylmalonic acidemia. Cyanocobalamin (10 mg/day) was administered orally to the mother in divided doses. The maternal serum B₁₂ level rose sixfold above normal, and the maternal urinary excretion of methylmalonic acid progressively decreased to slightly above normal by delivery. Amniotic fluid methylmalonic acid levels were three to four times the normal mean, despite prenatal treatment. Postnatally,

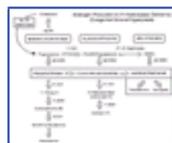

Figure 11-10 Pathway of metabolism of cholesterol to cortisol. Blockage of 21-hydroxylase leads to excess 17-hydroxyprogesterone.

the diagnosis of methylmalonic acidemia was confirmed. The newborn suffered no acute neonatal complications, and had an extremely high serum level of vitamin B₁₂. In this case, the prenatal therapy certainly improved the fetal biochemical status and secondarily the maternal status as well. Whether this represented a direct clinical benefit to this fetus cannot be sufficiently ascertained.

Evans and colleagues followed a dose-response vitamin B₁₂ regimen in the treatment of methylmalonic acidemia and showed a need for an increasingly higher dose as the pregnancy progressed.^[26] In order to maintain plasma and urinary methylmalonic acid within the normal range, vitamin B₁₂ doses needed to be increased sevenfold from the early second through the third trimester.

The report of Ampola and colleagues^[25] was the first example of the treatment of a vitamin-responsive inborn error of metabolism in utero. Further studies are needed to establish the risk/benefit ratio of this therapeutic approach.

Multiple Carboxylase Deficiency

Biotin-responsive multiple carboxylase deficiency is an inborn error of metabolism in which the mitochondrial biotin-dependent enzymes, pyruvate carboxylase, propionyl-coenzyme A carboxylase, and -methylcrotonyl coenzyme A carboxylase have decreased activity. Affected patients present as newborns or in early childhood with dermatitis, severe metabolic acidosis, and a characteristic pattern of organic acid excretion in their urine.^[27] Metabolism in patients and in cells cultured

in vitro can be restored toward normal levels by biotin supplementation. Such therapy has been utilized for fetuses affected with this severe disorder of metabolism. Roth and colleagues^[28] empirically treated a fetus prenatally in a family in which two siblings had died of multiple carboxylase deficiency. No untoward maternal effects were noted, and the maternal urinary biotin excretion increased 100-fold. Dizygotic twins were subsequently delivered at term. Cord blood and urinary organic acid profiles were normal in both newborns. Cord blood biotin concentrations, however, were four- and sevenfold greater than normal. Metabolically, the immediate neonatal courses were unremarkable for both infants. Cultured fibroblasts from twin B had virtually complete deficiency of all three carboxylase activities, whereas those obtained from twin A were normal.

Biotin administration effectively prevents neonatal complications in certain patients with biotin-responsive multiple carboxylase deficiency. No fetal or maternal toxicity has been observed. Further experience with vitamin-responsive disorders will be useful in the determination

of the optimal mode and dose interval for fetal therapy.

Smith-Lemli-Opitz Syndrome

Smith-Lemli-Opitz syndrome (SLOS) was first reported in 1964.^[29] In 1993, an inborn error of cholesterol biosynthesis in a patient with SLOS was confirmed to be a deficiency of the hepatic enzyme 7-dehydrocholesterol (7-DHC) reductase.^{[30] [31] [32]}

Characteristic features of SLOS include facial phenotype; growth and mental retardation; and anomalies of the heart, kidneys, central nervous system, and limbs. Cleft palate, postaxial polydactyly, 23 syndactyly of the toes, and cataracts are often seen in affected patients. The 23 syndactyly of the toes is very specific for this disorder and is seen in over 90 percent of affected patients. The facial phenotype is absolutely characteristic of the syndrome. Affected patients typically present with a narrow forehead, ptosis, anteverted nares, low-set ears, and micrognathia.

Patients with SLOS are deficient in cholesterol, and therefore also most likely have low levels of the steroid hormones necessary for masculinization of the male genitalia. The ambiguous genitalia seen in SLOS are the result of undermasculinization of male genitalia.

The biochemical defect in SLOS is due to deficiency of the enzyme 7-dehydrocholesterol reductase, which is responsible for the conversion of 7-DHC to cholesterol in the last step of cholesterol biosynthesis. Deficiency of this enzyme results in the characteristic biochemical pattern of low cholesterol and elevated 7-DHC and 8-dehydrocholesterol (8-DHC), its isomer. The values seen in affected patients are extremely variable. The diagnosis is made primarily by elevated levels of 7-DHC and not by a deficiency of cholesterol. The level of 7-DHC in affected patients is 100 to 1,000 times normal. Infants with more severe clinical manifestations have cholesterol levels that are quite low (usually < 10 to 15 mg/dl), while those with mild manifestations may present with levels of 40 to 70 mg/dl.

Prenatal diagnosis is possible by either amniocentesis at or after 13 weeks' gestation or chorionic villus sampling (CVS) at 10 to 12 weeks.

Fetal treatment has focused on providing cholesterol to the mother or to the fetus.^{[33] [33] [34] [35]} The former is not possible because cholesterol does not easily cross the placenta in the third trimester. Cholesterol is available only in a crystalline form that cannot be given intravenously or intramuscularly. It cannot be placed in the amniotic fluid because it would precipitate. However, cholesterol can be administered to the fetus in the form of low-density lipoprotein (LDL) cholesterol in fresh frozen plasma. Investigators at Tufts have attempted treatment in two patients late in pregnancy.^[34] The results are inconclusive. In general, if fetal therapy is to be successful, the earlier the diagnosis, the better.

Neural Tube Defects

Animal studies suggest that neural tube defects (NTDs) can arise from a variety of vitamin or mineral deficiencies. There are historical data in humans suggesting increased NTD frequencies in subjects with poor dietary histories or with intestinal bypasses. Biochemical evidence of suboptimal nutrition is present in some women bearing infants with NTDs. In 1980, Smithells et al. suggested that vitamin supplementation containing 0.36 mg folate can reduce the frequency of NTD recurrence by sevenfold in women with one or more prior affected children.^{[36] [37]} For almost a decade, there was a great deal of controversy regarding the benefit of folate supplementation for the prevention of NTDs.^{[38] [39] [40]} Finally, in 1991, a randomized double-blinded trial designed by the MRC Vitamin Study Research Group demonstrated that preconceptional folate reduced the risk of recurrence in high-risk patients.^[41] Subsequently, it was shown that preparations containing folate and other vitamins also reduced the occurrence of first-time NTDs.^[42] In response to these findings, the Centers for Disease Control (CDC) issued guidelines calling for consumption of 4.0 mg/day folic acid by women with a prior child affected with an NTD, for at least 1 month prior to conception through the first 3 months of pregnancy. In addition, 0.4 mg/day folic acid is recommended preconceptionally for *all women* of reproductive age. (Over half of all pregnancies in the United States are not planned.) The data on NTD recurrence prevention are now very well established, and routine for women with prior affected offspring. The majority of experts believe that the primary incidence of NTDs could be cut by perhaps half by folic acid supplementation. As of January 1998, the U.S. Food and Drug Administration has mandated that breads and grains be supplemented with folic acid. It is one of the largest public health experiments ever performed. It is hoped that a 30 to 50 percent reduction of NTDs will be seen.

Future Developments

Vitamin therapy has been utilized in the two vitamin-responsive genetic errors of metabolism discussed above. A significant number of other vitamin-responsive defects are known. The in utero treatment approach would seem to be a possibility for these conditions, especially those with neonatal manifestations. We speculate that in addition to these disorders there may be genetic defects for which prenatal vitamin E administration may be justifiable. Postnatally, vitamin E administration

prevents abnormalities of leukocyte function and improves shortened red blood cell (RBC) survival in glutathione synthetase deficiency. Because lowered intracellular glutathione levels in this mutant state seem to predispose to oxidant-mediated cellular damage, it might be desirable to consider prenatal antioxidant therapy with vitamin E. Most patients with glutathione synthetase deficiency have neurologic impairment, which can be progressive.

In betalipoproteinemia, which is associated with very low serum vitamin E levels, progressive and fatal neurologic impairment develops. It is now known that high-dose vitamin E supplementation can slow or prevent these neurologic changes. Prenatal treatment might therefore be justifiable in these disorders on an experimental basis. However, at present it is not known when this damage begins and therefore when in utero treatment should optimally be initiated.

Genetic Therapies

Genetic approaches to fetal therapy using preimplantation injection of deoxyribonucleic acid (DNA) into the male pronucleus of an in vitro fertilized embryo have been successful in ewes but are not likely to be used in the near future in humans. This subject has been reviewed extensively elsewhere and will not be reported here.^{[43] [44] [45]}

PRENATAL HEMATOPOIETIC STEM CELL TRANSPLANTATION

Hematopoietic stem cell therapy has recently been shown to be successful in the prenatal treatment of X-linked severe combined immunodeficiency disorder (SCID).^[45] Hematopoietic stem cell (HSC) therapy for the treatment of congenital disease has tremendous theoretical appeal. The replacement of defective cells with normal cells during specific periods of organ development and cellular ontogeny may have significant advantages over postnatal transplantation.

The engraftment and clonal proliferation of a relatively small number of normal HSCs can sustain normal hematopoiesis for a lifetime. This observation provides the compelling rationale for bone marrow transplantation (BMT) and is now supported by thousands of long-term survivors of BMT who otherwise would have succumbed to lethal hematologic disease. Realization of the full potential of BMT, however, continues to be limited by a critical shortage of immunologically compatible donor cells, the inability to control the recipient or donor immune response, and the requirement for recipient myeloablation to achieve engraftment. The price of HLA mismatch remains high: the greater the mismatch, the higher the incidence of graft failure, graft-versus-host disease (GVHD), and delayed immunologic reconstitution. Current methods of myeloablation have high morbidity and mortality. In combination, these problems remain prohibitive for most patients who might theoretically benefit from BMT. A potentially attractive alternative that could address many of the limitations of BMT is in utero transplantation of HSC. This approach may be applicable to any congenital hematopoietic disease that can be diagnosed prenatally and can be cured or improved by engraftment of normal HSCs.

Rationale for In Utero Transplantation

The rationale for in utero transplantation is to take advantage of the window of opportunity created by normal ontogeny of hematopoietic cell lines. There is a period, prior to population of the bone marrow and prior to thymic processing of self-antigen, when the fetus theoretically should be receptive to engraftment of foreign HSC without rejection and without the need for myeloablation. In the human fetus, the ideal window would appear to be prior to 14 weeks' gestation, before release of differentiated T lymphocytes into the circulation and while the bone marrow is just beginning to develop sites for hematopoiesis. The window certainly may extend beyond that in immunodeficiency states, particularly when T-cell development is abnormal. During this time, presentation of foreign antigen by thymic dendritic cells theoretically should result in clonal deletion of reactive T cells during the negative selection phase of thymic processing. Recent advances in prenatal diagnosis have made possible the diagnosis of a large number of congenital diseases during the first trimester. Technical advances in fetal intervention make transplantation feasible by 12 to 14 weeks' gestation. The ontologic window of opportunity falls well within these diagnostic and technical constraints, making application of this approach a realistic possibility.

Because of the unique fetal environment, prenatal HSC transplantation could theoretically avoid many of the current limitations of postnatal BMT. There would be no requirement for HLA matching, resulting in expansion of the donor pool. Transplanted cells would not be rejected, and space would be available in the bone marrow, eliminating the need for toxic immunosuppressive and myeloablative drugs. The mother's uterus may ultimately prove to be the ultimate sterile isolation chamber, eliminating the high risk and costly 2 to 4 months of isolation required after postnatal BMT and prior to immunologic reconstitution. Finally, prenatal transplantation would preempt the clinical manifestations of the disease, avoiding the recurrent infections, multiple transfusions, growth delay, and other

complications that cause immeasurable suffering for the patient and often compromise postnatal treatment.

Source of Donor Cells

The source of donor cells may prove to be critical for the success of engraftment. The most obvious advantage of the use of fetal HSCs is the minimal number of mature T cells in fetal liver-derived populations prior to 14 weeks' gestation. This alleviates any concern about GVHD and avoids the necessity of T-cell depletion processes, which can negatively impact potential engraftment.

Although there may be important homing, proliferative, and developmental advantages to the use of fetal cells, there are practical and ethical advantages to the use of cord blood or postnatal HSC sources. Legitimate ethical concerns regarding the use of fetal tissue for transplantation must be addressed by the medical and lay community. Fetal tissue obtained by the usual methods at the time of elective abortion has a high degree of microbial contamination.^[46] Transplantation of transmissible viral, fungal, or bacterial disease could have disastrous consequences for the recipient fetus or mother. Although the fetal liver is a rich source of HSC, small size limits total cell yield, and current technology does not yet allow undifferentiated expansion of donor cells. In contrast, use of adult-derived cells would allow a renewable, relatively infection-free, ethically acceptable source of donor cells. Tolerance induction by in utero transplantation of highly purified adult bone marrow HSC from a living related donor, followed by a single or multiple postnatal "booster"; injections offers an intriguing approach in situations where postnatal BMT is necessary but an HLA-matched donor is not available.

Diseases Amenable to Prenatal Treatment

Generally speaking, any disease that can be diagnosed early in gestation, that is improved by BMT, and for which postnatal treatment is not entirely satisfactory is a target disease. Some diseases, however, are far more likely to benefit from prenatal transplantation than others. The list can be divided into three general categories: hemoglobinopathies, immunodeficiency disorders, and inborn errors of metabolism. Each of the diseases has unique considerations for treatment, and in fact each disease may respond differently. Issues such as availability of engraftment sites within the bone marrow at the time of transplantation, and capacity of a needed enzyme to cross the blood-brain barrier at a particular gestational age must be considered. Of particular relevance to the prenatal approach, in which experimental levels of engraftment have been relatively low, is the observation that in many of the target diseases, engrafted normal cells would be predicted to have a significant survival advantage over diseased cells. This would have the clinical effect of amplification of the level of engraftment in the peripheral circulation. In addition, even with minimal levels of engraftment, specific tolerance for donor antigen should be induced, allowing additional cells from the same donor to be given to the tolerant recipient after birth.

Hemoglobinopathies

The sickle cell anemia and thalassemia syndromes make up the largest patient groups potentially treatable by prenatal stem cell transplantation. Both groups can be diagnosed within the first trimester. Both have been cured by postnatal BMT, but BMT is not recommended routinely because of its prohibitive morbidity and mortality and the relative success of modern postnatal medical management. In both diseases, the success of BMT is indirectly related to the morbidity of the disease, that is, the younger the patient, the fewer transfusions received, and the less organ compromise from iron overload, the better the results. With both diseases the primary questions relevant to prenatal transplantation are: (1) what levels of normal peripheral cell expression are necessary to alleviate clinical disease, and (2) can

adequate levels of donor cell engraftment be achieved by in utero HSC transplantation? At present, only indirect evidence exists to answer these questions.

In sickle cell disease (SCD), the pathophysiology is directly related to the concentration of hemoglobin S (HbS) within red blood cells, which results in marked rheologic abnormality, including hyperviscosity, cellular adherence, and sickling, with a result of vaso-occlusion and tissue ischemia. In examining the in vitro relationships between hematocrit (Hct) and viscosity using mixtures of sickle and normal RBCs, Schmalzer et al. observed that the primary determinant of viscosity is the sickle Hct (fraction of RBCs that contain HbS).^[47] Adverse effects of Hct on viscosity were seen at a sickle Hct level in the low 20s. Oxygen delivery, as gauged by the maximal point on the Hct versus viscosity curve, was markedly improved by exchanging normal for sickle RBCs (even when the total Hct was held constant). The clinical correlate of this in vitro information presently is chronic exchange transfusion therapy with its inherent discomfort and potential complications. However, prenatal transplantation of normal HSCs may offer a solution to this problem. Normal cells may have a developmental advantage over HbS cells such that overall production of Hb-normal RBCs may exceed that of HbS cells. This could potentially decrease the overall HbS fraction, reducing the risk of hyperviscosity and vaso-occlusive/ischemic complications.

Clinical manifestations of thalassemia are secondary

to hypoxia related to severe anemia and ineffective erythropoiesis. It is now standard therapy to transfuse patients with thalassemia major chronically from an early age. This process suppresses endogenous erythropoiesis and maintains oxygen delivery. When instituted at an early age, it effectively prevents the bone marrow expansion and secondary bony changes, as well as the hemodynamic and cardiac manifestations of the disease. The necessary normal Hb level required is controversial, but good results have been achieved with maintenance of a Hb of 9 g/dl.

Although these levels of normal Hb are higher than have been achieved experimentally (30 percent donor Hb is maximal), there would be a significant survival advantage of normal cells in both diseases. In SCD, erythrocytes have a circulating half-life of 10 to 20 days (normal half-life, 120 days) prior to destruction. In thalassemia, most cells (80 percent) never leave the bone marrow and also have shortened survival in the periphery. Therefore, engraftment of even a relatively small number of normal HSCs could result in significantly increased levels of peripheral donor cell expression.

Immunodeficiency Diseases

These represent an extremely heterogeneous group of diseases, which differ in their likelihood of cure by their capacity to develop hematopoietic chimerism. Once again, the most likely to benefit from even low levels of donor cell engraftment are those diseases in which a survival advantage exists for normal cells. The best example of this situation is SCID. Several different molecular causes of SCID have been identified, with approximately two thirds of cases being of X-linked recessive inheritance (X-SCID). The genetic basis of X-SCID has been defined recently^[48] as a mutation of the gene encoding the common γ -chain (γ -c), which is a common component of several members of the cytokine receptor superfamily, including those for interleukin-2 (IL-2), IL-4, IL-7, IL-9, IL-15, and possibly IL-13. Children affected with X-SCID have simultaneous disruption of multiple cytokine systems, resulting in a block in thymic T-cell development and diminished T-cell response. Although present in normal or even increased numbers, B cells are dysfunctional, secondary to either the lack of helper T-cell function or an intrinsic defect in B-cell maturation. Another form of SCID is secondary to adenosine deaminase (ADA) deficiency. Clinical experience with HLA-matched sibling bone marrow, fetal liver, or thymus transplantation generally has been successful without myeloablative therapy, suggesting that the lymphoid progeny of relatively few engrafted normal HSC have a selective growth advantage in vivo over genetically defective cells.^[49] The competitive advantage of normal cell populations in X-SCID is best supported by the discovery of skewed X-inactivation in female carriers.^[50] Only T cells containing the normal X chromosome were found to be present in the circulation of recipients. Evidence that ADA production confers a survival advantage derives from the early experience with gene therapy for ADA deficiency SCID. ADA-gene-corrected autologous T cells have persisted for prolonged periods despite discontinuation of the T-cell infusions. Transfer of ADA-gene-corrected cells versus uncorrected cells from the same SCID patient into an immunodeficient BXH mouse results in survival of the corrected cells and death of the uncorrected cells, confirming a survival advantage for ADA-producing cells even when there is normal ADA production in the surrounding environment. Unfortunately, other diseases such as chronic granulomatous disease would not be expected to provide a competitive advantage for donor cells. Nevertheless, in all these conditions even a partial engraftment and expression of normal cell phenotype might at least partially ameliorate the clinical manifestations of the disease and should result in donor-specific tolerance for later transplantation. If higher levels of engraftment are needed, further HSC transplants from the same donor could be performed after birth without fear of rejection.

Flake et al. successfully treated a fetus with X-linked SCID in a family where a previously afflicted child died at 7 months of age. Diagnosis by CVS in the second pregnancy showed another affected male. For this couple, abortion was not an option. After lengthy informed consent, paternal bone marrow was harvested, T cells depleted, and enriched stem cell populations injected intraperitoneally into the fetus beginning at about 16 weeks' gestation. Subsequent injections were performed at 17 and 18 weeks. The baby presently shows a split chimerism with all of his T cells being his father's, whereas the majority of B cells are his. He has achieved normal milestones and immune progress through 2 years of age.^[49] Other cases have been recently tried using less T-cell-depleted populations resulting in higher T-cell concentrations. This approach has resulted in fetal demise.^[51]

Inborn Errors of Metabolism

An even more heterogeneous group of diseases, inborn errors of metabolism, can be caused by a deficiency of a specific lysosomal hydrolase, which results in the accumulation of substrates such as mucopolysaccharide, glycogen, or sphingolipid. Depending on the specific enzyme abnormality and the compounds that accumulate, certain patterns of tissue damage and organ failure occur. These include central nervous system (CNS) deterioration, growth failure, dysostosis multiplex and joint abnormalities, hepatosplenomegaly, myocardial or cardiac disease, upper airway obstruction, pulmonary

infiltration, corneal clouding, and hearing loss. The potential efficacy of prenatal HSC transplantation for the treatment of these diseases must be considered on an individual disease basis. The purpose of BMT in these diseases is to provide HSC-derived mononuclear cells that can repopulate various organs in the body, including the liver (Kupffer cells), skin (Langerhans' cells), lung (alveolar macrophages), spleen (macrophages), lymph nodes, tonsils, and the brain (microglia). Patients with disorders that have been corrected by postnatal BMT, such as Gaucher's disease or Maroteaux-Lamy syndrome (minimal CNS involvement), are certainly reasonable candidates for prenatal treatment. In many cases, postnatal BMT has corrected the peripheral manifestations of the disease and has arrested the neurologic deterioration. However, postnatal BMT has not reversed neurologic injury that is present in such disorders as metachromatic leukodystrophy and Hurler's disease. In these cases, the neurologic injury may begin well before birth. Postnatal maturation of the blood-brain barrier restricts access to the CNS of transplanted cells or the deficient enzyme. These considerations suggest that prenatal treatment may be beneficial and offer the possibility for a cure. The primary unanswered question is whether donor HSC-derived microglial elements would populate the CNS, providing the necessary metabolic correction inside the blood-brain barrier. To date, the only definitively successful transplants have been for SCID. All others have either failed to take or were afflicted with GVHD. More work needs to be done to determine the optimal dosing, timing, and specific protocols for these different conditions.

CONCLUSION

There are an increasing number of congenital and genetic abnormalities for which in utero treatment is possible. Advances in therapies have progressed at different paces for different disorders, but there is great hope and enthusiasm that progress will continue to expand the number of disorders for which therapy can be effective.

Key Points

Fetal therapy is possible for some anomalies, but only after proper diagnosis.

Fetal therapy can ameliorate the effect of some anomalies, for which waiting until birth can be too late.

Surgical techniques have been greatly refined over the years with a gradual shift to the endoscopic approach.

Indications for intervention in diaphragmatic hernia now focus on liver position, with only the worst cases (liver up) being candidates for fetal surgical intervention.

Surgery for congenital cystadenomatoid malformation and sacrococcygeal teratomas has reduced mortality in these conditions.

Surgery for meningomyelocele is showing promise, but will require many cases for proper evaluation.

Prenatal medical therapy with dexamethasone can prevent external genital masculinization in 21-hydroxylase deficiency congenital adrenal hyperplasia.

Folic acid supplementation of diet can reduce both the recurrence risk and the primary incidence of neural tube defects, but must begin preconceptionally.

Stem cell transplantation can achieve engraftment and correction of immunodeficiencies, such as SCID.

Stem cells have not yet been effective in nonimmunodeficiency disorders.

Chapter 12 - Antepartum Fetal Evaluation

Maurice L. Druzin
Steven G. Gabbe
Kathryn L. Reed

Not too long ago, the first aim of obstetric care was to prevent maternal death due to tuberculosis, syphilis, difficult deliveries, and haemorrhage. When this battle was won, at least in developed countries, and when perinatal mortality had dropped spectacularly, more time and interest could be focused on the fetus.^[1]

Antepartum fetal deaths now account for 48 percent of all perinatal mortality in the United States.^[2] The obstetrician must be concerned not only with prevention of this mortality, but with the detection of fetal compromise and the timely delivery of such infants in an effort to maximize their future potential.^[3] This chapter reviews the definition and causes of perinatal mortality, the techniques available for assessing fetal condition, how one may evaluate their diagnostic accuracy, and the clinical application of these techniques to obstetric practice.

THE ETIOLOGY OF PERINATAL MORTALITY

The perinatal mortality rate (PMR) has been defined by the National Center for Health Statistics (NCHS) as the number of late fetal deaths (fetal deaths of 28 weeks' gestation or more) plus early neonatal deaths (deaths of infants 0 to 6 days of age) per 1,000 live births plus fetal deaths.^[4] A live birth is the complete expulsion or extraction of a product of conception from its mother, irrespective of the duration of the pregnancy, that, after separation, breathes or shows any evidence of life, such as beating of the heart, pulsation of the umbilical cord, or definite movement of voluntary muscles, whether or not the umbilical cord has been cut or the placenta is attached; each product of such a birth is considered liveborn. According to the NCHS, the neonatal mortality rate is defined as the number of neonatal deaths (deaths of infants 0 to 27 days of age) per 1,000 live births; the postneonatal mortality rate, the number of postneonatal deaths (the number of infants 28 to 365 days of age) per 1,000 live births; and the infant mortality rate, the number of infant deaths (deaths of infants under 1 year of age) per 1,000 live births. The definition of PMR provided by the World Health Organization (WHO) is somewhat different, including the number of fetuses and live births weighing at least 500 g or, when birth weight is unavailable, the corresponding gestational age (22 weeks) or body length (25 cm crownheel) dying before day 7 of life per 1,000 such fetuses and infants. The American College of Obstetricians and Gynecologists (ACOG) has recommended that only deaths of fetuses and infants weighing 500 g or more at delivery be used to compare data among states in the United States.^[5] For international comparisons, only deaths of fetuses and infants weighing 1,000 g or more at delivery should be included.^[5]

Since 1965, the PMR in the United States has fallen steadily. Using the NCHS definition, the PMR reported in 1997 was 7.3 per 1,000.^[2] The neonatal mortality rate was 3.8 per 1,000, with fetal deaths at 3.5 per 1,000. The PMR for blacks, 13.2 per 1,000, was more than twice that of whites, 6.3 per 1,000. The significantly greater PMR in blacks results from higher rates of *both* neonatal and fetal deaths.

Although the majority of fetal deaths occur before 32 weeks' gestation, in planning a strategy for antepartum

fetal monitoring, one must examine the risk of fetal death in the population of women who are still pregnant at that point in pregnancy.^[6],^[7] When this approach is taken, one finds that fetuses at 40 to 41 weeks are at a threefold greater risk and those at 42 or more weeks are at a 12-fold greater risk for intrauterine death than fetuses at 28 to 31 weeks.

The overall pattern of perinatal deaths in the United States has changed considerably during the past 30 years. Data collected between 1959 and 1966 by the Collaborative Perinatal Project revealed that 30 percent of perinatal deaths could be attributed to complications of the cord and placenta.^[8] Other major causes of perinatal loss were maternal and fetal infections (17 percent), prematurity (10 percent), congenital anomalies (8 percent), and erythroblastosis fetalis (4 percent). In this series, 21 percent of the deaths were of unknown causes. In 1982, the major cause of early neonatal death was attributed to conditions originating in the perinatal period, such as infections, intraventricular hemorrhage, hydrops, meconium aspiration, and maternal complications such as diabetes mellitus and hypertension.^[9] Congenital anomalies were the second leading cause of early neonatal death, accounting for 23 percent of such losses, whereas intrauterine hypoxia and birth asphyxia were responsible for 5 percent.

The infant mortality rate has fallen progressively from 47.0 per 1,000 in 1940 to 26.0 per 1,000 in 1960, 12.6 per 1,000 in 1980, 9.2 per 1,000 in 1990, and 7.2 per 1,000 in 1997.^[9] Although the infant mortality rate includes all deaths of infants under 1 year of age, 50 percent of all infant deaths occur in the first week of life, and 50 percent of these losses result during the first day of life.^[5] Clearly, perinatal events play an important role in infant mortality. In 1994, the leading cause of infant mortality reported by the NCHS was "perinatal conditions not separately listed," including maternal complications such as hypertension and substance abuse, multiple pregnancy, placenta previa and abruption, breech delivery, prolonged pregnancy and macrosomia, congenital pneumonia and viral infections, meconium aspiration, and Rh isoimmunization. This diverse category accounted for 25.4 percent of infant mortality, whereas congenital anomalies and sudden infant death syndrome were responsible for 20.3 and 14.8 percent, respectively. Short gestation and low birth weight contributed 12.3 percent and respiratory distress syndrome 6.7 percent. Only 2.1 percent of infant mortality was attributed to intrauterine hypoxia/birth asphyxia. Birth defects have been the single most important contributor to infant mortality for the past 20 years. In 1995, malformations were responsible for 22 percent of all infant deaths, with one third caused by cardiac abnormalities and respiratory, central nervous system, and chromosomal defects each contributing approximately 15 percent.^[11]

Fetal deaths may be divided into those that occur during the antepartum period and those that occur during labor, intrapartum stillbirths. From 70 to almost 90 percent of fetal deaths occurred before the onset of labor.^[12] Manning et al.^[13] point out that antepartum deaths may be divided into four broad categories: (1) chronic asphyxia of diverse origin; (2) congenital malformations; (3) superimposed complications of pregnancy, such as Rh isoimmunization, placental abruption, and fetal infection; and (4) deaths of unexplained cause. If it is to succeed, a program of antenatal surveillance must identify malformed fetuses ([see Chapter 10](#)) and recognize those at risk for asphyxia.

Recent data describing the specific etiologies of fetal deaths in the United States are not available. Fretts and colleagues^[14],^[15] have analyzed the causes of deaths in fetuses weighing more than 500 g in 94,346 births at the Royal Victoria Hospital in Montreal from 1961 to 1993. The population studied was predominantly white and included patients from all socioeconomic groups. Approximately 95 percent made four or more prenatal visits. The autopsy rate in this series was greater than 95 percent. Overall, the fetal death rate declined by 70 percent, from 11.5 per 1,000 in the 1960s to 3.2 per 1,000 during 1990 to 1993.^[15] The decline in the fetal death rate may be attributed to the prevention of Rh sensitization, antepartum fetal surveillance, improved detection of intrauterine growth restriction (IUGR) and fetal anomalies with ultrasound, and improved care of maternal diabetes mellitus and preeclampsia. Fetal deaths attributable to intrapartum asphyxia and Rh isoimmunization fell dramatically, from 13.1 to 1.2 per 1,000 for intrapartum asphyxia and 4.3 to 0.7 per 1,000 for Rh disease.^[14] Deaths caused by lethal anomalies declined by 50 percent, 10.8 to 5.4 per 1,000, because early terminations of pregnancy were performed for anencephaly. Whereas fetal mortality resulting from IUGR fell 60 percent, 17.9 to 7.0 per 1,000 births, the growth-restricted fetus still had a more than 10-fold greater risk for fetal death than an appropriately grown fetus ([see Chapter 25](#)).

Fretts et al. noted that most of these deaths occurred between 28 and 36 weeks' gestation and that the diagnosis of IUGR was rarely identified before death. In addition to IUGR, leading causes of fetal death after 28 weeks' gestation included abruption and unexplained antepartum losses. Despite a marked fall in unexplained fetal deaths, 38.1 to 13.6 per 1,000, these losses were still responsible for more than 25 percent of all stillbirths. Fetal/maternal hemorrhage may occur in 10 to 15 percent of cases of unexplained fetal deaths. Fetal deaths caused by infection, most often associated with premature rupture of the membranes before 28 weeks'

gestation, did not decline over the 30 years of the study. Fretts et al.^[11] also noted that, after controlling for risk factors such as multiple gestation, hypertension,

diabetes mellitus, placenta previa and abruption, previous abortion, and prior fetal death, women 35 years of age or older had a nearly twofold greater risk for fetal death than women under 30. Data from Denmark have confirmed the J-shaped curve relationship between maternal age and fetal deaths with the highest rates in teenagers and women over age 35.^[16], ^[17]

Schauer et al.^[18] summarized data from seven studies evaluating the causes of fetal death after 20 weeks. The largest group was unexplained, mostly asphyxial intrauterine deaths, 9 to 50 percent; major anomalies, 7 to 21 percent; antepartum hemorrhage with or without verified abruption (as in the Fretts et al. data the single largest known cause of fetal death), 12 to 17 percent; IUGR, 7 to 15 percent; hypertension, 1.9 to 15.7 percent; isoimmunization, 2.3 to 7.7 percent; diabetes mellitus, less than 1 to 4.8 percent; and infection, 2.1 to 6.1 percent. In a prospective study of 107 late fetal deaths, all of which had a full autopsy, Schauer et al. ^[18] observed a similar distribution of causes: asphyxia, 66 percent; multiple anomalies, 6 percent; chromosomal disorders, 6 percent; infection, 3 percent, and unknown, 19 percent. The chromosomal abnormalities included trisomy 21, trisomy 18, and 45,XO.

In summary, based on available data, approximately 30 percent of antepartum fetal deaths may be attributed to asphyxia (IUGR, prolonged gestation), 30 percent to maternal complications (placental abruption, hypertension, preeclampsia, and diabetes mellitus), 15 percent to congenital malformations and chromosomal abnormalities, and 5 percent to infection. At least 20 percent of stillbirths will have no obvious etiology.

Can these antepartum fetal deaths be prevented? Grant and Elbourne ^[7] have noted that "antepartum late fetal death is the component of perinatal mortality that has shown greatest resistance to change over recent years. In part, this reflects its relative unpredictability; in part, it reflects the relatively long period of time over which it can occur." Obstetric and pediatric assessors reviewed the circumstances surrounding each case of perinatal death in the Mersey region of England to identify any avoidable factors contributing to the death.^[19] There were 309 perinatal deaths in this population, consisting of 157 stillbirths and 152 deaths in the first week of life. Of the 309 perinatal deaths, 182 (58.9 percent) were considered to have had avoidable factors. Most avoidable factors were found to be obstetric rather than pediatric or maternal and social. A high proportion (73.8 percent) of normal-birth-weight infants with no fetal abnormalities and no maternal complications had avoidable factors. The failure to respond appropriately to abnormalities during pregnancy and labor, including results from the monitoring of fetal growth or intrapartum fetal well-being, significant maternal weight loss, or reported reductions in fetal movement, constituted the largest groups of avoidable factors. Kirkup and Welch ^[20] confirmed these results in an analysis of avoidable factors contributing to fetal death in nonmalformed infants weighing 2,500 g or more. Patients at highest risk for fetal death included women of a parity of 3 or more and those who had no prenatal care before 20 weeks. The Mersey Region Working Party on Perinatal Mortality concluded that, in light of increasing public awareness about obstetric management and, in some instances, an antipathy toward modern procedures, the failure to act on abnormalities discovered during monitoring would assume greater importance.^[19] These workers found that in no case was the induction of labor as a result of such monitoring considered an avoidable factor.

A large clinical experience has demonstrated that antepartum fetal assessment can have a significant impact on the frequency and causes of antenatal fetal deaths. Schneider and colleagues^[21] reviewed a decade of experience with antepartum fetal heart rate monitoring from 1974 through 1983. The contraction stress test was used primarily during the first 2 years of the study, followed by the nonstress test. Overall, the perinatal mortality rate was found to be 22.4 per 1,000 in the nontested population and 11.8 per 1,000 in the tested high-risk population, a highly significant difference. The stillbirth rate in the nontested population, 11.1 per 1,000, was twice that of patients who were followed with antepartum surveillance. When corrected for congenital anomalies, the stillbirth rate in the tested high-risk population was only 2.2 per 1,000. Of 18 stillbirths within 7 days of testing, the majority were because of congenital anomalies and placental abruption.

In a carefully performed study, Stubblefield and Berek^[22] reviewed the causes of perinatal death in term and postterm births at the Boston Hospital for Women. The most frequent cause of death of a term or postterm infant was extrinsic perinatal hypoxia, and the second most common cause was a lethal malformation. Overall, extrinsic perinatal hypoxia accounted for 56.1 percent of the deaths of term infants and 71.4 percent of the deaths of postterm infants. Major malformations were implicated in 26.3 percent of the deaths of term infants. Twenty-nine of the 32 antenatal deaths occurred between 37 and 42 weeks' gestation. The authors concluded that two thirds of the antenatal deaths were associated with chronic processes such as placental infarction that might have been detected had routine antepartum fetal surveillance been used. In obstetric populations in which high-risk patients are monitored,

the majority of stillbirths now occur in what had previously been considered normal pregnancies.

Gabbe: Obstetrics - Normal and Problem Pregnancies, 4th ed. , Copyright © 2002 Churchill Livingstone, Inc.

APPLICATION OF ANTEPARTUM FETAL TESTING

Before using antepartum fetal testing, the obstetrician must ask several important questions ^[23]

1. Does the test provide information not already known by the patient's clinical status?
2. Can the information be helpful in managing the patient?
3. Should an abnormality be detected, is there a treatment available for the problem?
4. Could an abnormal test result lead to increased risk for the mother or fetus?
5. Will the test ultimately decrease perinatal morbidity and mortality?

Unfortunately, few of the tests commonly employed today in clinical practice have been subjected to prospective and randomized evaluations that can answer these questions. ^[24] ^[25] ^[26] ^[27] In most cases, when the test has been applied and good perinatal outcomes were observed, the test has gained further acceptance and has been used more widely. In such cases, one cannot be sure whether it is actually the information provided by the test that has led to the improved outcomes or whether it is the total program of care that has made the difference. When prospective randomized investigations are conducted, large numbers of patients must be studied, since many adverse outcomes such as intrauterine death are uncommon even in high-risk populations. ^[28] Although several controlled trials have failed to demonstrate improved outcomes with nonstress testing, the study populations ranged from only 300 to 530 subjects. ^[29] ^[29] ^[30] ^[31]

Aspects of Fetal Condition That Might Be Predicted by Antepartum Testing

Perinatal death
Intrauterine growth restriction (IUGR)
Nonreassuring fetal status, intrapartum
Neonatal asphyxia
Postnatal motor and intellectual impairment
Premature delivery
Congenital abnormalities
Need for specific therapy

Adapted from Chard T, Klopper A: Introduction. In Placental Function Tests. New York, Springer-Verlag, 1982, p 1.

Obstetric Management That Might Be Influenced by Antepartum Testing

Preterm delivery
Route of delivery
Bed rest
Observation
Drug therapy
Operative intervention in labor
Neonatal intensive care
Termination of pregnancy for a congenital anomaly

Adapted from Chard T, Klopper A: Introduction. In Placental Function Tests. New York, Springer-Verlag, 1982, p 1.

The information one might predict from an antepartum fetal test is listed [in the box "Aspects of Fetal Condition that Might be Predicted by Antepartum Testing."](#) Although one would want to detect IUGR or discover the presence of a significant congenital malformation, the most valuable information provided by antepartum fetal assessment may be that the fetus is well and requires no intervention. In this way, the pregnancy may be safely prolonged and the fetus allowed to gain further

maturity.^[27] The second box lists those aspects of obstetric management that might be influenced by antepartum testing. Certainly, one would not want to begin a program of testing unless one were prepared to use the information.

Using the information has invariably meant prompt intervention by delivery that may not be indicated and could lead to potentially avoidable complications of prematurity. A more current approach is to use the term *intervention* to describe other types of procedures short of premature delivery. This strategy would include using combinations of antepartum tests in an organized sequence to evaluate the fetus further; administration of antenatal steroids; bed rest; prolonged oxygen therapy; and correction of maternal metabolic, cardiopulmonary, or other medical disorders. *Intervention* may also refer to fetal therapy such as intrauterine transfusion for anemia, removal of fluid from body cavities, diagnostic procedures, and direct administration of medication to the fetus.

Testing can be initiated at early gestational ages, 25 to 26 weeks, to identify the fetus at risk. Maternal and fetal interventions can then be considered. Obviously, prolongation of intrauterine life is the primary goal,

and better understanding of the pathophysiology of the premature fetus and the use of combinations of tests will allow this to be accomplished. In the event of impending in utero death or severe compromise, premature delivery, although the last resort, is a reasonable option, given the remarkable survival statistics being reported in modern neonatal intensive care units (see Chapter 20) and (Chapter 23). The use of postnatal surfactant and improved mechanical ventilators are only some of the advances leading to survival and intact neurologic survival statistics that would have been incomprehensible a decade ago.^{[32], [33], [34]}

Indications for Antepartum Fetal Monitoring	
1. Patients at high risk of uteroplacental insufficiency	
	Prolonged pregnancy
	Diabetes mellitus
	Hypertension
	Previous stillbirth
	Suspected IUGR
	Advanced maternal age
	Multiple gestation with discordant growth
	Antiphospholipid syndrome
2. When other tests suggest fetal compromise	
	Suspected IUGR
	Decreased fetal movement
	Oligohydramnios
3. Routine antepartum surveillance	

In selecting the population of patients for antepartum fetal evaluation, one would certainly include those pregnancies known to be at high risk of uteroplacental insufficiency (see the box "Indications for Antepartum Fetal Monitoring").^[27]

The question of routine antepartum fetal surveillance must be carefully examined. Antepartum fetal testing can more accurately predict fetal outcome than antenatal risk assessment using an established scoring system.^[35] Patients judged to be at high risk based on known medical factors but whose fetuses demonstrated normal antepartum fetal evaluation had a lower PMR than did patients considered at low risk, whose fetuses had abnormal antepartum testing results. Routine antepartum fetal evaluation would be necessary to detect most infants dying in utero as the result of hypoxia and asphyxia.^[22] It would seem reasonable, therefore, to consider extending some form of antepartum fetal surveillance to all obstetric patients. As described below, assessment of fetal activity by the mother may be an ideal technique for this purpose.

STATISTICAL ASSESSMENT OF ANTEPARTUM TESTING

To determine the clinical application of antepartum diagnostic testing, the predictive value of the tests must be considered. ^[36], ^[37] This information can most easily be presented in a 2 × 2 matrix. [Table 12-1](#) presents this matrix using the contraction stress test (CST) and intrauterine fetal death as examples. The sensitivity of the test is the probability that the test will be positive or abnormal when the disease is present. The specificity of the test is the probability that the test result will be negative when the disease is not present. Note that the sensitivity and specificity refer not to the actual numbers of patients with a positive or abnormal result, but to the proportion or probability of these test results. The predictive value of an abnormal test would be that fraction of patients with an abnormal test result who have the abnormal condition, and the predictive value of a normal test would be the fraction of patients with a normal test result who are normal ([Table 12-1](#)).

Antepartum fetal tests may be used to screen a large obstetric population to detect fetal disease. In this setting, a test of high sensitivity is preferable, since one would not want to miss patients whose fetuses might be compromised. One would be willing to overdiagnose the problem, that is, accept some false-positive diagnoses. In further evaluating the patient whose fetus may be at risk and when attempting to confirm the presence of disease, one would want a test of high specificity. One would not want to intervene unnecessarily and deliver a fetus that was doing well. In this setting, multiple tests may be helpful. When multiple test results are normal, they tend to exclude disease. When all

TABLE 12-1 -- TWO-BY-TWO MATRIX OF POSSIBLE RESULTS FOR THE CST

Test Result	Perinatal Outcome	
	Normal (Normal Newborn)	Abnormal (Intrauterine Fetal Death)
Normal (negative CST)	A True-negative	B False-negative
Abnormal (positive CST)	C False-positive	D True-positive

Sensitivity = $D/(D + B)$.
 Specificity = $A/(A + C)$.
 Predictive value of a positive test = $D/(C + D)$.
 Predictive value of a negative test = $A/(A + B)$.

TABLE 12-2 -- FIFTY PERCENT PREVALENCE

Test Result	Perinatal Outcome	
	Normal	Abnormal
Normal	490 True-negative	125 False-negative
Abnormal	10 False-positive	375 True-positive

Sensitivity = 75%.
 Specificity = 98%.
 Predictive value of a positive test = 97.4% (375 of 385).
 Predictive value of a negative test = 79.6% (490 of 615).

are abnormal, however, they tend to support the diagnosis of fetal disease.

The prevalence of the abnormal condition has great impact on the predictive value of antepartum fetal tests. [Table 12-2](#) presents data for a population of 1,000 patients in whom the prevalence of the disease is 50 percent. The sensitivity of the test being evaluated is 75 percent, and its specificity is 98 percent. These figures are similar to those observed for several antepartum tests now in use. In this setting, an abnormal test result is likely to be associated with a true fetal abnormality. The predictive value of a positive test is 97.4 percent. However, when the prevalence of the disease falls to 2 percent, as it may be for intrauterine fetal deaths, even tests with a high sensitivity and specificity are associated with many false predictions ([Table 12-3](#)). In this circumstance, an abnormal test is more likely to indicate a false-positive diagnosis ($n = 20$) than it is a true-positive diagnosis ($n = 15$).

In interpreting the results of studies of antepartum testing, the obstetrician must consider the application of that test to his or her own population. If the study has been done in a population of patients at great risk,

TABLE 12-3 -- TWO PERCENT PREVALENCE

Test Result	Perinatal Outcome	
	Normal	Abnormal
Normal	960 True-negative	5 False-negative
Abnormal	20	15

Sensitivity = 75%.

Specificity = 98%.

Predictive value of a positive test = 42.8% (15 of 35).

Predictive value of a negative test = 99.4% (960 of 965).

it is more likely that an abnormal test will be associated with an abnormal fetus. If the obstetrician is practicing in a community with patients who are, in general, at low risk, however, an abnormal test result would more likely be associated with a false-positive diagnosis.

For most antepartum diagnostic tests, a cut-off point used to define an abnormal result must be arbitrarily established. ^[38] The cut-off point is selected to maximize the separation between the normal and diseased populations (Fig. 12-1). Changing the cut-off will have a great impact on the predictive value of the test. For example, suppose that 10 accelerations in 10 minutes were required for a fetus to have a reactive nonstress test (threshold A). The fetus who fulfilled this rigid definition would almost certainly be in good condition. However, many fetuses who failed to achieve 10 accelerations in 10 minutes would also be in good condition, but would be judged to be abnormal by this cutoff. In this instance, the test would have many abnormal results. It would be highly sensitive and capture all of the abnormal fetuses, but it would have a low specificity. If the number of accelerations required

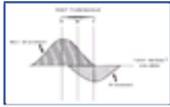

Figure 12-1 Hypothetical distribution of test results in a normal and diseased population, demonstrating the differences in test sensitivity and specificity with a change in test threshold. Making it more difficult for the fetus to pass the test by raising the test threshold (A) will increase the sensitivity, but decrease the specificity, of the test. On the other hand, making the test easier to pass by decreasing the test threshold (C) will increase the specificity of the test, but decrease the sensitivity. (Adapted from Carpenter M, Coustan D: *Criteria for screening tests for gestational diabetes*. *Am J Obstet Gynecol* 144:768, 1982.)

to pass a nonstress test were lowered to 1 in 10 minutes, it would decrease the sensitivity of the test (threshold C). That is, one might miss a truly sick fetus. At the same time, however, one would improve the specificity of the test or its ability to predict that percentage of the patients who are normal. Using the criterion of two accelerations of the fetal heart rate in 20 minutes for a reactive nonstress test (threshold B), one hopes to have a test with both high sensitivity and high specificity.

BIOPHYSICAL TECHNIQUES OF FETAL EVALUATION

Fetal State

When interpreting tests that monitor fetal biophysical characteristics, one must appreciate that, during the third trimester, the normal fetus may exhibit marked changes in its neurologic state.^[39], ^[40] Four fetal states have been identified. The near-term fetus spends approximately 25 percent of its time in a quiet sleep state (state 1F) and 60 to 70 percent in an active sleep state (state 2F). Active sleep is associated with rapid eye movement (REM). In fetal lambs, electrocortical activity during REM sleep is characterized by low-voltage, high-frequency waves. The fetus exhibits regular breathing movements and intermittent abrupt movements of its head, limbs, and trunk. The fetal heart rate in active sleep (state 2F) exhibits increased variability and frequent accelerations with movement. During quiet, or non-REM, sleep, the fetal heart rate slows and heart rate variability is reduced. The fetus may make infrequent breathing movements and startled movements. Electrocortical activity recordings at this time reveal high-voltage, low-frequency waves. Near term, periods of quiet sleep may last 20 minutes, and those of active sleep approximately 40 minutes.^[40] The mechanisms that control these periods of rest and activity in the fetus are not well established. External factors such as the mother's activity, her ingestion of drugs, and her nutrition may all play a role.

When evaluating fetal condition using the nonstress test or the biophysical profile, one must ask whether a fetus that is not making breathing movements or shows no accelerations of its baseline heart rate is in a quiet sleep state or is neurologically compromised. In such circumstances, prolonging the period of evaluation will usually allow a change in fetal state, and more normal parameters of fetal well-being will appear.

Maternal Assessment of Fetal Activity

Maternal assessment of fetal activity is a simple yet valuable method for monitoring fetal condition. Most patients can understand and follow protocols for counting fetal activity, and this method is obviously inexpensive. Therefore, maternal assessment of fetal activity may be ideal for routine antepartum fetal surveillance.

Studies performed using real-time ultrasonography have demonstrated that during the third trimester the human fetus spends 10 percent of its time making gross fetal body movements and that 30 such movements are made each hour.^[41] Periods of active fetal body movement last approximately 40 minutes, whereas quiet periods last about 20 minutes. Patrick et al.^[41] noted that the longest period without fetal movements in a normal fetus was approximately 75 minutes. The mother is able to appreciate about 70 to 80 percent of gross fetal movements. The fetus does make fine body movements such as limb flexion and extension, hand grasping, and sucking, which probably reflect more coordinated central nervous system (CNS) function. However, the mother is generally unable to perceive these fine movements. Fetal movement appears to peak between 9:00 P.M. and 1:00 A.M., a time when maternal glucose levels are falling.^[34] In a study in which maternal glucose levels were carefully controlled with an artificial pancreas, Holden et al.^[42] found that hypoglycemia was associated with increased fetal movement. Fetal activity does not increase after meals or after maternal glucose administration.^[43], ^[44]

Maternal evaluation of fetal activity may reduce fetal deaths caused by asphyxia. Using a sheep model, Natale et al.^[45] demonstrated that fetal activity is extremely sensitive to a decrease in fetal oxygenation. A small fall in fetal P_{O_2} was associated with a cessation of limb movements in the fetal lamb.

Several methods have been used to monitor fetal activity in clinical practice. In general, the presence of fetal movements is a reassuring sign of fetal health. However, the absence of fetal activity requires further assessment before one can conclude that fetal compromise exists. Sadvovsky et al.^[46] recommended that mothers count fetal activity for 30 to 60 minutes each day, two or three times daily. If the mother has fewer than three movements in 1 hour, or if she appreciates no movements for 12 hours, the movement alarm signal, further evaluation of fetal condition must be made. Rayburn et al.^[47] suggested that patients count fetal activity at least 60 minutes each day. Fewer than three movements an hour for 2 consecutive days may be a sign of fetal compromise. Pearson and Weaver^[48] advocated the use of the Cardiff Count-to-Ten chart. They found that only 2.5 percent of 1,654 daily movement counts recorded by 61 women who subsequently delivered healthy infants fell below 10 movements per 12 hours. Therefore, they accepted 10 movements as the minimum amount of fetal activity the patient should perceive in a 12-hour period. The patient is asked to start counting the movements in the morning and to

record the time of day at which the 10th movement has been perceived. Should the patient not have 10 movements during 12 hours, or should it take longer each day to reach 10 movements, the patient is told to contact her obstetrician. Sadvovsky et al.^[49] found that, of those techniques currently used in clinical management, the movement alarm signal and the technique of Pearson and Weaver are the most valuable.

Whatever technique is used must be carefully explained to the patient. Although most women are reassured by keeping a fetal activity chart and maternal-fetal attachment may be enhanced, some patients do become more anxious.^[50], ^[51] Women who were concerned about monitoring fetal movement complained that they were not given adequate information about variations in fetal activity patterns and maternal perception of movement.

Although there will be a wide but normal range in fetal activity, with fetal movement counting, each mother and her fetus serve as their own control.^[7] Fetal and placental factors that influence maternal assessment of fetal activity include placental location, the length of fetal movements, the amniotic fluid volume, and fetal anomalies.^[52] If the placenta is anterior, maternal perception of fetal movements may be decreased. Movements lasting 20 to 60 seconds are most likely to be felt by the mother.^[53] Hydramnios will reduce the mother's appreciation of fetal activity. Hydramnios may be associated with a fetal anomaly and should be further evaluated using ultrasonography. Rayburn and Barr^[54] reported that 26 percent of fetuses with major malformations show decreased fetal activity compared with only 4 percent of normal fetuses. Anomalies of the CNS are most commonly associated with decreased activity.

Approximately 80 percent of all mothers will be able to comply with a program of counting fetal activity.^[7], ^[55] Maternal factors that influence the evaluation of fetal movement include maternal activity, obesity, and medications. Mothers appear to appreciate fetal movements best when resting in the left lateral recumbent position. Patients should therefore be told to lie down when counting fetal movement, an additional benefit of this approach to fetal evaluation. Obesity decreases maternal appreciation of fetal activity. Maternal medications such as narcotics or barbiturates may depress fetal movement.

Several large clinical studies have demonstrated the efficacy of maternal assessment of fetal activity in preventing unexplained fetal deaths. In a prospective randomized study, Neldam^[56], ^[56] asked one group of 1,562 pregnant patients at 32 weeks' gestation to count fetal activity three times each week for 2 hours after their main meals. Fewer than three fetal movements each hour was regarded as a sign of potential fetal compromise and was further evaluated with an ultrasound examination and a nonstress test. In the monitored group of patients, only one stillbirth occurred. Ten stillbirths were noted in a control population of 1,549 women. Overall, 4 percent of patients in the monitored group reported their baby was not moving adequately, a low figure, but one similar to that observed in other studies. Of these 60 patients, almost 25 percent were found to have a fetus in distress based on further antepartum testing. Neldam^[56] attributed the prevention of 14 fetal deaths

to the use of maternal assessment of fetal activity.

Rayburn^[57] found that in the 5 percent of his patients who reported decreased fetal activity the incidence of stillbirths was 60 times higher, the risk of fetal distress in labor 2 to 3 times higher, the incidence of low Apgar scores at delivery 10 times greater, and the incidence of severe growth restriction 10 times higher. Rayburn also observed that the normal fetus does *not* decrease activity in the week before delivery.

Using the Cardiff Count-to-Ten chart, Liston et al. ^[58] noted that 11 of 150 high-risk patients (7.3 percent) reported fewer than 10 movements in a 12-hour period. Two of these patients suffered perinatal deaths, and 33 percent experienced fetal distress in labor. Overall, 60 percent of patients who reported decreased fetal activity did exhibit evidence of fetal compromise. The number of false alarms was quite manageable.

Two prospective studies have yielded conflicting results regarding the efficacy of fetal movement counting as a technique for preventing fetal deaths. Grant and co-workers^[59] recruited 68,000 European women who were randomly allocated within 33 pairs of clusters to either routine fetal movement counting using the Cardiff Count-to-Ten method or to standard care. Women counted for an average of almost 3 hours per day, and about 7 percent of the charts showed at least one alarm. Of concern, the rate of compliance for reporting decreased fetal movement was only 46 percent. Furthermore, compliance for charting movements and reporting alarms was lower among women who had a late fetal death. The antepartum death rates for nonmalformed singleton fetuses were equal in both experimental groups. However, in none of the 17 cases in which reduced movements were recognized and the fetus was still alive when the patient arrived at the hospital was an emergency delivery attempted. Why? Grant et al. ^[59] believe that intervention was not undertaken because of false reassurance from follow-up testing, especially heart rate monitoring, and because of errors in clinical judgment. One might conclude that this large prospective study failed to demonstrate a reduction in the antepartum fetal death rate as a result of fetal movement counting. However, what it seems to prove most clearly is that patient compliance is an essential part of this program as is appropriate evaluation of the patient who presents with decreased fetal activity.

In contrast, an investigation by Moore and Piacquadio ^[60]

demonstrated an impressive reduction in fetal deaths resulting from a formal program of fetal movement counting. Patients used the Count-to-Ten approach but were told to monitor fetal activity in the evening, a time of increased fetal movement. Most women observed 10 movements in an average of 21 minutes, and compliance was greater than 90 percent. Patients who did not perceive 10 movements in 2 hours, a level of fetal activity slightly more than 5 SD below the mean, were told to report immediately for further evaluation. During a 7-month control period, a fetal mortality rate of 8.7 per 1,000 was observed in 2,519 patients, and 11 of 247 women who came to the hospital with a complaint of decreased fetal movement had already suffered an intrauterine death. During the study period, the fetal death rate fell to 2.1 per 1,000, and only 1 of 290 patients with decreased fetal movement presented after fetal death had occurred. The number of antepartum tests required to assess patients with decreased fetal activity rose 13 percent during the study period. This investigation has been expanded to include almost 6,000 patients, and a fetal death rate of 3.6 per 1,000, less than half that found in the control period, has been achieved. ^[61]

In conclusion, there appears to be a clearly established relationship between decreased fetal activity and fetal death. Therefore, it would seem prudent to request that *all* pregnant patients, regardless of their risk status, monitor fetal activity starting at 28 weeks' gestation (Fig. 12-2). The Count-to-Ten approach developed by Moore and Piacquadio^[61] seems ideal.

Contraction Stress Test

The CST, also known as the oxytocin challenge test (OCT), was the first biophysical technique widely applied for antepartum fetal surveillance. It was well known that uterine contractions produced a reduction in blood flow to the intervillous space. Analyses of intrapartum fetal heart rate monitoring had demonstrated that a fetus with inadequate placental respiratory reserve would demonstrate late decelerations in response to hypoxia (see Chapter 14). The CST extended these observations to the antepartum period. The

Figure 12-2 Maternal assessment of fetal activity is a valuable screening test for fetal condition. Should the mother report decreased fetal activity, a NST is performed. In this situation most NSTs will be reactive.

response of the fetus at risk for uteroplacental insufficiency to uterine contractions formed the basis for this test.

Performing the CST

The CST may be conducted in the labor and delivery suite or in an adjacent area, although the likelihood of fetal distress requiring immediate delivery in response to uterine contractions or hyperstimulation is extremely small. The CST should be performed by staff familiar with the principles and technique of such testing. In many institutions, an antenatal diagnostic unit has been developed for this purpose. The patient is placed in the semi-Fowler's position at a 30- to 45-degree angle with a slight left tilt to avoid the supine hypotensive syndrome. The fetal heart rate is recorded using a Doppler ultrasound transducer, and uterine contractions are monitored with the tocodynamometer. Maternal blood pressure is determined every 5 to 10 minutes to detect maternal hypotension. ^[62] Baseline fetal heart rate and uterine tone are first recorded for a period of approximately 10 to 20 minutes. In some cases, adequate uterine activity will occur spontaneously, and additional uterine stimulation will not be necessary. An adequate CST requires uterine contractions of moderate intensity lasting approximately 40 to 60 seconds with a frequency of three in 10 minutes. These criteria were selected to approximate the stress experienced by the fetus during the first stage of labor. If uterine activity is absent or inadequate, nipple stimulation is used to initiate contractions or intravenous oxytocin is begun. Oxytocin is administered by an infusion pump at 0.5 mU/min. The infusion rate is doubled every 20 minutes until adequate uterine contractions have been achieved. ^[27] One does not usually need to exceed 10 mU/min to produce adequate uterine activity. After the CST has been completed, the patient should be observed until uterine activity has returned to its baseline level. With nipple stimulation, the test may take approximately 30 minutes. If oxytocin is needed, 90 minutes may be required to perform the CST.

Contraindications to the test include those patients at high risk for premature labor, such as patients with premature rupture of the membranes, multiple gestation, and cervical incompetence, although the CST has not been associated with an increased incidence of premature labor. ^[63] The CST should also be avoided in conditions in which uterine contractions may be dangerous, such as placenta previa and a previous classical cesarean section or uterine surgery.

Interpreting the CST

Most clinicians utilize the definitions proposed by Freeman to interpret the CST ^[63], ^[64] (Table 12-4). In an attempt

TABLE 12-4 -- INTERPRETATION OF THE CONTRACTION STRESS TEST

Interpretation	Description	Incidence (%)
Negative	No late decelerations appearing anywhere on the tracing with adequate uterine contractions (three in 10 minutes)	80
Positive	Late decelerations that are consistent and persistent, present with the majority (>50 percent) of contractions without excessive uterine activity; if persistent late decelerations seen before the frequency of contractions is adequate, test interpreted as positive	35
Suspicious	Inconsistent late decelerations	5

Hyperstimulation	Uterine contractions closer than every 2 minutes or lasting >90 seconds, or five uterine contractions in 10 minutes; if no late decelerations seen, test interpreted as negative	5
Unsatisfactory	Quality of the tracing inadequate for interpretation or adequate uterine activity cannot be achieved	5

to decrease the frequency of suspicious tests that would require further evaluation, Martin and Schiffrin^[65] developed the "10-minute window" concept. A positive test would be any 10-minute segment of the tracing that includes three contractions, all showing late decelerations. A negative test is one in which no positive window is seen and there is at least one negative window, three uterine contractions in 10 minutes with no late decelerations (Fig. 12-3) and (Fig. 12-4). The CST would be read as negative and not suspicious if an occasional late deceleration were seen, but a negative window was also present. They used the term *equivocal* rather than *suspicious* for a CST with an occasional late deceleration but no negative window. Equivocal implies that one is unable to make a determination of fetal condition based on the available information. A CST with both a positive and negative window would be interpreted as positive.

Variable decelerations that occur during the CST may indicate cord compression often associated with oligohydramnios. In such cases, ultrasonography should be performed to assess amniotic fluid volume. However, even if the amniotic fluid volume is demonstrated to be adequate, cord compression patterns need careful follow-up, because cord accidents with subsequent fetal death may occur in the presence of normal amounts of amniotic fluid on sonography. What appears to be a normal volume of amniotic fluid may contain meconium, which has a specific gravity different from clear amniotic fluid and therefore does not allow the cord to float freely. In cases of early placental insufficiency, the amount of Wharton's jelly in the umbilical cord may be diminished prior to the clinical appearance of oligohydramnios. The loss of the protective Wharton's jelly may make the umbilical vessels vulnerable to compression and lead to diminished blood flow.

A negative CST has been consistently associated with good fetal outcome. A negative result therefore permits the obstetrician to prolong a high-risk pregnancy safely. Nageotte et al.^[66] reported only one preventable fetal death in 1,337 high-risk patients within 7 days after a negative CST. In a series of 679 pregnancies complicated by a prolonged gestation, Freeman et al.^[67] observed no perinatal deaths when the CST was used as the primary method of surveillance. Of 337 women with a previous intrauterine fetal death, none had a stillbirth during a pregnancy in which they were followed with CSTs. ^[68] Druzin et al. ^[69] reported no antepartum deaths in a series of 819 patients tested at 280

Figure 12-3 A reactive and negative CST. With this result, the CST would ordinarily be repeated in 1 week.

323

Figure 12-4 A nonreactive and negative CST. After this result, the test would ordinarily be repeated in 24 hours.

days or more gestation, using both the nonstress test (NST) and nipple stimulation CST. There were no differences in perinatal outcome in the group with a reactive NST, irrespective of the CST result. Similarly, Gabbe et al.^[70] and Lagrew et al.^[71] have reported only one fetal death within 1 week of a negative CST in 811 pregnancies complicated by type 1 diabetes mellitus. Other studies have shown the incidence of perinatal death within 1 week of a negative CST to be less than 1 per 1,000.^[72] ^[73] ^[74] Many of these deaths, however, can be attributed to cord accidents, malformations, placental abruption, and acute deterioration of glucose control in patients with diabetes. Thus, the CST, like most methods of antepartum fetal surveillance, cannot predict acute fetal compromise. If the CST is negative, a repeat study is usually scheduled in 1 week. Although testing patients with a weekly CST is practical, it is also arbitrary. Changes in the patient's clinical condition may warrant more frequent studies.

A positive CST has been associated with an increased incidence of intrauterine death, late decelerations in labor, low 5-minute Apgar scores, IUGR, and meconium-stained amniotic fluid (Fig. 12-5).^[75] In a prospective and blinded study, Ray et al.^[75] observed 3 fetal deaths in 15 patients with positive CSTs. The incidence of low Apgar scores in this group was 53 percent. Overall, the likelihood of perinatal death after a positive CST has ranged from 7 to 15 percent. On the other hand, there has been a significant incidence of false-positive CSTs that, depending on the endpoint used, will average approximately

Figure 12-5 A nonreactive and positive CST with fetal tachycardia. At 34 weeks, a poorly compliant patient with type 1 diabetes mellitus, reported decreased fetal activity. The NST revealed a fetal tachycardia of 170 bpm and was nonreactive. The CST was positive, and a BPP score was 2. The patient's cervix was unfavorable for induction. The patient underwent a low transverse cesarean delivery of a 2,200-g male infant with Apgar scores of 1 and 3. The umbilical arterial pH was 7.21.

324

30 percent.^[76] The positive CST is more likely to be associated with fetal compromise if the baseline heart rate lacks accelerations or "reactivity" and the latency period between the onset of the uterine contractions and the onset of the late deceleration is less than 45 seconds.^[77] ^[78]

There is no doubt that the high incidence of false-positive CSTs is one of the greatest limitations of this test, as such results could lead to unnecessary premature intervention. False-positive CSTs may be attributable to misinterpretation of the tracing; supine hypotension, which decreases uterine perfusion; uterine hyperstimulation, which is not appreciated using the tocodynamometer; or an improvement in fetal condition after the CST has been performed. The high false-positive rate also indicates that a patient with a positive CST need not necessarily require an elective cesarean delivery. If a trial of labor is to be undertaken after a positive CST, the cervix should be favorable for induction so that direct fetal heart rate monitoring and careful assessment of uterine contractility with an intrauterine pressure catheter can be performed. False-positive results are not increased when the CST is used early in the third trimester.^[76] A negative or positive CST obtained between 28 and 33 weeks' gestation appears to have the same diagnostic significance as it would later in gestation. Merrill et al.^[79] reported prolongation of pregnancy for up to 13 days in the presence of a nonreactive nonstress test and a positive CST test if the biophysical profile (BPP) score was 6 or greater. This approach should only be used in the premature fetus and when careful follow-up with daily assessment, using the nonstress test, CST, and BPP can be reliably performed.

A suspicious or equivocal CST should be repeated in 24 hours. Most of these tests will become negative. Bruce et al.^[80] did observe that 5 of 67 patients (7.5 percent) with an initially suspicious CST exhibited positive tests on further evaluation. In 36 patients, the CST became negative, whereas in 26 patients it remained suspicious. Like the suspicious CST, a test that is unsatisfactory or shows hyperstimulation should be repeated in 24 hours.

In follow-up studies of children who demonstrated a positive CST, few have exhibited abnormalities in neurologic and psychological development.^[81] ^[82] ^[83] An important determinant in the long-term outcome for these children would be the early recognition of nonreassuring fetal heart rate patterns and the prevention of intrapartum compromise.

The Nipple Stimulation CST

Many centers utilize nipple stimulation to produce the uterine contractions needed for the CST. With nipple stimulation, the CST can generally be completed in less time, and an intravenous infusion is not required. Therefore, this approach would appear to be an ideal first step in performing a CST.

Several methods have been used to induce adequate uterine activity.^[27] ^[84] ^[85] The patient may first apply a warm moist towel to each breast for 5 minutes. If uterine activity is not adequate, the patient is asked to massage one nipple for 10 minutes. Using this protocol, Oki et al.^[84] achieved adequate uterine contractions in 30 minutes or less in 87.5 percent of 657 patients tested. The incidence of negative tests (72 percent) and positive tests (2 percent) was not different from that seen with the oxytocin-induced CST. Huddleston et al.^[86] reported great success using intermittent nipple stimulation. The patient gently strokes the nipple of one breast with the

palmar surface of her fingers through her clothes for 2 minutes and then stops for 5 minutes. This cycle is repeated only as necessary to achieve adequate uterine activity. In a series of 193 patients and 345 CSTs, 97 percent of the tests required only three cycles of stimulation. The average time for a CST performed in this way was 45 minutes, and 67.5 percent of the patients completed their tests in 40 minutes or less. The nipple stimulation CST was negative in 80.3 percent of patients and positive in 2.6 percent of patients. All the patients in the Huddlestone et al. [89] series were able to achieve adequate uterine contractions with nipple stimulation, and none required an oxytocin infusion. Intermittent rather than continuous nipple stimulation is important in avoiding hyperstimulation. Defined as contractions lasting more than 90 seconds or five or more contractions in 10 minutes, hyperstimulation has been reported in approximately 2 percent of tests when intermittent nipple stimulation is employed. [87], [88]

The Nonstress Test

In 1969, Hammacher [89] noted that "the fetus can be regarded as safe, especially if reflex movements are accompanied by an obvious increase in the amplitude of oscillations in the basal fetal heart rate." This observation that accelerations of the fetal heart rate in response to fetal activity, uterine contractions, or stimulation reflect fetal well-being has formed the basis for the NST, the most widely applied technique for antepartum fetal evaluation.

In late gestation, the healthy fetus exhibits an average of 34 accelerations above the baseline fetal heart rate each hour. [90] These accelerations, which average 20 to 25 bpm in amplitude and approximately 40 seconds in duration, require intact neurologic coupling between the fetal CNS and the fetal heart. [90] Fetal hypoxia will disrupt this pathway. At term, fetal accelerations are associated with fetal movement more than 85 percent of the time, and more than 90 percent of gross movements

325

are accompanied by accelerations. Fetal heart rate accelerations may be absent during periods of quiet fetal sleep. Studies by Patrick et al. [90] demonstrated that the longest time between successive accelerations in the healthy term fetus is approximately 40 minutes. However, the fetus may fail to exhibit heart rate accelerations for up to 80 minutes and still be normal.

Although an absence of fetal heart rate accelerations is most often attributable to a quiet fetal sleep state, CNS depressants such as narcotics and phenobarbital, as well as the β -blocker propranolol, can reduce heart rate reactivity. [91], [92] Chronic smoking is known to decrease fetal oxygenation through an increase in fetal carboxyhemoglobin and a decrease in uterine blood flow. Fetal heart rate accelerations are also decreased in smokers. [93]

The NST is usually performed in an outpatient setting. In most cases, only 10 to 15 minutes are required to complete the test. It has virtually no contraindications, and few equivocal test results are observed. The patient may be seated in a reclining chair, with care being taken to ensure that she is tilted to the left to avoid the supine hypotensive syndrome. [27], [94] The patient's blood pressure should be recorded before the test is begun and then repeated at 5- to 10-minute intervals. Fetal heart rate is monitored using the Doppler ultrasound transducer, and the tocodynamometer is applied to detect uterine contractions or fetal movement. Fetal activity may be recorded by the patient using an event marker or noted by the staff performing the test. The most widely applied definition of a reactive test requires that at least two accelerations of the fetal heart rate of 15 bpm amplitude and 15 seconds' duration be observed in 20 minutes of monitoring (Fig. 12-6). [94] Since almost all accelerations are accompanied by fetal movement, fetal movement need not be recorded with the accelerations for the test to be considered reactive. However, fetal movements do provide another index of fetal well-being.

If the criteria for reactivity are not met, the test is considered nonreactive (Fig. 12-7). The most common cause for a nonreactive test will be a period of fetal inactivity or quiet sleep. Therefore, the test may be extended for an additional 20 minutes with the expectation that fetal state will change and reactivity will appear. Keegan et al. [95] noted that approximately 80 percent of tests that were nonreactive in the morning became reactive when repeated later the same day. In an effort to change fetal state, some clinicians have manually stimulated the fetus or attempted to increase fetal glucose levels by giving the mother orange juice. There is no evidence that such efforts will increase fetal activity. [96], [97] If the test has been extended for 40 minutes, and reactivity has not been seen, a BPP or CST should be performed. Of those fetuses that exhibit a nonreactive NST, approximately 25 percent will have a positive CST on further evaluation. [94], [98], [99] Reactivity that occurs during preparations for the CST has proved to be a reliable index of fetal well-being.

Overall, on initial testing, 85 percent of NSTs will be reactive and 15 percent will be nonreactive (Fig. 12-8). [94] Fewer than 1 percent of NSTs will prove unsatisfactory because of inadequately recorded fetal heart rate data. On rare occasions, a sinusoidal heart rate pattern may be observed as described in Chapter 14. This undulating heart rate pattern with virtually absent variability has been associated with fetal anemia, fetal

Figure 12-6 A reactive NST. Accelerations of the fetal heart that are greater than 15 bpm and last longer than 15 seconds can be identified. When the patient appreciates a fetal movement, she presses an event marker on the monitor, creating the arrows on the lower portion of the tracing.

326

Figure 12-7 A nonreactive NST. No accelerations of the fetal heart rate are observed. The patient has perceived fetal activity as indicated by the arrows in the lower portion of the tracing.

asphyxia, congenital malformations, and medications such as narcotics. In one of the earliest reports on the use of the NST, Rochard et al. [100] described a sinusoidal pattern in 20 of 50 pregnancies complicated by Rh isoimmunization. One half of these pregnancies ended in a perinatal death, and 40 percent of the surviving infants required prolonged hospitalization. Only 10 percent of the babies with a sinusoidal pattern had an uncomplicated course.

The NST is most predictive when normal or reactive. Overall, a reactive NST has been associated with a perinatal mortality of approximately 5 per 1,000. [94], [101] At least one half of the deaths of babies dying within 1 week of a reactive test may be attributed to placental abruption or cord accidents. The perinatal mortality rate associated with a nonreactive NST, 30 to 40 per

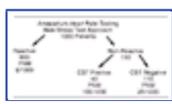

Figure 12-8 Results of nonstress testing in 1,000 high-risk patients. In general, 85 percent of the NSTs will be reactive and 15 percent nonreactive. Of those patients with a nonreactive NST, approximately 25 percent will have a positive CST on further evaluation. The highest perinatal mortality (PNM) will be observed in patients with a nonreactive NST and positive CST. Patients with a nonreactive NST and negative CST will have a perinatal mortality rate higher than that found in patients whose NST is initially reactive. (PNM rates based on data from Everson et al. [99])

1,000, is significantly higher, for this group includes those fetuses who are truly asphyxiated. On the other hand, when considering perinatal asphyxia and death as endpoints, a nonreactive NST has a considerable false-positive rate. Most fetuses exhibiting a nonreactive NST will not be compromised but will simply fail to exhibit heart rate reactivity during the 40-minute period of testing. Malformed fetuses also exhibit a significantly higher incidence of nonreactive NSTs. [102] Overall, the false-positive rate associated with the nonreactive NST is approximately 75 to 90 percent. [94]

The likelihood of a nonreactive test is substantially increased early in the third trimester. [103] Between 24 and 28 weeks' gestation, approximately 50 percent of NSTs are nonreactive. [104] Fifteen percent of NSTs remain nonreactive between 28 and 32 weeks. [105], [106] After 32 weeks, the incidences of reactive and nonreactive tests are comparable to those seen at term. In summary, when accelerations of the baseline heart rate are seen during monitoring in the late second and early third trimesters, the NST has been associated with fetal well-being.

Before 27 weeks' gestation, the normal fetal heart rate response to fetal movement may in fact be a bradycardia.^[107] However, in some settings such as IUGR associated with antiphospholipid syndrome, bradycardia at a gestational age of 26 to 28 weeks may be a predictor of fetal compromise and impending fetal death. Druzin et al.^[108] reported three cases in which antenatal steroid administration and elective premature delivery led to good perinatal outcome. In these challenging cases, the entire clinical situation needs to be evaluated, and a full discussion with the patient, including neonatal consultation, should be initiated prior to intervention and delivery of the very preterm fetus exhibiting fetal heart rate decelerations.

327

When nonreactive, the NST is extended in an attempt to separate the fetus in a period of prolonged quiet sleep from those who are hypoxemic or asphyxiated.^[109]^[110]^[111] In three studies, approximately 3 percent of fetuses tested remained nonreactive after 80 to 90 minutes of evaluation. Brown and Patrick^[109] noted that all NSTs that were to become reactive did so by 80 minutes or remained nonreactive for up to 120 minutes. Two stillbirths and one neonatal death occurred in seven cases with prolonged absence of reactivity. The mean arterial cord pH at delivery in this group was 6.95! In 27 pregnancies in which the fetus failed to exhibit accelerations during 80 minutes of monitoring, Leveno et al.^[110] reported 11 perinatal deaths. In this study, IUGR was documented in 74 percent of cases, oligohydramnios in 81 percent, fetal acidosis in 41 percent, meconium staining of the amniotic fluid in 30 percent, and placental infarction in 93 percent. Therefore, if the NST is extended and a persistent absence of reactivity is observed, the fetus is likely to be severely compromised.

Vibroacoustic stimulation (VAS) may be utilized to change fetal state from quiet to active sleep and shorten the length of the NST (Fig. 12-9). Most studies have employed an electronic artificial larynx that generates sound pressure levels measured at 1 m in air of 82 dB with a frequency of 80 Hz and a harmonic of 20 to 9,000 Hz.^[112] Whether it is the acoustic or vibratory component of this stimulus that alters fetal state is unclear. Gagnon et al.^[113] reported that a low-frequency vibratory stimulus applied at term changed fetal state within 3 minutes and was associated with an immediate and sustained increase in long-term fetal heart rate variability, heart rate accelerations, and gross fetal body movements. VAS may produce a significant increase in the mean duration of heart rate accelerations, the mean amplitude of accelerations, and the total time spent in accelerations.^[114] Using VAS, the incidence of nonreactive NSTs was reduced from 12.6 to 6.1 percent in a retrospective study and from 14 to 9 percent in a prospective investigation.^[115]^[116] A reactive NST after VAS stimulation appears to be as reliable an index of fetal well-being as spontaneous reactivity. However, those fetuses that remain nonreactive even after VAS may be at increased risk for poor perinatal outcome.^[117] Intrapartum fetal distress, growth restriction, and low Apgar scores were increased in fetuses that were nonreactive after acoustic stimulation.^[118] Auditory brain stem response appears to be functional in the fetus at 26 to 28 weeks' gestation.^[117] VAS significantly increases the incidence of reactive NSTs after 26 weeks' gestation.^[119]

In most centers that use VAS, the baseline fetal heart rate is first observed for 5 minutes.^[120] If the pattern is nonreactive, a stimulus of 3 seconds or less is applied near the fetal head. If the NST remains nonreactive, the stimulus is repeated at 1-minute intervals up to three times. If there continues to be no response to VAS, further evaluation should be carried out with a BPP or CST. In summary, VAS may be helpful in shortening the time required to perform an NST and may be especially useful in centers where large numbers of NSTs are done.

Could the sound generated by an electronic artificial larynx damage the fetal ear? Using intrauterine microphones, Smith and colleagues^[120] documented baseline intrauterine sound levels of up to 88 dB during labor. Transabdominal stimulation with an electronic artificial larynx increased these levels minimally, up to 91 to

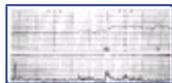

Figure 12-9 Reactive NST after VAS. The stimulus was applied in panel 54042 at the point marked by the musical notes. A sustained fetal heart rate acceleration was produced.

328

111 dB. Sound vibrations and intensity are attenuated by amniotic fluid.^[121] Therefore, a 90-dB sound pressure produced by VAS in air results in exposure of the fetal ear to the equivalent of 40 dB, the level of normal conversation at about 3 feet. Arulkumaran et al.^[121] concluded that intrauterine sound levels from VAS were not hazardous to the fetal ear. Two studies have confirmed the safety of VAS use during pregnancy with no long-term evidence of hearing loss in children followed in the neonatal period and up to 4 years of age.^[122]^[123]

Significant fetal heart rate bradycardias have been observed in 1 to 2 percent of all NSTs.^[124]^[125]^[126]^[127]^[128]^[129] Druzin et al.^[124] defined such bradycardias as a fetal heart rate of 90 bpm or a fall in the fetal heart rate of 40 bpm below the baseline for 1 minute or longer (Fig. 12-10). This definition has been most widely applied. In a review of 121 cases, bradycardia was associated with increased perinatal morbidity and mortality, particularly antepartum fetal death, cord compression, IUGR, and fetal malformations.^[130] Although about one half of the NSTs associated with bradycardia were reactive, the incidence of a nonreassuring fetal heart rate pattern in labor leading to emergency delivery in this group was identical to that of patients exhibiting nonreactive NSTs. Clinical management decisions should be based on the finding of bradycardia, *not* on the presence or absence of reactivity. Bradycardia has a higher positive predictive value for fetal compromise (fetal death or fetal intolerance of labor) than does the nonreactive NST. In this setting, antepartum fetal death is most likely because of a cord accident.^[124]^[128]^[129]

If a bradycardia is observed, an ultrasound examination should be performed to assess amniotic fluid volume and to detect the presence of anomalies such as renal agenesis. Expectant management in the setting of a bradycardia has been associated with a perinatal mortality rate of 25 percent. Several reports have therefore recommended that delivery be undertaken if the fetus is mature. When the fetus is premature, one might elect to administer corticosteroids to accelerate fetal lung maturation before delivery. Continuous fetal heart rate monitoring is necessary if expectant management is followed.

In most cases, mild variable decelerations are not associated with poor perinatal outcome. Meis et al.^[131] reported that variable decelerations of 20 bpm or more below the baseline heart rate but lasting less than 10 seconds were noted in 50.7 percent of patients having an NST. Whereas these decelerations were more often associated with a nuchal cord, they were not predictive of IUGR or a nonreassuring fetal heart rate pattern, or more severe variable decelerations during labor. Phelan^[112] has added, however, that when mild variable decelerations are observed, even if the NST is reactive, an ultrasound examination should be done to rule out oligohydramnios. A low amniotic fluid index and mild variable decelerations increase the likelihood of a cord accident.

In selected high-risk pregnancies, the false-negative rate associated with a weekly NST may be unacceptably high.^[132]^[133] Boehm et al.^[134] reported a reduction in the fetal death rate in their high-risk population from 6.1 to 1.9 per 1,000 when the frequency of the NST was increased from once to twice weekly. Barrett et al.^[132] have emphasized that in pregnancies complicated by IUGR and diabetes mellitus, twice-weekly testing should be utilized. In reviewing the literature, they noted that the fetal death rate within 1 week after a

Figure 12-10 A NST in this primigravid patient of 43 weeks' gestation reveals a spontaneous bradycardia (panel 30692). The fetal heart rate has fallen from a baseline of 150 to 100 bpm. Upon induction of labor, the patient required cesarean delivery for fetal distress associated with severe variable decelerations. The amniotic fluid was decreased in amount and was meconium stained.

329

nonreactive NST was significantly increased in both diabetes mellitus (14 per 1,000) and IUGR (20 per 1,000). Miyazaki and Miyazaki,^[135] reported an 8 percent false-negative rate in 125 prolonged gestations evaluated with the NST. In the prolonged pregnancy and IUGR, oligohydramnios may occur, leading to cord compression and fetal demise. The assessment of amniotic fluid volume has clearly proved important in such cases. Barss and co-workers^[136] reviewed the incidence of stillbirths within 1 week of a reactive test in patients with a prolonged gestation. For the general high-risk population, a false-negative rate of 2.7 per 1,000 was reported. Although the incidence in pregnancies complicated by a prolonged gestation was not higher (2.8 per 1,000), Barss et al.^[136] noted that even this low rate can be considered excessively high in view of the fact that these fetuses are otherwise normal and mature. In summary, it appears that the frequency of the NST should

be increased to *twice* weekly in pregnancies complicated by diabetes mellitus, prolonged gestation, and IUGR. ^[134]

Which antepartum heart rate test is best? The NST has proved to be an ideal screening test and remains the primary method for antepartum fetal evaluation at most centers. It can be quickly performed in an outpatient setting and is easily interpreted. In contrast, the CST is usually performed near the labor and delivery suite, may require an intravenous infusion of oxytocin, and may be more difficult to interpret. In initial studies, a reactive NST appeared to be as predictive of good outcome as a negative CST. Nevertheless, as more data have been gathered, it appears that the ability of the CST to stress the fetus and evaluate its response to intermittent interruptions in intervillous blood flow provides an earlier warning of fetal compromise. Murata et al. ^[137] found that, in the dying fetal rhesus monkey, the fetal pH at which late decelerations appear is significantly higher (7.32) than the pH at which fetal heart rate accelerations disappear (7.22). In a large collaborative project in which 1,542 patients were evaluated primarily with the NST and 4,626 with the CST, Freeman et al. ^[139] observed that the corrected perinatal mortality associated with a reactive NST, 3.2 per 1,000, was significantly higher than that observed with a negative CST, 1.4 per 1,000. Whereas both fetal death rates are extremely low for a high-risk population, that associated with the CST is clearly better.

The healthy fetus should exhibit a reactive baseline heart rate with no late decelerations when a CST is performed. However, as the fetus deteriorates, one will first observe late decelerations, and, finally, the most ominous fetal heart rate pattern, the nonreactive NST and positive CST ^[72], ^[78], ^[139] (Fig. 12-5). When a nonreactive NST is followed by a positive CST, the incidence of perinatal mortality has been approximately 10 percent, a nonreassuring fetal heart rate pattern has occurred in most laboring patients, and IUGR has been reported in 25 percent of cases. The unusual combination of a reactive NST and a positive CST has been associated with a higher incidence of IUGR and late decelerations in labor than that seen with a negative CST. ^[140] The likelihood of fetal death is increased in patients demonstrating a nonreactive NST followed by a negative CST. ^[73], ^[141], ^[142] Consequently, repeating the NST in 24 hours appears the prudent course in such cases (Fig. 12-11).

Finally, arguments about the "best test" are counter-productive. Each test has its strengths and weaknesses, and a thorough understanding of the nature of the antepartum test, taking into consideration its advantages and disadvantages, is essential. The type of test and its application should be "condition" or diagnosis specific in which a similar basic screening approach is used, adding different types of evaluation and increased

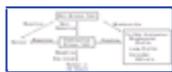

Figure 12-11 A branched testing scheme using the NST, CST, and BPP. Delivery is considered when the NST is nonreactive and the CST is positive. Delivery is also considered when a bradycardia is observed during the NST. The fetal BPP may be used to decrease the incidence of unnecessary premature intervention.

frequency of testing as appropriate for the clinical situation.

Fetal Biophysical Profile

The use of real-time ultrasonography to assess antepartum fetal condition has enabled the obstetrician to perform an in utero physical examination and evaluate dynamic functions reflecting the integrity of the fetal CNS. ^[143] As emphasized by Manning et al., ^[144] "fetal biophysical scoring rests on the principle that the more complete the examination of the fetus, its activities, and its environment, the more accurate may be the differentiation of fetal health from disease states."

Fetal breathing movements were the first biophysical parameter to be assessed using real-time ultrasonography. It is thought that the fetus exercises its breathing muscles in utero in preparation for postdelivery respiratory function. With real-time ultrasonography, fetal breathing movement (FBM) is evidenced by downward movement of the diaphragm and abdominal contents and by an inward collapsing of the chest. Fetal breathing movements become regular at 20 to 21 weeks and are controlled by centers on the ventral surface of the fourth ventricle of the fetus. ^[145] They are observed approximately 30 percent of the time, are seen more often during REM sleep, and, when present, demonstrate intact neurologic control. Although the absence of FBMs may reflect fetal asphyxia, this finding may also indicate that the fetus is in a period of quiet sleep. ^[39], ^[40]

Several factors other than fetal state and hypoxia can influence the presence of FBM. As maternal glucose levels rise, FBM becomes more frequent, and, during periods of maternal hypoglycemia, FBM decreases. Maternal smoking will also reduce FBM, probably as a result of fetal hypoxemia. ^[146] Narcotics that depress the fetal CNS will also decrease FBM.

Platt and colleagues ^[147] were among the first to examine the ability of FBM to predict perinatal outcome. Using real-time ultrasonography, they judged FBM to be present if at least one episode of FBM of at least 60 seconds' duration was observed within any 30-minute period of observation. Of 136 fetuses studied, 116 (85 percent) exhibited FBM. The incidence of fetal distress was significantly higher in fetuses without FBM, 60 percent (12 of 20), as was the incidence of low Apgar scores at 5 minutes, 50 percent (10 of 20). The comparable figures for fetuses demonstrating FBM were 3 percent (4 of 116) for a nonreassuring fetal heart rate pattern and 4 percent (5 of 116) for low Apgar scores.

Further research demonstrated that the evaluation of FBM could be used to distinguish the truly positive CST from a false-positive CST. Those fetuses that displayed FBM but had a positive CST were unlikely to exhibit fetal distress in labor. However, when a fetus failed to show FBM and demonstrated late decelerations during the CST, the likelihood of fetal compromise was great. A pattern emerged from these studies that as long as one antepartum biophysical test was normal, the likelihood that the fetus would have a normal outcome was high. ^[148], ^[149] As the number of abnormal tests increased, however, the likelihood that fetal asphyxia was present increased as well.

Using these principles, Manning et al. ^[150] developed the concept of the fetal BPP score. These workers elected to combine the NST with four parameters that could be assessed using real-time ultrasonography: FBM, fetal movement, fetal tone, and amniotic fluid volume. FBM, fetal movement, and fetal tone are mediated by complex neurologic pathways and should reflect the function of the fetal CNS at the time of the examination. On the other hand, amniotic fluid volume should provide information about the presence of chronic fetal asphyxia. Finally, the ultrasound examination performed for the BPP has the added advantage of detecting previously unrecognized major fetal anomalies.

Vintzileos et al. ^[145] stressed that those fetal biophysical activities that are present earliest in fetal development are the last to disappear with fetal hypoxia. The fetal tone center in the cortex begins to function at 7.5 to 8.5 weeks. Fetal tone would therefore be the last fetal parameter to be lost with worsening fetal condition. The fetal movement center in the cortex-nuclei is functional at 9 weeks and would be more sensitive than fetal tone. As noted above, FBM becomes regular at 20 to 21 weeks. Finally, fetal heart rate control, residing within the posterior hypothalamus and medulla, becomes functional at the end of the second trimester and early in the third trimester. An alteration in fetal heart rate would theoretically be the earliest sign of fetal compromise.

A BPP score was developed that is similar to the Apgar score used to assess the condition of the newborn. ^[150] The presence of a normal parameter, such as a reactive NST, was awarded 2 points, whereas the absence of that parameter was scored as 0. The highest score a fetus can receive is 10, and the lowest score is 0. The BPP may be used as early as 26 to 28 weeks' gestation. The time required for the fetus to achieve a satisfactory BPP score is closely related to fetal state, with an average of only 5 minutes if the fetus is in a 2F state but over 25 minutes if it is in a 1F state. ^[151] Twice-weekly testing is recommended in pregnancies complicated by IUGR, diabetes mellitus, prolonged gestation, and hypertension with proteinuria. The criteria proposed by Manning et al., ^[150] and the clinical actions recommended in response to these scores, are presented in Table 12-5 and Table 12-6. Regardless of a low score on the BPP, Manning et al. have emphasized that vaginal

TABLE 12-5 -- TECHNIQUE OF BIOPHYSICAL PROFILE SCORING

Biophysical Variable	Normal (Score = 2)	Abnormal (Score = 0)
Fetal breathing movements	At least one episode of >30 seconds' duration in 30 minutes' observation	Absent or no episode of 30 seconds' duration in 30 minutes

Gross body movement	At least three discrete body/limb movements in 30 minutes (episodes of active continuous movement considered a single movement)	Up to two episodes of body/limb movements in 30 minutes
Fetal tone	At least one episode of active extension with return to flexion of fetal limb(s) or trunk; opening and closing of hand considered normal tone	Either slow extension with return to partial flexion or movement of limb in full extension or absent fetal movement
Reactive fetal heart rate	At least two episodes of acceleration of 15 bpm and 15 seconds' duration associated with fetal movement in 30 minutes	Fewer than two accelerations or acceleration <15 bpm in 30 minutes
Qualitative amniotic fluid volume	At least one pocket of amniotic fluid measuring 2 cm in two perpendicular planes	Either no amniotic fluid pockets or a pocket <2 cm in two perpendicular planes

delivery is attempted if other obstetric factors are favorable.

In a prospective blinded study of 216 high-risk patients, Manning and colleagues^[150] found no perinatal deaths when all five variables described above were normal, but a perinatal mortality rate of 60 percent in fetuses with a score of zero. Fetal deaths were increased 14-fold with the absence of fetal movement, and the perinatal mortality rate was increased 18-fold if FBM was absent. Any single test was associated with a significant false-positive rate ranging from 50 to 79 percent. However, combining abnormal variables significantly decreased the false-positive rate to as low as 20 percent. The false-negative rate, that is, the incidence of babies who were compromised but who had normal testing, was quite low, ranging from a perinatal mortality rate of 6.9 per 1,000 for infants with normal amniotic fluid volume to 12.8 per 1,000 for fetuses demonstrating a reactive NST. These investigators found that, in most cases, the ultrasound-derived BPP parameters and NST could be completed within a relatively short time, each requiring approximately 10 minutes.

Manning et al.^[152] have presented their experience with 26,780 high-risk pregnancies followed with the BPP. In Manning et al.'s protocol, a routine NST is not performed if all of the ultrasound parameters are found to be normal for a score of 8.^[153] An NST is performed when one ultrasound finding is abnormal. The corrected PMR in this series was 1.9 per 1,000, with less than 1 fetal death per 1,000 patients within 1 week of a normal profile. Of all patients tested, almost 97 percent had a score of 8, which means that only 3 percent required further evaluation for scores of 6 or less. In a study of 525 patients with scores of 6 or less, poor perinatal outcome was most often associated with either a nonreactive NST and absent fetal tone or a nonreactive NST and absent FBM.^[154] A significant inverse linear relationship was observed between the last BPP

TABLE 12-6 -- MANAGEMENT BASED ON BIOPHYSICAL PROFILE

Score	Interpretation	Management
10	Normal infant; low risk of chronic asphyxia	Repeat testing at weekly intervals; repeat twice weekly in diabetic patients and patients at 41 weeks' gestation
8	Normal infant; low risk of chronic asphyxia	Repeat testing at weekly intervals; repeat testing twice weekly in diabetics and patients at 41 weeks' gestation; oligohydramnios is an indication for delivery
6	Suspect chronic asphyxia	If 36 weeks' gestation and conditions are favorable, deliver; if >36 weeks and L/S <2.0, repeat test in 46 hours; deliver if oligohydramnios is present
4	Suspect chronic asphyxia	If 36 weeks' gestation, deliver; if <32 weeks' gestation, repeat score
02	Strongly suspect chronic asphyxia	Extend testing time to 120 minutes; if persistent score 4, deliver, regardless of gestational age

score and both perinatal morbidity and mortality (Fig. 12-12) and (Fig. 12-13).^[152] The false-positive rate, depending on the endpoint used, ranges from 75 percent for a score of 6 to less than 20 percent for a score of 0. Manning^[155] has summarized the data reported in eight investigations using the BPP for fetal evaluation. Overall, 23,780 patients and 54,337 tests were reviewed. The corrected perinatal mortality rate, excluding lethal anomalies, was 0.77 per 1,000.

The BPP correlates well with fetal acid-base status. Vintzileos et al.^[156] studied 124 patients undergoing cesarean birth *before* the onset of labor. Deliveries were undertaken for severe preeclampsia, elective repeat cesarean section, growth restriction, breech presentation, placenta previa, and fetal macrosomia. Acidosis was defined as an umbilical cord arterial pH less than 7.20. The earliest manifestations of fetal acidosis were a nonreactive NST and loss of FBM. With scores of 8 or more, the mean arterial pH was 7.28, and only 2 of 102 fetuses were acidotic. Nine fetuses with scores of 4 or less had a mean pH of 6.99, and all were acidotic.

Recent studies have demonstrated that antenatal corticosteroid administration may have an effect on the BPP, decreasing the profile score. Because corticosteroids are used in cases of anticipated premature delivery (24 to 34 weeks), any false-positives on biophysical testing may lead to inappropriate intervention and delivery. Kelly et al. reported that BPP scores were decreased in more than one third of the fetuses tested at 28 to 34 weeks' gestation. This effect was seen within 48 hours of corticosteroid administration. Neonatal outcome was not affected. Repeat BPPs within 24 to 48 hours were normal in cases in which the BPP score had decreased by 4 points. The most commonly affected variables were FBM and the NST.^[157] Similarly Deren et al.^[158] and Rotmensch et al.^[159] reported transient suppression of FBM, fetal body movements, and heart rate reactivity following corticosteroid administration at less than 34 weeks' gestation. These changes were transient and returned to normal by 48 to 96 hours after corticosteroid treatment. This effect must be considered at institutions where daily BPPs are used to evaluate the

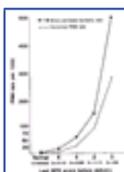

Figure 12-13 The relationship between perinatal mortality, both total and corrected for major anomalies, and the last BPP score before delivery. A highly significant inverse and exponential relationship is observed. 333

fetus in cases of preterm labor or preterm premature rupture of the membranes.

There has been some controversy concerning the utility of the BPP in predicting chorioamnionitis in pregnancies complicated by preterm labor or preterm premature

rupture of the membranes. Sherer et al.^[160] reported that the absence of FBM is associated with histologic evidence of fetal inflammation and intrauterine infection in patients with preterm labor and intact membranes before 32 weeks' gestation. However, they recommend that this finding not be used to guide clinical management because of the low positive predictive value of absent FBM. Lewis et al.^[161] performed a randomized trial of daily NSTs versus BPP in the management of preterm premature rupture of the membranes. They concluded that neither daily NSTs nor BPPs had high sensitivity in predicting infectious complications in these patients. Daily BPPs increased cost without apparent benefit.

Manning et al. have described the correlation between biophysical scoring and the incidence of cerebral palsy in Manitoba. In patients referred for a BPP, there was an inverse, exponential, and highly significant relationship between last BPP score and the incidence of cerebral palsy. Scores of 6 or less had a sensitivity of 49 percent. The more abnormal the last BPP, the greater the risk of cerebral palsy. Gestational age, birth weight, or assumed timing of the injury were not related to the incidence of cerebral palsy. The incidence of cerebral palsy ranged from 0.7 per 1,000 live births, for a normal BPP score; to 13.1 per 1,000 live births, for a score of 6; and 333 per 1,000 live births, for a score of 0.^[162]

Is an NST needed if all ultrasound parameters of the BPP are normal? Prospective and blinded studies by Platt et al.^[163] and Manning et al.^[164] using both the BPP and NST have demonstrated that each of these tests is a valuable predictor of normal outcome. In the experience of Manning et al., an NST was needed in less than 5 percent of tests. As emphasized by Eden et al.,^[165] however, the NST will allow the detection of fetal heart rate decelerations. In the presence of reduced amniotic fluid, these decelerations may be associated with a cord accident. Eden et al. reported that when spontaneous fetal heart rate decelerations lasting at least 30 seconds with a decrease of at least 15 bpm are seen in the presence of normal amniotic fluid, there is an increased likelihood of late decelerations in labor and cesarean delivery for fetal distress.

Several drawbacks of the BPP should be considered. Unlike the NST and CST, an ultrasound machine is required, and, unless the BPP is videotaped, it cannot be reviewed. If the fetus is in a quiet sleep state, the BPP can require a long period of observation. The present scoring system does not consider the impact of hydramnios. In a pregnancy complicated by diabetes mellitus, the presence of excessive amniotic fluid is of great concern.

The false-positive (false-abnormal) rate of a particular test has always been of concern because of the possibility of unnecessary intervention (usually delivery) and subsequent iatrogenic complications. The BPP was developed in part to address the issue of the high false-abnormal rate of the CST and the NST. There has been little attention paid to the possible false-positive rate of the abnormal or equivocal BPP. This is particularly relevant because the BPP is most commonly used as the final backup test in the NST and CST sequence of testing and is critically important when dealing with the premature fetus. As noted above, the false-positive rate of a score of 0 is less than 20 percent, but for a score of 6 is up to 75 percent. Inglis et al.^[166] used VAS to define fetal condition with BPP scores of 6 or less in 81 patients at 28 to 42 weeks. Obstetric and neonatal outcomes of 41 patients whose score improved to normal after VAS were compared with those of 238 patients who had normal scores without VAS. The obstetric and neonatal outcomes were not significantly different between the two groups. VAS improved the BPP in about 80 percent of cases. Use of VAS for an equivocal BPP did not increase the false-negative rate and may reduce the likelihood of unnecessary obstetric intervention.^[166]

DOPPLER ULTRASOUND

With the introduction of Doppler ultrasound, noninvasive assessment of the fetal, maternal, and placental circulations became possible. Evaluation of blood flow in the fetus and placenta had previously entailed such invasive procedures as injection of radioactive microspheres or direct application of transducers, with the potential of jeopardy to the fetus and mother. Investigators could now examine the association of changes in umbilical blood flow with fetal morbidity in the ongoing human pregnancy.

The Doppler principle is based on changes in the frequency of sound (or light) produced by a changing relationship between two objects. The frequency of sound produced by an object moving away from an observer is perceived as lower than the same frequency of sound produced by an object moving toward the observer. ^[167] A common example of this is the sound of a train horn as it moves toward, then past and away from the listener. Ultrasound waves beamed with a particular frequency will return to a receiver at a lower frequency when the target is moving away from the transducer, and at a higher frequency when the target is moving towards the transducer. The speed and direction

334

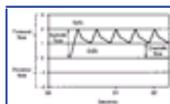

Figure 12-14 Diagram of a normal umbilical artery flow velocity waveform. Note the forward flow during both systole and diastole, the latter indicating low resistance in the placental bed. (Adapted from Warsof SL, Levy DL: *Doppler blood flow and fetal growth retardation*. In Gross TL, Sokol RJ (ed): *Intrauterine Growth Retardation, A Practical Approach*. Chicago, Year Book, 1989, p 158.)

of moving red blood cells have been investigated using this information, and converting it into waveforms interpretable by the human eye and ear. By convention, information received from objects moving away from the transducer is recorded below a zero line, and information received from objects moving toward the transducer is recorded above a zero line (Fig. 12-14) and (Fig. 12-15). The frequency of the reflected sound is proportional to the velocity of the moving red blood cells. Information about blood flow velocity provides an indirect assessment of changes in blood flow. Calculation of flow velocity is derived from the equation

where f_d is the change in ultrasound frequency or Doppler shift, f_0 is the transmitted frequency of the

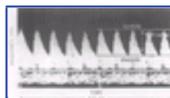

Figure 12-15 Doppler flow velocity waveforms of the normal umbilical artery. Note that umbilical arterial flow velocities are recorded above the baseline, whereas nonpulsatile umbilical vein flow in the opposite direction is found below the baseline (a). Measurement of the S/D ratio is also illustrated (b). (From Bruner JP, Gabbe SG, Levy DW, et al: *Doppler ultrasonography of the umbilical cord in normal pregnancy*. *J South Med Assoc* 86:52, 1993, with permission.)

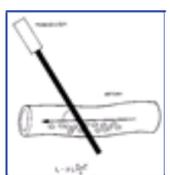

Figure 12-16 Application of the Doppler principle to determine blood flow velocity. The frequency (f_0) of the ultrasound beam directed at a moving column of red blood cells with velocity V will be increased to f_d in proportion to V and the cosine of the angle of intersection of the vessel by the beam (θ).

ultrasound beam, V is the velocity of the red blood cells, θ is the angle between the beam and the direction of movement of the reflector or red blood cells, and c is the velocity of sound in the medium (Fig. 12-16). The speed of sound in tissues is 1,540 m/sec. The number 2 in the equation accounts for the time spent from the transmission of the sound signal at its origin to its return. Volume flow may be calculated by multiplying the mean velocity by the cross-sectional area of the vessel. Velocities are measured in meters per second.

The combination of real-time ultrasound imaging

335

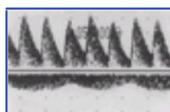

Figure 12-17 Umbilical arterial and venous Doppler flow velocity waveforms during an episode of fetal breathing. Venous velocities vary with every two to three arterial waveforms.

with pulsed wave Doppler allows the identification of a specific area or vessel for sampling. A vessel can be identified, and the ultrasound beam placed across that vessel using range gating. Ideally, the angle between the beam and the insonated vessel should be less than 30 degrees. As the angle increases, large errors may be made in estimating flow velocity. Determinations of the volume of blood flow require accurate measurements of the diameter of the vessel studied in order to calculate its cross-sectional area. A small error in the measurement of the diameter can produce substantial errors in the determination of the volume of blood flow, since the radius is squared to calculate the area of the blood vessel. If blood flow is expressed in milliliters per kilogram per minute, fetal weight must be accurately estimated. Usually, a minimum of three to five waveforms is used to obtain measurements. In umbilical vessels, multiple sites are sampled.

Given the difficulty of estimating the angle between the Doppler ultrasound beam and the direction of blood flow in a particular vessel, a variety of angle-independent indices have been developed to characterize flow velocity waveforms produced. Indices rely on systolic, diastolic, and mean velocities. Systolic velocities are peak

velocities that result from cardiac contraction. Diastolic velocities result from an interaction between peak flows, vessel compliance, heart rate, and the vascular impedance of the sites perfused. These indices do not measure the volume of blood flow. A commonly used index is the systolic (S)/diastolic (D) velocity ratio, the S/D ratio (Fig. 12-14) and (Fig. 12-15). The pulsatility index is calculated as the systolic minus diastolic values divided by the mean of the velocity waveform (S-D/mean). An additional ratio, the resistance index, or Pourcelot ratio, is expressed as S-D/S. The latter two ratios are useful when the diastolic flow is absent or reversed. Higher indices occur with relatively lower diastolic velocities that are thought to be the result of increased resistance or vascular impedance. ^[170]

Variations in umbilical artery blood flow occur during episodes of fetal breathing (Fig. 12-17). ^[171] Changes in abdominal and thoracic pressure that occur with fetal breathing produce changes in preload, stroke volume, and afterload. Variations in fetal heart rate may shorten or lengthen diastole, with changes in stroke volume and less or more time for diastolic run-off, resulting in subsequent changes in both systolic and diastolic velocities. Sites closer to the fetal abdomen have relatively higher diastolic velocities, and sites closer to the placenta have relatively lower diastolic velocities. ^[172] For these reasons, it is recommended that umbilical velocity studies be performed in midportions of the umbilical cord while fetuses are relatively quiet.

Values of normal umbilical artery flow velocity waveforms during pregnancy have been reported by many investigators (Fig. 12-18). ^[173], ^[174] Prior to 15 weeks' gestation, diastolic flow is not consistently identified in the umbilical artery. ^[175] As the normal pregnancy progresses, there is proportionately more blood flow during diastole, and indices decrease. The normal decrease in umbilical artery velocity indices is consistent with a decrease in placental resistance with advancing gestational age. ^[176]

The main application of umbilical artery Doppler flow velocity measurements has been in the pregnancy at risk for or demonstrating IUGR (see Chapter 25). ^[177] Intrauterine growth restriction is seen more often in fetuses with umbilical artery velocity indices that are elevated for their gestational age. ^[178] In some cases, end-diastolic flow is absent or reversed (Fig. 12-19) and (Fig. 12-20).

The association of umbilical artery flow velocity

336

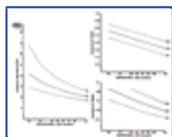

Figure 12-18 Normal ranges for the various indices used to quantify the flow velocity waveform patterns of the umbilical artery during pregnancy. (Derived from Thompson et al. ^[173])

waveform indices with alterations in placental blood flow was examined by Trudinger et al. in a sheep model. ^[179] The umbilical placental circulation was embolized with microspheres each day for 9 days in late gestation. The umbilical artery S/D ratio increased at 4 days, as did vascular resistance in the placental bed. The volume of umbilical blood flow did not fall significantly until the end of the study period. Using a similar

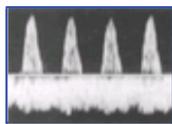

Figure 12-19 Umbilical arterial waveforms with absent end-diastolic velocities. In this case, venous velocities also demonstrate variation with the arterial waveforms.

337

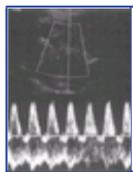

Figure 12-20 Umbilical arterial waveforms with reverse flow at end-diastole. Umbilical venous velocities have marked pulsations.

experimental model, Morrow and Ritchie, ^[180] reported a progressive increase in the S/D ratio leading to absent and then reversed diastolic flow. Hypoxia did not alter the S/D ratio, an observation also reported by Copel et al. ^[181] using a sheep model in which umbilical blood flow and S/D ratio were measured shortly after placental embolization. Copel et al. reported normal umbilical artery S/D ratios in the presence of fetal acidosis. Therefore, the umbilical artery S/D ratio more likely reflects placental vascular resistance than acute fetal hypoxemia.

The most extreme abnormalities in umbilical artery waveforms are those in which the velocities are absent or reversed. ^[182] Absence of end-diastolic velocities is associated with an increase in perinatal morbidity and mortality. Reverse flow is even more predictive of poor perinatal outcome than absent diastolic flow. In addition to an association with intrauterine growth restriction, markedly abnormal Doppler studies have been reported in fetuses with congenital malformations, including chromosomal abnormalities. Farine et al. summarized information from 31 studies with a total of 904 fetuses demonstrating absent or reversed end-diastolic velocities. ^[183] They found a perinatal mortality of 36 percent. Eighty percent of the fetuses were below the 10th percentile in weight for gestational age. Abnormal karyotypes were found in 6 percent, and malformations in 11 percent. The average duration from diagnosis to delivery ranged from 0 to 49 days, averaging 6 to 8 days. Absence or reversal of end-diastolic flow velocities in the umbilical artery, although not an indication for immediate delivery, is considered an indication for immediate and intensive ongoing fetal surveillance. Delivery is usually based on the results of

338

fetal heart rate monitoring or the BPP, with consideration of maternal condition and gestational age.

Most Doppler ultrasound studies of the fetus have focused on the umbilical arterial circulation. Examination of the fetal venous circulation has allowed some refinement in our understanding of the normal fetal circulation as well as fetal well-being. Most commonly, the fetal umbilical venous blood flow is monophasic (Fig. 12-15). Fetuses with abnormal arterial velocities, or with abnormal cardiac function, may develop "pulsations" in the venous velocity waveform (Fig. 12-19). ^[184] These pulsations occur during late diastole, and can be distinguished from breathing changes produced during fetal breathing episodes by their regularity, persistence, and association with the fetal heart rate. Umbilical venous pulsations can be produced in fetal lambs by volume-loading the venous circulation, and are associated with increases in central venous pressure. ^[185] Serial studies of human fetuses with absent end-diastolic velocities in the umbilical artery showed that the development of umbilical venous pulsations was associated with a shorter time between diagnosis and delivery with the deliveries performed for abnormal fetal heart rate patterns. ^[186] Fetuses with abnormally high umbilical artery velocity indices have a higher perinatal morbidity and mortality if abnormal venous velocities also develop. ^[187] Umbilical venous pulsations have been demonstrated in fetuses with late decelerations, during the deceleration itself. ^[188] These findings suggest that fetuses with abnormal umbilical arterial velocities may develop higher central venous pressures and umbilical venous pulsations as their condition deteriorates. Furthermore, fetuses with abnormal cardiac function or cardiac failure may demonstrate umbilical venous velocity pulsations even when umbilical arterial velocities are normal. Prospective clinical studies utilizing umbilical venous velocities will be needed before the value of this parameter can be determined.

The effectiveness of umbilical artery Doppler studies as an antepartum fetal surveillance technique has been summarized in an editorial by Divon and Ferber, in which the results of several meta-analyses were reviewed. ^[182] A meta-analysis by Giles and Bisit of six published, peer-reviewed, randomized controlled, clinical trials showed a reduction in perinatal mortality in the 2,102 fetuses studied with Doppler compared with the 2,133 fetuses not evaluated with this technique. ^[189] An analysis

of 12 published and unpublished randomized controlled clinical trials in 7,474 high-risk patients revealed fewer antenatal admissions, inductions of labor, cesarean deliveries for fetal distress, and perinatal mortality in high-risk pregnancies monitored with Doppler velocimetry. ^[190] A recent report by Neilson and Alfirevic confirmed these findings. ^[191] Divon and Ferber conclude that Doppler ultrasound is useful in high-risk pregnancies and will decrease perinatal mortality without increasing maternal or neonatal morbidity. Studies of low-risk pregnancies have not shown a benefit from the use of Doppler ultrasound. ^[192]

THE ASSESSMENT OF FETAL PULMONARY MATURATION

This section reviews those techniques that enable the obstetrician to predict accurately the risks of respiratory distress syndrome (RDS) for the infant requiring premature delivery and to avoid the unnecessary tragedy of iatrogenic prematurity.

RDS is caused by a deficiency of pulmonary surfactant, an antiatelectasis factor that is able to maintain a low stable surface tension at the air-water interface within alveoli. Surfactant decreases the pressure needed to distend the lung and prevents alveolar collapse (see Chapter 20). The type II alveolar cell is the major site of surfactant synthesis. Surfactant is packaged in lamellar bodies, discharged into the alveoli, and carried into the amniotic cavity with pulmonary fluid.

Phospholipids account for more than 80 percent of the surface active material within the lung, and more than 50 percent of this phospholipid is dipalmitoyl lecithin. The latter is a derivative of glycerol phosphate and contains two fatty acids as well as the nitrogenous base choline. Other phospholipids contained in the surfactant complex include phosphatidylglycerol (PG), phosphatidylinositol (PI), phosphatidylserine (PS), phosphatidylethanolamine (PE), sphingomyelin, and lysolecithin. PG is the second most abundant lipid in surfactant and significantly improves its properties.

An accurate assessment of gestational age and fetal maturity is essential before an elective induction of labor or cesarean delivery or before the delivery of a patient whose fetus may not have matured normally such as a growth-restricted fetus or the fetus of a poorly controlled diabetic mother. Many of the techniques used in clinical practice in the past not only failed to predict gestational age, but provided little information about fetal pulmonary maturation. ^[193]

Prior to the now-common practice of using ultrasound to establish gestational age and amniotic fluid studies to assess fetal pulmonary maturation, iatrogenic prematurity was an important clinical problem. In 1975, Goldenberg and Nelson ^[194] concluded that untimely or unwarranted intervention was responsible for 15 percent of their cases of RDS. In a similar study, Hack et al. ^[195] observed that 12 percent of all infants with RDS in their neonatal intensive care unit were born after elective deliveries. None of these infants had had documentation of pulmonary maturation before delivery.

Several changes in clinical practice appear to have decreased the incidence of RDS caused by iatrogenic prematurity. More patients who have had a previous low transverse cesarean delivery are attempting a vaginal birth. In such cases, since the onset of spontaneous labor is awaited, documentation of fetal pulmonary maturation prior to elective intervention is not required. Most importantly, ultrasound documentation of gestational age in the first trimester or early in the second trimester has proven extremely reliable in timing elective inductions or cesarean deliveries (see Chapter 10).

Assessment of Fetal Pulmonary Maturity

Available methods for evaluating fetal pulmonary maturity can be divided into three categories: (1) quantitation of pulmonary surfactant, such as the lecithin/sphingomyelin (L/S) ratio; (2) measurement of surfactant function including the shake test; and (3) evaluation of amniotic fluid turbidity. ^[196], ^[197]

With the exception of amniotic fluid specimens obtained from the vaginal pool, the evaluation of fetal pulmonary maturation requires that a sample of amniotic fluid be obtained by amniocentesis. In the past, third-trimester amniocentesis was associated with significant fetal and maternal risks. Fetal complications have included fetal bleeding from laceration of the placenta or umbilical cord, fetomaternal bleeding, premature labor and premature rupture of the membranes, placental abruption, and fetal injury. Maternal complications, though rare, have included hemorrhage, in some cases from perforation of the uterine vessels, abdominal wall hematomas, Rh sensitization, and infection.

Ultrasound guidance for third-trimester amniocentesis has significantly decreased the risks of the procedure. In a review of seven studies that included 4,115 third-trimester amniocenteses, the frequency of complications was 3 percent for rupture of the membranes within 24 hours, 7 percent for a bloody tap, 4.4 percent for failed amniocentesis, 3.3 percent for labor within 24 hours, 1 percent for fetal trauma, and 0.05 percent for fetal death. ^[198]

A bloody tap warrants careful observation. ^[199] At term, the fetal blood volume is relatively small, and fetal bleeding may have disastrous consequences. When a bloody tap occurs, the patient should be evaluated with continuous electronic fetal heart rate monitoring until an Apt test or Kleihauer-Betke test confirms that the blood is of maternal origin and the fetus has demonstrated no evidence of compromise. Should a non-reassuring fetal heart rate pattern be observed, cesarean delivery is performed. When fetal blood is recovered, the fetus is delivered if its pulmonary status is mature even if it has not exhibited fetal distress. For those fetuses with pulmonary immaturity, treatment with corticosteroids and delivery thereafter is recommended. ^[200]

Quantitation of Pulmonary Surfactant

Lecithin/Sphingomyelin Ratio

The L/S ratio was the first reliable assay for the assessment of fetal pulmonary maturity. ^[201], ^[202] The amniotic fluid concentration of lecithin increases markedly at approximately 35 weeks' gestation, whereas sphingomyelin levels remain stable or decrease. Rather than determine the concentration of lecithin that could be altered by variations in amniotic fluid volume, Gluck and co-workers used sphingomyelin as an internal standard and compared the amount of lecithin to that of sphingomyelin. Amniotic fluid sphingomyelin exceeds lecithin until 31 to 32 weeks, when the L/S ratio reaches 1. Lecithin then rises rapidly, and an L/S ratio of 2.0 is observed at approximately 35 weeks. Wide variation in the L/S ratio at each gestational age has been noted. Nevertheless, a ratio of 2.0 or greater has repeatedly been associated with pulmonary maturity. In more than 2,100 cases, a mature L/S ratio predicted the absence of RDS in 98 percent of neonates. ^[203] With a ratio of 1.5 to 1.9, approximately 50 percent of infants will develop RDS. Below 1.5, the risk of subsequent RDS increases to 73 percent. Thus, the L/S ratio, like most indices of fetal pulmonary maturation, rarely errs when predicting fetal pulmonary maturity, but is frequently incorrect when predicting subsequent RDS. ^[203] Many neonates with an immature L/S ratio will not develop RDS.

Several important variables must be considered in interpreting the predictive accuracy of the L/S ratio. A prolonged interval between the determination of an immature L/S ratio and delivery will necessarily increase the number of falsely immature results. It is probably best to discard amniotic fluid samples heavily contaminated by blood or meconium, because the effects of these compounds on the determination of the L/S ratio are quite unpredictable. ^[204], ^[205] Blood has been reported to both increase and decrease the ratio, and meconium can produce falsely mature results. The presence of PG in a bloody or meconium-stained amniotic fluid sample remains a reliable indicator of pulmonary maturity. ^[206] PG is not normally found in blood, and meconium generally does not interfere with the identification of PG. ^[207], ^[208] Finally, it is essential that the obstetrician know the analytic technique used and the predictive value of a mature L/S ratio in his or her laboratory.

Many perinatal processes alter the final interpretation of the L/S ratio. Surfactant deficiency, immaturity, and intrapartum complications are the prime factors in determining the pathogenesis of RDS. ^[209] Birth asphyxia

may lead to RDS in many infants despite an L/S ratio greater than 2.0. In earlier studies, infants with severe Rh disease and infants of diabetic mothers were reported to have developed RDS despite mature L/S ratios. More recent data indicate that the L/S ratio is reliable in both high-risk conditions. ^[210], ^[211] Kjos and colleagues^[211] found no cases of RDS caused by surfactant deficiency in a study of women with pregestational and gestational diabetes.

PG, which does not appear until 35 weeks' gestation and increases rapidly between 37 to 40 weeks, is a marker of completed pulmonary maturation. ^[212] Most infants who lack PG but who have a mature L/S ratio fail to develop RDS. However, PG may provide further insurance against the onset of RDS despite intrapartum complications.

Slide Agglutination Test for PG

A rapid immunologic semiquantitative agglutination test (Amniostat-FLM) can be used to determine the presence of PG. ^[213] This assay can detect PG at a concentration greater than 0.5 g/ml of amniotic fluid. The test takes 20 to 30 minutes to perform and requires only 1.5 ml of amniotic fluid. Besides being highly sensitive, several studies have found a positive Amniostat-FLM to correlate well with the presence of PG by thin-layer chromatography and the absence of subsequent RDS. In a study evaluating samples from the vaginal pool and those obtained by amniocentesis, the overall concordance for the Amniostat-FLM and thin-layer chromatography results was 89 percent. ^[213] No cases of RDS were observed when the Amniostat-FLM assay demonstrated PG. This technique can be applied to samples contaminated by blood and meconium.

Fluorescence Polarization

TDx Test (Surfactant Albumin Ratio)

The TDx analyzer, an automated fluorescence polarimeter, has been utilized to assess surfactant content in amniotic fluid. ^[215] ^[216] ^[217] The test requires 1 ml of amniotic fluid and can be run in less than 1 hour. The surfactant albumin ratio (SAR) is determined with amniotic fluid albumin used as an internal reference. A value of 70 was considered mature with the original assay, whereas with the newer FLM-II test, 55 is the mature cut-off. ^[196] A mature value reliably predicts the absence of RDS requiring intubation in infants of diabetic mothers. ^[218] The TDx test correlates well with the L/S ratio and has few falsely mature results, making it an excellent screening test. ^[219] The TDx assay proved to be reliable in predicting fetal lung maturity in vaginal pool specimens in patients with preterm premature rupture of the membranes at 30 to 36 weeks. ^[220] Approximately 50 percent of infants with an immature TDx result will develop RDS.

Measurement of Surfactant Function

Foam Stability Index

The test is based on the manual foam stability index (FSI), and is a variation of the shake test. ^[221] The kit currently available contains test wells with a predispensed volume of ethanol. The addition of 0.5-ml amniotic fluid to each test well in the kit produces final ethanol volumes of 44 to 50 percent. A control well contains sufficient surfactant in 50 percent ethanol to produce an example of the stable foam endpoint. The amniotic fluid/ethanol mixture is first shaken, and the FSI value is read as the highest value well in which a ring of stable foam persists. ^[222]

This test appears to be a reliable predictor of fetal lung maturity. ^[223] Subsequent RDS is very unlikely with an FSI value of 47 or higher. The methodology is simple, and the test can be performed at any time of day by persons who have had only minimal instruction. The assay appears to be extremely sensitive, with a high proportion of immature results being associated with RDS, as well as moderately specific, with a high proportion of mature results predicting the absence of RDS. Contamination of the amniotic fluid specimen by blood or meconium invalidates the FSI results. The FSI can function well as a screening test.

Evaluation of Amniotic Fluid Turbidity

Visual Inspection

During the first and second trimesters, amniotic fluid is yellow and clear. It becomes colorless in the third trimester. By 33 to 34 weeks' gestation, cloudiness and flocculation are noted, and, as term approaches, vernix appears. Amniotic fluid with obvious vernix or fluid so turbid it does not permit the reading of newsprint through it will usually have a mature L/S ratio. ^[224]

Lamellar Body Counts

Lamellar bodies are the storage form of surfactant released by fetal type II pneumocytes into the amniotic fluid. Because they have the same size as platelets, the amniotic fluid concentration of lamellar bodies may be determined using a commercial cell counter. ^[225] ^[226] ^[227] ^[228] The test requires less than 1 ml of amniotic fluid and takes only 15 minutes to perform. A lamellar body count greater than 30,000 to 55,000/l is highly predictive of pulmonary maturity, whereas a count below 10,000/l suggests a significant risk for RDS. Lewis et al. have recently reported that a lamellar body count of less than 8,000 predicted an immature L/S and PG assay in

all cases, whereas a value over 32,000 predicted a mature L/S or PG assay in 99 percent of cases. ^[229] The cutoff used to predict fetal pulmonary status will depend on the type of cell counter used and the speed of centrifugation of the amniotic fluid specimen. Neither meconium nor lysed blood has a significant effect on the lamellar body count.

Determination of Fetal Pulmonary Maturation in Clinical Practice

A large number of techniques are now available to assess fetal pulmonary maturation. ^[196] Several rapid screening tests, including the TDx test, Amniostat-FLM, and lamellar body count appear to be highly reliable when mature. In an uncomplicated pregnancy, when a screening test such as the TDx demonstrates fetal pulmonary maturation, one can safely proceed with delivery. ^[217], ^[229] This sequential approach is also extremely cost effective. ^[196], ^[197], ^[230], ^[231] However, when the screening test is immature, the L/S ratio should be used. Similarly, in complicated pregnancies such as those with diabetes mellitus, IUGR, and Rh isoimmunization, the L/S ratio should be determined to assess fetal pulmonary maturation.

A PRACTICAL APPROACH TO TESTING

How can one most efficiently use all the techniques available for antepartum fetal surveillance? Obstetricians should take a "diagnosis-specific" approach to testing. That is, they must consider the pathophysiology of the disease process that will be evaluated and then select the best method or methods of testing for that problem. For example, in the pregnancy complicated by significant Rh isoimmunization, one might want to use serial evaluations of fetal hemoglobin. In a pregnancy complicated by diabetes mellitus, careful monitoring of maternal glucose levels should accompany antepartum heart rate testing. In contrast, in a pregnancy complicated by suspected growth restriction, one would want to make serial evaluations of amniotic fluid volume with ultrasound to detect oligohydramnios.

In a prolonged pregnancy, one would use a parallel testing scheme. In this situation, the obstetrician is not concerned with fetal maturity, but rather with fetal well-being. Several tests are performed at the same time, such as antepartum fetal heart rate testing and the BPP. It is acceptable in this high-risk situation to intervene when a single test is abnormal. One is willing to accept a false-positive test result to avoid the intrauterine death of a mature and otherwise healthy fetus. In a study of prolonged gestations in Canada between 1980 and 1995, Sue-A-Quan et al. reported a decline in the stillbirth rate for deliveries at 41 or more weeks' gestation that they attribute to an increased rate of labor induction.^[232] Patients may have been induced electively or selectively for abnormal tests of fetal well-being.

In most other high-risk pregnancies, such as those complicated by diabetes mellitus or hypertension, it is preferable to allow the fetus to remain in utero as long as possible. In these situations, a branched testing scheme is used. To decrease the likelihood of unnecessary premature intervention, the obstetrician uses a series of tests and, under most circumstances, would only deliver a premature infant when all parameters suggest fetal compromise. In this situation, one must consider the likelihood of neonatal RDS as predicted by the evaluation of amniotic fluid indices and review these risks with colleagues in neonatology.

Maternal assessment of fetal activity would appear to be an ideal first-line screening test for both high-risk and low-risk patients. The use of this approach may decrease the number of unexpected intrauterine deaths in so-called normal pregnancies. Although a negative CST has been associated with fewer intrauterine deaths than a reactive NST, the NST appears to have significant advantages in screening high-risk patients. It can be easily and rapidly performed in an outpatient setting. Most clinicians use the BPP or CST to assess fetal condition in patients exhibiting a persistently nonreactive NST. This sequential approach may be particularly valuable in avoiding unnecessary premature intervention.

Figure 12-21 (Figure Not Available) presents a practical testing scheme that has been utilized successfully by several centers.^{[112], [143], [233], [234]} The NST, an indicator of present fetal condition, may be combined with the amniotic fluid index (AFI) (see Chapter 10), a marker of long-term status, in a modified BPP. In this setting, an AFI greater than 5 cm is usually considered normal, although different criteria have been applied.^[235] VAS may be used to shorten the time required to achieve a reactive NST. While most patients are evaluated weekly, patients with diabetes mellitus, IUGR, or a prolonged gestation are tested twice weekly. If the NST is nonreactive despite VAS or extended monitoring, or if the AFI is abnormal, either a full BPP or CST is performed. Using this approach, Clark et al.^[233] found no unexpected antepartum fetal deaths in a series of 2,628 high-risk pregnancies. VAS shortened the mean testing time to 10 minutes. Only 2 percent of all NSTs were nonreactive. However, 17 percent of these were followed by a positive CST or BPP score of 4 or less. Clark et al. have extended their experience with this technique to include an additional 3,005 tests. One fetus died 2 days after a reactive NST because of a cord accident. Therefore, only one fetal death has been observed in almost 9,000 tests after a

Figure 12-21 (Figure Not Available) Flow chart for antepartum fetal surveillance in which the NST and AFI are used as the primary methods for fetal evaluation. A nonreactive NST and/or decreased AF are further evaluated using either the CST or the BPP. Further details regarding the use of the BPP are provided in Table 12-7. *If the fetus is mature and amniotic fluid volume is reduced, delivery should be considered before further testing is undertaken. (Adapted from Finberg HJ, Kurtz AB, Johnson RL, et al: *The biophysical profile: a literature review and reassessment of its usefulness in the evaluation of fetal well-being*. *J Ultrasound Med* 9:583, 1990.)

reactive NST and normal AFI! In a series of 6,543 fetuses, Vintzileos et al.^[236] reported no fetal deaths attributable to hypoxia within 1 week of a reactive NST and an ultrasound study demonstrating normal amniotic fluid. Nageotte et al.^[237] demonstrated that the modified BPP was as good a predictor of adverse fetal outcome as a negative CST. Furthermore, the CST as a backup test was associated with a higher rate of intervention for an abnormal test than the use of a complete BPP as a backup test. Miller et al. described 56,617 antepartum tests in 15,482 women identified as high risk.^[238] Six indications (postdates pregnancy, diabetes mellitus, decreased fetal movement, suspected IUGR, hypertension, and a history of previous stillbirth) accounted for over 90 percent of patients tested. The modified BPP including the NST and AFI was used primarily with the full BPP as a backup test. Sixty percent of those delivered for an abnormal test had no evidence of fetal compromise. However, false-positive tests led to preterm deliveries in only 1.5 percent of those tested before 37 weeks. The false-negative rate was similar to that of the CST and complete BPP, 0.8 per 1,000 women tested. Overall, the modified BPP had a false-positive rate comparable to the NST but higher than the CST and full BPP. The low false-negative rate and ease of performance of the modified BPP make it an excellent approach for the evaluation of large numbers of high-risk patients.

STRATEGIES TO REDUCE ANTEPARTUM FETAL DEATHS

What strategies can be utilized to reduce antepartum fetal deaths? ^[239] (See the box "Strategies to Reduce Antepartum Fetal Deaths.") (Box Not Available)

343

First, it is important to determine the cause of a fetal death so that the patient and her partner can be counseled, the risk of recurrence described, and a plan of care for subsequent pregnancies developed. The obstetrician should write a detailed note describing the stillborn fetus, amniotic fluid, umbilical cord, placenta, and membranes. If the infant is malformed, growth restricted, or hydropic, chromosomal studies should be obtained. An autopsy should be requested. ^[239], ^[240] Incerpi et al. observed that an autopsy and evaluation of the placenta were the most valuable tests in determining the cause of fetal death. ^[241] Tests for syphilis, antiphospholipid antibodies, and lupus anticoagulant should be done. If the patient has not been screened for diabetes mellitus during gestation, a fasting glucose should be ordered. Because significant fetal-maternal hemorrhage has been observed in approximately 5 percent of all fetal deaths, a Kleihauer-Betke test should be obtained.

Strategies to Reduce Antepartum Fetal Deaths

(Not Available)

From Gabbe SG: Prevention of antepartum fetal deaths. OB/GYN Clinical Alert, April 1998, p 94, with permission.

To prevent antepartum deaths, routine fetal movement counting should be considered in all pregnancies, starting at 28 weeks' gestation. The modified Count-to-Ten method developed by Moore and Piacquadio is a simple and valuable technique. ^[60] To reduce fetal deaths resulting from fetal malformations, a triple analyte screen should be offered and routine ultrasound performed at 18 to 20 weeks (see Chapter 8) and (Chapter 10). To detect IUGR, careful serial measurements of fundal height should be performed with an ultrasound examination at 30 to 32 weeks in high-risk patients including those with vascular disease and in patients with lagging uterine growth (see Chapter 25). Finally, to reduce fetal deaths caused by placental abruption, patients who are known to be abusing cocaine should be counseled and enrolled in treatment programs.

Gabbe: Obstetrics - Normal and Problem Pregnancies, 4th ed. , Copyright © 2002 Churchill Livingstone, Inc.

Key Points

The prevalence of an abnormal condition (i.e., fetal death) has great impact on the predictive value of antepartum fetal tests.

The near-term fetus spends approximately 25 percent of its time in a quiet sleep state (state 1F) and 60 to 70 percent in an active sleep state (state 2F).

Approximately 5 percent of women monitoring fetal movement will report decreased fetal activity.

The incidence of perinatal death within 1 week of a negative CST is less than 1 in 1,000.

The observation that accelerations of the fetal heart rate in response to fetal activity, uterine contractions, or stimulation reflect fetal well-being is the basis for the NST.

The frequency of the NST should be increased to twice weekly in pregnancies complicated by diabetes mellitus, prolonged gestation, and IUGR.

Use of VAS for an equivocal BPP does not increase the false-negative rate and may reduce the likelihood of unnecessary obstetric intervention.

Reversed end-diastolic flow in the umbilical artery flow velocity waveform has been associated with an increased perinatal mortality rate.

Most amniotic fluid indices of fetal pulmonary maturation rarely err when predicting maturity, but are frequently incorrect when predicting subsequent RDS.

The NST, an indicator of present fetal condition, and the amniotic fluid index, a marker of long-term fetal status, have been combined in the modified BPP.

Chapter 13 - Labor and Delivery

Errol R. Norwitz
Julian N. Robinson
John T. Repke

The reader is referred to the Appendix for illustrations of anatomy relevant to this discussion.

DEFINITIONS

Labor is the physiologic process by which a fetus is expelled from the uterus to the outside world. Labor is defined as an increase in myometrial activity or, more precisely, a switch in the myometrial contractility pattern from "contractures" (long-lasting, low-frequency activity) to "contractions" (frequent, high-intensity, high-frequency activity),^[1] resulting in effacement and dilatation of the uterine cervix. In normal labor, there appears to be a time-dependent relationship between the biochemical connective tissue changes in the cervix, which usually precede uterine contractions and cervical dilatation. All of these events usually occur before rupture of the membranes. Spontaneous rupture of the fetal membranes prior to the onset of uterine activity is seen in only 8 percent of term pregnancies.^[2]

The mean duration of human singleton pregnancy is 280 days (40 weeks) from the first day of the last menstrual period. "Term" is defined as the period from 36 completed (37.0) to 42.0 weeks of gestation. "Preterm" (premature) labor refers to the onset of labor prior to 36 completed weeks' gestation ([see Chapter 23](#)). "Postterm" (prolonged) pregnancy refers to pregnancies continuing beyond 42.0 weeks' gestation ([see Chapter 27](#)).

Diagnosis

Labor is a clinical diagnosis. The classic diagnosis of labor includes regular painful uterine contractions, progressive cervical effacement and dilatation, and a show (bloody discharge). Cervical dilatation in the absence of uterine contractions is seen most commonly in the second trimester and is suggestive of cervical incompetence ([see Chapter 23](#)). Similarly, the presence of uterine contractions in the absence of cervical change does not meet criteria for the diagnosis of labor.

PHYSIOLOGY OF NORMAL LABOR AT TERM

Historical Perspective

Considerable evidence suggests that, in most viviparous animals, the fetus is in control of the timing of labor.^{[3] [4] [5]} During the Hippocratic period, it was believed that the fetus presented head first so that it could kick its legs up against the fundus of the uterus, thereby propelling itself through the birth canal. While we have moved away from this simple mechanical view of labor, the factors responsible for the initiation and maintenance of labor at term are not well defined.

The last few decades have seen a marked change in the nature of the hypotheses to explain the onset of labor. Initial investigations centered on changes in the profile of circulating hormone levels in the maternal and fetal circulations (i.e., endocrine events). More recent studies have focused on the dynamic biochemical dialogue that exists between the fetus and the mother (i.e., paracrine and autocrine events) in an attempt to understand in detail the molecular mechanisms that regulate such interactions.

Phases of Parturition

Labor at term may be regarded physiologically as a release from the inhibitory effects of pregnancy on the

myometrium rather than as an active process mediated by uterine stimulants. Strips of quiescent myometrium obtained from a uterus at term and placed in an isotonic water bath, for example, will contract vigorously and spontaneously without added stimuli.^{[6] [7]} In vivo, however, it is likely that both inhibitory and stimulatory mechanisms are important.

It is useful to consider the regulation of uterine activity during pregnancy as being divided into four distinct physiologic phases (Fig. 13-1).^{[8] [9]} During pregnancy, the uterus is maintained in a state of functional quiescence (phase 0) through the action of various putative inhibitors including, but not limited to, progesterone, prostacyclin (prostaglandin I₂ [PGI₂]), relaxin, parathyroid hormone-related peptide, nitric oxide, calcitonin gene-related peptide, adrenomedullin, and vasoactive intestinal peptide. Before term, the uterus undergoes activation (phase 1) and stimulation (phase 2). Activation occurs in response to uterotopins, including estrogen, and is characterized by increased expression of a series of contraction-associated proteins (including myometrial receptors for prostaglandins and oxytocin), activation of certain ion channels, and an increase in connexin-43 (a key component of gap junctions). An increase in gap junctions between adjacent myometrial cells leads to electrical synchrony within the myometrium and allows for effective coordination of contractions. Following activation, the "primed" uterus can be stimulated to contract by the action of uterotopins such as the stimulatory prostaglandins (PGE₂ and PGF₂) and oxytocin. Involution of the uterus after delivery occurs during phase 3 and is mediated primarily by oxytocin.

The Endocrine Control of Labor

Horse-donkey crossbreeding experiments performed in the 1950s resulted in a gestational length intermediate between that of horses (340 days) and that of donkeys (365 days), suggesting a role for the fetal genotype in the initiation of labor.^{[5] [10]} The hypothesis that the fetus is in control of the timing of labor has been elegantly demonstrated in domestic ruminants, such as sheep and cows, and involves activation at term of the fetal hypothalamic-pituitary-adrenal axis.^{[11] [12] [13] [14]} However, this mechanism does not apply to humans. The slow progress in our understanding of the biochemical mechanisms involved in the process of labor in humans in large part reflects the difficulty in extrapolating from the endocrine-control mechanisms in various animals to the paracrine/autocrine mechanisms of parturition in humans, processes that preclude direct investigation.

Regardless of whether the trigger for labor begins within the fetus or outside the fetus, the final common pathway for labor ends in the maternal tissues of the uterus and is characterized by the development of regular phasic uterine contractions. As in other smooth muscles, myometrial contractions are mediated through the adenosine triphosphate (ATP)-dependent binding of myosin to actin. In contrast to vascular smooth muscle, however, myometrial cells have a sparse innervation,

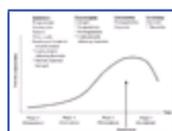

Figure 13-1 Regulation of uterine activity during pregnancy and labor. (Adapted from Challis JRG, Gibb W: Control of parturition. *Prenat Neonat Med* 1:283, 1996.)

which is further reduced during pregnancy.^[15] The regulation of the contractile mechanism of the uterus is therefore largely humoral and/or dependent on intrinsic factors within myometrial cells.

It is likely that there is a "parturition cascade" at term that removes the mechanisms maintaining uterine quiescence and recruits factors promoting uterine activity (Fig. 13-2).^[16] Given its teleologic importance, such a cascade would likely have multiple redundant loops to ensure a fail-safe system of securing pregnancy success and ultimately the preservation of the species. In such a model, each element is connected to the next in a sequential fashion, and many of the elements demonstrate positive feed-forward characteristics typical of a cascade mechanism. The sequential recruitment of signals that serve to augment the labor process suggest that it may not be possible to single out any one signaling mechanism as being responsible for the initiation of labor. It may therefore be prudent to describe such mechanisms as being responsible for *promoting*, rather than *initiating*, the process of labor.^[17] A comprehensive analysis of each of the individual paracrine/autocrine pathways implicated in the process of labor have been reviewed in detail elsewhere.^{[8] [9] [10] [16] [17] [18] [19]} In brief, human labor at term is a multifactorial physiologic event involving an integrated set of changes within the maternal tissues of the uterus (myometrium, decidua, and uterine cervix) that occur gradually over a period of days to weeks. Such changes include, but are not limited to, an increase in prostaglandin synthesis and release within the uterus, an increase in myometrial gap junction formation, and up-regulation of myometrial oxytocin receptors (uterine activation). Once the myometrium and cervix are prepared, endocrine and/or paracrine/autocrine factors from the fetoplacental unit bring about a switch in the pattern of myometrial activity from irregular contractures to regular contractions (uterine stimulation). The fetus may coordinate this switch in myometrial activity through its influence on placental steroid hormone production, through mechanical distention of the uterus, and through secretion of neurohypophyseal hormones and other stimulators of prostaglandin synthesis. The final common pathway towards

labor appears to be activation of the fetal hypothalamic-pituitary-adrenal axis, and is probably common to all species. In the human, the fetal adrenal provides abundant C19 estrogen precursor (dehydroepiandrosterone) directly from its intermediate (fetal) zone. This is because the human placenta is an incomplete steroidogenic organ and estrogen synthesis by the human placenta has an obligate need for C19 steroid precursor ^[21] (Fig. 13-2). In the rhesus monkey, infusion of C19 precursor (androstenedione) leads to preterm delivery. ^[21], ^[22] This effect is blocked by concurrent infusion of an aromatase inhibitor, ^[23] demonstrating that conversion to estrogen is important. However, systemic infusion of estrogen failed to induce delivery, suggesting that the action of estrogen is likely paracrine/autocrine. ^[21], ^[22]

MECHANICS OF LABOR

Mechanics of Normal Labor at Term

Labor and delivery are not passive processes in which uterine contractions push a rigid object through a fixed aperture. The ability of the fetus to successfully negotiate the pelvis during labor and delivery is dependent on the complex interaction of three variables: the powers, the passenger, and the passage.

The Powers

The powers refer to the forces generated by the uterine musculature. Uterine activity is characterized by the frequency, amplitude (intensity), and duration of contractions. Assessment of uterine activity may include simple observation, manual palpation, external objective assessment techniques (such as external tocodynamometry), and direct measurement of intrauterine pressure (using either internal manometry or pressure transducers). External tocodynamometry measures the change in shape of the abdominal wall as a function of uterine contractions and, as such, is qualitative rather than quantitative. Although it permits graphic display of uterine activity and allows for accurate correlation of fetal heart rate patterns with uterine activity, external tocodynamometry does not allow measurement of contraction intensity or basal intrauterine tone. The most precise method for determination of uterine activity is the direct measurement of intrauterine pressure. Such techniques, however, require insertion of a fluid-filled catheter and/or pressure transducer directly into the uterine cavity usually through the cervix after rupture of the fetal membranes. A risk of uterine injury (perforation) exists during placement of the catheter and such catheters may be associated with an increased incidence of intrauterine infection.

Despite technological improvements, the definition of "adequate" uterine activity during labor remains unclear. Classically, three to five contractions in 10 minutes has been used to define adequate labor, and is seen in around 95 percent of women in spontaneous labor at term. In the active management of labor protocols, seven contractions in 15 minutes is regarded as adequate.^[24], ^[25] The more recent introduction of intrauterine pressure transducers has enabled objective measurement

356

Figure 13-2 Proposed "parturition cascade" for labor induction at term. The spontaneous induction of labor at term in the human is regulated by a series of paracrine/autocrine hormones acting in an integrated parturition cascade responsible for promoting uterine contractions. PGE₂, prostaglandin E₂; PGEM, 13, 14-dihydro-15-keto-PGE₂; PGF₂, prostaglandin F₂; PGFM, 13,14-dihydro-15keto-PGF₂. (Modified from Norwitz ER, Robinson JN, Repke JT: The initiation of parturition: a comparative analysis across the species. *Curr Prob Obstet Gynecol Fertil* 22:41, 1999.)

357

of uterine activity.^[26] Various units have been devised to objectively measure uterine activity, the most common of which is *Montevideo units* (the average strength of contractions in millimeters of mercury multiplied by the number of contractions per 10 minutes), which is a measure of average frequency and amplitude above basal tone. Two hundred to 250 Montevideo units defines adequate labor.^[26], ^[27] It is generally believed that the more optimal the powers, the more likely a successful outcome. However, there are no data to support this statement. The ultimate measure of uterine activity is a clinical one. If uterine contractions are "adequate" to effect vaginal delivery, one of two things will happen. Either the cervix will efface and dilate and the fetal head will descend, or there will be worsening caput succedaneum (scalp edema) and/or moulding of the fetal head (overlapping of the skull bones) without cervical effacement and dilatation. The latter situation suggests the presence of cephalopelvic disproportion (CPD), which can be either absolute (in which a given fetus is simply too large to negotiate a given pelvis) or relative (in which delivery of a given fetus through a given pelvis would be possible under optimal conditions but is precluded by malposition or abnormal attitude of the fetal head).

The Passenger

The passenger is the fetus. There are several fetal variables that influence the course of labor and delivery. These are summarized below.

1. Absolute fetal size can be estimated both clinically by abdominal palpation or with ultrasound, but both are subject to a large degree of error. Fetal macrosomia (defined by the American College of Obstetricians and Gynecologists (ACOG) as an absolute fetal size 4,500 g^[28]) may be associated with failure to progress in labor.
2. *Lie* refers to the longitudinal axis of the fetus relative to the longitudinal axis of the uterus. Fetal lie can be either longitudinal, transverse, or oblique (Fig. 13-3). In a singleton pregnancy, only fetuses in a longitudinal lie can be safely delivered vaginally.
3. *Presentation* refers to the fetal part that directly overlies the pelvic inlet. In a fetus presenting in the longitudinal lie, the presentation can be either cephalic (vertex), breech, or (rarely) shoulder. Compound presentation refers to the presence of more than one fetal part overlying the pelvic inlet. Funic presentation refers to presentation of the umbilical cord, and is rare at term. In a cephalic fetus, the presentation is classified according to the leading bony landmark of the skull, which can be either the occiput, the mentum (chin), or the brow (Fig. 13-4). *Malpresentation* refers to any presentation that is not cephalic with the occiput leading, and is seen in around 5 percent of all term labors (see Chapter 16).
4. *Attitude* refers to the position of the head with regard to the fetal spine (i.e., the degree of flexion and/or extension of the fetal head). Flexion of the head is important to facilitate *engagement* of the head in the maternal pelvis. When the fetal chin is optimally flexed onto the chest, the suboccipitobregmatic diameter (9.5 cm) presents at the pelvic inlet (Fig. 13-5). This is the smallest possible presenting diameter in the cephalic presentation. As the head deflexes (extends), the diameter presenting to the pelvic inlet progressively increases even before the malpresentations of brow and face are encountered (Fig. 13-5), and may contribute to failure to progress in labor. The architecture of the pelvic floor along with increased uterine activity may correct deflexion in the early stages of labor.
5. *Position* of the fetus refers to the relationship of a nominated site of the presenting part to a denominating location on the internal pelvis, and can be assessed most accurately on transvaginal examination. In a cephalic presentation, the nominated site is the occiput (e.g., right occiput anterior [ROA]). In the breech presentation, the nominated site is the sacrum (e.g., right sacrum anterior [RSA]). The various positions of a cephalic presentation are illustrated in Figure 13-6. *Malposition* refers to any position in labor which is not ROA, OA, or LOA.

6. *Station* is a measure of descent of the presenting part of the fetus through the birth canal (Fig. 13-7). The old classification was an arbitrary subjective assignment of seven stations (-3 to +3), whereas the new classification (-5 to +5) is an attempt to quantitate in centimeters the distance of the leading bony edge from the ischial spines. In both classifications,

the midpoint (0 station) is defined as the plane of the maternal ischial spines.

7. *Multifetal pregnancies* (twins, triplets, and/or higher order multifetal pregnancies) increase the probability of abnormal lie and malpresentation in labor.

Abnormality in any of the above fetal variables may influence the decision of whether or not to proceed with vaginal delivery, and may affect the course of labor. Failure to progress in labor should prompt a careful reevaluation of the above fetal parameters to exclude absolute or relative CPD.

The Passage

The passage consists of the bony pelvis (composed of the sacrum, ilium, ischium, and pubis) and the resistance provided by the soft tissues. The bony pelvis is divided into the false (greater) and true (lesser) pelvis by the pelvic brim, which is demarcated by the sacral promontory, the anterior ala of the sacrum, the arcuate line of the ilium, the pectineal line of the pubis, and the pubic crest culminating in the symphysis (Fig. 13-8). Measurements of the various parameters of the bony female pelvis have been made with great precision, directly in cadavers and using radiographic imaging in living women. Such measurements have divided the true

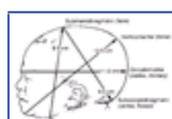

Figure 13-5 Presenting diameters of the average term fetal skull. (From O'Brien WF, Cefalo RC: *Labor and delivery*. In Gabbe SG, Niebyl JR, Simpson JL [eds]: *Obstetrics: Normal and Problem Pregnancies*, 3rd ed. New York, Churchill Livingstone, 1996, p 377, with permission.)

pelvis into a series of planes that must be negotiated by the fetus during passage through the birth canal, which can be broadly classified into the pelvic inlet, midcavity and outlet. X-ray pelvimetry^[29] has defined average and critical limit values for the various parameters of the bony pelvis (Table 13-1). Critical limit values are measurements that are associated a high probability of CPD.^[30] X-ray pelvimetry is now rarely used, having been replaced in large part by a clinical trial of the pelvis (a "trial of labor"). Computed tomography (CT) has the potential for highly reproducible measurements of the bony pelvis.^[31] However, concerns over cost and exposure of the fetus to even small amounts of ionizing radiation have limited its use. Clinical pelvimetry is currently the only method of assessing the shape and dimensions of the bony pelvis in labor. A useful protocol for clinical pelvimetry is detailed in Figure 13-9, and involves assessment of three parameters of the pelvic inlet, midcavity, and outlet. The inlet of the true pelvis is largest in its transverse diameter (usually 12.0 cm). The *diagonal conjugate* (the distance from the sacral promontory to the inferior margin of the symphysis pubis as assessed on bimanual examination)

* The critical limit values cited imply a high likelihood of cephalopelvic disproportion.

is a clinical representation of the anteroposterior diameter of the pelvic inlet. The *true conjugate* (or *obstetric conjugate*) of the pelvic inlet is the distance from the sacral promontory to the superior aspect of the symphysis pubis. This measurement cannot be made clinically, but can be estimated by subtracting 1.5 to 2.0 cm from the obstetric conjugate. This is the smallest diameter of the inlet, and usually measures around 10 to 11 cm. The limiting factor in the midcavity is the interspinous diameter (the measurement between the ischial

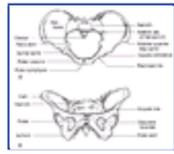

Figure 13-8 Superior (A) and anterior (B) view of the female pelvis. (From Repke JT: *Intrapartum Obstetrics*. New York, Churchill Livingstone, 1996, p 68, with permission.)

361

Figure 13-9 A protocol for clinical pelvimetry.

362

spines), which is usually the smallest diameter of the pelvis, but should be greater than 10 cm. The pelvic outlet is rarely of clinical significance. The anteroposterior diameter from the coccyx to the symphysis pubis is usually around 13 cm, and the transverse diameter between the ischial tuberosities around 8 cm.

The shape of the female bony pelvis can be classified into one or more of four broad categories: gynecoid, anthropoid, android, and platypelloid (Fig. 13-10). This classification, based on the radiographic studies of Caldwell and Moley,^[32] separates those with favorable characteristics (gynecoid, anthropoid) from those that are less favorable for vaginal delivery (android, platypelloid). In reality, however, many women fall into intermediate classes and the distinctions become arbitrary. The gynecoid pelvis is the classic female shape with an oval-shaped inlet, diverging midpelvic sidewalls, and far-spaced ischial spines. The anthropoid pelvis has an exaggerated oval shape to the inlet with the largest diameter being anteroposterior, and with limited anterior capacity to the pelvis. Such pelvises are more often associated with delivery in the occiput posterior position. The android pelvis is male in pattern, with a heart-shaped inlet, prominent sacral promontory and ischial spines, shallow sacral hollow, and converging midpelvic sidewalls. Women with such pelvises are at increased risk of CPD. The platypelloid pelvis is a broad, flat pelvis with an exaggerated oval-shaped inlet, but with the largest diameter being the transverse diameter. Although the assessment of fetal size along with pelvic shape and capacity is useful to predict women at risk of CPD in labor, it is an inexact science. An adequate trial of labor is the only way to determine whether a given fetus will be able to safely negotiate a given pelvis.

Pelvic soft tissues may provide resistance in both the first and second stages of labor. In the first stage, resistance is offered primarily by the cervix; whereas in the second stage, it is by the muscles of the pelvic floor. It has been proposed that rapid labors result from low pelvic resistance rather than from high myometrial activity.^[33] Indeed, intrauterine pressures are lower when cervical ripening is used prior to augmentation of labor with oxytocin as compared with augmentation alone.^[34] However, this hypothesis has not received wide acceptance. In the second stage of labor, the resistance of the pelvic musculature is believed to play an important role

Figure 13-10 Characteristics of the four types of female bony pelvis. (Modified from Callahan TL, Caughey AB, Heffner LJ [eds]: *Blueprints in Obstetrics & Gynecology*. Malden, MA, Blackwell Science, 1998, p 45.)

363

in the rotation and movement of the presenting part through the pelvis.

Stages of Labor

Although labor is a continuous process, for reasons of study and to assist in clinical management it has traditionally been divided into three stages, with the first stage further subdivided into three phases.

First Stage

The first stage of labor refers to the interval between the onset of labor and full cervical dilatation. It has been subdivided by Friedman^[35],^[36] in his classic studies on the course of labor in primigravida into three phases according to the rate of cervical dilatation (Fig. 13-11). The *latent phase* is defined as the period between the onset of labor and a point at which a change in the slope of the rate of cervical dilatation is noted.^[35],^[36] It is characterized by slow cervical dilatation and is of variable duration. The *active phase* is associated with a greater rate of cervical dilatation and usually begins at around 2 to 3 cm dilatation.^[35],^[36],^[37] The active phase is further subdivided into an acceleration phase, a phase of maximum slope, and a deceleration phase. A *descent phase* was described in the original manuscript that usually coincides with the second stage of labor. Not all investigators accept the existence of a separate descent phase. Subsequent studies have shown that the characteristics of the labor curve do not differ between various ethnic groups,^[38] although there are significant differences between the labor curve of primigravida and multiparous women. Friedman^[35],^[36] has described averages and a statistical maximum (2 SD greater than the mean) for each phase (Table 13-2). As evidenced in Table 13-2, the minimum rate of cervical dilatation of 1.2 cm/h for a nulliparous patient represents 2 SD from the mean, and not the average rate of dilatation. From the normal profile produced by Friedman, it is possible to identify abnormal labor patterns and thereby pregnancies at risk for adverse events in labor. For any individual patient, the clinician responsible for managing the labor should have a sense at any point in time of where on the normal labor curve the patient is. This task can be facilitated by the use of the partogram,^[39] a graphical representation of the labor curve against which a patient's progress in labor is plotted. In this way,

abnormal labor patterns can easily be identified and appropriate measures taken.

Second Stage

The second stage of labor is the interval between full cervical dilatation (10 cm) and delivery of the infant. It is characterized by descent of the presenting part through the maternal pelvis culminating in expulsion of the fetus. The mother can assume a more active role in the second stage, using maternal effort to aid descent of the fetus. In modern obstetric practice, the nulliparous patient is recommended to push for a maximum of 2 hours without regional anesthesia (or 3 hours with regional

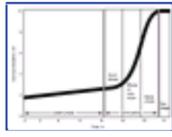

Figure 13-11 Characteristics of the average cervical dilatation curve for nulliparous labor. (Adapted from Friedman EA: *Labor: Clinical Evaluation and Management*, 2nd ed. Norwalk, CT, Appleton-Century-Crofts, 1978.)

TABLE 13-2 -- PROGRESSION OF SPONTANEOUS LABOR AT TERM

Parameter	Mean	5th Percentile
Nulliparas		
Total duration of labor	10.1 h	25.8 h
Stage of labor		
Duration of the first stage	9.7 h	24.7 h
Duration of the second stage	33.0 min	117.5 min
Duration of latent phase	6.4 h	20.6 h
Rate of cervical dilatation during active phase	3.0 cm/h	1.2 cm/h
Duration of the third stage	5.0 min	30.0 min
Multiparas		
Total duration of labor	6.2 h	19.5 h
Stage of labor		
Duration of the first stage	8.0 h	18.8 h
Duration of the second stage	8.5 min	46.5 min
Duration of latent phase	4.8 h	13.6 h
Rate of cervical dilatation during active phase	5.7 cm/h	1.5 cm/h
Duration of the third stage	5.0 min	30.0 min

Data from Friedman EA: *Labor: Clinical Evaluation and Management*, 2nd ed. Norwalk, CT, Appleton-Century-Crofts, 1978.

anesthesia). The multiparous patient is recommended to push for a maximum of 1 hour without regional anesthesia (or 2 hours with regional anesthesia).^[40] In practice, full cervical dilatation is not a prerequisite for descent of the presenting part and descent can commence during the first stage. However, no active intervention (either maternal expulsive efforts or obstetric intervention) should be attempted until full cervical dilatation has been achieved.

Third Stage

The third stage of labor refers to delivery of the placenta and fetal membranes. The third stage usually lasts less than 10 minutes, but up to 30 minutes may be allowed before active intervention is considered, as long as blood loss is not excessive.

Cardinal Movements in Labor

The mechanisms of labor, also known as the cardinal movements, refer to the changes in position of fetal head during its passage through the birth canal. Because of the asymmetry of the shape of both the fetal head and the maternal bony pelvis, such rotations are required for the fetus to successfully negotiate the birth canal. Although labor and birth is a continuous process, seven discrete cardinal movements of the fetus are described: engagement, descent, flexion, internal rotation, extension, external rotation or restitution, and expulsion (Fig. 13-12).

Engagement

Engagement refers to passage of the widest diameter of the presenting part to a level below the plane of the pelvic inlet (Fig. 13-13). In the cephalic presentation with a well-flexed head, the largest transverse diameter of the fetal head is the biparietal diameter (9.5 cm). In the breech, the widest diameter is the bitrochanteric diameter. Clinically, engagement can be confirmed by palpation of the presenting part both abdominally and vaginally. With a cephalic presentation, engagement is achieved when only two fifths of the fetal head are palpable abdominally or when the presenting part is at 0 station (at the level of the maternal ischial spines) on bimanual examination. This is because the average distance between the plane of the pelvic inlet and the ischial spines is approximately 5 cm, while the distance between the biparietal plane and the occiput averages 3 to 4 cm. Engagement is considered an important clinical parameter as it demonstrates that, at least at the level of the pelvic inlet, the maternal bony pelvis is sufficiently large to allow descent of the fetal head. In nulliparas, engagement of the fetal head usually occurs by 36 weeks' gestation and the inability of the head to engage by this time may be an early sign of CPD. In multiparas, however, engagement can occur later in gestation or even during labor.

Descent

Descent refers to the downward passage of the presenting part through the pelvis. Descent of the fetus, however, is not continuous, with the greatest rate of descent occurring during the deceleration phase of the first stage of labor and during the second stage of labor.

Flexion

Flexion of the fetal head occurs passively as the head descends due to the shape of the bony pelvis and the resistance offered by the soft tissues of the pelvic floor. Although flexion of the fetal head onto the chest is present to some degree in most fetuses before labor, complete flexion usually only occurs during the course of labor. The result of complete flexion is to present the smallest diameter of the fetal head (the suboccipitobregmatic diameter) for optimal passage through the pelvis.

Internal Rotation

Internal rotation refers to rotation of the presenting part from its original position (usually transverse with

365

Figure 13-12 Cardinal movements of labor.

366

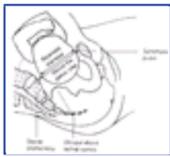

Figure 13-13 Engagement of the fetal head.

regard to the birth canal) to the anteroposterior position as it passes through the pelvis. As with flexion, internal rotation is a passive movement resulting from the shape of the pelvis and the pelvic floor musculature. The pelvic floor musculature, including the coccygeus and ileococcygeus muscles, form a V-shaped hammock that diverges anteriorly. As the head descends, the occiput of the fetus rotates towards the symphysis pubis (or, less commonly, towards the hollow of the sacrum), thereby allowing the widest portion of the fetus to negotiate the pelvis at its widest dimension. Due to the angle of inclination between the maternal lumbar spine and pelvic inlet, the fetal head engages in an asynclitic fashion (i.e., with one parietal eminence lower than the other). With uterine contractions, the leading parietal eminence descends and is first to engage the pelvic floor. As the uterus relaxes, the pelvic floor musculature causes the fetal head to rotate until it is no longer asynclitic.

Extension

Extension occurs once the fetus has descended to the level of the introitus. This descent brings the base of the occiput into contact with the inferior margin at the symphysis pubis. At this point, the birth canal curves upwards. The fetal head is delivered by extension and rotates around the symphysis pubis. The forces responsible for this motion are the downward force exerted on the fetus by the uterine contractions along with the upward forces exerted by the muscles of the pelvic floor.

External Rotation

External rotation, also known as restitution, refers to the return of the fetal head to the correct anatomic position in relation to the fetal torso. This can occur to either side depending on the orientation of the fetus. This is again a passive movement resulting from a release of the forces exerted on the fetal head by the maternal bony pelvis and its musculature and mediated by the basal tone of the fetal musculature.

Expulsion

Expulsion refers to delivery of the rest of the fetus. After delivery of the head and external rotation, further descent brings the anterior shoulder to the level of the symphysis pubis. The anterior shoulder is delivered in much the same manner as the head, with rotation of the shoulder under the symphysis pubis. After the shoulder, the rest of the body is usually delivered without difficulty.

MANAGEMENT OF NORMAL LABOR AND DELIVERY

Initial Assessment in Labor

Initial assessment in labor should include a review of the patient's prenatal information, a focused history (including the time of onset of contractions, status of fetal membranes, presence or absence of vaginal bleeding, perception of fetal movement), physical examination, and necessary laboratory testing as indicated. Physical examination should include documentation of the patient's vital signs; notation of fetal position and presentation; an assessment of fetal well-being; and an estimation of the frequency, duration, and quality of uterine contractions. The size, presentation, and lie of the fetus can be assessed by abdominal palpation. A systematic method of examination of the gravid abdomen was first described by Leopold and Sporlin in 1894.^[41] Although abdominal examination has several limitations (small fetus, maternal obesity, multifetal pregnancies, polyhydramnios), it is safe, well tolerated, and may add valuable information in the management of labor. Palpation is divided into four separate Leopold's maneuvers (Fig. 13-14). Each maneuver is designed to identify specific fetal landmarks or to reveal a specific relationship between the fetus and the mother. These are summarized below.

Leopold's maneuver #1. The gravid uterus is slightly dextrorotated (deviated to the right) because of the

367

368

position of the sigmoid colon. With the patient lying supine and her knees comfortably flexed, the examiner corrects for dextrorotation of the uterus with the back of one hand and delineates the fundus of the uterus with the other. The "fundal height" refers to a midline measurement from the symphysis pubis to the top of the uterine fundus. This is a useful measurement to estimate gestation age, although it has some limitations (multifetal pregnancies, poly- or oligohydramnios, uterine fibroids).

Leopold's maneuver #2. The examiner runs their hands down the maternal abdomen on either side of the fetus to determine the fetal lie, and uses their fingers to locate the fetal spine and small parts (extremities). Fetal parts can usually be identified by palpation at 25 to 26 weeks' gestation. If fetal movements are noted, these should be documented.

Leopold's maneuver #3. Also known as Pawlik's grip, this maneuver involves the examiner firmly grasping the upper and lower poles of the fetus by placing their fingers laterally above the symphysis pubis and at the fundus. In this way, the characteristics of the two fetal poles can be determined and compared, and the presentation documented. The fetal breech is often larger, softer, less well defined, and less ballotable than the cranium. This maneuver also allows an estimation of amniotic fluid volume and fetal size. If the estimated fetal weight is less than expected for gestational age, if the head is disproportionately firm in a small fetus, and/or if the fetal parts can be very easily felt (a clinical proxy for low amniotic fluid volume), a diagnosis of intrauterine growth restriction should be entertained.

Leopold's maneuver #4. In this maneuver, the examiner faces the patient's feet and moves their hands in bilaterally from the anterior superior iliac crests to determine whether or not the presenting part of the fetus is engaged in the maternal pelvis. In a cephalic presentation, the head is regarded as unengaged (greater than three fifths above the pelvic brim) if the examiner's hands are seen to converge below the fetal head. If the examiner's hands are noted to diverge as they trace the fetal head into the pelvis, the vertex is regarded as engaged (greater than three fifths below the pelvic brim). This procedure also allows the practitioner to assess the attitude (degree of flexion/extension) of the fetal head.

Figure 13-14 Leopold's maneuvers for palpation of the gravid abdomen.

In most pregnant women, abdominal palpation will be sufficient to determine the lie, presentation, and engagement of the fetus. However, abdominal palpation cannot accurately assess fetal position or station. If there are no contraindications to pelvic examination, the degree of cervical dilatation, effacement, status of the fetal membranes, and the position and station of the presenting part should be noted. If the practitioner is still uncertain about fetal presentation or if the clinical examination suggests an abnormality (such as a multifetal pregnancy, low amniotic fluid volume, or intrauterine growth restriction), an ultrasound examination is indicated. At term, estimation of fetal weight by the physician, and even the mother, is at least as good as sonographic estimations, with an error of 15 to 20 percent.^[42]

Intrapartum Management

Approximately 25 to 30 percent of pregnancies will be identified either antenatally or during the course of labor as being at high risk for adverse perinatal outcome because of the presence of underlying maternal or fetal conditions. Such pregnancies account for 75 to 80 percent of all perinatal morbidity and mortality.^[43] However, the remaining 20 to 25 percent of perinatal morbidity and mortality arise from pregnancies with no underlying risk factors for adverse outcome. As such, all pregnant women require adequate surveillance throughout labor and delivery.

After the patient has been admitted in labor, she and her family should be introduced to the members of the health care team responsible for her care. The patient and her family should be consulted and involved in such decisions as the use of oxytocin to augment labor, the choice of agent for intrapartum pain management, and the need for assisted vaginal delivery. Emotional support of the patient during the birthing process has been shown repeatedly to lower intrapartum analgesia requirements, to decrease intrapartum complications, and to minimize postpartum emotional difficulties,^[44] ^[45] and is strongly encouraged.

Assessment of the quality of the uterine contractions as well as cervical examinations at appropriate intervals should be performed in order to follow the progress of labor. Vaginal examinations should be kept to a minimum to avoid promoting intra-amniotic infection. Cleansing of the perineum with an antiseptic and the use of a sterile lubricant may decrease potential contamination. Although walking during the first stage of labor is often recommended and may reduce patients' discomfort, it does not alter the duration of labor, the need for labor augmentation with oxytocin, the use of analgesia, or the rate of assisted vaginal delivery and cesarean

section.^[46] During the first stage of labor, the fetal heart rate should be recorded at least every 30 minutes and should be auscultated during and immediately after a contraction.

During the second stage of labor, the fetal heart should be auscultated at least every 15 minutes, and

369

after each uterine contraction. Either manual auscultation or continuous electronic fetal monitoring is acceptable.^[47] Maternal oral intake is usually limited during this period because of the risk of aspiration pneumonitis, a major cause of anesthetic-associated morbidity and mortality. Some authors have suggested that, since the pneumonitis results from the acidity of the aspirated gastric contents, a clear antacid (such as 0.3 M sodium citrate) be administered to all women in labor. However, neither of these protocols are universally recommended.

Clinical Assistance at Delivery

Preparation for delivery should take into account the patient's parity, the progression of labor, presentation of the fetus, and complications of the labor. If it is anticipated that fetal manipulation may be necessary (such as women at risk for shoulder dystocia, breech presentation, or twin pregnancies), it may be appropriate to transfer the patient to a large and better equipped delivery room. It may also be appropriate to remove the foot of the bed and to encourage delivery in the lithotomy position. If no complications are anticipated, delivery can be accomplished with the mother in almost any position. Common positions include the lateral (Sims) position or the partial sitting position.

The goals of clinical assistance at spontaneous delivery are the reduction of maternal trauma, prevention of fetal injury, and initial support of the newborn if required. When the fetal head crowns and delivery is imminent, pressure from the accoucheur's hand is used to hold the head flexed and to control delivery, thereby preventing precipitous expulsion, which has been associated with perineal tears as well as intracranial trauma. If there is a delay in delivery of the fetal head, a modified Ritgen's maneuver may be attempted. Using a sterile towel, the fetal chin is palpated through the perineum or rectum, and upward pressure is applied to facilitate extension of the fetal head. Once the fetal head is delivered, external rotation (restitution) is allowed to occur. If the cord is around the neck, it should be looped over the head or, if not reducible, doubly clamped and transected. Mucus can then be gently suctioned from the fetal mouth, oropharynx, and nares using a bulb syringe. In the presence of meconium, aspiration with a DeLee suction catheter may reduce the risk of meconium aspiration syndrome. However, care should be taken not to suction too vigorously, as posterior pharyngeal stimulation can cause a vagal response and fetal bradycardia. Once the fetal airway has been cleared, a hand is placed on each parietal eminence and the anterior shoulder is delivered with the next contraction by downward traction towards the mother's sacrum in concert with maternal expulsive efforts. In this way, the anterior shoulder is encouraged to slip under the symphysis pubis. The posterior shoulder is then delivered by upward traction. These movements should be performed with as little downward or upward force as possible to avoid perineal injury and/or traction injuries to the brachial plexus. The infant should be cradled as delivery is completed, either spontaneously or with a gentle maternal push. After delivery, there is a net transfer of blood from the placenta to the fetus. Spasm of the umbilical artery occurs within approximately 1 minute of birth. However, the remaining communication between the neonate and placenta, the umbilical vein, permits passage of blood for up to 3 minutes after birth. Delay in clamping of the cord will allow an increase in the volume of transfusion. In most instances, however, the volume of transfusion is not clinically significant. As such, the timing of cord clamping is dictated by convenience and is usually performed immediately after delivery. The infant should be held securely and wiped dry with a sterile towel, while any mucus remaining in the airway is suctioned.

Delivery of the Placenta and Fetal Membranes

The third stage of labor can be managed either passively or actively. Passive management is characterized by patiently waiting for the three classic signs of placental separation: (1) lengthening of the umbilical cord, (2) a gush of blood from the vagina signifying separation of the placenta from the uterine wall, and (3) a change in the shape of the uterine fundus from discoid to globular with elevation of the fundal height.

In active management, uterotonic agents such as oxytocin can be administered at delivery of the anterior shoulder or after the fetus is out (either intramuscularly, intravenously, or infused into the umbilical vein) to hasten delivery of the placenta and reduce blood loss. Active management of the third stage of labor has been shown to reduce total blood loss and the incidence of postpartum hemorrhage,^[48] but can complicate management in cases involving an undiagnosed second twin or placenta accreta. In addition, two techniques of controlled cord traction are described to facilitate separation and delivery of the placenta: the *Brandt-Andrews maneuver* (in which an abdominal hand secures the uterine fundus to prevent uterine inversion while the other hand exerts sustained downward traction on the umbilical cord [Fig. 13-15]) or the *Créde maneuver* (in which the cord is fixed with the lower hand while the uterine fundus is secured and sustained upward traction is applied using the abdominal hand). Care should be taken to avoid avulsion of the cord.

After delivery, the placenta, umbilical cord, and fetal membranes should be examined. Placental weight (excluding membranes and cord) varies with fetal weight,

370

Figure 13-15 Delivery of the placenta and fetal membranes using controlled traction on the cord and suprapubic pressure with the abdominal hand to prevent uterine inversion.

with a ratio of approximately 1:6. Abnormally large placentae are associated with such conditions as fetal hydrops fetalis and congenital syphilis. Inspection and palpation of the placenta should include the fetal and maternal surfaces and may reveal areas of fibrosis, infarction, or calcification. Although each of these conditions may be seen in the normal term placenta, excessive loss of surface area can result in impairment of exchange between mother and fetus. Abnormalities of lobulation (a missing placental cotyledon or a membrane defect suggesting a missing succenturiate lobe) may suggest retention of a portion of placenta, which can lead to postpartum hemorrhage or infection. The classic hallmark of placental abruption is a depressed area on the maternal side of the placenta with an attached blood clot. The absence of such a finding, however, does not exclude the diagnosis. The site of insertion of the umbilical cord into the placenta should be noted. Abnormal insertions include marginal insertion (in which the cord inserts into the edge of the placenta) and membranous insertion (in which the vessels of the umbilical cord course through the membranes prior to attachment to the placental disk). The cord itself should be inspected for length, the correct number of umbilical vessels (normally two arteries and one vein), true knots, hematomas, and strictures. The average cord length is 50 to 60 cm. Extremes of length have been associated with a number of clinical entities, including oligohydramnios and cord compression. A single umbilical artery is associated with other structural anomalies in 20 percent of cases.^[49] The fetal membranes should also be examined for meconium staining and for opacification of the membranes, which may suggest chorioamnionitis. A membrane defect might provide the only clue to a retained accessory lobe.

Following delivery of the placenta, the cervix, vagina, and perineum should be carefully examined for evidence of birth injury. If a laceration is seen, its length and position should be noted and repair initiated. Adequate analgesia (either regional or local) is essential for repair (see Chapter 17). Special attention should be paid to repair of the perineal body, the external anal sphincter, and the rectal mucosa. Failure to recognize and repair rectal injury can lead to serious long-term morbidity, most notably fecal incontinence.

The need for manual and/or surgical exploration of the uterus after delivery is controversial. Adequate analgesia is essential for any such procedure. Although it has been proposed by some investigators that manual exploration be performed after all deliveries,^[50] it is usually reserved for women in whom there is suspicion of retained products of conception, where there is excessive vaginal bleeding, and in cases of premature delivery or vaginal birth after cesarean (VBAC).^[51] If a transmural defect in a prior cesarean scar is palpated following delivery, it should be repaired only if there is excessive bleeding. In the absence of bleeding, the patient can be managed expectantly, although a subsequent vaginal birth after cesarean should probably be discouraged.

ABNORMAL PATTERNS OF LABOR

371

Abnormalities of the First Stage

Abnormalities of the first stage of labor imply a deviation from the normal pattern of cervical dilatation described by Friedman ^[35], ^[36], ^[52] (Fig. 13-11). The abnormality may be either protraction or arrest, and may occur during the latent or active phases of the first stage.

Disorders of the Latent Phase

Latent phase arrest implies simply that labor has not truly begun. *Prolonged latent phase* refers to a latent phase of 20 hours or longer in the nulliparous patient or 14 hours or longer in the multiparous patient. ^[53] Although the duration of the latent phase of labor is highly variable and prolongation of the latent phase does not correlate with adverse perinatal outcome, this situation can be taxing to both the mother and the practitioner. The management of the prolonged latent phase should be individualized. Unless there is a maternal or fetal indication for expediting delivery, expectant management is usually recommended. On occasion, administration of an analgesic agent such as 15 to 20 mg of morphine may allow the patient to rest for a few hours or days (so-called therapeutic rest). If the decision is made to proceed with augmentation of labor, oxytocin infusion is the technique of choice. Amniotomy in such patients should be deferred because of the association between prolonged rupture of the membranes (defined as >18 hours) and intra-amniotic infection. Prolonged latent phase is not itself an indication for cesarean delivery.

Disorders of the Active Phase

Disorders of the active phase of the first stage of labor are classified into three broad categories according to the pattern of their departure from the norm. All such diagnoses are retrospective. Once identified, the underlying etiology should be sought.

A diagnosis of *primary dysfunctional labor* implies that the gravida has entered the active phase of labor but that the rate of active phase cervical dilatation is less than the fifth percentile, defined as less than 1.2 cm/h in nulliparas and less than 1.5 cm/h in multiparas ^[35], ^[36], ^[52] (Table 13-2 and Fig. 13-16). Although such pregnancies are at risk for secondary arrest and poor perinatal outcome, primary dysfunctional labor is not itself an indication for cesarean delivery. In the nulliparous patient, inadequate uterine activity is the most common cause of primary dysfunctional labor. Once diagnosed, augmentation with amniotomy and/or oxytocin infusion should be attempted. Reports from the National Maternity Hospital in Dublin ^[54] suggest that this approach is effective, but not all investigators

372

have been able to confirm these results. ^[55] In the multiparous patient, CPD due to malposition is the most common cause.

Secondary arrest is defined as cessation of previously normal active phase cervical dilatation for a period of 2 hours or more. ^[56] The duration of arrest of normal cervical dilatation is somewhat arbitrary, and arrest of only 1 hour has been associated with an increase in second-stage abnormalities and fetal morbidity. A hypothetical "action line" has been proposed by Studd ^[39] that attempts to define labor dystocia in primigravid patients. In this model, a delay in cervical dilatation of greater than or equal to 2 hours over that expected in the presence of adequate uterine contractions suggests labor dystocia and requires further evaluation. Intrapartum management should include confirmation of adequate uterine contractions and exclusion of CPD. Vaginal examination should be performed to verify cervical dilatation as well as fetal presentation, position, and station. Clinical pelvimetry should be performed with notation of pelvic type and overall pelvic capacity. If uterine activity is suboptimal, amniotomy and/or oxytocin infusion should be initiated. The majority of gravidas with secondary arrest (70 to 80 percent) will respond to such maneuvers and resume progression of cervical dilatation, although such pregnancies remain at increased risk of second-stage abnormalities and operative deliveries. Continued arrest over 2 to 4 hours with adequate uterine contractions is an indication for cesarean delivery.

A *combined disorder* of active phase dilatation is defined as arrest of dilatation occurring when the patient has previously exhibited primary dysfunctional labor. This pattern is associated with a less favorable outcome with regard to vaginal delivery than in gravidas with secondary arrest alone. ^[56]

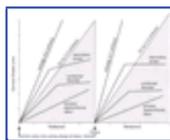

Figure 13-16 Disorders of the first stage of labor. Combined disorder implies an arrest in a gravida previously exhibiting primary dysfunctional labor.

An alternative classification system for disorders of the active phase of labor has been proposed based on the electromechanical state of the uterus. ^[25], ^[57] Two broad categories are described on the basis of clinical and monometric criteria:

Hypotonic dysfunction reflects an inefficient generation and/or propagation of action potentials through the myometrium or lack of contractile response of myometrial cells to the contractile signal. It can occur in either nulliparas or multiparas, and may indicate underlying CPD, malposition, or maternal fatigue. In this setting, uterine contractions are infrequent, of low amplitude, and accompanied by low or normal basal intrauterine pressures. Maternal discomfort is minimal.

Hypertonic dysfunction is primarily a condition of primiparas and usually occurs in early labor. It is characterized by the presence of regular uterine contractions that fail to effect cervical effacement and dilatation. Frequent contractions of low amplitude are often associated with an elevated basal intrauterine pressure. As such, maternal discomfort is significant and backache frequent.

Abnormalities of the Second Stage

The second stage of labor is the interval between full cervical dilatation and delivery of the infant. Abnormalities of the second stage can be classified into two broad categories:

Protraction of Descent

Protraction of descent is defined as descent of the presenting part during the second stage of labor occurring at less than 1 cm/h in nulliparas and less than 2 cm/h in multiparas.^[58] This diagnosis relies on the subjective assessment of station at vaginal examination, which is subject to wide interobserver error. Despite these limitations, it is clear that labors complicated by protraction of descent leading to prolonged second stage are associated with increased perinatal mortality and morbidity. Review of electronic fetal heart rate tracings obtained during prolonged second stage labors have documented a high incidence of variable decelerations and prolonged decelerations^[59] (see Chapter 14) . The gradual fall in fetal scalp capillary pH that occurs throughout labor is accelerated during the second phase.^[60] Deliveries complicated by prolonged second stage therefore place the fetus at increased risk of acidosis. For these reasons, the ACOG has recommended that intervention be considered once the second stage of labor is prolonged, defined as greater than or equal to 2 hours in nulliparas without regional analgesia (3 hours with regional analgesia) and greater than or equal to 1 hour in multiparas without regional analgesia (2 hours with regional analgesia).^[40] In practice, however, a short period of expectant management is reasonable provided that electronic fetal monitoring is reassuring, descent is progressive, and vaginal delivery is imminent.^[61]^[62]^[63]^[64]

Arrest of Descent

Arrest (failure) of descent is more accurately diagnosed (especially when examinations are limited to a single examiner) than protraction of descent. As in arrest of dilatation, arrest of descent requires prompt reevaluation of uterine contractions, maternal and fetal well-being, and cephalopelvic relationships (including clinical pelvimetry, fetal station, position, and the presence of caput succedaneum and/or moulding of the skull bones). Obvious problems such as inadequate uterine contractions, overdistended bladder, ineffectual maternal

expulsive efforts, dense conduction anesthesia, or strong perineal resistance (soft-tissue dystocia) should be managed appropriately and are associated with a high expectation of success. In the absence of such factors, however, good clinical judgment is the cornerstone of management. The decision to continue oxytocin infusion or to proceed with operative intervention (assisted vaginal delivery or cesarean) should be individualized. If the practitioner is uncertain how to proceed, consultation may prove useful.

Abnormalities of the Third Stage

Separation of the placenta is a consequence of continued uterine contractions following expulsion of the fetus. These contractions reduce the area of the uterine placental bed with subsequent disruption of the placental attachment along a plane in the spongiosa layer of the decidua vera. Continued powerful and prolonged contractions serve to expel the placenta and control blood loss through compression of the spiral arterioles. Since placental separation relies exclusively on uterine contractions, interference with this process by either fundal pressure or excessive traction on the umbilical cord can increase the incidence of complications such as hemorrhage, cord avulsion, or uterine inversion (see Chapter 17) .

The interval between delivery of the infant and delivery of the placenta and fetal membranes usually lasts less than 10 minutes and is complete within 15 minutes in 95 percent of all deliveries. After 30 minutes, intervention is indicated to expedite delivery of the placenta. Controlled trials have demonstrated that dilute intravenous oxytocin is superior to intravenous or intramuscular ergometrine in this regard.^[65] If bleeding is excessive or if there is no response to uterotonic agents, manual removal of the placenta may be required. Prophylactic antibiotics should be administered to such patients to prevent postpartum endomyometritis.

INDUCTION OF LABOR

Induction of Labor

Induction of labor refers to the initiation of uterine contractions before the spontaneous onset of labor by medical and/or surgical means for the purpose of delivery. The patient and her family should be actively involved in the decision to proceed with induction, and should be informed of the risks, benefits, and potential complications of the various options available, including the possibility of cesarean delivery. Induction of labor may be either indicated or elective.

Indicated Induction of Labor

In general, induction of labor is indicated when the benefits of delivery to the mother and/or fetus outweigh the potential risks of continuing the pregnancy. The appropriate timing for induction is the point at which the benefits to the mother and/or the fetus are greater if the pregnancy is interrupted than if the pregnancy is continued, and is gestational-age dependent. If obstetric criteria confirm that the pregnancy is at term or if fetal pulmonary maturity has been documented ([Table 13-3](#)), the decision to induce labor is not difficult. The decision to induce labor prior to term, on the other hand, is far more difficult. In such cases, there should be clear benefit to the fetus of premature delivery, which outweighs the potential problems associated with iatrogenic prematurity.

TABLE 13-3 -- CRITERIA FOR CONFIRMATION OF GESTATIONAL AGE AND/OR FETAL PULMONARY MATURITY IN PREPARATION FOR INDUCTION OF LABOR

Parameters
<i>Clinical criteria</i>
1. 39 weeks' gestation have elapsed since the first day of the last menstrual period in a woman with a regular menstrual cycle and no immediate antecedent use of oral contraceptives.
2. Fetal heart tones have been documented for 20 weeks' gestation by nonelectronic fetoscope or for 30 weeks by Doppler ultrasound.
<i>Laboratory determinations</i>
1. 36 weeks' gestation have elapsed since a positive serum human chorionic gonadotropin pregnancy test.
2. Ultrasound estimation of gestational age is considered accurate if it is based on crown-rump measurements obtained at 6 to 11 weeks' gestation or it is based on biparietal diameter measurements obtained before 20 weeks' gestation.
<i>Fetal pulmonary maturity</i>
According to the Guidelines for Perinatal care, ² term gestation can be confirmed if two or more of the above obstetric clinical or laboratory criteria are present. If term gestation cannot be confirmed, amniotic fluid analysis can be used to provide evidence of fetal lung maturity. A number of tests are available:
1. Lecithin/sphingomyelin (L/S) ratio >2.1 is regarded as evidence of pulmonary maturity.
2. Phosphatidylglycerol if present, fetal pulmonary maturity can be assumed.
3. TDx-FLM assay 70 mg surfactant per 1 g albumin is regarded as evidence of pulmonary maturity, <50 is regarded as evidence of pulmonary immaturity, and 50 to 69 is a borderline result and a secondary test is indicated (usually L/S ratio).
4. Saturated phosphatidylcholine (SPC) 500 ng/ml is regarded as evidence of fetal lung maturity (1,000 ng/ml in pregestational diabetic patients).

With recent technologic advances, the therapeutic armamentarium available to the obstetrician has increased, as has the temptation to intervene. A firm indication for delivery is a prerequisite for induction. In the absence of a clear indication, intervention may not be in the best interest of the mother or the fetus. Indications and contraindications for induction of labor at term are detailed in Table 13-4 and Table 13-5, respectively. Indications for delivery may be absolute or relative. If relative, a staged approach may be taken, and an attempted induction may be deferred or stopped if not successful. Having made the decision to induce labor, a number of factors should be documented to determine a patient's suitability for induction (Table 13-6).

Elective Induction of Labor

Elective induction of labor is defined as termination of pregnancy without an acceptable medical indication. In general, elective induction of labor should not be attempted simply for the convenience of the patient and practitioner, although such a strategy may be appropriate in select patients (such as patients who live a great distance from the hospital or who have a history of rapid labors). The major potential complication of elective induction is iatrogenic prematurity, which can be minimized by using strict criteria for gestational age (Table 13-3). Although it has traditionally been taught that elective induction of labor at term is associated

TABLE 13-5 -- CONTRAINDICATIONS FOR INDUCTION OF LABOR

Absolute Contraindications	Relative Contraindications
Maternal contraindications	
Active genital herpes	Cervical carcinoma
Serious chronic medical conditions	Grandmultiparity
Absolute cephalopelvic disproportion (such as women with pelvic deformities)	Uterine overdistention (secondary to polyhydramnios or multiple gestation)
Fetal contraindications	
Malpresentation (transverse or oblique lie)	Malpresentation (breech)
Extreme fetal compromise	Fetal macrosomia
Uteroplacental contraindications	
Cord prolapse	Low-lying placenta
Placenta previa	Unexplained vaginal bleeding
Vasa previa	Cord presentation
Prior high vertical hysterotomy ("classical" cesarean section)	Myomectomy involving the uterine cavity

with an increased incidence of cesarean delivery resulting from failed induction, [66], [67] more recent studies [68] [69] [70] have demonstrated that routine induction of labor at 41 weeks' gestation is not associated with an increased risk of cesarean section overall or in any subgroup of women, regardless of parity, state of the cervix, or method of induction. Prerequisites for elective induction of labor are similar to those for indicated induction.

Cervical Ripening

The success of a labor induction is determined, in large part, by the initial state of the cervix. When induction

TABLE 13-6 -- PATIENT ASSESSMENT PRIOR TO INDUCTION OF LABOR

Maternal Parameters	Fetal Parameters
Confirm indication for induction	Confirm gestational age
Review for contraindications to labor and/or vaginal delivery	Estimate fetal weight (clinically or by ultrasound)
Assess shape and adequacy of bony pelvis (clinical pelvimetry)	Determine fetal position
Assess cervical exam (Bishop score)	Confirm fetal well-being
Review risks and benefits of induction of labor with the patient and her family	Assess need for documentation of fetal lung maturity

of labor is attempted against an unfavorable cervix, the likelihood of a successful outcome is reduced. [71] [72] [73] [74] In 1964, Bishop [75] developed a scoring system to evaluate multiparous patients for elective induction of labor at term. The scoring system is based on the properties of the cervix that can be assessed clinically; namely, dilatation, effacement, station, consistency, and position (Table 13-7). Although the original goal of this scoring system was to prevent iatrogenic prematurity in the preultrasound era, it has subsequently been used to predict the success of induction of labor at term. [72], [76] When the cervical score exceeded 8, the incidence of vaginal delivery subsequent to induction was similar to that for spontaneous labor. Based on such studies, the ACOG has recommended that a Bishop score of greater than or equal to 6 be deemed favorable and likely to result in a successful induction of labor. [77] It would seem logical, therefore, that enhancement of cervical maturation would be an appropriate first step toward induction of labor when the cervix is unfavorable. Indeed, preinduction cervical maturation is associated with fewer failed inductions, fewer serial inductions, lower fetal and maternal

morbidity, a shorter hospital stay, lower medical cost, and (possibly) a lower rate of cesarean delivery. [73], [74], [78], [79]

Cervical maturation (or cervical "ripening") describes a complex series of hormonally mediated biochemical events that alter both cervical collagen and ground substance, resulting in a softer and more pliable cervix prior to induction of labor. [80] A number of agents are available to facilitate cervical maturation (Table 13-8).

Methods of Cervical Maturation and Labor Induction

The choice of which method to use to promote cervical maturation and to induce labor should be individualized. A single technique is rarely effective on its own, and a combination of maneuvers may be required. The options available for induction of labor are reviewed in Table 13-9.

Nonpharmacologic Methods

Nonpharmacologic methods for cervical maturation and/or labor induction include surgical techniques (stripping of the membranes, amniotomy) and mechanical dilatation.

STRIPPING OF THE MEMBRANES.

Stripping or sweeping of the fetal membranes refers to digital separation of

the chorioamniotic membrane from the wall of the cervix and lower uterine segment, and was first reported for induction of labor at term in 1810. [81] In order for stripping of the membranes to be successful, the vertex should be well applied to the cervix and the cervix must be dilated sufficiently to admit the practitioner's finger. Stripping of the membranes is believed to work by release of endogenous prostaglandins from the membranes and adjacent decidua. [82] Indeed, levels of 13,14-dihydro-15-keto-prostaglandin F₂, the primary metabolite of decidual PGF₂, increase markedly in the maternal circulation within a short time after stripping of the membranes and/or amniotomy. [83] Prostaglandins may be involved in stimulating myometrial contractions and in the onset of labor. In addition, manual exploration of the cervix may trigger an autonomic neural reflex, the Ferguson reflex, which promotes the release of oxytocin from the maternal posterior pituitary, [84] although the existence of such a reflex remains controversial. Several trials have demonstrated a benefit of this procedure, [85] [86] [87] whereas others have not been able to reproduce these favorable results. [88] A recent meta-analysis suggests that sweeping of the membranes is able to reduce the interval to spontaneous onset of labor, but there is no evidence of a reduction in operative vaginal delivery, cesarean section rates, or maternal or neonatal morbidity. [89] Since the effects of membrane stripping are not predictable and the efficacy of this method has not been proven, it should not be relied on as the sole method of labor induction.

AMNIOTOMY.

The technique of amniotomy, artificial rupture of the membranes, involves perforation of the chorioamniotic membranes using either a toothed clamp (Allis) or a plastic hook (Amniohook, Hollister, Chicago, IL). Before amniotomy is performed, the vertex should be seen to be engaged in the pelvis and well applied to the cervix to prevent prolapse of the umbilical cord. The membranes should be swept away from the cervix and the instrument of choice gently applied to the membranes and turned so as to hook or scratch the membranes. The opening in the membranes should be widened by blunt dissection using the examining finger to retract the membranes over the vertex without dislodging the vertex. The amount and character of released amniotic fluid should be noted. Since a degree of cervical dilatation is necessary to perform the procedure, amniotomy can only be carried out once the cervix is favorable.

Amniotomy was introduced into clinical practice by Kreis in 1929. [90] Despite its wide acceptance, there is a paucity of scientific literature on the efficacy of amniotomy in inducing labor. In patients with a favorable cervical examination (a high Bishop score) at term, amniotomy alone has been reported to be effective in inducing labor in 88 percent of cases [91] and to shorten the interval to delivery by around 0.8 to 2.3 hours. [92], [93] There are a small number of controlled trials in the literature comparing amniotomy alone to combined amniotomy and oxytocin. [94] [95] [96] [97] All of these trials report a shorter induction to delivery time with combined amniotomy and oxytocin, with no apparent difference in safety profile. Whether this reduction in time to delivery translates into an improvement in clinical outcome is not clear. [98] The timing of oxytocin augmentation, however, remains controversial and should be individualized.

Amniotomy is associated with benefits and risks. Advantages of amniotomy include (1) a high success rate for induction of labor; (2) observation of the amniotic fluid for blood or meconium; and (3) ready access to the intrauterine cavity and to the fetus for placement of an intrauterine pressure catheter, a fetal scalp electrode, or for fetal scalp blood sampling. Although early amniotomy has been shown to reduce the incidence of labor dystocia and the length of labor, it does not appear to lower the rate of cesarean delivery. [99], [100], [101] Complications of amniotomy include (1) umbilical cord prolapse, (2) fetal injury, (3) prolonged rupture of the membranes and resultant increased risk of intra-amniotic infection, (4) adverse change in fetal position as amniotomy is associated with a greater frequency of malposition and asynclitism, [102] and (5) rupture of vasa previa and subsequent fetal hemorrhage. With due caution, many of the risks can be avoided. The fetal heart rate should be monitored electronically or by auscultation during and immediately after amniotomy. A transient fetal tachycardia is common after amniotomy, but decelerations or bradycardia are rare in the absence of overt or occult cord prolapse. Contraindications to early amniotomy include maternal infection with human immunodeficiency virus, an active perineal herpes simplex viral infection, and possibly viral hepatitis.

MECHANICAL DILATORS.

Mechanical dilators all rely on release of endogenous prostaglandins from the membranes and maternal decidua to promote cervical maturation and/or labor induction. When compared with no preinduction cervical ripening, an intracervical balloon catheter has been shown to significantly shorten the induction to delivery interval and to increase the rate of vaginal delivery.^[98] A more recent randomized comparison between intracervical PGE₂ gel and intracervical Foley catheter for cervical ripening at term showed them to be equally effective, with no difference in side-effect profile, intrapartum complications, or mode of delivery.^[99] Hygroscopic dilators including laminaria (desiccated seaweed), Dilapan (polyacrylonitrile), and lamitel (magnesium sulfate in polyvinyl alcohol) rely on absorption of water to swell and forcibly dilate the cervix, and have been found to be at least as effective in promoting cervical maturation as PGE₂ gel.^{[100] [101] [102]} A

377

significant disadvantage of mechanical dilators, however, is patient discomfort both at the time of insertion and with progressive cervical dilatation. With equally efficacious pharmacologic agents available, there is no obvious advantage to the routine use of mechanical dilators. However, in specific clinical circumstances where prostaglandins should be avoided (such as glaucoma or pulmonary disease) or where other products are unavailable because of supply or cost, mechanical dilators can be used both safely and effectively.

Pharmacologic Methods

Pharmacologic methods available for cervical maturation and/or induction of labor are summarized in [Table 13-8](#) and [Table 13-9](#), respectively.

PROSTAGLANDINS.

The use of prostaglandins to induce cervical ripening at term was introduced in the 1970s in an attempt to mimic events that occur during spontaneous labor.^{[103] [104] [105]} Prostaglandins are a family of 20-carbon bioactive lipids. Human uterine tissues are selectively enriched with arachidonic acid, an essential fatty acid and the obligate precursor of prostaglandins of the 2 series.^[106] An increase in the biosynthesis of prostaglandins of the E and F series in the uterus is a consistent element in the transition into labor, both at term and preterm.^{[106] [107] [108]} Prostaglandins are predominantly paracrine/autocrine hormones, meaning that they act locally at their site of production on contiguous cells. Their half-life in the peripheral circulation is approximately 1 to 2 minutes. The production of prostaglandins is discretely compartmentalized within the uterus. The maternal decidua is the main source of PGF₂ in the uterus; the fetal membranes, especially the amnion, produce primarily PGE₂; and the myometrium produces predominantly prostacyclin (PGI₂).^[109] In vitro, both PGF₂ and PGE₂ cause myometrial contractions. In vivo, however, decidual PGF₂ acts primarily to promote myometrial contractility, whereas PGE₂ appears to be important for cervical maturation. Indeed, exogenous PGE₂ preparations have been shown to be more potent at promoting cervical maturation than PGF₂.^{[104] [109]} Unlike oxytocin, the response of the uterus to prostaglandins does not change significantly throughout gestation. This has led to the widespread use of prostaglandins to effect midtrimester pregnancy termination or induction of labor following intrauterine death remote from term.

Initial clinical trials using transvaginal PGE₂ gel preparations (240 to 2,000 mg) to promote cervical maturation 1 day prior to induction of labor suggested that the rate of failed induction, defined as the inability to establish labor, was only 0.8 to 6.3 percent.^{[109] [110] [111] [112] [113]} In a recent meta-analysis of all randomized, placebo-controlled trials on the effect of prostaglandins on preinduction cervical ripening and on subsequent induction success, Keirse^[114] demonstrated that PGE₂ administered by any route improved the rate of spontaneous vaginal delivery and decreased the rate of both cesarean and operative vaginal delivery. Gastrointestinal side effects from PGE₂ are reported with all routes of administration, but appeared to be minimized with vaginal administration. Local application of PGE₂ gel has now become the gold standard for cervical ripening in clinical practice. The most commonly used transvaginal PGE₂ preparation is 0.5 mg dinoprostone gel (Prepidil), which received Food and Drug Administration (FDA) approval for this indication in the United States in 1992. Placement of PGE₂ within the cervical canal will have a more marked effect on cervical maturation than placement in the posterior fornix of the vagina, but with no significant difference in labor delivery outcomes.^{[115] [116]} In 1995, a sustained release preparation of 10 mg PGE₂ (Cervidil) was approved by the FDA. The advantage of this preparation is that, unlike the gel, it can be easily removed if clinical complications such as tachysystole or uterine hypertonus ensue.^[117]

More recent attention has been focused on the use of the PGE₁ analogues such as misoprostol (Cytotec) for cervical ripening. Although such preparations are FDA approved only for the treatment of peptic ulcer disease and have not received approval for use during pregnancy, they have been used for induction of labor. They can be administered either transvaginally (50 µg every 3 hours to a maximum of six doses,^[118] or 25 µg every 3 hours to a maximum of eight doses^[119]) or orally (50 µg every 4 hours^[120]). To date, there has been no evidence of teratogenic or carcinogenic effects in animal studies.^[121] Results of clinical trials suggest that misoprostol is as effective as PGE₂ for cervical ripening and labor induction,^{[118] [119] [120]} and at least two groups have found it to be more effective.^{[122] [123]} The cost of misoprostol is a fraction that of any of the PGE₂ preparations. The optimal dosage regimen for PGE₁ preparations has yet to be determined. However, the less-frequent, higher dosage schedules appear to be associated with shorter intervals to delivery, less requirement for oxytocin infusion, and fewer failed inductions.^[124] On a cautionary note, the authors would like to emphasize that this drug is not approved by the FDA for use in pregnancy, and that a higher prevalence of tachysystole, meconium passage, and possibly uterine rupture has been reported with its use.^[119] Misoprostol is not recommended for patients with a previous cesarean birth due to the possibility of uterine rupture.

Oxytocin

Oxytocin is a potent endogenous uterotonic agent that is capable of stimulating uterine contractions at intravenous infusion rates of 1 to 2 mIU/min at term.^[125] Maternally

378

derived oxytocin is a peptide hormone synthesized in the hypothalamus and released from the posterior pituitary in a pulsatile fashion. Its biologic half-life is approximately 3 to 4 minutes, but appears to be shorter when higher doses are infused. Oxytocin is inactivated largely in the liver and kidney. During pregnancy, oxytocin is degraded primarily by placental oxytocinase. Concentrations of oxytocin in the maternal circulation do not change significantly during pregnancy or prior to the onset of labor, but do rise late in the second stage of labor.^{[125] [126]} Studies on fetal pituitary oxytocin production, the umbilical arteriovenous difference in plasma oxytocin, amniotic fluid oxytocin levels, and fetal urinary oxytocin output demonstrate conclusively that the fetus secretes oxytocin that reaches the maternal side of the placenta.^{[125] [127]} Furthermore, the calculated rate of oxytocin secretion from the fetus increases from a baseline of 1 mIU/min prior to labor to around 3 mIU/min after spontaneous labor, a level similar to that normally administered to women to induce labor at term (2 to 8 mIU/min). Specific receptors for oxytocin are present in the myometrium, and there appear to be regional differences in oxytocin receptor distribution, with large numbers of receptors in the fundal area and few receptors in the lower uterine segment and cervix.^[128]

Myometrial oxytocin receptor concentrations increase on average 100- to 200-fold during pregnancy, reaching a maximum during early labor.^{[125] [126] [129] [130]} This rise in receptor concentration is paralleled by an increase in uterine sensitivity to circulating levels of oxytocin. Specific high-affinity oxytocin receptors have also been isolated from human amnion and decidua parietalis, but not decidua vera.^{[125] [129]} Neither amnion nor decidual cells are contractile, and the action of oxytocin on these tissues remains uncertain. It has been suggested that oxytocin plays a dual role in parturition. It may act directly through both oxytocin receptor-mediated and nonreceptor, voltage-mediated calcium channels to affect intracellular biochemical pathways and promote uterine contractions. It may also act indirectly through stimulation of amniotic and decidual prostaglandin production.^{[128] [131] [132]} Indeed, induction of labor at term is successful only when the oxytocin infusion is associated with an increase in PGF₂ production, in spite of seemingly adequate uterine contractions in both induction failures and successes.^[129]

Oxytocin in the form of crude pituitary extracts has been used in clinical obstetrics since the early 1900s. Intravenous oxytocin for induction of labor was initiated by Theobald et al.^[133] in 1948. Oxytocin was subsequently successfully purified in 1951, and synthetic preparations became available 2 years later. Only intravenous preparations are approved by the FDA for induction and augmentation of labor. Continuous low-dose (1 to 4 mIU/min) oxytocin infusion has been shown to be effective in promoting cervical maturation,^[134] and appears to be as effective as PGE₂ gel preparations in this regard.^[135] High-dose oxytocin significantly shortens

labor without any adverse fetal effect^[136] (see Active Management of Labor, below). With continuous intravenous oxytocin infusion, plasma oxytocin concentrations increase during the first 20 to 30 minutes. After 30 minutes, the concentration of oxytocin reaches a steady state in maternal plasma and does not change significantly. Because of its short half-life, plasma levels of oxytocin fall rapidly after the intravenous infusion is discontinued.^[137]

Overall, PGE₂ gel is probably a better agent for preinduction cervical ripening than oxytocin, being equally if not more effective, easier to administer, and possibly safer for the fetus.^[139] The incidence of neonatal hyperbilirubinemia, for example, is higher with oxytocin than with prostaglandins.^[139] However, the use of continuous low-dose oxytocin is still considered safe, and is a reasonable treatment alternative in most circumstances.

Progesterone Receptor Antagonists

RU-486 (Mifepristone) is a competitive steroid receptor antagonist that affects the action of both progesterone and glucocorticoids. ZK98299 (Onapristone) is a more selective progesterone receptor antagonist. Pretreatment with RU-486 (200 mg vaginally daily for 2 days) prior to planned induction of labor has been shown to produce cervical maturation, to cause uterine contractions and cervical dilatation,^[140]^[141]^[142]^[143] to diminish oxytocin requirements in labor,^[144] and to lower the cesarean section rate.^[142] More recently, a placebo-controlled study using RU-486 for labor induction after cesarean delivery demonstrated that it is an effective agent at term and, furthermore, can diminish oxytocin requirements in labor.^[145] There were no differences in terms of mode of delivery or neonatal outcome. Further clinical studies are awaited.

MANAGEMENT OF ABNORMAL LABOR AND DELIVERY

Augmentation of Labor at Term

Abnormalities of the first stage of labor may be either protraction or arrest disorders, and many occur during the latent or active phases of the first stage (Fig. 13-16). When such an abnormality is noted and uterine activity is suboptimal, administration of an oxytocic agent is recommended. Care should be taken to exclude other possible contributing factors such as malpresentation, especially in multiparous patients.

379

Intravenous oxytocin infusion is the agent of choice. Variability in patient sensitivity and response to intravenous oxytocin is the rule rather than the exception. As such, the recommended rate of oxytocin administration is that which produces contractions every 2 to 3 minutes, lasting 60 to 90 seconds with a peak intrauterine pressure of 50 to 60 mm Hg and a resting uterine tone of 10 to 15 mm Hg if intrauterine pressure monitoring is used. Dosage may vary from 0.5 to 30 to 40 mIU/min of oxytocin. Control of the intravenous dose is best achieved by using a constant-infusion pump. A number of different low-dose oxytocin protocols have been investigated.^[139], ^[146], ^[147] Augmentation is usually started at 0.5 mIU/min, and the rate is doubled every 15 to 20 minutes until adequate uterine contractions are observed. Approximately 30 to 40 minutes are needed for the full effect of an increase in dosage to be reflected in the contraction pattern. A slow rate of increase in oxytocin administration is as effective for inducing labor as a fast rate of increase, while at the same time minimizing oxytocin requirements.^[146] Similar results are seen with pulsatile oxytocin administration.^[147] Recent studies have demonstrated that, when used in patients demonstrating a protraction disorder, oxytocin infusion rates greater than 6 mIU/min are rarely required.^[148] It is unusual for a patient to require more than 30 to 40 mIU/min of oxytocin to achieve adequate uterine contractions, and some authorities recommend a maximal rate of 20 mIU/min.^[149], ^[150] As labor progresses, the frequency and intensity of contractions may increase, and the oxytocin infusion may need to be reduced.

The decision to initiate oxytocin infusion in the setting of a protraction disorder with adequate contractions is controversial. Nevertheless, it is clear that the use of oxytocin infusion is associated with a high rate of success. Overall, around 80 percent of patients with documented disorders of labor will respond to oxytocin infusion with subsequent progression of labor and vaginal delivery.^[56], ^[151]

The advantages of intravenous oxytocin lie in its cost, its familiarity for the clinician, and its short half-life, which allows for titration of infusion rate against uterine contractions. Monitoring of uterine contractions and fetal heart rate is recommended throughout the induction and is best accomplished with continuous electronic monitoring. A number of complications of intravenously administered oxytocin are described.

Uterine Hyperstimulation

The most frequently encountered problem is *uterine hyperstimulation*, which refers to excessive frequency of contractions (polysystole) or increased uterine tone (hypertonia). Uterine hyperstimulation may produce a non-reassuring fetal heart rate tracing, placental abruption, or uterine rupture. The use of electronic fetal monitoring has increased the early detection of these potentially damaging maternal or fetal complications. The detection of fetal heart rate abnormalities secondary to uterine hyperstimulation should prompt discontinuation of the oxytocin infusion, positioning of the patient on her left side, and oxygen administration.

Water Intoxication

Oxytocin is structurally and functionally related to vasopressin (antidiuretic hormone). Although rarely seen in low-dose infusion protocols, high-dose oxytocin infusions (30 to 40 mIU/min) have been associated with excessive fluid retention caused by binding of oxytocin to vasopressin and oxytocin receptors in the kidney leading to *water intoxication*, characterized by hyponatremia, confusion, convulsions, coma, congestive heart failure, and death. A slight elevation in blood pressure may also be noted. Fluid overload and hyponatremia can be prevented by strict recordings of fluid intake and output, use of balanced salt solutions, and by avoiding prolonged administration of high-dose oxytocin infusion.

Hypotension

Bolus injections of oxytocin may cause *hypotension*. When administered intravenously as dilute solutions at recommended rates, few cardiovascular side effects are noted.

Uterine Rupture

Uterine rupture has been associated with excessive oxytocin administration, although how much oxytocin constitutes "excessive" is not clear. Other risk factors for uterine rupture include prior uterine surgery, fetal malpresentation, grandmultiparity, and a markedly overdistended uterus. After uterine rupture, contractions may cease even if the oxytocin infusion is continued.

Prostaglandins have been compared with oxytocin infusion for augmentation of labor at term. These studies have generally failed to demonstrate a superiority of prostaglandins over oxytocin in terms of efficacy.^[139], ^[139], ^[152] Since prostaglandins have more side effects and are more difficult to titrate, it is unlikely that prostaglandins will replace oxytocin for augmentation of labor.

Episiotomy

Episiotomy is an incision into the perineal body made during the second stage of labor to facilitate delivery. It is still performed in over 50 percent of vaginal deliveries in the United States.^[153] ^[154] ^[155] ^[156] Although there is general

380

agreement that episiotomy is indicated (1) in cases of arrested or protracted descent, (2) in association with an instrumental delivery, or (3) to expedite delivery in the setting of fetal heart rate abnormalities, the use of prophylactic episiotomy is widely debated. Cited advantages of prophylactic episiotomy include substitution of a straight surgical incision for a ragged spontaneous laceration, reduction in the duration of the second stage, and reduction of trauma to the pelvic floor musculature

that would reduce the likelihood of subsequent pelvic relaxation. However, the data to support these contentions are limited. ^[157]

Episiotomy can be classified into two broad categories: median and mediolateral. *Median (midline) episiotomy* refers to a vertical midline incision from the posterior forchette towards the rectum, and is preferred in the United States. The incision should be performed when the fetal head has distended the vulva to 2 to 3 cm, and once adequate analgesia, either local or regional, has been achieved. A straight Mayo scissors is generally used to perform the episiotomy, although a scalpel may be used. Care should be taken to displace the perineum from the fetal head. The size of the incision will depend on the length of the perineum but is generally around one half of the length of the perineum, and should be extended vertically up the vaginal mucosa for a distance of 2 to 3 cm. Every effort should be made to avoid injury to the anal sphincter. Complications of median episiotomy include increased blood loss, especially if the incision is made too early, fetal injury, and localized pain. Furthermore, in contrast to the stated goal of reducing perineal trauma, recent studies have demonstrated conclusively that median episiotomies are associated with an increased incidence of third- and fourth-degree lacerations (see Chapter 17). ^[153], ^[156] Such injuries are associated with a high incidence of long-term incontinence and pelvic prolapse. *Mediolateral episiotomy* is performed by incision at a 45 degree angle from the inferior portion of the hymeneal ring. The length of the incision is less critical than with median episiotomy, but longer incisions require more lengthy repair. The side to which the episiotomy is performed is usually dictated by the dominant hand of the practitioner. Such incisions are favored in Europe, and do not appear to increase the incidence of third- and fourth-degree lacerations. Indeed, a number of studies suggest that such procedures are less likely to be associated with damage to the anal sphincter and the rectal mucosa. Since such incisions appear to protect against severe perineal trauma, they are the procedure of choice for women with inflammatory bowel disease because of the critical need to prevent rectal injury. Chronic complications such as unsatisfactory cosmetic results and inclusions within the scar may be more common with mediolateral episiotomies, and blood loss is greater. Although it is often said that mediolateral episiotomy causes more pain in the postpartum period than medial episiotomy and that they are associated with prolonged dyspareunia, the literature does not support this statement. ^[158] Bilateral mediolateral episiotomies are rarely, if ever, indicated. *Anterior episiotomy* is rarely performed, and is reserved for women with prior female genital mutilation or female circumcision.

Primary approximation of the episiotomy affords the best opportunity for functional repair, especially if there is evidence of rectal sphincter injury. The external anal sphincter should be repaired by direct apposition or overlapping the cut ends and securing them using interrupted sutures (see Chapter 17).

In view of the lack of objective evidence of benefit of prophylactic episiotomy and the data suggesting that median episiotomy is associated with an increased incidence of severe perineal trauma, prophylactic median episiotomy should be discouraged.

Assisted Vaginal Delivery

Assisted vaginal delivery refers to any operative procedure designed to effect vaginal delivery, and includes forceps delivery and vacuum extraction. Randomized studies comparing forceps with vacuum have not shown a significant difference in success rate. ^[159] ^[160] ^[161] The choice of which method to use is dependent largely on clinician preference and experience. Manual rotation is described, but results vary considerably.

Forceps-Assisted Vaginal Delivery

Forceps were invented by the Chamberlain family in the 17th century in Europe. Obstetric forceps vary greatly in design, but all consist of two separate blades that are inserted into the vagina sequentially. Each half consists of the blade proper, which has a cephalic curvature designed to be applied to the fetal head, a shank, and a handle. The halves are joined by a lock usually located at the junction of the shanks and the handle. The angle of the blade to the shank defines the pelvic curvature, designed to compensate for the curvature of the birth canal. Several different types of forceps have since been developed (Fig. 13-17). These can be classified into three broad categories according to their intended use.

"Classical" forceps have a cephalic curvature, a pelvic curve yielding a concave longitudinal axis, and an "English" lock in which the articulation is fixed. Examples include (1) Simpson forceps, which have fenestrated blades and separated (nonoverlapping) shanks; (2) Tucker-McLane forceps, which have solid (nonfenestrated) blades and overlapping shanks; and (3) Elliot forceps, which have fenestrated blades, overlapping shanks, and a greater cephalic curvature. Forceps in

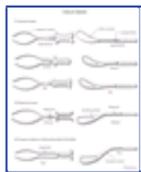

Figure 13-17 Classification of forceps.

this category are primarily intended for use when the fetal head does not require rotation prior to delivery, but they may be used for rotation as in the Scanzoni-Smellie maneuver.

Rotational forceps have a cephalic curvature to grasp the fetal head, but no pelvic curvature and a "sliding" lock, which permits movement between the forceps halves along the longitudinal axis of the shanks to correct for asynclitism of the fetal head. Examples include Kielland and Barton forceps. Kielland forceps also have blades that lie below rather than above the plane of the shanks. This modification, along with the lack of pelvic curvature, facilitates rotation of the forceps around a point rather than around a circle as is required with the classical instruments. Once the fetal head has been rotated into the anteroposterior position, it is recommended that the rotational forceps be replaced by classical forceps, as the pelvic curvature of the classical forceps will minimize perineal trauma. Barton forceps were designed for use in a platypelloid pelvis, since they allow traction of the fetal head in a transverse position until the introitus has been reached, but are rarely, if ever, used in modern obstetric practice.

Forceps designed to assist vaginal breech deliveries such as Piper forceps lack a pelvic curve and have blades below the plane of the shanks. These modifications are designed to facilitate application to the aftercoming head of the breech. In addition, the shanks are elongated, which allows the practitioner to rest the body of the breech on the shanks while effecting delivery of the aftercoming head.

Forceps deliveries are classified according to the station of the fetal head at the time of application. In 1988, the Committee on Obstetrics: Maternal and Fetal Medicine of the ACOG ^[162] proposed a new classification of obstetric forceps deliveries (Table 13-10) that correlates better with short-term maternal and neonatal morbidity than did the older classifications. ^[40], ^[163] The old category of "high-forceps," in which forceps were placed with the fetal head floating and ballotable above the brim of the true pelvis, has been abandoned because of excessive fetal risk.

TABLE 13-10 -- CLASSIFICATION OF OPERATIVE VAGINAL DELIVERIES

Type of Procedure	Criteria
Outlet forceps	Scalp is visible at the introitus without separating the labia
	Fetal skull has reached the level of the pelvic floor
	Sagittal suture is in the direct anteroposterior diameter or in the right or left occiput anterior or posterior position
	Fetal head is at or on the perineum
	Rotation is 45 degrees
Low forceps	Leading point of the fetal skull (station) is +2 or more but has not as yet reached the pelvic floor

	1. Rotation is 45 degrees
	2. Rotation is > 45 degrees
Midforceps	The head is engaged in the pelvis but the presenting part is above +2 station
High forceps	(Not included in this classification)

Adapted from American College of Obstetricians and Gynecologists: Operative vaginal delivery, ACOG Technical Bulletin No. 196. Washington, DC, American College of Obstetricians and Gynecologists, 1994.

Few areas in obstetrics have been surrounded with as much controversy as the use of obstetric forceps. The ACOG has concluded that the use of elective outlet forceps to shorten the second stage of labor does not adversely affect either the mother or the fetus.^[40],^[164] The use of low or midforceps deliveries, however, should be limited to women with an absolute indication for assisted vaginal delivery (Table 13-11). Midforceps deliveries should be performed only by competent operators and after careful consideration of alternative approaches (such as oxytocin administration, cesarean delivery, or simply expectant management) and of the potential fetal risks. Cases in which instrumental rotation is considered may prove amenable to digital or manual rotation.

Once the decision has been made to proceed with forceps delivery, several criteria (summarized in Table 13-12)

TABLE 13-11 -- INDICATIONS FOR OPERATIVE VAGINAL DELIVERY

Maternal Indications	Fetal Indications	Other Indications
Maternal exhaustion	Nonreassuring fetal testing	Prolonged second stage of labor
Inadequate maternal expulsive efforts (such as women with spinal cord injuries or neuromuscular diseases)		Nulliparas: 2 h without regional analgesia, 3 h with regional analgesia
Need to avoid maternal expulsive efforts (such as women with certain cardiac or cerebrovascular diseases)		Multiparas: 1 h without regional analgesia, 2 h with regional analgesia
? Lack of maternal expulsive effort		? Elective shortening of the second stage of labor using outlet forceps

Data from American College of Obstetricians and Gynecologists: Operative vaginal delivery, ACOG Technical Bulletin No. 196. Washington, DC, American College of Obstetricians and Gynecologists, 1994.

383

TABLE 13-12 -- PREREQUISITES FOR OPERATIVE VAGINAL DELIVERY: A NUMBER OF CRITERIA NEED TO BE FULFILLED PRIOR TO ATTEMPTING OPERATIVE VAGINAL DELIVERY

Maternal Criteria	Fetal Criteria	Uteroplacental Criteria	Other Criteria
Adequate analgesia	Vertex presentation	Cervix fully dilated	Experienced operator who is fully acquainted with the use of the instrument
Lithotomy position	The fetal head must be engaged in the pelvis	Membranes ruptured	The capability to perform an emergency cesarean delivery if required
Bladder empty	The position of the fetal head must be known with certainty	No placenta previa	
Clinical pelvimetry must be adequate in dimension and size to facilitate an atraumatic delivery	The station of the fetal head must be +2		
Verbal or written consent	The attitude of the fetal head and the presence of caput succedaneum and/or moulding should be noted		

must be met before application of the forceps. The patient should be placed in the modified lithotomy position and cleansed and draped in the usual fashion. The bladder should be emptied by catheterization. Adequate analgesia is mandatory for both maternal indications and fetal safety. Estimated fetal weight should be compatible with a high probability of successful vaginal delivery. A thorough examination of the fetal presenting part and characteristics of the maternal pelvis should follow. Exact knowledge of fetal position, station, and degree of asynclitism is essential to proper application. A "phantom application" should be performed by the operator by positioning the forceps in front of the perineum in the correct position of the final application. The phantom application aids in the evaluation of proper placement. There are three broad categories of forceps deliveries, and the technique used to place the forceps and to effect delivery is different for each.

Nonrotational forceps delivery is delivery that is effected without rotation or with rotation of less than 45 degrees (Fig. 13-18). Following separation of the blades of the classical forceps, two fingers of the operator's right hand should be placed transvaginally along the fetal head to protect the vaginal tissues. The left forceps blade is then passed over the palmar aspect of the fingers in the following manner: the handle is held loosely by the left hand of the operator so that the initial position of the blade is essentially vertical over the maternal pubis; the handle is then allowed to drop, almost under its own weight, in a wide arc as the blade is guided along the parietal eminence of the fetal head by the operator's right (intravaginal) hand. The right blade is then applied in a similar manner. The handles are then locked comfortably together. All classical forceps are designed such that the lock will articulate only if the left forceps blade is placed prior to the right-handled blade. Before traction is initiated, it is mandatory that the application be checked for correct positioning. This will ensure that the compressive and traction forces to the fetal skull will occur in the biparietal or bimalar position thereby minimizing cranial or neurologic damage. Proper application is determined by assessing the position of the forceps in relation to three landmarks on the fetal skull, the posterior fontanelle, the sagittal suture, and the parietal bones. An illustration of proper application is shown in Fig. 13-19. If rotation is required, it should be performed at this time. The fetal head should be flexed by lowering the handles of the forceps, and the handles rotated in an arc until the sagittal suture rests in the direct anteroposterior position. After rotation, the position of the forceps should be rechecked before traction. After application of the forceps, delivery is accomplished according to the principle of axis traction. The pelvis is curved in a J shape, and it is in this direction that the series of force vectors should be applied. When the fetal head lies at the midpelvis, the initial traction is directly posteriorly at a 45-degree angle. Once the head has reached the pelvic floor, the traction is directed horizontally and, finally, upward (anteriorly) to facilitate expulsion of the fetal head by extension. Such force vectors can be achieved either manually using the Saxtorph-Pajot maneuver, in which one hand pulls downwards on the handles while the other hand directs the traction upward or downward at the level of the shanks, or by axis-traction attachments.

Scanzoni-Smellie maneuver refers to complete instrumental rotation of the fetal head from an occiput posterior to anterior position. This was described first by Smellie in 1752 and subsequently modified by Scanzoni in 1853.^[165] Classical forceps are placed over the occiput posterior as detailed above. The forceps are then locked and the handles elevated to flex the fetal head. Rotation from the

384

occiput posterior to anterior position is facilitated by dislodging the fetal head very slightly upwards. *The head should not be disengaged from the pelvis.* Rotation should be carried out in a wide arc toward the fetal back (commonly in the direction of the shortest distance to the symphysis pubis) to avoid cervical spine injury. Once the occiput anterior position is reached, the blades will be upside down with the pelvic curve facing the sacrum. To facilitate traction and prevent maternal perineal trauma, it is then necessary to replace the blades in the correct position before traction is applied. In the original description, both blades were removed and replaced. On occasion, however, the head would rotate back toward the original position before reapplication could be attempted. For this reason, the anterior blade is initially removed and repositioned while the posterior blade is temporarily retained to "splint" the head in the anterior position. Thereafter, the posterior blade is removed and repositioned. After the head has been rotated to the occiput anterior position, the reapplication is checked and, if found to be satisfactory, traction is begun. An alternative to the Scanzoni-Smellie maneuver, which is currently the preference of most clinicians, is to deliver the fetus in the direct occiput posterior position.

Rotational forceps deliveries should be reserved for practitioners with the requisite experience. Indications for rotational forceps are limited. The classic indication is arrest of descent in the occiput transverse position (so-called deep transverse arrest), which is often accompanied by asynclitism of the fetal head. In this setting, rotational forceps (such as Kielland forceps) are able to correct the asynclitism (because of their sliding lock) and rotate the fetal head to the anteroposterior position. The same criteria should be fulfilled as for classic forceps (Table 13-12). A "phantom application" of the forceps should be performed with the knobs on the posterior surfaces of the handles facing the occiput. The anterior blade is applied first in one of three ways: (1) the *wandering technique*, in which the blade is held vertically with the handle pointing upwards (the blade is then inserted posteriorly and wandered 180 degrees across the fetal face to its anterior position); (2) the *direct technique*, in which the blade is held vertically with the handle pointing downwards towards the floor, and inserted directly over the parietal eminence of the fetal head with the handle coming to rest in the horizontal position; and (3) the *classical technique* used by Kielland in his original description in 1916,^[166] in which the blade is held vertically with the handle pointing towards the ceiling. The blade is then slipped under the symphysis pubis until it comes to rest with the handle in the horizontal position and the cephalic curvature of the blade facing upwards. The blade is then rotated 180 degrees until the cephalic curve of the forceps articulates with the head of the fetus. This application is of historical interest only, and should not be used

because of the high incidence of maternal injury. After the anterior blade is in place, the posterior blade is held vertically with the handle pointing toward the ceiling and inserted in the standard fashion. Keeping the handles depressed down against the perineum, the handle tips are brought into alignment correcting the asynclitism and the head is rotated to the anteroposterior position, either OA or OP. The position is then rechecked, and traction is applied with contractions. Some practitioners recommend replacing the rotational forceps with classic forceps after the rotation is complete to facilitate traction and delivery of the head.

Vaginal breech delivery is reviewed in detail in Chapter 16. Delivery of the aftercoming head of the breech can be facilitated by the application of forceps. The Piper forceps were designed specifically to assist the obstetrician in delivering the aftercoming head of the breech. These forceps are placed directly on either side of the fetal head after the body has been delivered, and the body is draped over the elongated shanks. A controlled delivery of the head is then effected by raising the handles of the forceps to facilitate flexion of the fetal head. This instrument is particularly useful if the obstetrician is not assisted. If an assistant is available to lift the legs of the breech, it may be easier to use classic forceps to flex the aftercoming head of the breech.

Figure 13-18 Stepwise approach to application of obstetric forceps.

Figure 13-19 Proper application of obstetric forceps. (From O'Brien WF, Cefalo RC: *Labor and delivery*. In Gabbe SG, Niebyl JR, Simpson JL [eds]: *Obstetrics: Normal and Problem Pregnancies*, 3rd ed. New York, Churchill Livingstone, 1996 p 377, with permission.)

Following delivery, the fetus and the maternal perineum should be carefully examined. Common fetal findings include facial bruising and, on occasion, facial laceration. Facial nerve palsy, skull fractures, cervical spine injuries, and intracranial hemorrhage are extremely rare, and almost never seen with low or outlet forceps.^[164] Maternal perineal injury including sulcus tears and third- and fourth-degree lacerations are increased with forceps deliveries, especially if a forceps rotation is performed.

Vacuum-Assisted Vaginal Delivery

Vacuum extraction was first described by James Yonge in 1705,^[167] well before the invention of the forceps. First popularized by Malmström^[168] during the mid-1950s, the use of vacuum extraction-assisted delivery has become widespread in Europe. The first classical Malmström vacuum extractor or "ventouse" used a metal disk-shaped cup (the "M" cup) through which a vacuum of up to 0.8 kg/cc² is applied to the fetal scalp. The suction induces an artificial caput succedaneum or chignon within the cup to which a traction force is applied in concert with uterine contractions. Current instruments are disposable and made of plastic, polyethylene, or silicone. There are two general types: those with a firm, mushroom-shaped cup similar to the M cup, the rigid cup available in three sizes (40, 50, and 60 mm); or with a pliable, funnel-shaped cup, the soft cup. Manual or electronically operated vacuum sources are available.

A number of technical considerations should be borne in mind when performing a vacuum extraction-assisted delivery. The suction cup should be placed on the fetal scalp symmetrically astride the sagittal suture with the posterior margin of the cup around 1 to 3 cm anterior to the posterior fontanelle, the so-called median flexing point. It should not be placed over the fontanelle. This placement will promote flexion of the fetal head with traction. After application, a low suction (100 mm Hg) is applied to establish a vacuum of around 0.2 kg/cc² as the cup is held in place. After ensuring that no maternal soft tissue is trapped between the cup and the fetal head, suction is increased slowly by 0.2 kg/cc² every 2 minutes to a final vacuum of 0.7 to 0.8 kg/cc² (500 to 600 mm Hg). These slow increments in vacuum are necessary for the proper development of the chignon. Once a proper vacuum has been reached, sustained downward traction is applied along the pelvic curve using a two-handed technique in concert with uterine contractions and maternal expulsive efforts. Suction is released between contractions. Ideally, an episiotomy should be avoided, as pressure of the perineum on the vacuum cup will help to keep it applied to the fetal head and assist in flexion and rotation. It is suggested that the procedure be abandoned if the cup detaches three times, if no descent of the head is achieved, or if delivery is not effected within 30 minutes.

Indications for vacuum extraction-assisted delivery are similar to those for forceps delivery. One potential advantage of vacuum extraction is that delivery can be accomplished with minimal maternal analgesia. Relative contraindications include extreme prematurity (<34 weeks' gestation), suspected fetal coagulation disorder, and suspected fetal macrosomia. Although the overall rate of complications is similar between forceps and vacuum deliveries, the complication profile is different. Failed delivery is commonly encountered using the vacuum extractor, and may be more common with the soft cup (10 to 54 percent) as compared with the M cup (4 to 30 percent).^[169],^[170] Maternal perineal injuries are less common than with forceps deliveries. However, there is an increased incidence of fetal cephalohematoma or bleeding into the scalp which, if large, may be associated with neonatal jaundice, scalp lacerations (especially so-called cookie-cutter injuries which result from attempts by the operator to manually rotate the head with the vacuum), and scalp bruising.^[169],^[169],^[170] Whether the incidence of fetal intracerebral hemorrhage is increased with vacuum extraction is not clear. In response

to reports of 12 fetal deaths and 9 serious injuries over a 4-year period, the FDA issued a Public Health Advisory on May 21, 1998,^[171] delineating the fetal risks associated with vacuum extraction and urging physicians to use caution when employing these devices. A follow-up statement by the ACOG^[172] argued that "while no

medical procedure is risk-free, vacuum extraction has an extraordinary low risk for adverse outcomes" (i.e., 5 adverse events per 228,354 vacuum deliveries per year, or 1 in 45,455 vacuum extractions per year), and strongly recommended the continued use of vacuum-assisted devices in appropriate clinical settings. A recent study by Towner et al. found that the rate of intracranial hemorrhage was higher in infants delivered by vacuum extraction, forceps, or cesarean section during labor than in infants delivered by cesarean section before labor, suggesting that abnormal behavior rather than the mode of delivery was the most important risk factor. ^[173]

Congenital Neurological Birth Injuries

Facial nerve paralysis results from pressure on the facial nerve (cranial nerve VII) as it exits the skull through the stylomastoid foramen. It is the most common neurologic birth injury, with an incidence of 0.1 to 7.5 per 1,000 live births. ^[174], ^[175] These injuries are usually associated with operative vaginal (forceps) delivery, although up to a third of cases follow spontaneous vaginal delivery. Facial paralysis may be immediately apparent or may develop within hours of birth. Resolution is usually complete within a few days.

Injuries to the neck and spine are rare, but may result from excessive traction and/or rotation of the spinal cord at delivery. There may be a fracture or dislocation of the vertebral column with resultant neurologic injury (usually at C1C3), and such injuries may prove fatal. Risk factors for cervical spinal cord injuries include vaginal breech delivery and forceps-assisted vaginal delivery involving a rotation of greater than 90 degrees. ^[181] The true incidence of spinal injuries is not known.

INTRAPARTUM COMPLICATIONS

Cord Prolapse

Cord prolapse refers to passage of the umbilical cord into the vagina ahead of the presenting part following rupture of the fetal membranes. It is a true obstetric emergency, with a reported perinatal mortality rate of 50 percent. ^[176] Fetal perfusion is rapidly diminished either by mechanical distortion in the vagina and/or by vasospasm triggered by the precipitous drop in temperature outside the uterus. Cord prolapse is a rare event in term cephalic pregnancies (0.4 percent), but is more common with malpresentations (0.5 percent of frank breech, 4 to 6 percent of complete breech, and 15 to 18 percent of footling breech presentations, and probably greater than 20 percent in pregnancies complicated by transverse lie). ^[176] , ^[176] Other risk factors include a small fetus and prematurity. ^[177] , ^[178] Diagnosis is made by palpation of the cord on vaginal examination with or without fetal bradycardia. Management involves manual replacement of the cord, pushing the presenting part up away from the cord, and immediate delivery, usually by emergent cesarean section. Prevention of iatrogenic cord prolapse can be achieved by performing amniotomy with fundal pressure and only when the vertex is well applied to the cervix. ^[179]

CONTROVERSIAL ISSUES IN LABOR MANAGEMENT

Active Management of Labor

The increasing incidence of cesarean deliveries in the United States since the 1970s has prompted a systematic examination of labor management. There are two established methods of managing labor at term, traditional management and active management. The major difference between these two approaches is in the definition of failure to progress and in the oxytocin protocol chosen for labor augmentation.

Traditional Management

Traditional management uses a lower dose oxytocin regimen as compared with active management protocols, with longer intervals between dose increments. Low-dose oxytocin infusion, starting at an infusion rate of 1 mIU/min and increasing by 1 to 2 mIU/min at intervals of not less than 30 minutes, significantly shortens the interval from initiation of oxytocin augmentation to full dilation as compared with physician-directed regimens.^[77],^[149] There has been considerable debate as to whether a low-dose or high-dose oxytocin protocol is more effective for augmentation of labor at term, but there are few publications that directly compare these two protocols. High-dose oxytocin (starting at an infusion rate of 4 mIU/min and increasing by 4 mIU/min every 15 minutes "until adequate uterine contractility were obtained") may shorten the length of labor in both nulliparous and multiparous patients as compared with low-dose protocols.^[136],^[182] It remains unclear, however, whether high-dose oxytocin actually improves obstetric outcome or whether it merely produces the same outcome in a shorter period of time.

Active Management of Labor

Active management of labor refers to a philosophy of labor management based on the premise that optimizing uterine contractions will improve the progress of labor and subsequent outcome.^[24],^[54] An extension of this philosophy is the belief that fetal and maternal injuries are less with propulsion than with traction. It applies specifically to nulliparous patients in spontaneous labor with a cephalic presentation, and is not applicable to the multiparous patient, to patients undergoing induction of labor, or the management of patients attempting vaginal delivery after cesarean.

Active management describes a pragmatic protocol of clinical management that focuses on the first stage of labor. It is based on the premise that, by foreshortening the first stage of labor, the outcome of the second stage can be improved.^[24],^[54] The popularized view of the active management of labor is that of a high-dose oxytocin regimen. However, there are many other important components to this approach of management. The basic principles of active management include the following:

Strict criteria for admission to labor and delivery. In active management of labor protocols, labor is defined strictly as the presence of regular, painful contractions in conjunction with at least one further finding (complete cervical effacement, bloody show, or rupture of the fetal membranes).

Early amniotomy.

Hourly cervical examinations.

Early diagnosis of inefficient uterine activity. If the patient does not achieve and maintain a cervical dilatation rate of greater than or equal to 1.0 cm/h, a diagnosis of inefficient uterine activity is made and augmentation with intravenous oxytocin infusion is initiated immediately.

High-dose oxytocin infusion. In patients requiring oxytocin augmentation, a high-dose oxytocin infusion protocol is used. Oxytocin infusion is initiated at a rate of 6 mIU/min and increased by the same amount every 15 minutes until a uterine contraction frequency of seven contractions per 15 minutes is achieved or until the maximum oxytocin infusion rate of 36 mIU/min is reached.

Active intervention. Using this protocol, the expected duration of the first stage of labor is less than 12 hours and less than 2 hours for the second stage. If these expectations are not met, active intervention, operative vaginal or cesarean delivery, is recommended.

Patient education. The logistic component of the active management protocol aimed at allaying patient fear and anxiety is often overlooked. Emphasis has been placed on antenatal education with a view to realistic expectations for the patient, close supervision by a senior obstetrician, and one-on-one nursing care. An emphasis on peer review of all cesarean sections was highlighted in the original protocol.

Since its introduction in 1968, adherence to these principles at the National Maternity Hospital in Dublin, Ireland, through 1980 has been associated with a sustained primary cesarean section rate in nulliparous women of around 5 percent to 6 percent.^[183] It should not be forgotten that the initial objective of the active management protocol was to shorten the length of nulliparous labor, not to lower the cesarean section rate. Since the rate of cesarean deliveries is dependent on a number of demographic factors, including maternal age and race, extrapolation from one population to another is difficult. Despite these limitations, trials of active management have been carried out in several institutions around the world, some of whom have reported a decrease in cesarean deliveries as compared with historic controls.^[184]^[185] However, there have been only two randomized trials comparing the active management of labor with preexisting management strategies.^[187],^[189] In 1992, Lopez-Zeno et al.^[187] reported a controlled trial carried out in the United States in which 705 nulliparous, term, singleton pregnancies were randomized to either active management or to a more traditional management protocol. The active management protocol was similar to that carried out in previous trials, with strict criteria for the diagnosis of labor, amniotomy within an hour of labor onset, augmentation when cervical dilatation was not maintained at greater than or equal to 1.0 cm/h, and a high-dose oxytocin augmentation regimen (initial infusion rate of 6 mIU/min that was increased by the same amount every 15 minutes with a maximum oxytocin infusion rate of 36 mIU/min). Less emphasis was placed on antenatal education and individualized obstetric nursing care than in the original Dublin studies. Results of this trial suggested that the active management group had a 26 percent reduction in the rate of cesarean deliveries when compared with controls (10.5 percent vs. 14.1 percent, respectively; odds, ratio 0.57; 95% confidence interval, 0.36, 0.95). The length of labor was decreased by an average of 1.66 hours in the active management group. There was also decrease in maternal infectious morbidity, but no other differences in maternal or neonatal morbidity or mortality. The second randomized trial, that of Frigoletto et al.^[189] in 1995, adhered more strictly to the logistic concerns of the active management protocol, with greater patient participation, antenatal classes, improved patient education, and individualized nursing. The oxytocin augmentation protocol was slightly different from the study by Lopez-Zeno et al., with a starting rate of 4 mIU/min

and a 4 mIU/min incremental rate every 15 minutes to a maximum of 40 mIU/min; 1,934 nulliparous, low-risk women were randomly assigned to either active management or usual care prior to 30 weeks' gestation. Outcome data included cesarean delivery rates and various measures of maternal and neonatal morbidity and mortality. Results showed that the cesarean delivery rates were similar between the two groups (19.4 percent vs. 19.5 percent, respectively). Again, the length of labor and infectious morbidity were decreased with active management. The evidence regarding the rate of cesarean delivery rates and active management of labor is therefore contradictory. Multivariate analysis by the Oxford Collaborative Group^[189] aimed at dissecting apart the individual components of the active management of labor strategy showed that oxytocin augmentation, either on its own or in combination with amniotomy, did not reduce the rate of cesarean delivery. The authors did find, interestingly, that psychological support during labor was associated with a decrease in operative delivery, but only when the patient's partner was not present. In support of the argument that active management does not decrease the rate of cesarean deliveries, attention has been drawn to centers with similar cesarean section rates to that reported in the original active management studies using a minimal intervention management style.^{[190], [191]}

Regardless of the effect on cesarean section rates, the active management strategy is associated with a shortening in the duration of labor. Whether this is a result of the presence of a supportive "doula-like" figure, to the lower incidence of epidural anesthesia, to the more aggressive oxytocin augmentation protocol, to the delayed diagnosis of labor, or to a combination of these factors, is not clear. It has also been suggested that the aggressive introduction of high-dose oxytocin may overcome early, subclinical labor dystocia before uterine infection and fatigue make it less responsive to augmentation.^[192]

The Effect of Epidural Analgesia on the Progress of Labor

The question of whether or not epidural analgesia prolongs the length of labor and increases the incidence of operative delivery is controversial [\(see Chapter 15\)](#). The mode of pain relief during labor should be individualized and is a decision that is best left in the hands of the patient and her care provider.

Premature Rupture of the Membranes at Term

Premature rupture of the membranes is defined as rupture of the fetal membranes prior to the onset of labor, and occurs in 8 percent of term pregnancies.^[2] The management of this condition is controversial. Immediate delivery is indicated if there is evidence of chorioamnionitis, vaginal bleeding, and/or fetal compromise. It may also be prudent to expedite delivery in women colonized with group B streptococci, because of the increased risk of neonatal sepsis.^[193] Premature rupture of the membranes is not a contraindication to cervical ripening using transvaginal prostaglandin preparations.^{[194], [195]}

Initial studies suggested that expectant management of women with premature rupture of the membranes at term in the absence of obstetric complications was associated with a lower rate of cesarean delivery as compared with active management.^{[196], [197]} Subsequent larger and better designed studies^{[198], [199]} as well as a recent meta-analysis^[200] have refuted these observations. These investigations conclude that immediate induction of labor with intravenous oxytocin, induction of labor with vaginal PGE₂ gel, and expectant management are all reasonable options for women and their babies if membranes rupture before the start of labor at term, since they result in similar rates of neonatal infection and cesarean delivery.^{[199], [200]} However, an increase in maternal chorioamnionitis and endometritis with expectant management was a consistent finding in all of the trials. In one large randomized trial, women themselves viewed induction of labor more positively than expectant management.^[199]

Key Points

Labor is a clinical diagnosis.

The classical diagnosis of labor includes regular painful uterine contractions, progressive cervical effacement and dilatation, and a show (bloody discharge).

It is likely that the fetus is in control of the timing of labor, although the precise mechanism by which this occurs is not clear.

The ability of the fetus to successfully negotiate the pelvis during labor and delivery is dependent on the complex interaction of three variables: the powers, the passenger, and the passage.

The two major potential complications of elective induction of labor are iatrogenic prematurity and increased cesarean delivery resulting from failed induction.

Recent studies have demonstrated that routine induction of labor at 41 weeks' gestation is not associated with an increased

390

risk of cesarean section regardless of parity, state of the cervix, or method of induction.

When induction of labor is attempted against an unfavorable cervix, the likelihood of a successful outcome is reduced. The choice of which method to use to promote cervical maturation and to induce labor should be individualized. A single technique is rarely effective on its own, and a combination of maneuvers may be required.

In view of the lack of objective evidence of benefit of prophylactic episiotomy and the data suggesting that median episiotomy is associated with an increased incidence of severe perineal trauma, prophylactic median episiotomy should be discouraged.

Abnormal labor itself, not the mode of delivery, may be the most important risk factor for intracranial hemorrhage in the neonate.

Active management of labor refers to a philosophy of labor management based on the premise that optimizing uterine contractions will improve the progress of labor and subsequent outcome.

Induction of labor with intravenous oxytocin, induction of labor with vaginal PGE₂ gel, and expectant management are all reasonable options for women and their babies if membranes rupture before the start of labor at term, since they result in similar rates of neonatal infection and cesarean delivery.

Chapter 14 - Intrapartum Fetal Evaluation

Thomas J. Garite

The question being asked by the clinician evaluating the fetus in labor is quite simple: What is the status of fetal oxygenation? If hypoxia is severe enough and lasts long enough, fetal tissue and organ damage will result, which may result in long-term injuries and/or death. Hypoxia severe enough to cause tissue damage virtually always occurs only in the face of a significant metabolic acidosis, and the term "asphyxia" is used in this situation ([Fig. 14-1](#)). To clarify the terminology used in these situations, a Glossary is provided.

Although there are other less frequent causes of fetal injury and/or death in labor (e.g., infection, hemorrhage), hypoxia is by far the most common etiology and the one for which medical and surgical interventions have the potential for preventing injury and death. Prior to intensive intrapartum fetal heart rate (FHR) monitoring, relatively uniform intrapartum fetal death rates of 3 to 4 per 1,000 were reported.^[1] Thus, on an obstetric service of 200 to 300 monthly deliveries, 1 intrapartum death would occur each month; but now such events are extremely rare in monitored fetuses. Fetal hypoxia that is severe and associated with metabolic acidosis, but not sufficient to result in death, may alternatively cause asphyxial injury to the fetus and newborn. The fetal central nervous system (CNS) is the organ system most vulnerable to long-term injury. However, the fetus destined to have permanent neurologic damage will virtually always have multiorgan dysfunction in the newborn period. Usually, complications such as seizures, respiratory distress, pulmonary hypertension with persistent fetal circulation, renal failure, bowel dysfunction, and pulmonary hemorrhage are seen in the baby who will ultimately have permanent neurologic injury.^[2] Babies who recover from these complications and survive may be normal or may develop cerebral palsy. Cerebral palsy is defined as a movement disorder, usually spastic in nature, that is present at birth, nonprogressive and often, but not always, associated with varying degrees of mental retardation.^[3] Seizures are often seen in children with cerebral palsy. However, mental retardation or seizures, in the absence of spasticity, are rarely the result of peripartum asphyxia. It is still unclear whether other neurologic dysfunction in children, such as learning and behavioral disorders, can be the result of perinatal asphyxia. Cerebral palsy will develop in 0.5 percent of all births and is prevalent in about 0.1 percent of all school-age children.^[3], ^[4] Prematurity remains the leading cause of cerebral palsy. It is estimated that peripartum events contribute to no more than 25 percent of the overall rate of this disease.^[5]

Thus, the goal of intrapartum monitoring is to detect hypoxia in labor and allow the clinician to implement nonoperative interventions such as positioning and oxygen (O₂) administration to correct or ameliorate the oxygen deficiency. If this is unsuccessful, the monitor should help the clinician to determine the severity and duration of the hypoxia and whether there is a metabolic acidosis. And finally, if there is sufficient hypoxia and metabolic acidosis present, the monitor should give adequate warning and time to permit the clinician to deliver the baby expeditiously, whether by operative vaginal means or cesarean section, to prevent damage or death from occurring. Unfortunately, the fetus is quite inaccessible, and until recently we have had crude and limited tools available to determine all of the above information necessary to make correct and timely decisions to accomplish these goals.

HISTORY OF FETAL MONITORING

Because of the inaccessible location of the fetus, evaluating fetal well-being, or more specifically, fetal oxygen

396

Figure 14-1 The purpose of FHR monitoring is to detect fetal hypoxia and metabolic acidosis. Many fetuses develop hypoxia intermittently but never progress to metabolic acidosis. The ideal is to avoid intervention for hypoxia, but to intervene in the presence of early metabolic acidosis before it can result in tissue damage or fetal death.

status, has been an ongoing and difficult challenge. In the 1600s, Kilian first proposed that the fetal heart rate might be used to diagnose fetal distress and to indicate when the clinician should intervene on behalf of the fetus. The sound of the fetal heart had first been detected by Marsac of France in the 1600s and described in a poem by his colleague, Phillipe LeGaut. This observation went unnoticed until 1818, when Mayor, and subsequently Kergaradec, described the fetal heart sounds by placing an ear on the maternal abdomen. Kergaradec suggested that auscultation of the fetal heart could be used to determine fetal viability and fetal lie. In 1893, VonWinckel described the criteria for fetal distress that were to remain essentially unchanged until the arrival of electronic FHR monitoring. These included tachycardia (FHR >160 bpm), bradycardia (FHR <100 bpm), irregular heart rate, passage of meconium, and gross alteration of fetal movement. ^[1]

These criteria went unquestioned until 1968, when Benson et al. published the results of the Collaborative Project. ^[6] These authors reviewed the benefits of auscultation in over 24,000 deliveries and concluded "there was no reliable indicator of fetal distress in terms of fetal heart rate save in extreme degree." Thus, it became apparent that other, more sophisticated means of intrapartum fetal evaluation were required. In 1906, Cremer described the use of the fetal electrocardiogram (ECG) using abdominal and intravaginal electrical leads. ^[7] Several investigators made attempts using ECG waveforms to detect fetal hypoxia, but ultimately concluded that there was no consistent fetal electrocardiographic changes with fetal distress. ^[8] The subsequent history of electronic FHR monitoring (EFM) is a story of technological development and empiric observations of alterations in FHR associated with various causes of fetal hypoxia and acidosis.

In 1958, Edward Hon (the "father of EFM" in the United States) reported on the instantaneous recording of the fetal ECG from the maternal abdomen. ^[9] He and his colleagues painstakingly measured R-R intervals from a continuous ECG tracing and mathematically converted these to rate, in beats per minute (bpm), and then hand-recorded each interval on graph paper. From these efforts Hon, Caldeyro-Barcia in Uruguay, and Hammacher in Germany began to describe various FHR patterns associated with fetal distress. ^[10] ^[11] ^[12] Despite attempts by these and subsequent leaders in the field, universal standards for monitoring and terminology were never really established. For example, Europeans tend to refer to electronic fetal heart rate monitoring (EFM in the United States) as "cardiotocography" (CTG) and run their tracings at a paper speed of 1 cm/min as compared to 3 cm/min in this country. The first commercially available electronic fetal monitor was produced in the late 1960s, and by the mid-1970s, EFM was in use in most labor and delivery units in the United States. Today, the vast majority of all women giving birth in the United States have electronic FHR monitoring during labor.

INSTRUMENTATION FOR EFM

Many technological advances have been made since the first monitors were produced. External FHR monitoring using electrocardiography did not work in labor, and

397

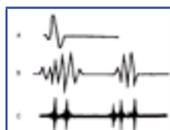

Figure 14-2 These complexes represent the types of signals that the FHR may be required to count. A, ECG; B, Doppler; C, phonocardiogram. Note the complexity of the Doppler signal. To consistently count the same place in the signal complex and avoid artifactually increasing variability, complex signal processing formulas are required.

phonocardiography was subject to fetal and maternal movement and other external noise. Doppler became the dominant modality for external monitoring. Initially, this modality was difficult to use because the complex Doppler signal made it difficult to determine which point within that signal the computer should use to measure the interval from beat to beat to convert to rate (Fig. 14-2). Logic, or computer processing formulas, were used to get apparently good continuous signals, but this process introduced artifact, and the apparent variability and other aspects of the FHR were often inaccurate. Ultimately, better Doppler devices coupled with autocorrelation formulas for processing the signal have resulted in excellent external FHR signals that can be relied upon clinically. External monitoring is necessary at all times when the membranes are intact and cannot or should not be ruptured (Fig. 14-3). In addition, certain clinical situations make it unwise to puncture the skin with a fetal electrode for fear of vertical transmission of infection to the fetus. Such conditions include maternal infection with human immunodeficiency virus (HIV), hepatitis C, and herpes simplex.

It is often necessary to apply an internal electrode to obtain a high-quality, accurate, continuous FHR tracing. This is especially true in patients who are obese, those with a premature fetus, or when the mother or fetus is moving too much to obtain an adequate signal. The original internal electrode was made from a modified skin clip that required a special instrument to place on the fetal scalp. In the mid-1970s, an easier to insert and less traumatic spiral electrode was introduced (Fig. 14-4). This is applied to the fetal scalp manually without additional instruments and without the requirement for a speculum to visualize the scalp. The electrical

Figure 14-3 Instrumentation for external monitoring. Contractions are detected by the pressure-sensitive tocodynamometer, amplified, and then recorded. Fetal heart rate is monitored using the Doppler ultrasound transducer, which both emits and receives the reflected ultrasound signal that is then counted and recorded.

398

Figure 14-4 Internal fetal heart rate data gathered at the standard recording speed of 3 cm/min for the first portion. The same data are being recorded at a speed of 1 cm/min in the last segment. Normal long-term and short-term variabilities are present. Note that the uterine activity channel has been calibrated so that the intrauterine pressure readings can be measured correctly.

circuit for this electrode includes the spiral electrode for one pole and a small metal bar at the base of the plastic which, bathed in vaginal secretions, completes the circuit through the mother's body. The spiral electrode has remained in use without substantial change since its introduction. The FHR tracing results from the signal processor, which counts every R-R interval of the ECG from the scalp electrode, converts this interval to rate, and displays every interval (in rate as beats per minute) on the top channel of the two-channel fetal monitor recording paper. The signal is amplified by an automatic gain amplifier, which increases the amplitude (gain) until an adequate signal is available to count (Fig. 14-5). It must be remembered that when the fetus is dead, the amplifier may increase the gain of the small maternal ECG transmitted through the dead fetus, and this may be easily misinterpreted as a fetal bradycardia (Fig. 14-6).

It is clear that the term "electronic fetal monitoring," unlike the European version "cardiotocography," undervalues the lower channel of the fetal monitor tracing, which provides information about the uterine contractions in labor. Contractions can also be monitored externally or internally. The external monitoring device, or tocodynamometer, is basically a ring-style pressure transducer attached to the maternal abdomen via a belt

Figure 14-5 Techniques used for direct monitoring of fetal heart rate and uterine contractions. Uterine contractions are assessed with an intrauterine pressure catheter connected to a pressure transducer. This signal is then amplified and recorded. The fetal electrocardiogram is obtained by direct application of the scalp electrode, which is then attached to a leg plate on the mother's thigh. The signal is transmitted to the monitor, where it is amplified, counted by the cardi tachometer, and then recorded.

399

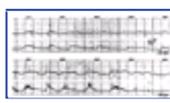

Figure 14-6 This is a tracing from an internal electrode demonstrating an apparent bradycardia with a rate of about 90 bpm. In actuality, this tracing is from a dead fetus, and the automatic gain amplifier increases the amplitude of the maternal ECG signal, allowing the monitor to count and display maternal heart rate.

that maintains tight continuous contact. When the uterus contracts, the change in shape and rigidity depresses the plunger of the sensor, which changes the voltage of the electrical current. The change in voltage is proportional to the strength of the uterine contractions. The tocodynamometer depicts the frequency of the

contractions accurately, but the strength of the contractions only relatively, since it cannot measure actual intrauterine pressure. In addition, the apparent duration of the contraction varies with the sensitivity of the monitor, which is negatively affected by variables such as maternal obesity and premature gestational age (Fig. 14-7). The advantage of the external monitor is that it can be used when membranes are intact and it is non-invasive. Its disadvantages, in addition to its inherently limited accuracy, is that it is more uncomfortable for the mother and limits her mobility. Contractions can be more accurately monitored via an intrauterine pressure catheter. The catheters require that the membranes be ruptured and are inserted transcervically beyond and above the fetal presenting part to rest within the uterine cavity. The original pressure catheters were open water-filled systems attached to a pressure transducer adjacent to the fetal monitor. These systems, while accurate, required frequent adjustments and flushing. Newer catheters have closed systems with the strain gauges in the tips or with sensors that relay the signal to a strain gauge at the base of the catheter. While more expensive, they are easier to use and require less nursing attention. Once the catheter is electronically "zeroed" (calibrated), the contractions are accurately recorded in terms of frequency, duration, and intensity on the lower channel of the two-channel recording paper or television monitor. This channel is conveniently calibrated at 0 to 100 mm Hg on its vertical scale, from which contraction amplitude can be read. These catheters also are often made with a second port through which saline can be infused for amnioinfusion (see below).

The goal of monitoring is to maintain adequate, high-quality, continuous FHR and contraction tracings while maintaining maximum maternal comfort and

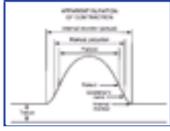

Figure 14-7 The sensitivity of the device used to monitor a uterine contraction can affect not only the apparent strength of the contraction but also the apparent duration of the contraction.

avoiding the risk of trauma and/or infection to the fetus and mother. External devices minimize risk but often give less accurate information and are more uncomfortable for the mother. In general, when the FHR is reassuring and there is an adequate tracing and when the progress of labor is adequate, the external devices are fine. When better quality FHR monitoring is required or it becomes important to accurately assess uterine contraction duration and intensity, then internal device(s) may be necessary.

THE PHYSIOLOGIC BASIS OF FHR MONITORING

The basis of FHR monitoring is, in a real sense, fetal brain monitoring. The fetal brain is constantly responding to stimuli, both peripheral and central, with signals to the fetal heart that alter the heart rate on a moment-to-moment basis. Such stimuli to which the brain responds include chemoreceptors, baroreceptors, and direct effects of metabolic changes within the brain itself. The benefit for the brain to modulate the FHR is derived from its goal of maintaining optimal perfusion to the brain without compromising blood flow to other organs any more than is necessary. It should be intuitively obvious, therefore, that the use of FHR to monitor fetal oxygenation is inherently crude and nonspecific, as many stimuli other than oxygen will either cause the brain to alter the fetal heart rate or may have a direct effect on the fetal heart itself. This really explains the most important basic premise of EFM: when the FHR is normal in appearance, one can be assured with high reliability that the fetus is well oxygenated, but when the FHR is not entirely normal, it may be the result of hypoxia or of other variables that may also affect fetal heart rate. In the past when the FHR became abnormal and the clinician decided intervention was necessary because of concern over fetal hypoxia, the term "fetal distress" was used. More often than not, however, such intervention results in the delivery of a well-oxygenated, nonacidotic, vigorous newborn. Thus, more recently, on the basis of recommendations of the American College of Obstetricians and Gynecologists (ACOG), the terminology was changed to reflect the inherent inaccuracy of the abnormal FHR. The term "fetal distress" has been abandoned in favor of the more intellectually honest term, "nonreassuring fetal status" (NRFS).^[13]

Fetal oxygenation is determined by many factors. The placenta functions as the fetal lung. Oxygen transfer across the placenta, as in the lung or any membrane, is proportional to the difference between partial pressures of oxygen between the mother and the fetus, the blood flow to the placenta, a coefficient of diffusion for the gas, and the surface area of the placenta. Transfer is inversely proportional to the thickness of the membrane (placenta). Thus, under normal circumstances during labor, the only variable that alters fetal oxygenation is the temporary interruption in blood flow to the placenta that occurs as a result of the compression of the spiral arteries by the wall of the uterus at the peak of the contraction. The duration that the spiral arteries will be compressed will thus depend on the duration and strength of the contraction (Fig. 14-8). Under normal circumstances, the fetus tolerates these periods of stasis well without a significant change in its oxygen content. Contractions that are unusually long or unusually strong may, however, result in transient periods of fetal hypoxemia.

Other variables that have the potential for altering fetal oxygenation most commonly include those that affect uterine perfusion. A laboring woman in the supine position can develop supine hypotension as a result of vena caval compression from the uterus. Maternal hypotension with redistribution of blood flow away from the placenta occurs not infrequently with regional anesthesia. Maternal hemorrhage, such as in placenta previa or abruptio placentae, may have similar effects. There are several forms of microvascular disease that can impair fetal oxygenation from poor perfusion within the uteroplacental vascular bed. Examples include hypertension, preeclampsia/eclampsia, collagen vascular disease, diabetic vasculopathy, and postmaturity. Abruptio placentae may compromise fetal oxygenation in several ways. These include maternal hypotension, as previously mentioned; a decrease in the surface area of the placenta; and uterine hyperactivity.

While the placenta functions as the fetal lung, the umbilical cord functions as its trachea, leading oxygen to the baby and carbon dioxide (CO₂) away. Alteration in umbilical cord blood flow is a very common occurrence during labor, either from direct compression or from stretch. Direct compression may occur when the cord becomes impinged between any part of the fetal body and the uterine wall, either with contractions or with fetal movement. This is especially more common when there is oligohydramnios, as there is less amniotic fluid to provide a cushion for the cord.^[14] Alternatively, cord stretch may occur as the fetus descends into the pelvis. Typically, this is seen just prior to complete dilation, when descent of the vertex normally occurs. There are three potent stimuli that produce spasm of the umbilical vessels and are intended to allow cessation of fetal umbilical cord blood flow following birth. These include a lower ambient temperature, a higher oxygen tension as the baby begins breathing, and the stretch of the umbilical cord as the baby falls from the birth canal.^[15] Thus, it should not be surprising that transient cessation of cord blood flow will occur with

401

Figure 14-8 In the resting state between contractions A, the intraluminal pressure within the spiral arteries exceeds the intramyometrial pressure. Thus uteroplacental blood flow is sustained. However, at the peak of a uterine contraction E, the myometrial pressure can exceed the arterial pressure and uterine blood flow will be transiently interrupted, temporarily halting oxygen delivery to the placenta.

402

Figure 14-9 A tachycardia with a fetal heart rate of 170 bpm seen in association with a maternal fever of 100.4°F.

stretching of the cord during descent if the cord is looped around the baby's neck and descent of the vertex occurs.

It becomes important, therefore, to understand the physiologic mechanisms that control the fetal heart rate. This is so not only because the FHR may be used to determine the severity of the hypoxia and whether a metabolic acidosis is ensuing, but also because the FHR pattern can elucidate the mechanism of the reduction in fetal oxygenation. Thus, by knowing the cause of any hypoxia, the treatment, when possible, can be more specifically directed at the cause. Finally, an understanding of the mechanism and progression of the FHR pattern can often also provide an opportunity to predict how fetal oxygenation will progress over time.

The FHR has many characteristics that we are able to use to accomplish this interpretation. These include the *baseline rate*; the *variability* of the FHR from beat to beat; transient alterations below the baseline, termed *decelerations*; and transient alterations above the baseline, termed *accelerations*. Rate and variability are generally included as *characteristics of the baseline* FHR, and decelerations and accelerations as *periodic changes*.^[16]

Tachycardia

The baseline FHR is typically between 120 and 160 bpm. In very early gestation (15 to 20 weeks), the FHR is significantly higher than in the term fetus. The decline in fetal heart rate represents a maturation of fetal vagal tone with progressing gestation.^[17] If atropine or other vagolytic drugs are administered, the FHR will regress to

the higher baseline of 160 bpm. Thus, the baseline heart rate is largely a function of vagal activity. Many factors have the potential to alter the fetal baseline. Rates above 160 bpm are called *tachycardia*. Tachycardia may have great clinical significance. The two most common causes of tachycardia are maternal fever and drugs that directly raise the fetal heart rate. Maternal fever raises the core temperature of the fetus, which is always about 1°F higher than the maternal temperature. With maternal fever, virtually all fetuses have tachycardia (Fig. 14-9). The FHR rises approximately 10 bpm for each 1°F increase in maternal temperature. Since at term with chorioamnionitis only 1 to 2 percent of fetuses are septic, the tachycardia is unlikely to indicate fetal sepsis, but rather is probably caused by an increase in fetal metabolic rate associated with the elevated temperature. Drugs that elevate the fetal heart rate fall into one of two categories: vagolytic and -sympathomimetic. Commonly used drugs that are vagolytic include scopolamine, atropine and phenothiazines, and hydroxyzine. These drugs, however, rarely raise the FHR above 160 bpm. -Sympathomimetics include terbutaline and ritodrine, used for preterm labor, and terbutaline and epinephrine, used for bronchospasm. Other less common causes of fetal tachycardia include fetal hyperthyroidism, fetal anemia, fetal heart failure, and fetal tachyarrhythmias. As fetal hypoxia becomes progressively worse and persists over time, fetal tachycardia often develops. However, when contractions are present, tachycardia is not the first physiologic response to hypoxia and, in the absence of decelerations, in the laboring patient, is rarely if ever caused by hypoxia. ^[19]

Bradycardia

An FHR less than 120 bpm is termed a *bradycardia*. One must distinguish between a baseline FHR less than 120 bpm and a deceleration from a previous normal baseline. Not only is a deceleration that is prolonged difficult to distinguish from a baseline change, but there is also some disagreement over terminology. This is an important issue, since a baseline bradycardia is usually innocuous (Fig. 14-10), whereas a prolonged deceleration to less than 120 bpm lasting more than 60 to 90 seconds may often indicate significant fetal hypoxia (Fig. 14-11). True fetal bradycardias are due to several possible causes. In the range of 90 to 120 bpm, a

*The terminology used in this chapter is fairly standard and is consistent with the most recent ACOG Technical Bulletin (Number 207, July, 1995) ^[16] however, a recent publication from the National Institute of Child Health and Human Development Research Planning Workshop has some notable differences, and these are discussed. ^[17]

Figure 14-10 A bradycardia with a fetal heart rate of 110 bpm. This patient is in premature labor at 34 weeks' gestation and is being treated with magnesium sulfate. The fetal bradycardia is probably because of maternal hypothermia, which can be seen with vasodilation caused by the magnesium sulfate.

bradycardia may often be a normal variant, and these fetuses are usually bradycardic after birth, but are otherwise well oxygenated and normal. As with tachycardia and fever, maternal hypothermia may cause fetal bradycardia. This is commonly seen with patients on magnesium sulfate ($MgSO_4$) who are vasodilated and has also been described with maternal hypoglycemia and hypothermia. ^[20], ^[21] A number of drugs may also result in fetal bradycardia. A fetal baseline heart rate in the range of 80 bpm or less, especially with reduced variability, may be caused by a complete heart block. Complete heart block may be caused by antibodies associated with maternal lupus erythematosus, may be seen with congenital cardiac anomalies, or is idiopathic. ^[22] Whereas a heart block is not associated with hypoxia, it makes the FHR essentially useless in monitoring fetal oxygenation, as the fetal brain is no longer communicating with the ventricle of the heart that is being monitored. Finally, when a patient is admitted with a baseline bradycardia, one should also consider the possibility of maternal heart rate being recorded with a dead fetus (whether internal or external monitor) (Fig. 14-6). Real-time ultrasound is used to verify that the bradycardia is fetal in origin.

Variability

The fetal cardiometer is unique among adult monitors in that it records the interval-to-interval difference in rate for every heart beat. Thus, differences in heart rate from beat to beat are recorded as "variability" reflected visually as a line that fluctuates above and below the baseline. This variability is a reflection of neuromodulation of the FHR by an intact and active CNS and also reflects normal cardiac responsiveness. Generally, the variability of the FHR is described as having two components: *short-term* and *long-term variability*. Short-term variability is the beat-to-beat irregularity in the FHR and is caused by the difference in rates between successive beats of the FHR. It is caused by the push-pull effect of sympathetic and parasympathetic nerve input, but the vagus nerve has the dominant role in affecting variability. Long-term variability is the waviness of the FHR tracing, and is generally seen in three to five cycles per minute. Previous texts spent considerable effort in distinguishing between the significance of short- and long-term variability, but in general they are reduced or increased together, and there is no clear evidence that distinguishing between the two is helpful clinically. The National Institute of Child Health and Human Development (NICHD) Research Planning Workshop also concluded that no distinction should be made between short- and long-term variability. ^[17]

This characteristic of the fetal baseline can be one of the most useful single parameters in determining the severity of fetal hypoxia if understood correctly. The simplest way to describe the causes of alterations, especially

Figure 14-11 The prolonged deceleration to 60 bpm in this case due to umbilical cord prolapse should be distinguished from a fetal "bradycardia", which is defined as the baseline heart rate.

reductions, in FHR variability is to say that this parameter reflects the activity of the fetal brain. When the fetus is alert and active, the FHR variability is normal or increased. When the fetus is obtunded, due to whatever cause, the variability is reduced. Since severe hypoxia, especially when it reaches the level of metabolic acidosis, will always depress the CNS, normal variability reliably indicates the absence of severe hypoxia and acidosis (Fig. 14-12A). Unfortunately, the converse is not true, as there are many things that cause the CNS to be depressed (see box, *Potential Causes of Decreased Variability of the FHR*); thus, reduced variability is a very nonspecific finding and must be interpreted in the context of other indicators of hypoxia, and other causes of reduced variability must be considered (Fig. 14-12B). In general, anything that is associated with depressed or reduced brain function will diminish variability. These include fetal sleep cycles; drugs, especially CNS depressants; fetal anomalies, especially of the CNS; and previous insults that have damaged the fetal brain. FHR variability is also affected by gestational age, and very immature fetuses of less than 26 weeks' gestation often have reduced variability from an immature CNS, although this varies from fetus to fetus. In addition, as heart rate increases with fetal tachycardia, variability is often reduced from the

Figure 14-12 A, The markedly decreased variability seen in this case is in association with persistent late decelerations. A scalp pH of 7.11 confirms that the loss of variability is because of CNS depression caused by acidosis. B, The abrupt decrease in variability seen here, in contrast to A, is not seen in association with any decelerations that might suggest hypoxia. Thus, the decreased variability must be because of another reason, and in this case, given the equally abrupt return to normal variability in B, is probably caused by a fetal sleep cycle.

rate alone, as sympathetic dominance overrides the natural influence of the vagus. Increased FHR variability, originally referred to as a "saltatory" FHR pattern, in nonlaboring animals has been shown to be associated with very early or minimal hypoxia. ^[23] This is a rare pattern and difficult to interpret. In labor, late, variable, or prolonged decelerations will virtually always be present with early hypoxia, and increased variability is not consistent with an acidotic fetus; so this finding can be interpreted in context with the entire FHR pattern.

Potential Causes of Decreased Variability of the FHR

Depression due to hypoxia and acidosis

Fetal anomalies, especially of the CNS

Fetal sepsis

Tumors of the CNS

Fetal heart block

Tachycardia

Extreme prematurity

Previous neurologic insult

Fetal sleep cycles

Drugs/medications

- Narcotics
- Barbiturates
- Tranquilizers
- Phenothiazines
- Parasympatholytics
- General anesthetics

Another problem with variability besides its nonspecificity is that the interpretation of variability is quite subjective. Variability is usually described quantitatively, as normal, increased, reduced, or absent. The NICHD Research Planning Workshop suggested that FHR variability be defined as follows:

Absent: amplitude undetectable
Minimal: amplitude > undetectable and 5 bpm
Moderate: amplitude 6 to 25 bpm
Marked: > 25 bpm.^[17]

Experts given tracings to interpret often disagree on the quantification of variability even using just these four categories. Trying to categorize variability any further is fraught with even more potential for disagreement and does not appear to have predictive value.

PERIODIC CHANGES

Variability, tachycardia, and bradycardia are characteristic alterations of the baseline heart rate. Periodic changes of the FHR include decelerations and accelerations. These are transient changes in the fetal heart rate of relatively brief duration with return to the original baseline FHR. In labor, these usually occur in response to uterine contractions, but may also occur with fetal movement.

Decelerations

There are four principal types of decelerations: *early*, *late*, *variable*, and *prolonged*. These are named for their timing, relationship to contractions, duration, and shape, but are important distinctions more because they describe the cause of the decelerations.

Early Decelerations

Early decelerations are shallow, symmetric, uniform decelerations with onset and return that are gradual, resulting in a U-shaped deceleration (Fig. 14-13). They begin early in the contraction, have their nadir coincident with the peak of the contraction, and return to the baseline by the time the contraction is over. Early decelerations are not associated with accelerations that precede or follow the deceleration. These decelerations rarely descend more than 30 to 40 bpm below the baseline rate. They are thought to be caused by compression of the fetal head by the uterine cervix as it overrides

Figure 14-13 Early decelerations.

the anterior fontanel of the cranium.^[24] This results in altered cerebral blood flow, precipitating a vagal reflex with the resultant slowing of the FHR. More nonspecific head compression can result in decelerations that are indistinguishable from variable decelerations. Because of the similar cause, these latter decelerations have often been called early decelerations, but are by definition not so. Because the cervix creates the pressure, these decelerations are usually seen between 4 and 6 cm of dilation (E.H. Hon, personal communication). They do not indicate fetal hypoxia and are only significant in that they may be easily confused with late decelerations because of their similar shape and depth. They are the most infrequent of decelerations, occurring in about 5 to 10 percent of all fetuses in labor.

Late Decelerations

Late decelerations are similar in appearance to early decelerations. They too are of gradual onset and return, U-shaped, and generally descend below the baseline no more than 30 to 40 bpm, although there are exceptions. However, in contrast to early decelerations, late decelerations are delayed in timing relative to the contraction. They begin usually about 30 seconds after the onset of the contraction or even at or after its peak. Their nadir is after the peak of the contraction. FHR variability may be unchanged or even increased during the decelerations. These decelerations are not associated with accelerations immediately preceding or following their onset and return (Fig. 14-14).

The physiology of late decelerations is quite complex, but an understanding of the physiology pays dividends in terms of interpreting and managing these important FHR changes. Late decelerations are generally said to be caused by "uteroplacental insufficiency." This implies that uteroplacental perfusion is temporarily interrupted during the peak of strong contractions. The fetus that normally will not become hypoxic with this temporary halt in blood flow may do so if there is insufficient perfusion and/or oxygen exchange at other times. Whereas this may be a correct idealized description, in reality any compromise of delivery, exchange, or uptake in fetal oxygen, other than by umbilical cord compression, can result in a late deceleration if the insult is sufficient. Physiologically, oxygen sensors within the fetal brain detect a relative drop in fetal oxygen tension in association with the uterine contraction. This change initially results in an increase in sympathetic neuronal response, causing an elevation in fetal blood pressure which, when detected by baroreceptors, produces a protective slowing in the FHR in response to the increase in peripheral vascular resistance. This has been referred to as the "reflex" type of late deceleration. This complex double reflex is probably the reason the deceleration is delayed.^[25] During this type of reflex, the depth of the deceleration is proportional to the severity of the hypoxia and the deceleration moves closer to the contraction as the hypoxia becomes more severe. However, there is also a second type of late deceleration, caused by "myocardial depression." As the hypoxia continues and becomes more severe, late decelerations are no longer vagally mediated and are seen even with interruption of the vagus nerve; thus, they are directly myocardial in origin. These decelerations are *not* proportional in their depth to the severity of the hypoxia, and actually may become more shallow as the hypoxia becomes quite severe. Because of this latter type of deceleration, it is generally agreed that the depth of the late deceleration cannot be used to judge the severity of the hypoxia. Because of the mechanisms causing these changes, *late decelerations always indicate fetal hypoxia*. Only the severity of the hypoxia and the overall duration of the late decelerations will determine whether a metabolic acidosis will occur, and this is highly unpredictable. One reason this may be so is found in recent data suggesting that the oxygen threshold that triggers the brain to slow the fetal heart in this characteristic way may be more related to the relative

Figure 14-14 A case complicated by third-trimester bleeding in which the external heart rate and uterine activity data are collected. Note the presence of persistent late decelerations with only three contractions in 20 minutes as well as the apparent loss of variability of the fetal heart rate. The rise in baseline tone of the uterine activity channel cannot be evaluated with the external system.

drop from baseline oxygenation rather than an absolute number.^[26] Thus, the fetus accustomed to higher than average oxygen saturation may have a drop in oxygen at or only slightly below the normal range; a level deep enough to signal a late deceleration, but not low enough to require anaerobic metabolism. Another important point in understanding the results of hypoxia associated with late decelerations is that the placenta's capacity for exchanging oxygen is substantially less than its capacity for exchanging carbon dioxide. In situations where there are persistent late decelerations and the fetus becomes sufficiently hypoxic to develop a metabolic acidosis, there may be no retention of carbon dioxide. This is quite analogous to the adult with lung but no airway disease where hypoxia is often seen without difficulty in eliminating CO₂. Thus, the metabolic acidosis is usually not mixed with a respiratory acidosis. The only common exception to this is with abruptio placentae, where CO₂ retention is seen with late decelerations.^[27]

Causes of late decelerations include any factor that can alter delivery, exchange, or uptake of oxygen at the fetal-maternal interface within the placenta. Most commonly, late decelerations are observed in patients without inherent pathology. Excessive uterine contractions, usually seen with oxytocin, are the single most common cause of late decelerations. In these situations, the duration of interruption of uterine blood flow is prolonged and the hypoxia is more than the normal fetus can endure, and late decelerations are expressed. Conduction anesthesia (spinal or epidural) can cause either systemic or local hypoperfusion/hypotension, and thus the level of contractions required to interrupt uterine blood flow is lower, and again the duration of interruption of uterine blood flow is prolonged (Fig. 14-15). The most common pathologic conditions of the placenta associated with late decelerations are those characterized by either microvascular disease in the placenta or local vasospasm compromising blood flow and thus exchange. Common causes include postmaturity, maternal hypertension (chronic hypertension or preeclampsia), collagen vascular diseases, and diabetes mellitus in its more advanced stages. Besides altering perfusion, abruptio placentae is an example of altered placental exchange caused by a combination of reduced placental surface area and increased contractions that typically result in late decelerations when the separation is sufficient to cause fetal hypoxia. Severe maternal anemia or maternal hypoxemia may compromise oxygen delivery and result in late decelerations. Conversely, chronic fetal anemia may diminish fetal oxygen uptake and be associated with late decelerations.

Variable Decelerations

The most common type of decelerations seen in the laboring patient are variable decelerations. Variable decelerations are, in general, synonymous with umbilical cord compression, and anything that results in the interruption of blood flow within the umbilical cord will result in a variable deceleration. The variable deceleration is the most difficult pattern to describe verbally, but the easiest to recognize visually. First and foremost, the term "variable" is by far the best single word to describe this type of deceleration. They are variable in all ways: size, shape, depth, duration, and timing relative to the contraction. The onset is usually abrupt and sharp. The return is similarly abrupt in most situations. The depth and duration are proportional to the severity and duration of interruption of cord blood flow. Variable decelerations are usually seen with accelerations immediately preceding the onset of the deceleration and immediately following the return to baseline. The NICHD Research Planning Workshop proposed that the duration of a variable deceleration should be limited to 2 minutes, and that beyond 2 minutes, it should

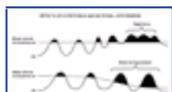

Figure 14-15 The two most common causes of late decelerations in labor are excessive uterine contractions (usually caused by oxytocin) and maternal hypotension. Both result in decrease in uteroplacental perfusion, hypertonus by interrupting the transmyometrial perfusion for a prolonged period, and hypotension by dropping the perfusion pressure, thus increasing the amount of time perfusion is interrupted even with a normal contraction. UA, uterine artery.

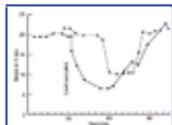

Figure 14-16 This is the original description of a variable deceleration in a fetal goat by Barcroft. The solid line A represents the fetal heart rate with temporary umbilical cord occlusion and the dotted line E is the fetal heart rate with temporary cord occlusion after the vagal nerve has been severed.

be called a prolonged deceleration.^[17] However, most definitions in the past have not put a limit on duration but rely more on the appearance of the deceleration. More than 50 years ago, Barcroft first described the variable deceleration when he ligated the umbilical cord of a fetal goat (Fig. 14-16).^[29] In 1975, Lee externalized the human umbilical cord at cesarean section prior to delivery and demonstrated that the reflex involved in the complex pattern of the variable deceleration is one that is caused primarily by changes in systemic blood pressure in the fetus and is mediated through baroreceptors (Fig. 14-17).^[29] When the umbilical cord is gradually compressed, the thinner walled umbilical vein collapses first and blood flow returning to the fetus is interrupted. This results in decreased cardiac return, fetal hypotension, and a baroreceptor reflex that leads the brain to accelerate the heart rate in order to maintain cardiac output. This increase in heart rate is the acceleration that precedes the variable deceleration. With continuing compression, the umbilical artery is compressed, and the fetus detects an increase in systemic vascular resistance as the previously low-resistance placental bed, to which 50 percent of fetal cardiac output normally flows, is occluded. The baroreceptors detect the increase in resistance and the heart slows as a protective mechanism. As the cord vessels gradually open, the arteries open first and the heart rate returns to baseline; but if the flow in the vein is still blocked, an acceleration of the same mechanism of the one that preceded the deceleration occurs. While this model is idealized, one might surmise that the orderly occlusion of vein, vein and artery, vein does not always occur. This is probably the reason that with variable decelerations any combination of deceleration with acceleration preceding, preceding and following, following only, neither, or even acceleration alone may be seen with cord compression as in Figure 14-18.

In reality, although we refer to umbilical cord compression as the single mechanism for interruption of cord blood flow, there are probably several different mechanisms that may have the same end result. Compression may be the mechanism that occurs when the cord is impinged between a fetal body part and the uterine wall during contractions or with fetal movement. As previously mentioned, cord stretch may be the

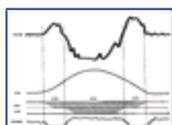

Figure 14-17 This figure represents FHR and fetal systemic blood pressure (FSBP) occurring during compression of the umbilical vein (UV) and umbilical artery (UA). UC is the uterine contraction. Note the acceleration of the FHR as the FSBP is decreased, marking a baroreceptor response to decreased cardiac return, and the deceleration of the FHR when the FSBP is increased, the baroreceptor response to increased peripheral resistance.

Figure 14-18 These are typical variable decelerations. Note that such decelerations are often recognized by the accelerations that precede and follow the decelerations.

reason the flow is compromised with nuchal cords and seen as the baby descends through the pelvis. If cold saline is infused too rapidly with amnioinfusion, the FHR may slow, presumably caused by cord spasm, the natural fetal reflex to cold stimulus. Whatever the mechanism, it is most important to realize that variable decelerations are initially caused by a reflex in response to changes in pressure and not hypoxia. Thus, variable decelerations (even deep and prolonged) can be seen in fetuses with no change in oxygen saturation (Fig. 14-19).

Variable decelerations are seen in the vast majority of all labors, and most often these decelerations occur without fetal hypoxemia. It is apparent that additional criteria are needed to separate those benign variable decelerations not likely to be associated with hypoxia from those that are. Kubli et al. described a category of mild, moderate, and severe variable decelerations based on depth and duration (see box, Classifications of the Severity of Variable Decelerations).^[30] While there is indeed a correlation between the severity of these decelerations and the likelihood of hypoxia, one can see from Figure 14-19 that it is difficult to pick a specific depth and duration that always predicts oxygen compromise. Therefore, in addition, characteristics of the fetal baseline are also used, including the development of tachycardia

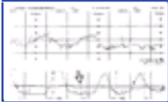

Figure 14-19 Superimposed on the contraction monitor tracing is a continuous tracing using a newly approved fetal pulse oximeter. The tracing shows an fetal oxygen saturation value ranging from 50 to 40 percent (normal = 35 to 60 percent). Note the consistently normal saturation values despite the prolonged FHR decelerations to 80 bpm.

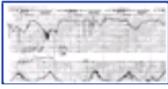

Figure 14-20 The association of loss of variability and tachycardia in association with these variable decelerations make this a nonreassuring FHR pattern.

Figure 14-21 These variable decelerations, although mild in depth and duration, are associated with a slow, rather than abrupt, return to baseline. This may be a sign of developing hypoxia as a result of repetitive umbilical cord compression with inadequate opportunity to reoxygenate between events. Generally, this finding makes the variable decelerations nonreassuring.

and loss of variability (Fig. 14-20). When cord compression occurs with each contraction and is sustained for a prolonged period of time, there will be a change from the usual abrupt return to baseline to a slow or delayed return to baseline (Fig. 14-21). This is also often called a late component, although a combined pattern of late and variable decelerations (Fig. 14-22) should be distinguished from progressive, severe variable decelerations that result in slow return to baseline, as the etiologies and thus the potential treatments will differ. This particular discriminator of variable decelerations can be one of the most confusing aspects in all of fetal monitoring. Since a slow return to baseline can represent fetal hypoxia from either progressive cord compression or from a coincident late deceleration, the question is, Does this finding always represent hypoxia? Many times this sign appears without significant cord compression preceding its onset; therefore, it is unlikely that a substantial oxygen deficit has developed. Thus, many times these are benign findings and may represent more slow release of the cord or some other unexplained phenomenon. Finally, in extreme

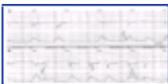

Figure 14-22 Here are repetitive variable decelerations with a slow return to baseline. However, the minimal depth and duration of the variable decelerations and the fact that one can see an independent late deceleration with the third contraction would suggest that this pattern is actually a combined one of mild variable and persistent late decelerations.

situations where there is profound fetal hypoxia and acidosis, the variable decelerations will appear smoother and rounded or "blunted" rather than having the usual abrupt changes seen with the more common benign decelerations. Such cases are virtually always seen in association with absent FHR variability and they can also be followed by a blunted acceleration following the return to baseline described by Goodlin and Lowe as "overshoot" (Fig. 14-23).^[31] This is a rare situation, and is only seen when all criteria are met including absent variability, blunted variable decelerations, no acceleration preceding the variable deceleration, and no other spontaneous accelerations of the FHR.

Classifications of the Severity of Variable Decelerations

Mild

Deceleration of a duration of <30 seconds, regardless of depth

Decelerations not below 80 bpm, regardless of duration

Moderate

Deceleration with a level < 80 bpm

Severe

Deceleration to a level < 70 bpm for > 60 seconds

Data from Kubli et al.^[30]

There are four categories of causes of cord compression patterns that are useful to consider from a management standpoint. Variable decelerations appearing early in labor are often caused by oligohydramnios. Other variable decelerations often first appear when the patient reaches 8 to 9 cm of dilation, the time in labor when the curve for descent of the presenting part becomes steep. This is probably most often because of nuchal cords, wherein the cord becomes stretched with descent of the fetal head, and as previously described, cord stretch is a profound stimulus for vasospasm in the cord vessels.^[19] Unusual types of abnormal umbilical cords, such as short cords, true knots, velamentous cord insertion, cord looped around the extremities, and occult cord prolapse, will produce variable decelerations. And finally, the rarest form of cord compression, and one that usually requires rapid delivery by cesarean section, is true umbilical cord prolapse.

Since the umbilical cord is most analogous to the adult trachea, interruption in cord flow results in both retention of CO₂ and cessation of O₂ delivery. When this becomes progressive, the intermittent compression often first leads to a progressive increase in fetal CO₂, which results in a respiratory acidosis. If the cord compression

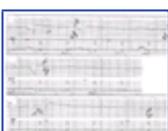

Figure 14-23 The accelerations following these variable decelerations, without any acceleration preceding, in association with absent variability fulfill the criteria to describe the accelerations as "overshoot." Such a finding can be an ominous finding and is often associated with marked metabolic acidosis.

continues and also is sufficiently severe to cause insufficient delivery of oxygen, then a metabolic acidosis can also develop. Thus, in a fetal acidosis resulting from cord compression, the acidosis can be respiratory or combined respiratory and metabolic, but should not be metabolic alone.

Prolonged Decelerations

Prolonged decelerations are isolated decelerations lasting 90 to 120 seconds or more. The NICHD Research Planning Workshop proposed that prolonged decelerations be defined as those lasting 2 to 10 minutes and that beyond 10 minutes this is a baseline change.^[17] While this proposal is meant to create uniform definitions, it belies the pathophysiology of the deceleration, as the sudden drop in FHR is the result of some adverse afferent stimulus and if sustained will result in a prolonged decrease in FHR. Thus, this is not really a baseline change, as the FHR will return to or near its original baseline when the stimulus is removed. Unlike the other three decelerations, where the type of deceleration defines the pathophysiologic mechanism, prolonged decelerations may be caused by virtually any of the mechanisms previously described, but usually are of a more profound and sustained nature. Prolonged umbilical cord compression, profound placental insufficiency, or possibly even sustained head compression may lead to prolonged decelerations.

The presence of and severity of hypoxia are thought to correlate with the following variables with a prolonged deceleration: the depth and duration of the deceleration, how abruptly it returns to baseline, how much variability is lost during the deceleration, and whether there is a rebound tachycardia and loss of variability following the deceleration (Fig. 14-24). Examples of the more profound stimuli that may result in this type of deceleration include prolapsed umbilical cord or other forms of prolonged cord compression, prolonged uterine hyperstimulation, hypotension following conduction anesthesia, severe degrees of abruptio placentae, paracervical anesthesia, an eclamptic seizure, and rapid descent through the birth canal. Occasionally, less severe stimuli such as examination of the fetal head, Valsalva's maneuvers, or application of a scalp electrode may cause milder forms of prolonged decelerations.

Accelerations

Accelerations are periodic changes of the FHR above the baseline (Fig. 14-25). They are not classified by type. Except for those accelerations previously described that are associated with variable decelerations, virtually all accelerations are a physiologic response to fetal movement.^[32] Accelerations are usually short in duration, lasting no more than 30 to 90 seconds, but in an unusually active fetus they can be sustained as long

Figure 14-24 Often following a prolonged deceleration, as with the one shown in this figure, there is a temporary period of tachycardia and loss of variability. Such a response would suggest that this was a significant hypoxic event. The etiology of this deceleration is not clear but may have been because of excessive uterine contractions compounded by maternal pushing.

Figure 14-25 These are accelerations of the fetal heart. They are usually seen with fetal movement, and are often coincident with uterine contractions as well, as in this patient.

as 30 minutes or more. Again, the NICHD Research Planning Workshop disagrees somewhat on this definition, in that they propose that accelerations of more than 10 minutes be defined as a change in baseline.^[17] However, sustained accelerations (Fig. 14-26) are associated with an actively moving fetus, and when the fetus becomes quiet, the FHR will return to baseline. It is important that this acceleration not be confused with a baseline change, because sustained accelerations, which are consistent with a well-oxygenated, vigorous fetus, can be confused visually with fetal tachycardia, and the return of the FHR to the original baseline can be confused with decelerations.

The presence of accelerations has virtually the same meaning as normal FHR variability, but the absence of accelerations means only that the baby is not moving. Since accelerations can be quantified in beats per minute above the baseline and duration, their presence is less subjective than quantifying FHR variability. The 15 bpm above the baseline lasting for more than 15 seconds definition of an acceleration, first described with the nonstress test, is the definition usually used for defining accelerations in labor. Earlier in gestation, accelerations are less frequent and of lower amplitude. Fetuses of less than 32 weeks have been defined as having accelerations if they exceed 10 bpm for more than 10 seconds.^[17] Clark et al. made the observation that in fetuses having otherwise nonreassuring FHR patterns, the presence of accelerations, using this definition, virtually always ruled out a pH less than 7.20 on scalp sampling.^[33] Subsequently, these authors and others have confirmed that the presence of spontaneous accelerations

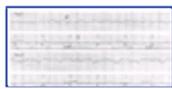

Figure 14-26 This figure shows prolonged and repetitive accelerations, especially on the lower panel. Accelerations that are sustained or confluent can be easily confused with a tachycardia and the return to baseline can be confused with decelerations.

Figure 14-27 The sinusoidal heart rate pattern with its even undulations is demonstrated. Internal monitoring shows the absence of beat-to-beat variability characteristic of true sinusoidal patterns.

or accelerations induced by stimulation of the fetal scalp or acoustic stimulation with a vibroacoustic stimulator has the same reliability.^{[34], [35]} If there is no acceleration in the face of an otherwise nonreassuring FHR, most studies have shown that about 50 percent of these fetuses have an acidotic pH value on scalp sampling. However, the absence of accelerations in a fetus without a nonreassuring deceleration pattern rarely indicates fetal acidosis.

Sinusoidal Patterns

This pattern was originally described by Kubli et al. in 1972^[36] and Shenker in 1973^[37] and is rare, but significant. This pattern is strongly associated with fetal hypoxia, most often seen in the presence of severe fetal anemia. Using strict criteria for this pattern, defined by Modanlou et al., there will be a high correlation with significant fetal acidosis and/or severe anemia.^[38] These criteria for identifying a sinusoidal FHR include (1) a stable baseline FHR of 120 to 160 bpm with regular sine wave-like oscillations, (2) an amplitude of 5 to 15 bpm, (3) a frequency of 2 to 5 cycles/min, (4) fixed or absent short-term variability, (5) oscillation of the sine wave above and below the baseline, and (6) absence of accelerations (Fig. 14-27). The pathophysiology of the sinusoidal pattern has been elucidated by Murata et al., who correlated the pattern with levels of fetal arginine vasopressin and subsequently reproduced the pattern with vagotomy and injection of arginine vasopressin.^[39] Arginine vasopressin is elevated with hemorrhage or acidosis, and it appears that in such situations with a severely compromised fetus and little vagal activity, the hormone directly affects the fetal heart and this FHR pattern results. The sinusoidal pattern has also been described after injection of certain narcotics such as butorphanol (Stadol)^[40] or meperidine (Demerol).^[41]

Unfortunately, there are relatively commonly seen FHR patterns that mimic sinusoidal patterns (pseudosinusoidal) that are associated with well-oxygenated and nonanemic fetuses.^[38] These can easily be confused with sinusoidal FHR patterns (Fig. 14-28); therefore, it is quite important to strictly apply all of the above six criteria before calling a pattern sinusoidal.

Evolution of FHR Patterns

One of the sources of greatest confusion regarding FHR pattern interpretation and management is that the patterns

Figure 14-28 More common than sinusoidal tracings are those that are actually normal but can easily be confused with a sinusoidal pattern. There are often small accelerations or above-average variability that mimics the sine wave-like pattern. It is important to use the strict criteria defined in the text before interpreting a pattern as sinusoidal.

416

have very poor specificity in terms of predicting fetal hypoxia and acidosis, newborn depression, or need for resuscitation. When patterns are normal or "reassuring," there is almost always normal oxygenation and the baby is born vigorous, with normal pH and Apgar scores. However, when the pattern is nonreassuring, the baby is more often normal than depressed or acidotic.

In addition to the inherent problem we have in trying to use EFM, a nonspecific modality, to determine fetal oxygenation, there is another reason why many studies have demonstrated such poor correlation with adverse perinatal outcome. Investigators have tried to correlate specific FHR findings in isolation without taking into account the expected evolution of the FHR patterns.^[19], ^[30] For example, if one attempts to correlate FHR variability with acidosis or depression, normal variability will correlate well with a normal pH and normal Apgar scores, but reduced or absent variability will correlate poorly with acidosis or depression. This is partly because of the multiple causes of reduced variability. However, in the fetus with persistent late decelerations who then loses FHR variability, the correlation with acidosis and depression should improve substantially because there was evidence that *hypoxia led to the acidosis*. This is a critical concept in understanding FHR monitoring. Murata and co-workers demonstrated in the fetal monkey, whose oxygenation was progressively reduced, that late decelerations consistently *preceded* the loss of variability and accelerations.^[42] Decelerations are the indicators of hypoxia. If hypoxia is the cause of the reduced variability, then those decelerations indicative of hypoxia should *precede* the development of tachycardia, loss of variability, and/or disappearance of accelerations ([Fig. 14-29](#)). Furthermore, the duration and appearance of the decelerations should be of sufficient magnitude to suggest that CNS depression could have resulted.

Therefore, the fetus who develops one of the latter variables (e.g., loss of accelerations) in the absence of decelerations is not likely to have hypoxia, and another cause should be considered (e.g., drugs, sleep cycle). It must be remembered that when the fetus demonstrates one of these baseline changes or absence of accelerations on admission, it is not possible to know whether evidence of hypoxia preceded these changes. In addition, this approach does not apply antepartum, when the nonstress test is used. Contractions are not present, and there will not be an opportunity to assess for the presence or absence of decelerations in response to contractions.

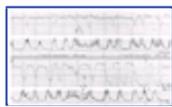

Figure 14-29 Loss of variability and tachycardia should only be interpreted as indicative of hypoxia and developing acidosis when they are associated with decelerations that suggest progressive hypoxia as with these variable decelerations, which are becoming deeper and more prolonged.

MANAGEMENT OF NONREASSURING FETAL HEART RATE PATTERNS

Traditionally, an FHR pattern that suggested fetal hypoxia would be called fetal distress if it was sufficiently concerning to warrant immediate operative intervention. But, as previously mentioned, in most cases, when a cesarean or forceps delivery was done for "fetal distress," the fetus was delivered without evidence of significant hypoxia or acidosis. This has led to the recommendation from the ACOG to use the term "nonreassuring fetal status" to indicate a more accurate description of the indication for such intervention.^[43] This is also descriptive of the approach to the management of the fetus with concerning FHR patterns. That is, when the FHR pattern is suggestive of hypoxia, and therefore nonreassuring, other means of reassurance should be used when possible.

Interventions for Nonreassuring Fetal Status

The ideal intervention for fetal hypoxia is a cause-specific, noninvasive one that permanently reverses the problem. While not always possible, this should certainly be the goal. Obviously, the first step in achieving this goal is to recognize the cause of the abnormal FHR pattern. A thorough knowledge of the pathophysiology of FHR changes coupled with a careful clinical patient evaluation and a knowledge of common causes of specific FHR changes will maximize the opportunity for this goal to succeed. In addition to cause-specific types of interventions, virtually all cases of hypoxia should theoretically also benefit by more generic interventions that have the potential to maximize oxygen delivery and placental exchange.

Nonsurgical Interventions

OXYGEN ADMINISTRATION.

One of the most obvious ways to maximize oxygen delivery to the fetus is to give additional oxygen to the mother. Whereas diffusion across the membrane is driven by P_{O_2} as opposed to oxygen content, and whereas maternal P_{O_2} can be raised substantially with mask O_2 , it is not well demonstrated that fetal P_{O_2} is raised substantially by routine maternal oxygen administration. Recent evidence, while still preliminary, from fetuses being monitored with pulse oximetry, does not substantiate a significant rise in fetal arterial oxygen saturation (Sa_{O_2}) using regular face mask.^[43] A tight-fitting rebreathing mask does appear to raise fetal Sa_{O_2} , at least somewhat.^[43] Whereas this is the state of current knowledge, routine O_2 administration via face mask has become such standard practice with nonreassuring FHR patterns that it is difficult to recommend otherwise until further studies are available to substantiate these preliminary data.

LATERAL POSITIONING.

Ideally, all patients should labor in the lateral recumbent position, at least from the standpoint of maximizing uterine perfusion. The reasons for this are, at least theoretically, twofold: (1) in being inactive and recumbent, the body is required to deliver the least amount of blood flow to other muscles; and (2) in the lateral position, there is no compression by the uterus on the vena cava or aorta, thus maximizing cardiac return and cardiac output.

HYDRATION.

Most patients in labor are either restricted or prohibited from taking oral fluids for fear of requiring an urgent operative delivery in the presence of a full stomach. If not fluid restricted, individuals involved in sustained exercise, and possibly by inference in active labor, do not voluntarily ingest adequate amounts of fluid because of a phenomenon called "autodehydration."^[44] In addition, recent evidence would suggest that the usual amount of intravenous fluid of 125 ml/h is a gross underestimate of the replacement required in labor.^[45] Thus, by increasing fluid administration, there is the potential to maximize intravascular volume and thus uterine perfusion.

OXYTOCIN.

In a patient with a nonreassuring pattern, the more time there is between contractions, the more time to maximally perfuse the placenta and deliver oxygen. In patients receiving oxytocin, there is potential to improve oxygenation by decreasing or discontinuing oxytocin. Often, however, this becomes a difficult situation, as many patients will stop progressing in labor in terms of continued dilation and/or descent if the oxytocin is discontinued. It is often necessary to restart the oxytocin, and this may be appropriate especially if there are accelerations or other means to document the absence of acidosis (e.g., oxygen saturation). Written documentation explaining the necessity and appropriateness of continuing oxytocin in this situation is especially important. The situation with patients who develop persistently nonreassuring patterns, especially with loss of accelerations or absence of other reassurance, and who require discontinuation of oxytocin, but then fail to progress because adequate contractions cannot be sustained, is often referred to as "fetal intolerance to labor."

TOCOLYTICS.

There are numerous references in the obstetric literature to the use of tocolytics to maximize oxygen delivery, by essentially the same mechanism described in the above paragraph on discontinuing oxytocin.^[46]^[47]^[48]^[49] Tocolytics are appropriate in at least two situations: (1) When patients are having spontaneous excessive contractions leading to nonreassuring FHR

Figure 14-30 This prolonged deceleration in a patient with a spontaneous prolonged contraction is treated with subcutaneous terbutaline with apparent resolution of both the contraction and the deceleration.

patterns, especially prolonged decelerations (Fig. 14-30) (different tocolytics have been described, but the most commonly used one, and perhaps the one that provides the most rapid response, is subcutaneous terbutaline, 0.25 mg); and (2) intrauterine resuscitation after the decision is made to perform an operative delivery while waiting for preparations to be made. Subcutaneous terbutaline has been demonstrated to improve Apgar scores and cord pH values without apparent complications such as postpartum hemorrhage.^[50]

AMNIOINFUSION.

In situations where variable decelerations appear to be caused by oligohydramnios, reestablishing intrauterine fluid volume via a process called "amnioinfusion" has been demonstrated in numerous randomized studies to ameliorate the variable decelerations, improve Apgar scores and cord pH values, and even reduce the need for cesarean section for NRFS. ^[51] ^[52] ^[53] Reference to this idea can be found as far back as 1925, ^[54] but was rediscovered and proposed by Miyazaki and Taylor in 1983. ^[55] Intrauterine pressure catheters are now made with a port that allows the simultaneous administration of saline to accomplish this goal. Thus, in the patient with variable decelerations that suggest progression to more nonreassuring types, and where the cause is likely to be caused by oligohydramnios, the implementation of amnioinfusion is warranted. What has not yet been established is whether in some situations amnioinfusion should be started prophylactically when there is an unusually high risk for the development of variable decelerations from oligohydramnios, such as preterm premature rupture of membranes (PROM).

Theoretically, using amnioinfusion before the onset of the decelerations in certain fetuses, such as very premature ones or those with intrauterine growth restriction who will progress to acidosis and depression much more rapidly with cord compression, will prevent the rapid evolution of hypoxia and acidosis. No studies are available as of yet to compare therapeutic as opposed to prophylactic amnioinfusion. Amnioinfusion also has been proposed, in several prospective randomized trials, to be used to avoid the fetal/neonatal pulmonary problems in the presence of meconium. ^[56] The evidence for efficacy in this setting is good. However, clear evidence that this modality avoids the meconium aspiration syndrome is lacking, since this complication is relatively infrequent. Some of these problems will be avoided with good oropharyngeal suctioning on the perineum and neonatal suctioning below the vocal cords when necessary. The theory behind this use of amnioinfusion is that (1) it dilutes the meconium by increasing fluid volume, and (2) by avoiding fetal gasping, which can occur with significant hypoxic episodes (i.e., sustained cord compression), the likelihood of meconium aspiration prior to delivery is reduced. Surveys of university hospitals suggest that amnioinfusion is used for both variable decelerations and meconium in the vast majority. ^[57]

MECONIUM.

The presence of meconium is an extremely confusing issue when evaluating the fetus in labor. The quandary arises from the fact that while a hypoxic insult eliciting a significant vagal response from the fetus often results in the passage of meconium from the fetal gut, passage of meconium can also occur in the absence of any significant or sustained hypoxia. Meconium is not only a potential sign of fetal hypoxia but is also a potential toxin if the fetus aspirates this particulate matter with a gasping breath in utero or when it takes its first breaths following birth. The thickness of the meconium is also a reflection of the amount of amniotic fluid, and thick meconium virtually always reflects some degree of oligohydramnios. Thus, there may be a vicious cycle in such a situation. Oligohydramnios often leads to cord compression; the vagal response to cord compression may also lead to further passage of meconium, but also when it is sustained or prolonged may lead to fetal gasping, increasing the likelihood that meconium aspiration can occur before birth. Furthermore, since oligohydramnios may be an indicator of failing placental function, meconium may also indicate that the fetus is at risk for placental insufficiency. In general, meconium should alert the clinician to the potential for oligohydramnios, umbilical cord compression, placental insufficiency, and meconium aspiration. Fortunately,

419

a reassuring FHR tracing is generally reliable, and patients with meconium can be managed expectantly. But in the presence of meconium, especially thick meconium, the risk factors associated with meconium should be entered in the equation when managing relatively nonreassuring patterns, as should all clinical variables.

Alternatives for Evaluating the Fetus with a Nonreassuring FHR Pattern

In the fetus with a persistently nonreassuring FHR pattern, where nonsurgical efforts at reversing or improving the pattern fail, the next step is to attempt to find out whether the hypoxia has progressed to metabolic acidosis.

FETAL SCALP pH.

Determination of fetal scalp pH is historically the oldest and most well-tested method for determining if the fetus is acidotic. Technically, a plastic cone is inserted transvaginally against the fetal vertex. The cervix needs to be at least 4 to 5 cm dilated and the vertex at a -1 station or below to accomplish this. Mineral oil or another lubricant is applied to the scalp so blood will bead, and then using a lancet, the scalp is pricked and blood is then collected in a long capillary tube (Fig. 14-31). The tube will hold about 100 μ l of blood, and about 30 μ l is needed to perform a pH test alone and 70 μ l to determine P_{CO_2} as well. To determine if an acidosis is metabolic or respiratory, the P_{CO_2} is needed. This is an important distinction, as the question being asked is whether there has been sufficient hypoxia to lead to metabolic acidosis. Respiratory acidosis is far less concerning, but without determining P_{CO_2} , this cannot be sorted out. Unfortunately, it is difficult to obtain enough blood for both pH and P_{CO_2} in most instances. P_{CO_2} determination is especially important when doing scalp pH for variable decelerations, as most acidosis is respiratory in this situation. A

Figure 14-31 Technique of fetal scalp blood sampling.

scalp pH less than 7.20 is consistent with fetal acidosis and a pH of 7.20 to 7.25 is borderline and should be repeated immediately. A reassuring value over 7.25 must be repeated every 20 to 30 minutes as long as the pattern persists and the fetus is not acidotic. In practice, because this technique is cumbersome, fraught with technical inaccuracy, uncomfortable for the patient, and with the requirement to perform repeated samples, it is used very infrequently. ^[58] Even in large teaching services accustomed to using this technique, its abandonment, coupled with an appreciation for the utility of accelerations for predicting presence or absence of acidosis, does not appreciably increase the need for operative intervention. ^[59]

ACCELERATIONS.

In the fetus with a nonreassuring pattern, spontaneous accelerations have the same significance as those elicited by scalp or acoustic stimulation. Thus, any accelerations spontaneous or induced indicates the absence of acidosis. It should be emphasized that the absence of accelerations as well as the absence of decelerations or other patterns suggesting hypoxia should not elicit concern. The fetus is often not moving in labor; and from a pathophysiologic perspective, without evidence of hypoxia, the fetus cannot develop a metabolic acidosis. Thus, the application of the interpretation of accelerations should generally be restricted to the fetus with an otherwise nonreassuring FHR pattern, where the question is being asked: Hypoxia is present. Is the fetus now developing a metabolic acidosis?

FETAL PULSE OXIMETRY.

One of the most exciting recent developments in obstetrics is the introduction of fetal pulse oximetry. Since FHR monitoring is specifically intended to monitor fetal oxygenation and since this modality is so nonspecific, it stands to reason that what we should be using ideally is a device that directly monitors fetal oxygenation and/or pH. Since the mid 1980s, the use of pulse oximetry has revolutionized monitoring of "air-breathing" adults, children, and neonates. Virtually all patients in the operating room and in intensive care units are monitored with this device, and direct benefit has been demonstrated in reducing hypoxia-related anesthetic deaths. ^[60] The application of this modality to the fetus has been hindered by several problems. The fetus is inaccessible. The vertex in labor poses problems for light transmission with pulse oximetry including hair, vernix, and meconium. Developing caput creates stasis, and the low pulse pressure of the fetus creates technical difficulty. Fetal hemoglobin will alter absorption curves of the normally used red and infrared wavelengths. It was not until a special sensor was developed that is placed transcervically to lie against the fetal cheek that many of these problems were overcome (Fig. 14-32). This device accurately determines

Figure 14-32 Technology for fetal pulse oximetry. *A*, This is the face of the sensor used to determine fetal oxygen saturation. On its surface are three gold-plated electrodes (contacts A, B, and C), which determine adequate electrical contact, and a photoemitter and photodetector. *B*, This figure shows the technique for insertion of the sensor. The device is inserted transcervically, as with an intrauterine pressure catheter, to lie against the fetal face, where it is held in place simply by the pressure of the uterine cervix or pelvic sidewall. *C*, The sensor is connected to this monitor, which processes the signal and displays (left to right) fetal oxygen saturation, pulse amplitude, fetal heart rate, and adequacy of electrical contact. This device can be connected to a conventional fetal monitor that displays the oxygen saturation continuously on the contraction channel (see Fig. 14-19).

fetal oxygen saturation and continually records the value on the lower (contraction) channel of the electronic FHR monitor.

The second hurdle to overcome was to determine if there was a reliable "critical threshold" that could be determined. The concept of the critical threshold is that a fetal metabolic acidosis will not develop until the fetal oxygen saturation falls below a certain value. In multiple animal and human studies there is essentially uniform agreement that this critical threshold is a saturation of 30 percent.^[61]^[62]^[63] Normal fetuses in labor have a range of oxygen saturation of about 40 to 70 percent.^[64] In animals, a fetal metabolic acidosis will not develop until levels below 30 percent are reached.^[61] In humans, this value has been compared to scalp pH in fetuses with nonreassuring FHR patterns, and there is an extremely high correlation between the cutoff value of 30 percent and the scalp pH value of 7.20.^[62] Furthermore, Dildy and colleagues demonstrated that in over 1,100 umbilical cord pH samples, there were no cases of significant metabolic acidosis with a fetal oxygen saturation above 30 percent.^[63] In addition, the saturation must remain below 30 percent for a substantial period of time (about 10 minutes or more) before a metabolic acidosis develops in most situations in labor.

Fetal pulse oximetry was approved by the Food and Drug Administration (FDA) for use in fetuses with nonreassuring FHR patterns in May 2000. The approval was made on the basis of the previously mentioned data and the results of a large multicenter trial of over 1,000 patients comparing FHR monitoring alone versus FHR monitoring backed up by pulse oximetry in fetuses already having nonreassuring FHR patterns.^[65] Whereas the trial did not demonstrate an overall reduction in cesarean section, there was a reduction in cesarean section for NRFS and an improved specificity and sensitivity of operative intervention for the fetus with depression, acidosis, and in need of resuscitation. Most importantly, in following the fetus with a nonreassuring FHR tracing but a reassuring oxygen saturation value (>30 percent), there was no increase in babies with adverse outcomes.

Therefore, fetal pulse oximetry may prove to be an excellent alternative to fetal scalp pH monitoring in patients with nonreassuring FHR patterns and may allow continued monitoring and avoid intervention of fetuses with apparently nonreassuring FHR patterns but with normal oxygenation. Since at this time there is such limited clinical experience in this country and few confirmatory studies of its value in practice are available, it is difficult to determine how it will impact practice; however, its potential is quite promising. It is unlikely that this modality will replace EFM for many years to come for several reasons. It cannot be used until the membranes are ruptured, and the cervix is at least 2 to 3 cm dilated. FHR monitoring is highly reliable when reassuring, and in the current format the monitor is needed to correlate and prognosticate changes in fetal oxygen saturation. Fetal pulse oximetry in its current form only gives an adequate signal about 70 percent of the time, although this will improve as the technology continues to be perfected.^[65] Finally, the FHR pattern gives some clues as to the mechanism of hypoxia, allowing specific therapy to be provided, and the pulse oximeter only quantifies the degree of hypoxia. These modalities are complementary, and the potential for improving intrapartum assessment of the hypoxic fetus is vast.

Operative Intervention for Nonreassuring Fetal Status

When the fetus is determined to have a persistently nonreassuring FHR pattern and backup methods (scalp pH, accelerations, pulse oximetry) cannot provide reassurance that the fetus is not acidotic, operative intervention is indicated to expeditiously deliver the baby to avoid further deterioration. Several questions arise when the decision has been made for intervention for NRFS. What is the best choice, operative vaginal delivery or cesarean section? How much time do we have to perform the delivery? What anesthetic should be used? What is the prognosis of the baby? And, finally, are there situations where the baby is already damaged or otherwise not likely to benefit from this intervention?

Choosing operative vaginal delivery or cesarean section is not difficult if the patient is in early labor. For the patient near or at complete dilation, this becomes a question of judgment. Which route is more likely to create the more rapid delivery while at the same time result in the least complications for mother and baby? When the clinician is unsure whether an attempt at operative vaginal delivery will succeed, the question is even more difficult. This decision will depend not only on the variables that predict success for an operative vaginal delivery (e.g., station, clinical pelvimetry, size of the baby, skill of the clinician) but also on the severity of the FHR pattern and whether there is time to find out whether an operative delivery will succeed. The time for intervention also is a question of judgment. Except for the situation of a prolonged deceleration to less than 70 bpm with loss of variability that will not recover and requires the most rapid intervention safely possible, most other situations require judgment and integration of the entire clinical picture of mother and baby.

The question of how much time is available to perform an operative intervention in the face of a nonreassuring FHR pattern is a complex one, muddled not only by the unpredictability of the nonreassuring pattern, but also by the medicolegal pressures that have arisen as a result of EFM. The ACOG recommends

that "all hospitals have the capability of performing a cesarean delivery within 30 minutes of the decision to operate,"^[66] but that "not all indications for a cesarean delivery will require a 30-minute response time." The examples given that mandate an expeditious delivery include hemorrhage from placenta previa, abruptio placentae, prolapse of the umbilical cord, and ruptured uterus. In some situations (e.g., sustained prolonged deceleration to <70 bpm with loss of variability), 30 minutes may be too long to avoid damage; in others, this may be too restrictive and may result in suboptimal anesthetic choices and compromised preoperative preparation. Thus, a judgment made on the basis of the severity of the FHR pattern and the overall clinical status of mother and baby must be integrated into this difficult decision.

MANAGEMENT OF NONREASSURING FHR PATTERNSA PROPOSED PROTOCOL

The following algorithm for management of nonreassuring patterns is proposed.

1. When the pattern suggests the beginning development of hypoxia or is already nonreassuring:
 - a. Identify when possible the cause of the problem (e.g., hypotension from an epidural).
 - b. Correct the cause (e.g., fluids and ephedrine to correct the hypotension).
 - c. Give measures to maximize placental oxygen delivery and exchange: oxygen by face mask, lateral positioning, hydration, consider decreasing or discontinuing oxytocin.
2. If the pattern becomes or remains nonreassuring and the above measures have been completed:
 - a. Attempt to provide other measures of reassurance to rule out metabolic acidosis.

Accelerations spontaneous or elicited
Scalp pH
Fetal pulse oximetry

- b. If reassurance using one of the above methods can be provided, and the pattern persists, continuous or intermittent (every 30 minutes) evidence of absence of acidosis must be ascertained.
- c. If reassurance of the absence of acidosis cannot be provided, deliver expeditiously by the safest and most reasonable means (operative vaginal or cesarean section).

Patterns that qualify as nonreassuring and cannot be corrected and therefore warrant evidence of the absence of metabolic acidosis include:

1. Persistent late decelerations (>50 percent of contractions).
2. Nonreassuring variable decelerations.
 - a. Progressively severe.
 - b. With developing tachycardia and loss of variability.
 - c. With developing slow return to baseline.
3. Sinusoidal tracing.
4. Recurrent prolonged decelerations.
5. The confusing pattern.
 - a. The patient presents with a pattern of absent variability but without explanatory decelerations.
 - b. An unusual pattern that does not fit into one of the categories defined above but does not have elements of a reassuring pattern.

Several of the above presentations and others warrant additional discussion. Prolonged decelerations that will not return to baseline are a potentially ominous situation. Causes of these patterns include virtually any substantial insult that can cause severe hypoxia, especially when the FHR goes below 80 bpm. Examples include abruptio placentae, ruptured uterus, cord prolapse or sustained cord compression, profound hypotension, maternal seizure or respiratory arrest, and rapid descent and impending delivery of the fetus. Generally, the following approach to these sustained prolonged decelerations should be taken. First, be patient. Often these are noticed on the central monitor and caregivers unnecessarily run to the room and frighten the patient and family. Since the vast majority of these decelerations will spontaneously resolve in 1 to 3 minutes, such action is usually unwarranted. If the deceleration does not resolve, the patient should be examined to rule out cord prolapse or sudden descent. If these are not present, determine if there is an apparent cause that can be specifically corrected. If the cause cannot be found, the general explanation by process of elimination is sustained cord compression, and repositioning the patient, oxygen administration, and discontinuing oxytocin is all that can be provided. Should none of these work, operative delivery will be required unless spontaneous delivery is imminent. How long one should wait for the corrective measures and/or spontaneous recovery to occur is somewhat variable. This will be determined by the depth of the deceleration, the loss of variability during the deceleration, whether evidence of hypoxia preceded the deceleration, and whether the heart rate is intermittently returning toward baseline or is just staying down. Evidence to recommend a precise amount of time wherein intervention must occur is difficult to integrate, as the vast majority of time we are dealing with relative hypoxia rather than complete anoxia. Complete anoxia in real life probably occurs only

with severe degrees of uterine rupture and complete abruption. Even with cord prolapse, the vast majority of time there is some cord blood flow. Windle performed the classic experiment using complete anoxia in fetal monkeys.^[67] Monkeys allowed to breathe in 6 minutes or less showed no clinical or pathologic ill effects. Asphyxiation for 7 to 12 minutes resulted in transient motor and behavioral changes, with some scarring in certain specific brain areas in some animals. Those anoxic for 12 to 17 minutes, if death did not occur, had the most severe neurologic and clinical effects. Therefore, in the worst case of all, if delivery occurs in less than 12 minutes from the onset of the deceleration, damage will be unlikely, unless there was some hypoxia prior to the deceleration.

The most difficult pattern to manage is in the fetus with recurrent prolonged decelerations that do recover (Fig. 14-33). Generally, these can be managed using the same algorithm for nonreassuring patterns as described above. However, even if one can provide reassurance that acidosis does not exist following any of the decelerations, there is a concern that this pattern portends a deceleration that will recur and will not recover, and one will be placed in the situation described in the previous paragraph. Therefore, there will be occasions when the recurrent prolonged decelerations are concerning enough that operative intervention is warranted even if there is no concern about acidosis at the present moment. One must integrate the frequency, severity, and duration of the deceleration; the fetal response in terms of tachycardia and loss of variability; and how much time is expected before spontaneous delivery will occur to make this difficult decision. Therefore, for example, in the nulliparous patient at 4 cm, having decelerations lasting 4 minutes to 70 bpm every 10 minutes, operative delivery may be warranted. Whereas in the multipara at 8 cm making normal progress with similar or less frequent decelerations, it may be justified to manage these expectantly, but with all preparations made for immediate delivery should one of the decelerations not recover.

Auscultation as an Alternative

Almost all randomized controlled trials have demonstrated that intermittent auscultation is as effective as EFM in detecting fetal hypoxia in labor. There are some limitations to this statement, however. Virtually all of these trials compared EFM to intermittent auscultation with one-on-one nursing, where the auscultation was performed every 15 minutes in the first stage and every 5 minutes in the second stage, and the auscultation was performed for a period of 60 seconds through and following an entire uterine contraction. This is a situation that is difficult to duplicate in everyday practice because of lower nurse/patient ratios and because

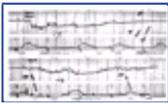

Figure 14-33 Recurrent unexplained prolonged decelerations.

Figure 14-34 These persistent late decelerations associated with absent variability are difficult to recognize even with an internal electrode. This is a nonreassuring FHR pattern, which is often ominous. It is unlikely that such decelerations, associated with a normal baseline rate, would be recognized with intermittent auscultation.

emergencies with other patients often take a nurse away from the bedside for long periods of time. Second, in most of the studies, fetuses who entered labor may have been monitored electronically prior to randomization, and often very-high-risk patients were excluded from study. Ingemarsson et al. have shown that 50 percent of patients who will develop nonreassuring FHR patterns in labor will have a nonreassuring FHR pattern on admission. ^[68] And finally, in virtually all of the studies comparing EFM with auscultation, when the auscultated FHR was abnormal, the patient was then monitored electronically. Furthermore, there are nonreassuring FHR tracings that are quite indicative of hypoxia and acidosis that are not likely to be detected with auscultation ([Fig. 14-34](#)).

Therefore, it is reasonable to conclude that auscultation is an acceptable option for monitoring the fetus in labor when certain conditions are in place. The fetus should have a reassuring FHR on admission monitored electronically. The patient should have one-on-one nursing. The standards for frequency from the ACOG for auscultation are at least every 30 minutes in the first stage and every 15 minutes in the second stage for the low-risk patient and every 15 minutes in the first stage and every 5 minutes in the second stage for the high-risk patient. ^[46] Fetuses with abnormal FHR patterns on auscultation should have electronic monitoring to define the pattern and monitor for progression to worsening or nonreassuring patterns.

ASSESSMENT OF FETAL CONDITION AT BIRTH

The Apgar score was originally introduced as a tool to be used in guiding the need for neonatal resuscitation. Subsequently, this means of fetal assessment became

425

used routinely for all births. However, the Apgar score has been expected to predict far more than was originally intended. Such expectations have included evaluating acid-base status at birth (i.e., the presence or absence of perinatal asphyxia) and even predicting long-term prognosis. Unfortunately, the Apgar is a nonspecific measure of these parameters, as many other causes of fetal depression may mimic that seen with asphyxia, such as drugs, anomalies, prematurity, suctioning for meconium, and so forth. In situations where FHR patterns have been concerning and other back-up methods for evaluating fetal oxygenation or fetal acid-base status have been utilized, or in cases where the baby is unexpectedly depressed, it is important to specifically evaluate these parameters at birth, using umbilical cord blood gases. To accomplish this, a doubly clamped 10- to 30-cm section of umbilical cord is taken after the original cord clamping and separation of the baby from the cord. Using heparinized syringes, samples of umbilical artery and vein are separately obtained. These samples are evaluated for respiratory gases. Normal ranges for umbilical cord gases are shown in Table 14-1. Cord blood PO₂ or O₂ saturation is not useful, as many normal newborns are initially hypoxemic until normal extrauterine respiration is established. While cord pH, especially arterial, is the essential value, PCO₂ is also very important, as if the pH is low, the PCO₂ is used to determine whether the acidosis is respiratory or metabolic. Respiratory acidosis is not predictive of newborn or long-term injury and should correlate with little or no need for resuscitation. In addition, the cord gases should be used to correlate interpretation of the FHR patterns, as previously described in the sections on their pathophysiology and to determine the appropriateness of operative intervention or lack of it. These gases can help the pediatrician in determining the etiology of immediate complications and the need for more intense observation of the baby. In addition, these values are

TABLE 14-1 -- NORMAL BLOOD GAS VALUES OF UMBILICAL ARTERY AND VEIN

	Mean Value	Normal Range*
Artery		
pH	7.27	7.15 to 7.38
PCO ₂	50	35 to 70
Bicarbonate	23	17 to 28
Base excess	-3.6	-2.0 to -9.0
Vein		
pH	7.34	7.20 to 7.41
PCO ₂	40	33 to 50
Bicarbonate	21	15 to 26
Base excess	-2.6	-1.0 to -8.0

Data derived from Thorp and Rushing.^[65]

* Values are ± 2 SD and represent a composite of multiple studies.

often useful if the baby develops any long-term neurologic injury in determining whether any such injury may have been related to peripartum asphyxia. Studies have shown that if such asphyxia is present, in order for it to result in long-term injury it must have been severe (metabolic acidosis with a pH <7.0 to 7.05) and be associated with multiple organ dysfunction in the newborn period.^[2]

RISKS AND BENEFITS OF EFM

Electronic FHR monitoring was introduced with the hope that this modality would reduce or eliminate the devastating consequences of asphyxia. Enthusiasm for this new technology established the role of continuous FHR monitoring in labor before studies demonstrated its accuracy. Initial retrospective studies evaluated more than 135,000 patients and showed more than a three-fold improvement in the intrapartum fetal death rate for patients monitored electronically.^[70] However, the majority of subsequent prospective, randomized, controlled trials have failed to demonstrate an improvement in the intrapartum fetal death rate using EFM.^{[70] [71] [72] [73] [74] [75] [76]} In these studies, however, electronic FHR monitoring was compared with frequent intermittent auscultation with one-on-one nursing, a standard that is difficult to maintain. Many patients with abnormal FHR patterns on admission were not randomized and, virtually always, patients with an abnormal FHR on auscultation were ultimately monitored electronically. A more recent randomized controlled trial of EFM versus intermittent auscultation did demonstrate a significant improvement in perinatal mortality in the electronically monitored group.^[77] The past three decades have not shown a change in the 2 per 1,000 incidence of cerebral palsy, suggesting that the widespread use of EFM has not affected this problem. However, these data are somewhat difficult to analyze because of other changes occurring simultaneously. There has been a dramatic improvement in the survival of very-low-birthweight premature babies during this time period, and prematurity accounts for the majority of cerebral palsy. Second, term babies with asphyxia have had an increase in survival during this time period, thus allowing for a potential increase in surviving children with brain damage. Any of these factors may obscure an effect that FHR monitoring may have had in reducing the incidence of cerebral palsy. EFM has other potential benefits. These include an ability to understand the mechanism of developing hypoxia and treat it more specifically. It provides the ability to accurately monitor uterine contractions so we can better understand progress or lack of progress in labor as well as monitor the effects of oxytocin-stimulated

contractions on fetal oxygenation. The monitor is ultimately, like all other monitors in intensive care situations, a labor-saving device allowing nurses to perform other tasks simultaneously.

EFM has several disadvantages, however. During the period in which FHR monitoring has risen in popularity, there was a parallel increase in the cesarean section rate. Certainly, this was not all caused by EFM, as there were many other changes in obstetric practice during this time period. In virtually all of the randomized controlled trials, EFM resulted in an increase in the cesarean section rate over intermittent auscultation without a concomitant improvement in outcome.^{[79] [71] [72] [73] [74]} There is also, however, a desire to deliver babies before significant hypoxia has any potential to damage the baby, and the nonspecific changes in FHR only fuel this concern, setting up the current environment of excessive intervention. In reality, metabolic acidosis occurs in only about 2 percent of all labors, and even allowing for a reasonable amount of latitude in early intervention, cesarean section rates should not exceed 4 to 5 percent for this indication. Unfortunately, rates of 10 percent for NRFS are common. Thus, the need for better, more specific modalities to allow us to evaluate hypoxia and acidosis in the fetus with a nonreassuring FHR pattern are needed. Fetal pulse oximetry appears to have great potential, but its effect on cesarean section rates in real practice remains to be seen.

The second major problem associated with EFM is the fear of a lawsuit should the child be compromised in any way. The monitor has created an expectation of perfect outcome. The interpretation of abnormal FHR tracings is highly subjective and variable, and "experts" often give diametrically opposite interpretations of the same tracing. The modality itself is nonspecific, and babies with anomalies or preexisting brain damage will often have abnormal FHR tracings easily confused with ongoing hypoxia. Finally, a jury cannot help but be sympathetic to a family and baby with disfiguring and debilitating cerebral palsy, and large financial awards seem to be the only way at present to compensate these unfortunate victims. However, these outcomes are not consistent with what we know about asphyxia. More than 75 percent of brain-damaged children have causes that are *not* related to perinatal asphyxia. Many cases of asphyxia occur *prior to* labor or early in labor before the patient arrives in the hospital. Very few of these cases are truly preventable. Again, a modality such as fetal pulse oximetry would seem to have the potential to clarify whether an abnormal FHR pattern is truly hypoxic in origin and eliminate any subjectivity in interpretation. One can only hope that once these pressures are removed from the labor and delivery suite, the opportunity to do what is best for the fetus and mother will be enhanced and this will be the only motivating force.

SUMMARY

Electronic FHR monitoring has become the standard means for evaluating fetal oxygenation in labor. Because of fetal inaccessibility and the lack of alternatives to more specifically evaluate fetal oxygenation, this modality has been the only alternative. FHR monitoring is reliable when it tells us the fetus is well oxygenated, but more often unreliable when it suggests the fetus is "in distress." The recent change in terminology describing the abnormal FHR pattern as "nonreassuring" is a more accurate and honest depiction of the limitations of EFM in this situation. Despite or even because of these limitations, it is imperative that the clinician understand as much as possible about the underlying physiologic explanations of normal and abnormal FHR patterns, as this allows the only reasonable opportunity to appropriately evaluate and manage these changes. The goal of FHR monitoring should be to carefully and thoroughly monitor all patients in active labor; avoid unnecessary operative and nonoperative intervention for benign and innocuous FHR patterns; correct nonreassuring FHR patterns with noninvasive, etiology specific therapies when possible; or if not possible use appropriate means such as scalp pH, accelerations, or fetal pulse oximetry to rule out acidosis; and finally, if acidosis cannot be ruled out, operatively intervene in an expeditious manner appropriate for the entire clinical situation.

Key Points

The goals of intrapartum fetal evaluation by electronic fetal heart rate monitoring and available back-up methods are to detect fetal hypoxia, reverse the hypoxia with nonsurgical means, or if unsuccessful, determine if the hypoxia has progressed to metabolic acidosis, and if so deliver the baby expeditiously to avoid the hypoxia and acidosis from resulting in any damage to the baby.

EFM is an inherently suboptimal method of determining fetal hypoxia and acidosis, because many factors besides these variables may alter the FHR and mimic changes caused by hypoxia and acidosis. When the FHR is normal, its reliability in predicting the absence of fetal compromise is high, but when the FHR is abnormal, its reliability in predicting the presence of asphyxia is poor.

427

The term "fetal distress" should be abandoned in favor of "nonreassuring fetal status," because when the fetal monitor suggests there may be a problem, in most circumstances we can only say that we are no longer reassured with a high degree of certainty that the fetus is well oxygenated.

Late decelerations are always indicative of relative fetal hypoxia, and are caused by inadequate oxygen delivery, exchange, or uptake that is aggravated by the additional hypoperfusion of the placenta caused by contractions. Variable decelerations are caused by a decrease in umbilical cord flow resulting from cord compression or cord stretch. Prolonged decelerations may be caused by any mechanism that decreases fetal oxygenation.

In labor, loss of variability, loss of accelerations, and tachycardia should only be interpreted as indicative of fetal compromise in the presence of nonreassuring decelerations (late, nonreassuring variable or prolonged decelerations), as signs of hypoxia should always precede signs of neurologic depression secondary to hypoxia.

In the presence of oligohydramnios and variable decelerations, or with meconium, intrapartum amnioinfusion has been shown to decrease rates of cesarean delivery for NRFS and to decrease neonatal respiratory complications caused by meconium aspiration.

In the presence of an otherwise nonreassuring FHR pattern, the presence of accelerations of the FHR, either spontaneous or elicited by scalp stimulation or vibroacoustic stimulation, indicate the absence of fetal acidosis. Their absence is associated with a 50 percent chance of fetal acidosis, but only in the setting of a nonreassuring FHR.

Umbilical cord blood gases should be obtained and documented in situations where there is a nonreassuring or confusing FHR pattern during labor, where there is neonatal depression following birth, with premature babies, and when suctioning for meconium is performed. These values will help clarify the reasons for abnormal FHR patterns or for neonatal depression.

Fetal pulse oximetry was approved in May 2000 by the FDA for use in term (36 weeks) patients with nonreassuring FHR patterns. This technology may improve our ability to more accurately interpret nonreassuring FHR patterns and may have the potential to decrease cesarean sections for NRFS.

Although there is correlation between a nonreassuring FHR pattern and neonatal depression, the FHR is a poor predictor of long-term neurologic sequelae. Furthermore, fetuses with previous neurologic insults may have significantly abnormal FHR patterns even when they are well oxygenated in labor.

GLOSSARY

Acidemia

increased hydrogen ion concentration in blood.

Acidosis

increased hydrogen ion concentration in tissue.

Asphyxia

hypoxia with metabolic acidosis.

Base deficit

buffer base content below normal (this is calculated from a normogram using pH and P_{CO_2}).

Base excess

buffer base content above normal.

Hypoxemia

decreased oxygen concentration in blood.

Hypoxia

decreased oxygen concentration in tissue.

pH

the negative log of hydrogen ion concentration ($7.0 = 1 \times 10^{-7}$).

Chapter 15 - Obstetric Anesthesia

Joy L. Hawkins
David H. Chestnut
Charles P. Gibbs

The reader is referred to the Appendix for illustrations of anatomy relevant to this discussion.

The word "anesthesia" encompasses all techniques used by anesthesiologists: general anesthesia, regional anesthesia, local anesthesia, and analgesia. Traditionally, general anesthesia includes four stages during which not only sensation but also consciousness and motor and reflex activities are gradually lost. During stage I, termed analgesia, memory and sensitivity to pain fade, yet consciousness and protective reflexes such as swallowing and laryngeal closure persist. Inhalation analgesia may be used for vaginal delivery, commonly in combination with local infiltration or pudendal block. Alone, this degree of anesthesia is not sufficient for even minor surgical incisions, including episiotomy. Stage II, the excitement stage, borders consciousness and unconsciousness. The patient may be agitated and uncooperative. Protective laryngeal reflexes may be either hyperactive or obtunded. Anesthesiologists avoid the second stage by keeping the patient in stage I or by rapidly inducing stage III with the aid of fast-acting barbiturates and muscle relaxants. The patient must also pass through this stage on awakening. Induction of and emergence from general anesthesia are usually the most dangerous times for the patient, because marked cardiovascular, respiratory, and laryngeal reflex changes occur.

Stage III, which is used for most surgical procedures, has four planes. As anesthesia deepens, it progressively depresses the central nervous, cardiovascular, and respiratory systems. Laryngeal reflexes nearly disappear; thus, vomiting or regurgitation render the patient particularly susceptible to aspiration unless her airway is protected by an endotracheal tube. Stage IV terminates in death.

Anesthesiologists can produce all stages of general anesthesia. With the proper dose, concentration, and combination of agents, a specific anesthetic technique is matched to the requirements of a given procedure. The requirements for general anesthesia for cesarean delivery differ considerably from those for craniotomy, cholecystectomy, or exploratory laparotomy for a ruptured ectopic pregnancy, yet all these patients will be rendered unconscious, immobile, and pain free.

Balanced general anesthesia is the type of general anesthesia used for obstetrics; it usually refers to various combinations of barbiturates, inhalation agents, opioids, and muscle relaxants as opposed to high concentrations of potent inhalation agents alone. General anesthesia is used in obstetrics mainly for cesarean section and rarely is required for vaginal delivery.

Regional analgesia/anesthesia uses local anesthetics to provide sensory as well as various degrees of motor blockade over a specific region of the body. In obstetrics, regional techniques include major blocks, such as spinal and lumbar or caudal epidural, as well as minor blocks, such as paracervical, pudendal, and local infiltration ([Fig. 15-1](#)). In some cases, the anesthesiologist may combine a local anesthetic and opioid for epidural or spinal administration.

PAIN PATHWAYS

Pain during the first stage of labor results primarily from cervical dilation and secondarily from uterine contractions themselves. Painful sensations travel from the uterus via visceral afferent (sympathetic) nerves that enter the spinal cord through the posterior segments of thoracic spinal nerves 10, 11, and 12 ([Fig. 15-1](#)). Pain during the second stage of labor results primarily from

432

Figure 15-1 Pain pathways of labor and delivery and nerves blocked by various anesthetic techniques.

distention of the pelvic floor, vagina, and perineum by the presenting part of the fetus. (Some physicians contend that uterine contractions themselves may also contribute to pain during the second stage.) The sensory fibers of sacral nerves 2, 3, and 4 (i.e., the pudendal nerve) transmit painful impulses from the perineum to the spinal cord ([Fig. 15-1](#)).

PERSONNEL

An anesthesiologist is a physician who has completed 4 years of postgraduate residency training in anesthesia. A nurse anesthetist is a registered nurse (with variable

433

background and training) who has completed a 2- to 3-year training program sponsored by the American Association of Nurse Anesthetists. Most states require that nurse anesthetists be supervised or directed by a physician. Ideally, an anesthesiologist assumes this role, which results in an efficient anesthesiologist/anesthetist team. Either an anesthesiologist working independently or an anesthesiologist/anesthetist team provides anesthesia for 96 percent of obstetric procedures in larger hospitals in the United States.^[1] Nurse anesthetists, independent of anesthesiologists, provide anesthesia for 4 percent of operations in larger hospitals, but 59 percent of obstetric procedures in hospitals with fewer than 500 births per year.^[1] Almost all hospitals with more than 300 beds will have an anesthesiologist on the medical staff, while only 16 percent of hospitals with fewer than 50 beds will have an anesthesiologist available.^[2] In this situation, the operating surgeon or obstetrician must assume the role of supervisor. When anesthetic-related untoward events occur, the nonanesthesiologist supervising a nurse anesthetist often will be ultimately responsible for the treatment and outcome of those events. The American Society of Anesthesiologists and the American College of Obstetricians and Gynecologists (ACOG) issued the Joint Statement on the Optimal Goals for Anesthesia Care in Obstetrics.^[3] That statement recommends that there be a qualified anesthesiologist responsible for all anesthetics in every hospital providing obstetric care. The statement notes: "There are obstetric units where obstetricians or obstetrician-supervised nurse anesthetists administer anesthetics. The administration of general or regional anesthesia requires both medical judgment and technical skills. Thus, a physician with privileges in anesthesiology should be readily available."^[3]

PAIN AND STRESS

When considering obstetric anesthesia, reasonable questions include the following: How painful is labor? How stressful is labor? What are the effects of pain and stress? What role does anesthesia play? Melzack and colleagues^[4] provided perhaps the most sophisticated, enlightened, and in-depth study of labor pain. Using the McGill Pain Questionnaire, which measures intensity and quality of pain, these investigators quantified and described the reaction of 87 nulliparous and 54 parous patients to labor pain. When pain rating index scores were assigned to each parturient's description of labor pain and compared with those of other patients suffering different kinds of pain, 59 percent of nulliparous and 43 percent of parous patients described their labor pain in terms more severe than did those suffering back and cancer pain. More than 50 percent of the obstetric patients described their pain as sharp, cramping, and intense; more than 33 percent as aching, throbbing, stabbing, shooting, heavy, and exhaustive; and 25 percent of nulliparous patients and 9 percent of parous patients as horrible or excruciating. In contrast, only 24 percent of parous patients and 9 percent of nulliparous patients described the pain as relatively minor. Although those with childbirth training reported less pain than those without such training, the differences were small. Eighty-one percent of trained patients requested epidural anesthesia compared with 82 percent of those without training. The most substantial predictors of pain intensity proved to be socioeconomic status and prior menstrual difficulties.

How does the body respond to the pain and stress of labor? Does the response affect mother, fetus, or both? Most investigators have described and quantified the body's response to stress in terms of the release of certain hormones, namely, adrenocorticotropic hormone (ACTH), cortisol, catecholamines, and -endorphins (Fig. 15-2).

What kind of response does labor invoke? The following have been reported: prolonged increases of plasma cortisol levels in early labor,^[5] increases of both ACTH and cortisol during labor and immediately postpartum,^[6] and increases in epinephrine, norepinephrine, and -endorphins throughout labor.^[7] These are the same responses described during other types of pain,^[9] surgical stress,^[10] and even hypoxia.^[11] Thus, many of the hormones associated with stress are elevated during labor.

What are the effects of these hormones on pregnancy? Elevated epinephrine levels are found in patients with anxiety and prolonged labor, which is not surprising, considering the well-known uterine relaxant effects of -adrenergic agents.^[12] Animal studies indicate that both epinephrine and norepinephrine can decrease uterine blood flow and cause fetal asphyxia.^[13] Furthermore, these alterations may occur without clinical signs, because uteroplacental blood flow can change in the absence of heart rate and blood pressure change.^[14] Maternal psychological stress can detrimentally affect the fetal cardiovascular system and acid-base status as demonstrated in baboons and monkeys.^[15] In pregnant sheep, catecholamines increase and uterine blood flow decreases after both painful and nonpainful stimuli (Fig. 15-3). In humans, sudden noise and flashing lights predictably increase maternal heart rate. Not so predictably, fetal heart rate responds similarly within 45 seconds.^[16] Fear produces similar effects.^[17]

If one accepts that anxiety, pain, and labor are forms of stress and that stress may be harmful, can anesthesia, by alleviating pain, minimize the effects of that stress? Postpartum women suffer objective deficits in cognitive and memory function.^[20] Intrapartum analgesia

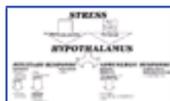

Figure 15-2 The stress response.

does not exacerbate, but rather *lessens* the defect compared to unmedicated parturients. Presumably, cognitive function is adversely affected by the stress of labor, which is mitigated by judicious use of analgesics. Epidural anesthesia prevents increases in both cortisol and 11-hydroxycorticosteroid levels during labor,^[21]^[22] but systemically administered opioids do not.^[23] Epidural anesthesia also attenuates elevations of epinephrine, norepinephrine,^[7] and endorphin levels.^[24] Presumably, regional anesthesia blocks afferent stimuli to the hypothalamus

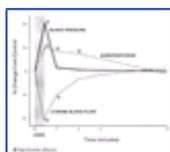

Figure 15-3 Effects of electrically induced stress (30 to 60 seconds) on maternal mean arterial blood pressure, plasma norepinephrine levels, and uterine blood flow. (Modified from Shnider SM, Wright RG, Levinson G, et al: *Uterine blood flow and plasma norepinephrine changes during maternal stress in the pregnant ewe. Anesthesiology* 50:526, 1979.)

and thus inhibits the body's response to stress^[25] (Fig. 15-4).

What of the fetus? There is convincing evidence that anesthesia, sedation, or both effectively decrease asphyxia-inducing effects of psychologically induced stress in monkey and baboon fetuses.^[18]^[26] Furthermore, acid-base status of human infants whose mothers receive epidural anesthesia during the first stage of labor is altered less than infants of mothers who do not receive regional anesthesia. During the second stage of labor, the salutary effects of anesthesia may be limited to the mother.^[27]

ANESTHESIA FOR LABOR

Psychoprophylaxis

Psychoprophylaxis is a nonpharmacologic method of minimizing the perception of painful uterine contractions. Relaxation, concentration on breathing, gentle massage (effleurage), and partner participation contribute to its effectiveness. One of the method's most valuable contributions is that it is often taught in prepared childbirth classes where patients learn about the physiology of pregnancy and the normal processes of labor and delivery. In many instances, partner and wife may visit the hospital and the labor and delivery suites before labor, to mitigate the fear of the unknown.

Although psychoprophylactic techniques may discourage the use of drugs, not all patients are alike and not all will be satisfied with psychoprophylaxis. ^[29] The greatest disadvantage is the potential for believing the use of drug-induced pain relief is a sign of failure and

435

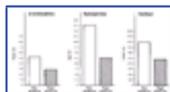

Figure 15-4 Effects of epidural analgesia on the response to stress.

will harm the child. Those who believe that accepting analgesia is a sign of failure do not understand that some labors are longer and/or more painful than others and that some patients have lower pain thresholds than others. Furthermore, there are times when anesthesia will be *required* for vaginal or cesarean delivery. In these instances, both mother and fetus should benefit from all that modern medicine can provide. Anyone who doubts that modern anesthetic techniques can be applied to the pregnant patient without harm to her or to her unborn child need only be aware that approximately 25 percent of all births in the United States today are cesarean births. All of these patients receive anesthesia, yet few believe that such anesthesia results in harm to the fetus, and no one would suggest that these patients avoid anesthesia.

Systemic Opioid Analgesia

Opioids (also known as narcotics) are drugs possessing morphine-like pharmacologic actions. ^[29] Morphine and codeine are natural alkaloids derived from opium. Opioids such as hydromorphone and heroin are semi-synthetic compounds made by a simple alteration of the morphine molecule. Meperidine, alphaprodine, and fentanyl are synthetic compounds resembling morphine. ^[29] All opioids provide pain relief and a sense of euphoria, hence their use in obstetrics. However, opioids also produce respiratory depression, the degree of which is usually comparable for equipotent analgesic doses. Also, all opioids freely cross the placenta to the newborn. ^[30], ^[31] Therefore, the risk associated with opioids for obstetrics is obvious all can produce respiratory depression in both mother and newborn. ^[32], ^[33] Nevertheless, when used properly, they can be safe and effective.

In the past, because large doses of the long-acting opioids (e.g., morphine) were given intramuscularly throughout labor, depressant effects on the infant were observed. ^[34] Currently, morphine is rarely used for pain relief during labor. Instead, smaller doses of other opioids are used and are administered via the more predictable intravenous route. Therefore, recent reports detail little neonatal depression. ^[35], ^[36] In addition, anesthesiologists recently have begun to give opioids (with or without local anesthetics) via the epidural or sub-arachnoid (i.e., spinal) space. Opioids may then bind to opioid receptors in the spinal cord and thereby produce segmental analgesia.

The immediate treatment for respiratory depression caused by opioids is ventilation. Infants depressed by opioids may be sleepy and may not breathe adequately. Initially, they typically are not hypoxic, hypercarbic, or acidotic; however, if they are not ventilated, then hypoxia, hypercarbia, and acidosis will result. Hypoxia and acidosis (not opioids per se) may cause neonatal injury. If properly cared for, infants with opioid-induced depression will suffer no ill effects. Proper care includes ventilation, oxygenation, gentle stimulation, and the judicious use of the opioid antagonist naloxone. Positive-pressure ventilation is the single most effective measure and can be provided via face mask or intubation. Without ventilation, other measures are fruitless.

Naloxone, 0.1 mg/kg, should be given intravenously if possible, but it can be given intramuscularly or subcutaneously. This dose (i.e., 0.1 mg/kg) is higher than that previously recommended and should ensure an increased likelihood of effectiveness. ^[37] It may be repeated in 3 to 5 minutes if there is no immediate response. If there is no response after two or three doses, the depression

436

is most likely *not* due to opioid effect. ^[38] Nursery personnel should be advised when naloxone has been given because it has a short duration of action, and therefore repeat administration may be necessary in the nursery. Naloxone should not be used prophylactically. Specifically, it should not be given to the mother just before delivery. Pain relief afforded the mother by the opioid will be antagonized. Furthermore, because of the unpredictability of placental transfer, it is difficult to estimate how much naloxone would get to the infant. Indeed, naloxone may not be necessary at all. It should not be given routinely to all opioid-exposed newborns. ^[48] Finally, naloxone should not be given to infants of opioid-dependent mothers, because this may precipitate withdrawal in the physically dependent newborn infant. ^[48] Naloxone is a useful drug that should be available whenever opioids are used. However, it is an adjunct to ventilation, not a substitute for it.

Opioids also may produce neurobehavioral changes in the newborn, and these changes may persist for as long as 2 to 4 days. ^[39], ^[40] Although some have indicated that the effects may persist and be influential in later life, such has not been proved true. ^[41] In fact, the significance of neurobehavioral changes in general is open to question.

An important and significant disadvantage of opioid analgesia is the prolonged effect of these agents on gastric emptying. When parenteral or epidural opioids are used, gastric emptying is prolonged, and if general anesthesia becomes necessary, the risk of aspiration is increased. ^[42] ^[43] ^[44]

Morphine

Morphine is now primarily used to provide sedation and rest during the early prodromal stages of labor. With intramuscular administration, the onset of analgesia

occurs in 10 to 20 minutes and lasts for approximately 2.5 to 4 hours.^[29] With intravenous administration, the onset of analgesia is less than 3 to 5 minutes and lasts approximately 1.5 to 2 hours. Occasionally, bradycardia will follow an injection of morphine. Also, histamine release may occur and result in orthostatic hypotension. One of the more frequent and bothersome side effects of morphine is nausea and vomiting. Urinary retention is also common. As with most opioids, a small amount of morphine is eliminated in the urine unchanged. The remainder is gradually detoxified by the liver.

Meperidine (Demerol)

Meperidine 100 mg is roughly equianalgesic to 10 mg morphine, but is reported to have a less depressive effect on respiration.^[33] Usually, 25 mg is administered intravenously, or 50 to 75 mg is given intramuscularly. Shnider and Moya^[32] showed that both timing and dosage influence neonatal depression. When administered within 1 hour of delivery, little neonatal depression as reflected by Apgar scores or time to sustained respiration occurs. With a 50-mg intramuscular dose, the greatest depression occurs during the second hour; when 75 to 100 mg is administered, this effect extends through the second and third hours. Notably, when secobarbital, 100 mg, is added, depression extends even further to the fourth hour after administration.^[32] The peculiar metabolism of meperidine may partially explain the lack of depression in the first hour. Normeperidine is an active metabolite of meperidine. Normeperidine concentrations increase slowly, and therefore it exerts its effect on the newborn during the second hour after administration.^[30],^[49] Furthermore, Kuhnert and colleagues^[46],^[47] observed that multiple doses of meperidine result in greater accumulation of both meperidine and normeperidine in fetal tissues.

The analgesic action of meperidine begins in approximately 10 to 20 minutes and persists for 2 to 3 hours after intramuscular administration. Lazebnik and colleagues^[48] noted that plasma concentrations of meperidine are higher after deltoid injection than after gluteus muscle injection. They suggested that the deltoid muscle might be the preferred intramuscular site during labor. Intravenously, the onset of analgesia begins almost immediately and lasts approximately 1.5 to 2 hours. Side effects are similar to those of morphine except that tachycardia occasionally results rather than bradycardia. As with morphine, nausea and vomiting are frequent, and there is considerable delay in gastric emptying. Slightly less urinary retention occurs with meperidine than with morphine.^[29]

Fentanyl

Fentanyl is a short-acting synthetic opioid with rapid pharmacokinetics and no active metabolites. In a randomized comparison with meperidine, fentanyl 50 to 100 g every hour provided equivalent analgesia, with fewer neonatal effects and less maternal sedation and nausea.^[36] The main drawback of fentanyl is its short duration of action requiring frequent redosing or the use of a patient-controlled intravenous infusion pump.^[49],^[50]

Butorphanol (Stadol)

Butorphanol is a synthetic agonist-antagonist opioid analgesic drug. One to 2 mg is administered intravenously and compares favorably with 40 to 80 mg of meperidine.^[35],^[51] Nausea and vomiting appear to occur less with butorphanol than with other opioids.^[35] The major advantage is a ceiling effect for respiratory depression; that is, respiratory depression from multiple doses appears

to plateau.^[52],^[53] The major side effects are somnolence, dizziness, dysphoria, and opioid withdrawal syndrome in an opioid-dependent patient.

Nalbuphine (Nubain)

Nalbuphine is another synthetic agonist-antagonist opioid. Its analgesic potency is similar to that of morphine when compared on a milligram-per-milligram basis. As with butorphanol, a reported advantage of nalbuphine is its ceiling effect for respiratory depression.^[54] It may cause less maternal nausea and vomiting than meperidine, but it tends to produce more maternal sedation and dizziness, as well as the risk of opioid withdrawal in susceptible patients.^[55]

Patient-Controlled Opioid Analgesia

In some centers, opioids are administered by patient-controlled intravenous infusion. The infusion pump is programmed to give a predetermined dose of drug upon patient demand. The physician may program the pump to include a lock-out interval (i.e., there is a minimum interval between doses of drug). Thus, the physician may limit the total dose administered per hour. Advantages of this method include the sense of autonomy, which patients appreciate, as well as the fact that one avoids lengthy delays between doses. In general, this practice results in a decreased total dose of opioid during labor.^[56],^[57]

Sedatives

Sedatives do not possess analgesic qualities and are most often used early in labor to relieve anxiety or to augment the analgesic qualities and reduce the nausea associated with opioids. All sedatives and hypnotics cross the placenta freely. Perhaps the most important property of these drugs is that, except for the benzodiazepines, they have no known antagonists. Those most frequently used are barbiturates, phenothiazines, and benzodiazepines.

Barbiturates

Because barbiturates and other sedatives are not analgesic, patients may be less able to cope with pain than if they had received no pharmacologic assistance at all; that is, normal coping mechanisms may be blunted.^[58],^[59] Although barbiturates can depress both cardiovascular and respiratory functions in mother and newborn, low doses have little effect. The combination of barbiturate (100 mg secobarbital) with opioid (50 to 100 mg meperidine) increases the degree of neonatal depression.^[32] In addition, effects that do occur may persist for a prolonged time. For example, attention span can be depressed for as long as 2 to 4 days.^[60] Thus, these drugs should rarely be used during labor.

Phenothiazines

Promethazine is perhaps the most widely used phenothiazine. However, propiomazine, promazine, and hydroxyzine are also commonly administered. When given in small doses in combination with an opioid, these drugs do not seem to produce additional neonatal depression.^[61],^[62] However, like the barbiturates, these agents rapidly cross the placenta and, in large doses, can depress the fetus for a significant period. Also like the barbiturates, they have no known antagonist.

Benzodiazepines

Diazepam was the first widely used benzodiazepine. A major disadvantage of diazepam is that it disrupts thermoregulation in newborns, which renders them less able to maintain body temperature.^[63] The drug may persist in the fetal circulation for as long as 1 week.^[64] As with many drugs, beat-to-beat variability of the fetal heart rate is reduced markedly even with a single intravenous dose (i.e., 5 to 10 mg). However, these doses have little effect on acidbase or clinical status of the newborn.^[65] Sodium benzoate, a buffer in the injectable form of diazepam, competes with bilirubin binding to albumin. Thus, unbound bilirubin is increased and could be a threat to infants susceptible to kernicterus.^[66] Unlike diazepam, midazolam is water soluble, and it is shorter acting than diazepam.^[67] There are conflicting data regarding its effects on the fetus/neonate.^[68],^[69]

A disadvantage of all the benzodiazepines is their tendency to cause maternal amnesia, a significant disadvantage if the drug is given near the time of delivery.^[70] Flumazenil, a specific benzodiazepine antagonist, can reliably reverse benzodiazepine-induced sedation and ventilatory depression.^[71]

PLACENTAL TRANSFER

Essentially, all analgesic and anesthetic agents except muscle relaxants cross the placenta, ^[72] ^[73] ^[74] ^[75] although muscle relaxants cross in only small amounts. That muscle relaxants do not readily cross the placenta is one of the major factors that enables anesthesiologists to utilize general anesthesia for cesarean delivery without causing fetal paralysis.

Placental transfer of any agent begins with uptake of the agent into the bloodstream of the mother and thus distribution to all internal organs, one of which is the uterus. The distribution of uterine blood flow determines

438

the final common pathway to the uterus and placenta. Eighty percent of uterine blood flow goes to the placenta, while 20 percent is directed to the myometrium and thus never comes into contact with either placenta or fetus. ^[76] The intermittent spurting character of the maternal spiral arterioles also prevents a portion of the drug from reaching the placental circulation and fetus. Because not all these spiral arterioles are functioning at the same time, some of the anesthetic by-passes the area of exchange and remains in the maternal circulation.

Factors Influencing Placental Transfer from Mother to Fetus	
Drug	
	Molecular weight
	Lipid solubility
	Ionization, pH of blood
	Spatial configuration
Maternal	
	Uptake into bloodstream
	Distribution via circulation
	Uterine blood flow
	Amount
	Distribution (myometrium vs. placenta)
Placental	
	Circulation: intermittent spurting arterioles
	Lipid membrane: Fick's law of simple diffusion
Fetal	
	Circulation: ductus venosus, foramen ovale, ductus arteriosus

Once in the fetal circulation, a part of the drug will travel directly to the liver, where some will be metabolized, eventually reaching the inferior vena cava. The other part will be shunted directly across the ductus venosus into the inferior vena cava. That portion of drug reaching the inferior vena cava will proceed to the right atrium, where some will enter the right ventricle, and hence the pulmonary artery. All but 10 percent will be shunted directly across the ductus arteriosus to the lower part of the systemic circulation, bypassing the cerebral circulation. The remainder of the drug that reaches the right atrium will be shunted across the foramen ovale into the left atrium, left ventricle, and out the aorta into the upper part of the fetal circulation, which includes the fetal brain, where the greatest effect occurs. Given the complexity of the fetal circulation, it is easy to see how the mother can be affected by a certain concentration of drug without the fetus being affected.

Because the placenta has the properties of a lipid membrane, most drugs and all anesthetic agents cross by a mechanism called simple diffusion. The physicochemical factors governing transfer across a lipid membrane by simple diffusion is described by Fick's law ^[77] $Q/T = [K A(C_m - C_f)]/X$ where Q/T is the rate of diffusion, K is the diffusion constant of the drug, A is the available area, C_m is the maternal blood concentration, C_f is the fetal blood concentration, and X is the thickness of the membrane. Thus the amount of drug that crosses the placenta increases as concentrations in the maternal circulation and total area of the membrane increase and decreases as the thickness of the membrane increases. The effective surface area of the human placenta is approximately 11 m^2 , and its thickness is approximately 3.5 m. The diffusion constant, K , accounts for the properties of the drug itself, including molecular weight, spatial configuration, degree of ionization, lipid solubility, and protein binding. For example, bupivacaine is highly protein bound, a characteristic that some believe explains why fetal blood concentrations are so much lower than with other local anesthetics. On the other hand, bupivacaine is also highly lipid soluble. The more lipid soluble a drug is, the more freely it passes through a lipid membrane. Furthermore, once in the fetal system, lipid solubility enables the drug to be taken up by fetal tissues rapidly, which again contributes to the lower blood concentration of the agent.

The degree of ionization of a drug is also important. Most drugs exist in both an ionized and nonionized state. It is the nonionized state that freely crosses lipid

membranes. Drugs such as muscle relaxants are highly ionized; thus little crosses to the fetus. The degree of ionization is influenced by the pH of the medium. For

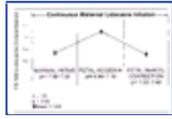

Figure 15-5 Fetal/maternal arterial (FA/MA) lidocaine ratios were significantly higher ($p < 0.02$) during fetal acidemia than during control or when pH was corrected with bicarbonate ($N = 10$; mean \pm SE). (From Biehl D, Shnider SM, Levinson G, Callender K: Placental transfer of lidocaine: effects of fetal acidosis. *Anesthesiology* 48:409, 1978, with permission.)

439

example, local anesthetics are more ionized at a lower pH. Such factors become clinically relevant in obstetrics, because occasionally the pH of the mother's blood will be 7.4, while that of the fetus will be 7.0 or less. In this instance, the nonionized portion of the drug in the maternal circulation crosses to the fetus, becomes ionized, and thus remains in the fetus (Fig. 15-5).^[77]

Lumbar Epidural Analgesia/Anesthesia

Epidural blockade is a major regional anesthetic technique in which local anesthetic is injected into the epidural space. Epidural blockade may be used to provide analgesia during labor, or surgical anesthesia for vaginal or cesarean delivery. A large-bore needle (16-, 17-, or 18-gauge) is used to locate the epidural space. Next, a catheter is inserted through the needle, and the needle is removed over the catheter. Local anesthetic is injected through the catheter, which remains taped in place to the mother's back to enable subsequent injections throughout labor (Fig. 15-1 and Fig. 15-6 (Figure Not Available)). Thus, it is often called continuous epidural analgesia. A test dose of local anesthetic is given first to be certain the catheter has not been unintentionally placed in the subarachnoid (spinal) space or in a blood vessel. Single dose techniques are occasionally used for vaginal or cesarean delivery when the duration of pain is expected to be brief. For the single-dose technique, the catheter is omitted.

Two forms of epidural analgesia are used for labor: lumbar and caudal. The catheter is placed via a lumbar interspace in the former and via the sacral hiatus in the latter (Fig. 15-1) . More local anesthetic is necessary for the caudal technique, because the local anesthetic must fill the entire sacral canal before filling the epidural space up to T10; 15 to 20 ml of local anesthetic is required. In contrast, for the lumbar technique, 8 to 10 ml (and often less) suffices, because the local anesthetic is injected much closer to its site of action.

For the caudal approach, because the local anesthetic is injected at the sacral area, sacral nerves 2, 3, and 4 are always affected. Because these nerves innervate the pelvic floor, the muscles of the pelvic floor will become insensitive and relaxed throughout labor. Moreover, the patient's legs will be affected and occasionally will be rendered immobile, depending on the strength of the local anesthetic. Pressure exerted on the pelvic floor by the descending vertex plays a major role in ensuring proper rotation of the fetal head to the occiput anterior position, and resistance may not be adequate to rotate the head when muscles of the pelvic floor are relaxed. Thus, an increase in occiput transverse or occiput posterior positions may result with the caudal technique. Also, because the patient's perception of pressure on the perineum by the presenting part is a stimulus for her to increase voluntary effort, blocking or minimizing this perception may prolong the second stage. Because of the large volume of local anesthetic used, adverse effects on muscle tone in the legs and pelvic floor, and the highly variable anatomy of the sacral hiatus in adults, the caudal approach has fallen out of favor for labor analgesia. A rare but serious complication of caudal anesthesia is accidental injection of local anesthetic into the fetal head leading to newborn apnea, bradycardia, and convulsions.^[78]

Most anesthesiologists now prefer the lumbar approach and use a technique described as segmental epidural analgesia (Fig. 15-7) (Figure Not Available) . Because nerves that carry painful impulses during the first stage of labor are small sympathetic nerves and because they are easily blocked, only the smallest amount and the weakest effective concentration of local anesthetic is injected via the L2-3, L3-4, or L4-5 interspace. Thus, both sensation and motor function of the perineum and lower extremities remain mostly intact. The patient can move about and perceive the impact of the presenting part on the perineum. If perineal anesthesia is needed for delivery, a larger concentration and dose of local anesthetic can be administered at that time through the catheter (Fig. 15-7) (Figure Not Available) . Alternatively, for perineal anesthesia, the obstetrician can perform a pudendal block or local infiltration of the perineum.

The segmental epidural technique, when performed properly, is effective and safe for both mother and fetus. In most instances, total or near total pain relief is accomplished without resorting to depressant and sometimes disorienting drugs. The mother remains awake, alert, and aware of her surroundings. She can communicate with her husband, her physician, and the nursing personnel. She will remember and appreciate her entire labor and delivery. Finally, because anesthesia can be extended to the perineum at the time of delivery, the obstetrician can accomplish whatever kind of delivery is necessary, spontaneous or instrumental, with or without an episiotomy.

A new technique of labor analgesia involves passing a small-gauge pencil-point spinal needle through the epidural needle prior to catheter placement. This combined spinal-epidural or coaxial technique provides rapid onset of analgesia using a very small dose of opioid or a local anesthetic and opioid combination.^[79],^[80] Because the dose of drug used in the subarachnoid space is much smaller than that used for epidural analgesia, the risks of local anesthetic toxicity or high spinal block are avoided. Side effects are usually mild, and include pruritus and nausea. The risk of postdural puncture headache is no different than using epidural analgesia alone.^[81] Some practitioners have used this technique to allow parturients to ambulate during labor since there is little or no interference with motor function.^[79]

Even though the advantages would seem to make

440

Figure 15-6 (Figure Not Available) Technique of lumbar epidural puncture by the midline approach. A, This side view shows left hand held against patient's back, with thumb and index finger grasping hub. Attempts to inject solution while point of needle is in the interspinous ligament meet resistance. B, Point of needle is in the ligamentum flavum, which offers marked resistance and makes it almost impossible to inject solution. C, Entrance of the needle's point into epidural space is discerned by sudden lack of resistance to injection of saline. Force of injected solution pushes dura-arachnoid away from point of needle. D, Catheter is introduced through needle. Note that hub of needle is pulled caudad toward the patient, increasing the angle between the shaft of the needle and the epidural space. Also note technique of holding the tubing: it is wound around the right hand. E, Needle is withdrawn over tubing and held steady with the right hand. F, Catheter is immobilized with adhesive tape. Note the large loop made by the catheter to decrease risk of kinking at the point where the tube exits from the skin. (From Bonica JJ: *Obstetric Analgesia and Anesthesia*. Amsterdam, World Federation of Societies of Anesthesiologists, 1980, with permission.)

epidural or combined spinal-epidural analgesia the ideal analgesic technique, and many believe it to be so, there are disadvantages. These include hypotension, local anesthetic toxicity, allergic reaction, high or total spinal anesthesia, neurologic injury, and spinal headache. Recent reports have not found an adverse effect on progress of labor when lower concentrations of anesthetic are used for regional analgesia.^[82]

441

Figure 15-7 (Figure Not Available) Segmented epidural analgesia for labor and delivery. A single catheter is introduced into the epidural space and advanced so that its tip is at L2. Initially, small volumes of low concentrations of local anesthetic are used to produce segmental analgesia. For the second stage, the analgesia is extended to the sacral segments by injecting a larger amount of the same concentration of local anesthetic, with the patient in the semirecumbent position. After internal rotation, a higher concentration of local anesthetic is injected to produce motor block of the sacral segments and thus achieve perineal relaxation and anesthesia. The wedge under the right buttock causes the uterus to displace to the left. (From Bonica JJ: *Obstetric Analgesia and Anesthesia*. Amsterdam, World Federation of Societies of Anesthesiologists, 1980, with permission.)

Hypotension

Hypotension is defined variably, but most often it as a systolic blood pressure less than 100 mm Hg or a 20 percent decrease from control measurements. It occurs after approximately 10 percent of epidural blocks given during labor, but the incidence has been reported to be as low as 1.4 percent in some large series.^[83]^[84]^[85] Hypotension occurs primarily as a result of sympathetic blockade. Local anesthetics block not only pain fibers but sympathetic fibers as well, which normally maintain blood vessel tone. When these fibers are blocked, vasodilation results and blood pools in the lower extremities, decreasing the return of blood to the right side of the heart. Cardiac output then decreases, and hypotension results. Hypotension threatens the fetus by decreasing uterine blood flow and threatens the mother by

decreasing cerebral blood flow. When hypotension is recognized promptly and treated effectively, few, if any, untoward effects accrue to either mother or fetus (Table 15-1).^[86]^[87]^[88] However, in the acutely or chronically compromised fetus, hypotension could further worsen fetal status if not treated immediately.

Treatment of hypotension begins with prophylaxis, which demands an intravenous catheter and an infusion of isotonic crystalloid solution. The infusion fills the expanded vascular space caused by vasodilation. Glucose is easily transported across the placenta; therefore, dextrose-containing solutions are avoided for this purpose because they can lead to neonatal hypoglycemia.^[89] Left uterine displacement must be maintained during the block because compression of the inferior vena cava and aorta may decrease cardiac output and/or uteroplacental perfusion. Proper treatment depends on immediate diagnosis. Therefore, the individual administering the anesthesia must be present and attentive. Once diagnosed, hypotension is corrected by increasing the rate of intravenous fluid infusion and exaggerating left uterine displacement. If these simple measures do not suffice, a vasopressor is indicated. The vasopressor of

(From Ralston DH, Shnider SM, deLorimier AA: Effects of equipotent ephedrine, metaraminol, mephentermine, and methoxamine on uterine blood flow in the pregnant ewe. *Anesthesiology* 40:354, 1974, with permission.)

choice is ephedrine, given in 5- to 10-mg doses. Ephedrine is a mixed - and - agonist, and it is less likely to compromise uteroplacental perfusion than the pure -agonists.^[90] -Adrenergic agents such as methoxamine or phenylephrine are avoided in most cases (Fig. 15-8), although they may be useful when a parturient is excessively tachycardic in association with hypotension, or if tachycardia associated with ephedrine may be detrimental. Clinical studies have suggested that phenylephrine in small doses may be given safely to treat hypotension during regional anesthesia for cesarean delivery.^[91]

Local Anesthetic Toxicity

The incidence of systemic local anesthetic toxicity (high blood concentrations of local anesthetic) after lumbar epidural analgesia is 0.01 percent.^[92] However, convulsions due to local anesthetic toxicity were the most common damaging events in obstetric patients in the ASA Closed Claims Project database. In 83 percent of these cases, neurologic injury or death to the mother, newborn, or both occurred.^[93] Maternal mortality data also show that local anesthetic toxicity is the most common cause of death resulting from regional anesthesia during cesarean delivery.^[94] Most often, toxicity occurs when the local anesthetic is injected into a vessel rather than into the epidural space or when too much is administered even though injected properly. Occasionally, the dosage can be miscalculated: 1 ml of 1 percent lidocaine contains 10 mg of lidocaine, not 1 mg. All local anesthetics have maximal recommended doses, and these should not be exceeded. For example, the maximum recommended dose of lidocaine is 4 mg/kg when used without epinephrine and 7 mg/kg when used with epinephrine. Epinephrine delays and decreases the uptake of local anesthetic into the bloodstream. Package inserts for all local anesthetics contain appropriate dosing information (Table 15-2).

Local anesthetic reactions have two components, central nervous system (CNS) and cardiovascular. Usually, the CNS component precedes the cardiovascular component. Prodromal symptoms of the CNS reaction include excitation, bizarre behavior, ringing in the ears, and disorientation. These symptoms may culminate in convulsions, which are usually brief. After the convulsions, depression follows and manifests predominantly by the postictal state. The cardiovascular component of the local anesthetic reaction usually begins with hypertension and tachycardia but is soon followed by hypotension, arrhythmias, and in some instances cardiac arrest. Thus, the cardiovascular component also has excitant and depressant characteristics. Usually, the CNS and cardiovascular components are widely separated, because it takes a significantly higher blood concentration

TABLE 15-2 -- MAXIMAL RECOMMENDED DOSES OF COMMON LOCAL ANESTHETICS

With Epinephrine		Without Epinephrine

of local anesthetic to cause the cardiovascular symptoms than it does the CNS symptoms. Thus, one frequently sees the CNS component without the more serious cardiovascular component. Bupivacaine may represent an exception to this principle.^[95]^[96] There are reports of several patients who experienced serious arrhythmias and marked cardiovascular depression after administration of 0.75 percent bupivacaine. Most anesthesiologists now believe there is little difference in the

doses required to cause the two types of reactions to bupivacaine. Moreover, resuscitation of these patients was difficult or impossible, probably because of the drug's prolonged blocking effect on sodium channels.^[97] Indeed there now is laboratory evidence that bupivacaine is more cardiotoxic than equianalgesic doses of other amide local anesthetics. Several manufacturers of bupivacaine have recommended that the 0.75 percent concentration not be used in obstetric patients or for paracervical block.^[98] Of course, it is possible to give the same total dose of bupivacaine by giving a larger volume of 0.5 percent bupivacaine. However, use of a more dilute concentration of drug does not guarantee safety. Thus, it is important that the physician give bupivacaine, or any other local anesthetic, by slow, incremental injection.^[99]

The bupivacaine controversy has resulted in greater emphasis on the administration of a safe and effective test dose to exclude unintentional intravenous or subarachnoid injection of local anesthetic before injection of a therapeutic dose of local anesthetic. Many anesthesiologists give a test dose that includes 15 g of epinephrine.^[100], ^[101] An increase in heart rate of at least 25 to 30 bpm would signal intravascular injection. Others have questioned whether an epinephrine-containing test dose is the best choice in obstetric patients.^[102]

Treatment of a local anesthetic reaction depends on recognizing the signs and symptoms as they occur. Again, to recognize this complication, the anesthesia-care provider must be present. If possible, once prodromal symptoms arise, the injection of local anesthetic should be stopped. However, if convulsions have already occurred, treatment is aimed at maintaining proper oxygenation and preventing the patient from harming herself. Convulsions use considerable amounts of oxygen, which results in hypoxia and acidosis (Table 15-3).^[103] Adequate oxygenation is essential for both mother and fetus, because a hypoxic mother results in a hypoxic and acidotic fetus. Should the convulsions continue for more than a brief period, small intravenous doses of thiopental (25 to 50 mg) or midazolam (1 to 2 mg) are useful. In obstetrics, because of the adverse effects of benzodiazepines on the neonate, thiopental would be the agent of choice. Occasionally, succinylcholine is used for paralysis to prevent the muscular activity associated with the convulsions and to facilitate ventilation and perhaps intubation. Before using thiopental, diazepam, or succinylcholine, consideration must be given to the depressant effects that these agents will add to the depressant phase of the local anesthetic reaction. Therefore, appropriate equipment and personnel must be available to maintain oxygenation, a patent airway, and cardiovascular support. Resuscitation

* Bag and mask with oral Guedel airway and artificial respiration. Nasal prongs.

of the pregnant patient is essentially the same as that of the nonpregnant patient except that left uterine displacement must be maintained. Usually, this means that the uterus will have to be elevated off the inferior vena cava manually for resuscitation with the patient supine. Delivery of the infant may facilitate maternal resuscitation. The American Heart Association has stated: "Several authors now recommend that the decision to perform a perimortem cesarean section should be made rapidly, with delivery effected within 4 to 5 minutes of the arrest."^[104]

Allergy to Local Anesthetics

There are two classes of local anesthetics: amides and esters. A true allergic reaction to an amide-type local anesthetic (e.g., lidocaine, bupivacaine, ropivacaine) is extremely rare. Allergic reactions to the esters (2-chloroprocaine, procaine, tetracaine) are also uncommon but do occur more often. When a patient reports that is "allergic" to local anesthetics, she is frequently referring to a normal reaction to the epinephrine that is occasionally added to local anesthetics, particularly by dentists. Epinephrine can cause increased heart rate, pounding in the ears, and nausea, symptoms that may be interpreted as an allergy. It is therefore important to document any history of allergy. Was there a rash? Hives? Difficulty breathing? If so, which local anesthetic was used? If a specific local anesthetic can be identified, choosing one from the other class should be safe, or meperidine can be used as an alternative to local anesthetics in the subarachnoid space.^[105]

High Spinal or "Total Spinal" Anesthesia

This complication occurs when the level of anesthesia rises dangerously high, resulting in paralysis of the respiratory muscles, including the diaphragm. The incidence of total spinal anesthesia after epidural anesthesia is less than 0.03 percent and after spinal anesthesia is 0.2 percent.^[92], ^[106] Total spinal anesthesia can result from a miscalculated dose of drug, unintentional subarachnoid injection during an epidural block, or improper positioning of a patient after spinal block with hyperbaric local anesthetic solutions. Motor nerves to the diaphragm, the major respiratory muscle, emanate from C3 to C5; therefore, the anesthetic must be at this level before phrenic nerve paralysis results. Moreover, the phrenic nerve is a large motor nerve, which requires considerable local anesthetic for complete block. Because the accessory muscles of respiration are paralyzed earlier, their paralysis may result in apprehension and anxiety. The patient usually can breathe adequately as long as the diaphragm is not paralyzed. However, treatment must be individualized, and dyspnea, real or imagined, should always be considered an effect of paralysis until proved otherwise. In addition to respiratory symptoms, cardiovascular components, including hypotension and even cardiovascular collapse, may occur.

Treatment of total spinal anesthesia includes rapidly assessing the true level of anesthesia. Therefore, individuals performing major regional anesthesia should be thoroughly familiar with dermatome charts (Fig. 15-9) and should also be able to recognize what a certain sensory level of anesthesia means with regard to innervation of other organs or systems. For example, a T4 sensory level may represent total sympathetic nervous system blockade. Numbness and weakness of the fingers and hands indicates that the level of anesthesia has reached the cervical level (C6 to C8), which is dangerously close to the innervation of the diaphragm. If the diaphragm is not paralyzed, the patient is breathing adequately, and cardiovascular stability is maintained, administration of oxygen and reassurance may suffice. If the patient remains anxious or if the level of anesthesia seems to be involving the diaphragm, then assisted ventilation is indicated. Occasionally, this can be accomplished with a bag and face mask without rendering the patient unconscious. Most often, however, endotracheal intubation will be necessary. If so, induction of

general anesthesia will facilitate the process. Cardiovascular support is provided as necessary. If the person administering regional anesthesia is well acquainted with the signs and symptoms of high spinal anesthesia and its treatment, serious sequelae should be extremely rare. The onset can be easily recognized, and the treatment is relatively simple. However, the same admonition applies as with hypotension and local anesthetic toxicity: early symptoms cannot be diagnosed if the person administering the block is not present and attentive.

Paralysis and Nerve Injury

Paralysis after either epidural or spinal anesthesia is extremely rare; even minor injuries such as foot-drop and segmental loss of sensation are uncommon. Nerve injury occurs in 0.06 percent of spinal anesthetics and 0.02 percent of epidural anesthetics.^[92] With commercially prepared drugs, ampules, and disposable needles, infection and caustic injury rarely occur. Several years ago there were several cases of neurologic deficit after use of 2-chloroprocaine, primarily after unintentional subarachnoid (i.e., spinal) injection of large volumes of the drug.^{[107] [108] [109]} These cases prompted performance of several laboratory studies to evaluate any potential neurotoxicity of 2-chloroprocaine. The earlier formulation of 2-chloroprocaine contained the antioxidant 0.2 percent sodium bisulfite. Currently the consensus is that 2-chloroprocaine itself is not neurotoxic, but that the low pH of the local anesthetic solution and the inclusion of

445

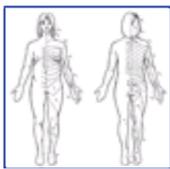

Figure 15-9 Dermatome chart. (Adapted from Haymaker L, Woodhall B: *Peripheral Nerve Injuries*. Philadelphia, WB Saunders Company, 1945.)

the sodium bisulfite together may produce neurologic dysfunction.^[119] Following reformulation using ethylene diamine tetraacetic acid (EDTA) as a preservative, there were reports of transient back pain after epidural use of the new formulation of 2-chloroprocaine in nonpregnant patients.^{[111] [112]} This appeared to be due to the calcium chelating effects of EDTA in the paraspinous muscles causing tetany and painful muscle spasms. The current formulation does not contain preservatives.

When nerve damage follows regional analgesia during obstetric or surgical procedures, the anesthetic technique must be suspected. Nerve damage can result from other causes, however. For example, incorrectly positioned stirrups may cause nerve injury after both gynecologic and obstetric procedures.^{[113] [114] [115]} Also, nerve damage can be secondary to a difficult forceps application. During abdominal procedures, overzealous or prolonged application of pressure with retractors on sensitive nerve tissues may result in injury. Fortunately, most neurologic deficits after labor and delivery are minor and transient.^[116] Nonetheless, one should consider consultation with a neurologist or neurosurgeon. Although patients are often concerned about the development of back pain following epidural anesthesia, the incidence of back pain in postpartum women is the same with or without the use of regional anesthesia. The incidence of back pain after childbirth is 44 percent at 1 to 2 months postpartum^[117] and 49 percent at 12 to 18 months postpartum,^[118] again unrelated to the use of epidural anesthesia.

One of the more dramatic and correctable forms of nerve damage follows compression of the spinal cord by a hematoma that has formed during the administration of spinal or epidural anesthesia, presumably from accidental puncture of an epidural vessel. If the condition is diagnosed early, usually with the aid of a neurologist

446

or neurosurgeon, the hematoma can be removed by laminectomy and the problem resolved without permanent damage. Fortunately, this is a rare complication. Nonetheless, spinal and epidural blocks are contraindicated if coagulation is abnormal.^{[119] [120]} Any prolonged motor or sensory deficit after regional anesthesia should be investigated immediately and thoroughly.

Spinal Headache

Spinal headache may follow uncomplicated spinal anesthesia. This complication can also occur when, during the process of administering an epidural block, the dura is punctured and spinal fluid leaks out (i.e., "wet tap"). The incidence of this complication varies between 1 and 3 percent, and its occurrence depends on the experience of the person performing the epidural block.^[121] Once a wet tap occurs, a spinal headache results in as many as 70 percent of patients. The incidence is much less following spinal anesthesia, because smaller needles are used. Characteristically the headache is more severe in the upright position and is relieved by the prone position. The headache is thought to be caused by loss of cerebrospinal fluid, which allows the brain to settle and thus meninges and vessels to stretch. Hydration, abdominal binders, and the prone position have all been advocated as prophylactic measures. However, most anesthesiologists now agree that these actions are of little value.^[122] In some hands, epidural saline injected through the catheter has proven to be an effective prophylactic measure.^[123]

Treatment of the headache, once it has occurred, may be initiated with oral analgesics, caffeine,^[124] and continued hydration. If these simple measures do not prove immediately effective, an epidural blood patch is placed. Approximately 15 ml of the patient's own blood is placed aseptically into the epidural space; the blood coagulates over the hole in the dura and prevents further leakage.^[125] Patients can be released within 1 to 2 hours.^[126] Patients should be instructed to avoid coughing or straining at stool for the first several days after performance of the blood patch. The epidural blood patch has been found to be remarkably effective and nearly complication free.^{[127] [128] [129]} There remains controversy regarding whether one should perform a prophylactic blood patch before the onset of spinal headache.^{[130] [131] [132]}

Because epidural anesthesia is associated with these side effects and complications, those who administer it must be thoroughly familiar not only with the technical aspects of its administration but also with the signs and symptoms of complications and their treatment. Specifically, the American Society of Anesthesiologists and ACOG have stated: "Persons administering or supervising obstetric anesthesia should be qualified to manage the infrequent but occasionally life-threatening complications of major regional anesthesia such as respiratory and cardiovascular failure, convulsions due to toxic levels of local anesthetic, or vomiting and aspiration. Mastering and retaining the skills and knowledge necessary to manage these complications require adequate training and frequent application."^[3]

Effects on Labor and Method of Delivery

One of the more controversial aspects of regional anesthesia for obstetrics is the question of whether these techniques influence the length and pattern of labor, the incidence of malposition, the use of forceps, and the rate of cesarean delivery. The perspectives of the anesthesiologist and the obstetrician differ when trying to answer these questions. The anesthesiologist is concerned primarily with relieving pain and sees regional anesthesia as the ideal method because it depresses neither mother nor fetus, provides exceptional pain relief, and even optimal operating conditions for the obstetrician. The obstetrician, although concerned with pain relief, is also concerned with the progress of labor and the method of delivery. Reports on the effects of epidural analgesia on labor are numerous and conflicting.

STUDY DESIGN.

Most published studies on the effect of epidural analgesia on the progress of labor are retrospective and, if prospective, are nonrandomized. Studies that compare patients who received epidural analgesia versus those who did not are typically biased in favor of the nonepidural group of patients. Specifically, patients who have rapid, uncomplicated labor are less likely to ask for, and even if they ask for it are less likely actually to receive, epidural analgesia. In other words, the epidural group will include more patients with dysfunctional, difficult, and complicated labors. In fact, it is possible that the very reason why some, but not all, parturients request and receive epidural analgesia may relate to a greater likelihood of abnormal labor. For example, prolonged latent phase is associated with an increased need for cesarean delivery,^[133] and rupture of membranes prior to the onset of labor increases the likelihood of operative delivery.^[134] In both of these situations, labor may be prolonged, oxytocin use is more common, and epidural analgesia may be requested more often. Furthermore, severe pain during early labor also predicts an increased risk for abnormal labor and operative delivery.^[135] It is also problematic when one attempts to evaluate the influence of epidural analgesia on labor by using historical controls. For example, if one compares the incidence of midforceps delivery after the introduction of epidural analgesia in a hospital (e.g., in 1989) versus the incidence of midforceps delivery before the use of epidural analgesia in that hospital (e.g., in 1979), one might note no change in the incidence of midforceps

not affect the incidence of midforceps delivery. However, other changes in obstetric practice may have occurred during that 10-year interval. For example, some obstetricians are less willing to perform difficult midforceps delivery today than they were a decade ago. Therefore, it would be inappropriate to conclude that epidural analgesia did not influence the incidence of midforceps delivery in that hospital.

VARIATION IN EPIDURAL TECHNIQUE.

A second difficulty with interpretation of existing studies is that epidural analgesia is not a generic procedure. The influence of epidural analgesia on the progress of labor may vary according to the technique used, as well as the choice and dose of the local anesthetic administered. The use of combined spinal-epidural (CSE) analgesia with or without ambulation has increased. Furthermore, anesthesiologists today use more dilute solutions of local anesthetic for epidural analgesia than were used a decade ago. Anesthesiologists now give greater attention to titrating the dose of the local anesthetic to the specific needs of the patient. For example, Naulty and colleagues^[136] made an abrupt change in their epidural analgesia technique in June 1987. Specifically, they had been providing epidural analgesia during labor with either 1.5 percent lidocaine or 0.25 to 0.5 percent bupivacaine, but they changed their technique to include 0.125 to 0.25 percent bupivacaine with fentanyl. They then compared the results during the 9 months before the change versus those during the 9 months after the change. They noted a significant decrease in the percentage of patients admitted for labor who eventually underwent cesarean delivery. During the 9 months before the change, 20 percent of patients in labor were delivered by cesarean section, whereas after the change 15 percent required this procedure. Furthermore, there was a significant decrease in the percentage of patients who received epidural analgesia and who subsequently underwent cesarean delivery. Finally, the incidence of forceps deliveries decreased from 17 percent before the change to 6 percent after the change.

More recently, Olofsson et al.^[137] randomized 1,000 women of mixed parity (who requested epidural analgesia during labor) to receive either 0.25 percent bupivacaine with 1:200,000 epinephrine or 0.125 percent bupivacaine with sufentanil. The incidence of cesarean delivery was 15 percent in the high-dose bupivacaine group and 10 percent in the low-dose bupivacaine group ($p < 0.05$).

Another potential source of variation in management and outcome is the timing of administration of epidural analgesia. Although controversial, many physicians believe that institution of analgesia during the latent phase of the first stage of labor is more likely to delay the progress of labor. Friedman^[138] stated:

Spinal anesthesia given prior to the onset of the phase of dilatation in the first stage of labor will impede progress of the latent phase, and forestall the normal progressive changes of late labor. It would seem that spinal block given after the latent phase has ended, in a patient whose labor is otherwise normal, and to a level which does not exceed that necessary for uterine pain relief (tenth thoracic) should not influence labor. The general impression of caudal or epidural anesthesia as it affects labor is that of negligible influence unless misused.

The Committee on Obstetrics: Maternal and Fetal Medicine of the American College of Obstetricians and Gynecologists issued a statement about dystocia. Regarding the latent phase of labor, they stated: "The latent phase may be prolonged by excessive medication and inappropriate timing of conduction anesthesia." Regarding the active phase, they stated: "The normal active phase tends to be resistant to the inhibitory effects of the usual amounts of analgesia. At times, further sedation or epidural anesthesia, hydration, or ambulation may be advantageous." Furthermore, the Committee stated: "A hypertonic pattern may be observed in the active phase. Prolongation of a hypertonic pattern may result in maternal exhaustion, marked pain, and decreased uteroplacental blood flow. The combination of sedation, epidural anesthesia and oxytocin infusion may prove effective."^[139]

The problem with delaying institution of epidural analgesia until the onset of the active phase of labor is that it is often difficult to make that diagnosis prospectively. Furthermore, it is also inappropriate to delay institution of epidural analgesia until the patient has reached an arbitrary cervical dilation.^[140] For example, approximately 50 percent of patients will enter the active phase of labor by 4 cm cervical dilation, but a minority will not enter active labor until more than 5 cm cervical dilation.^[140] If one delays institution of epidural analgesia until the patient reaches an arbitrary dilation (e.g., 5 cm cervical dilation), one will subject some patients to unnecessary periods of severe pain. Early institution of epidural analgesia may slow labor in some patients, but this can usually be corrected with the use of oxytocin.

MANAGEMENT OF THE SECOND STAGE.

A third problem with interpretation of studies of epidural anesthesia and progress of labor relates to the indication for performance of instrumental delivery. In general, an obstetrician is more likely to perform elective forceps delivery in a comfortable patient with effective epidural anesthesia than in an uncomfortable patient with no anesthesia. Furthermore, heretofore some obstetricians have arbitrarily terminated the second stage at 2 hours in nulliparous patients and at 1 hour in parous patients. There is evidence that effective epidural analgesia may slightly prolong the second stage of labor.^[141],^[142] However, a delay in the second stage is not necessarily harmful to infant or to mother, provided there is reassuring electronic fetal heart rate monitoring and adequate

maternal hydration and analgesia.^[141],^[143],^[144],^[145] Indeed, the ACOG has defined a prolonged second stage as more than 3 hours in nulliparous patients with regional anesthesia as compared with more than 2 hours in nulliparous patients without regional anesthesia.^[146]

PROSPECTIVE STUDIES OF EPIDURAL ANESTHESIA AND PROGRESS OF LABOR.

It is difficult to perform prospective, randomized studies of the effect of epidural analgesia on the progress of labor. The fact that epidural analgesia provides analgesia superior to other techniques causes physicians to be reluctant to randomize patients to a nonepidural group. Robinson and colleagues^[147] randomized 386 parturients to receive either epidural anesthesia or systemic analgesia (i.e., meperidine with inhalation analgesia) during labor. They noted that "epidural block was more effective than systemic analgesia in the relief of pain and discomfort in all stages of labor." They also noted that there was a significant increase in the incidence of instrumental delivery in the epidural group. Unfortunately, the randomization occurred before final consent was obtained. Patients were free to withdraw from the study after they learned their group assignment, and many did. Only 93 of the original patients completed the study. One can suspect that more patients with a long, difficult labor dropped out of the systemic analgesia group. This suspicion is confirmed when one notes that there was a threefold increase in the incidence of induction of labor in the epidural group. Furthermore, patients in the epidural group received 0.5 percent bupivacaine, a concentration higher than that used by most anesthesiologists today. Finally, the authors did not report the incidence of cesarean delivery in either group.

Philipsen and Jensen^[148] reported the second published study in which patients were randomized to receive either epidural analgesia or systemic opioid during the first stage of labor. Patients in the epidural group received 0.375 percent bupivacaine, although the authors noted that they attempted to produce a segmental block from T10 to L1. They also stated: "In an attempt to retain the bearing-down reflex and to allow the mother to take active part in the second stage of labor, the analgesic effect was allowed to wear off at the beginning of the second stage and a top-up dose was not given if the cervix was dilated beyond 8 cm." There was no significant difference between groups in the method of delivery.

There are several studies in which nulliparous patients already receiving epidural analgesia were randomized with respect to management of epidural analgesia during the second stage.^[141],^[149],^[150],^[151] Phillips and Thomas^[149] reported no increase in duration of the second stage, and a nonsignificant decrease in the incidence of instrumental delivery, in 28 nulliparous women who received additional epidural bupivacaine (i.e., 0.25 percent) at complete cervical dilatation compared with 28 women who received no additional bupivacaine. However, this study was randomized but nonblinded, and it is unclear as to how the two groups actually differed, as there was no significant difference between groups in total dose of bupivacaine or in mean number of doses of bupivacaine (i.e., four doses per patient in each group).

Chestnut and colleagues^[150] performed a study in which nulliparous patients already receiving a continuous epidural infusion of 0.75 percent lidocaine were randomized to receive either additional 0.75 percent lidocaine or saline placebo after 8 cm cervical dilation. The epidural infusion of lidocaine or saline placebo was continued in all patients until delivery. Maintenance of the epidural infusion of 0.75 percent lidocaine until delivery did not prolong the second stage or increase the

frequency of instrumental delivery, but it also did not reliably provide second-stage analgesia or perineal anesthesia. Specifically, women who continued to receive epidural lidocaine until delivery did not clearly perceive that they had better analgesia than did women who received saline placebo.

Subsequently, Chestnut and colleagues^[141] performed a study in which nulliparous women already receiving a continuous epidural infusion of 0.125 percent bupivacaine were randomized to receive either additional 0.125 percent bupivacaine or saline placebo beyond 8 cm cervical dilation. Patients continued to receive the epidural infusion of bupivacaine or saline placebo until delivery. Maintenance of the epidural infusion of bupivacaine until delivery resulted in second-stage analgesia that was clearly superior to that provided by replacement of the bupivacaine with placebo. Infusion of bupivacaine until delivery prolonged the second stage of labor approximately 30 minutes, and it also increased the incidence of instrumental delivery. However, maintenance of epidural bupivacaine analgesia did not result in an increased incidence of abnormal position of the vertex, and it did not result in an increased incidence of cesarean delivery. Furthermore, there were nonsignificant tendencies toward better neonatal condition in the bupivacaine group as evaluated by umbilical cord blood acid-base status and Apgar scores.

CESAREAN DELIVERY RATE.

Does the use of epidural analgesia for labor influence the cesarean delivery rate? Gribble and Meier found no difference in the cesarean delivery rate before and after the availability of "on-demand" epidural analgesia for labor.^[152] The patients were managed by the same group of obstetricians using the same management techniques in both time intervals. Before the introduction of an epidural analgesia service, the cesarean delivery rate was 9.0 percent. After the use of epidural analgesia had risen from 0 percent to 48 percent, the cesarean delivery rate was 8.6 percent. A

449

number of other authors have also shown that cesarean section rates can actually decrease while the use of epidural analgesia rises. Larson et al.^[153] found the cesarean delivery rate actually fell from 28 percent to 23 percent ($p = 0.0007$) after a 24-hour in-house obstetric anesthesiology service was established. The use of epidural analgesia rose from 0 percent to 32 percent during the same time period.^[153] Yancey et al.^[154] compared operative vaginal and abdominal delivery rates in a large population (9,637 patients) before and after on-demand labor epidural analgesia became available. Despite an increase from less than 1 percent to 59 percent in labor epidural analgesia use, the rate of neither cesarean delivery nor operative vaginal delivery increased. In a study of 6,928 patients, Fogel et al.^[155] found that expanded epidural analgesia use (from 1 percent to 29 percent) did not change the overall dystocia cesarean delivery rate, although dystocia was more common among women who chose epidural analgesia.

Iglesias et al.^[156] and Socol et al.^[157] assessed the impact of changes in obstetric management on the incidence of cesarean delivery. Both groups found that they could decrease the cesarean delivery rate at the same time that the use of epidural analgesia was increasing in their hospitals. The decline in cesarean delivery rates in these studies is achieved primarily by increasing the use of vaginal birth after cesarean (VBAC), active management of labor, and use of oxytocin. The availability of epidural analgesia may be an important factor in patient acceptance of VBAC and in the obstetrician's willingness to aggressively manage labor and use oxytocin. This active management of labor is exemplified by the National Maternity Hospital in Dublin. At that institution, the epidural rate rose from 10 percent in 1987 to 45 percent in 1992, whereas the cesarean section rate remained unchanged at 4 to 5 percent.^[158] The practitioners in Dublin note that "epidural analgesia may be of major benefit in labor and need not reduce the chance of spontaneous vaginal delivery if the passive phase of second stage of labor is lengthened."

Other work has also shown that obstetric management influences outcome independent of the type of labor analgesia utilized. In a retrospective review of epidural analgesia *managed by obstetricians*, women having epidural analgesia for labor actually had a *decreased* risk of cesarean delivery.^[159] Neuhoff and colleagues retrospectively investigated cesarean deliveries for failed progress in labor at their hospital. The cesarean birth rate on the resident clinic service was 5 percent versus 17 percent on the private service, while the use of epidural analgesia was comparable on both services (42 percent in each group).^[160] Cesarean births were increased on the private service when epidural analgesia was used, but cesarean delivery rates remained stable on the clinic service whether or not epidural analgesia was used. Segal et al.^[161] analyzed data from 110 obstetricians at their institution over 5 years. They found no relationship between the frequency of epidural analgesia and rate of cesarean delivery for dystocia across practitioners. They concluded that obstetric practitioners and, to a limited extent, the characteristics of their patient populations are major determinants of these rates.

A series of articles by Thorp and colleagues on the relationship between epidural analgesia and cesarean section caused great concern among obstetricians, anesthesiologists, and parturients.^[162]^[163]^[164] The first publication, a retrospective review of 711 consecutive nulliparous women in spontaneous labor at term,^[162] reported that women who received epidural analgesia had a longer duration of labor, were more likely to receive oxytocin, and had a 10.3 percent cesarean delivery rate for dystocia versus 3.8 percent in the nonepidural group. A subsequent retrospective study of 500 consecutive patients again showed an increased cesarean delivery rate in the epidural versus nonepidural group (11.4 vs. 2.4 percent) and noted that nulliparous women who had epidural analgesia administered before 5 cm of cervical dilation seemed to have the greatest effect on the incidence of cesarean delivery.^[163] The authors concluded that "epidural analgesia in first labors may have contributed significantly to the cesarean epidemic." Thorp and colleagues^[164] subsequently published a prospective study in which nulliparous women were randomized to receive intravenous meperidine or epidural bupivacaine. Twelve of 48 (25 percent) women in the epidural group versus 1 of 45 (2.2 percent) women in the meperidine group underwent cesarean delivery. Eleven of the 12 cesarean deliveries in the epidural group occurred in women who had received epidural analgesia before 5 cm dilation. Neonatal outcome was similar in both groups, and pain relief was rated superior in the epidural group by nurses and patients.

Three prospective, randomized trials were performed at Parkland Hospital in Dallas. Ramin^[165] randomized 1,330 women of mixed parity to receive either epidural bupivacaine-fentanyl or intravenous meperidine analgesia during labor. Approximately one third of the women in each group did not receive the allocated treatment. When the authors evaluated outcome according to intention-to-treat analysis, they noted that 60 (9 percent) of the 664 women in the epidural group, versus 35 (5 percent) of the 666 women in the meperidine group, underwent *operative* delivery for dystocia. However, operative delivery was defined as either cesarean or low-forceps delivery. Within the intention-to-treat analysis, the authors did not report the number of cesarean deliveries in the two groups. Thus, it is unclear that there was an increased incidence of cesarean delivery in the women randomized to an offer of epidural analgesia.

Sharma et al.^[166] reported this group's second randomized

450

trial of epidural versus intravenous meperidine analgesia during labor. The authors randomized 715 women of mixed parity in spontaneous labor at term to receive either epidural analgesia or patient-controlled intravenous analgesia (PCIA) with meperidine. Enrollment and randomization occurred when the patients were admitted to the nurse-midwifery service at Parkland Hospital. Subsequently, an anesthesiologist offered epidural analgesia to the patients randomized to the epidural group, but not to the patients randomized to the PCIA group. Among the 358 patients who were randomized to an offer of epidural analgesia, only 243 actually received epidural analgesia. Of the remaining 115 patients, 78 labored rapidly and never requested or received epidural analgesia, and the remaining 37 refused epidural analgesia. Among the 357 patients who were randomized to an offer of PCIA, only 259 patients completed the study as allocated. Of the remaining 98 patients, 73 labored rapidly and did not receive any analgesia, 20 refused PCIA, and 5 who received meperidine PCIA "crossed over" to epidural analgesia because of unsatisfactory pain relief.

Using an intention-to-treat analysis, the authors observed no difference between the two groups in the incidence of cesarean delivery (i.e., 4 percent in the epidural group and 5 percent in the PCIA group). The authors also observed no difference between the two groups in the incidence of cesarean section when they evaluated outcome for protocol-compliant patients (i.e., 5 percent in the epidural analgesia group and 6 percent in the PCIA group). Women in the epidural group had lower pain scores during both the first and the second stages of labor, and women in the PCIA group were more sedated. There was no difference between the two groups in neonatal outcome, except that more babies in the PCIA group received naloxone for treatment of respiratory depression at birth.^[166]

Gambling et al.^[167] reported this group's third randomized trial, in which patients received either CSE or intravenous meperidine analgesia during labor. Profound fetal bradycardia, which prompted emergency cesarean section within 1 hour of intrathecal administration of sufentanil, occurred in 8 of 400 parturients who received CSE analgesia, versus none of 352 women who received intravenous meperidine ($P < 0.01$). However, CSE analgesia did *not* increase the overall incidence of cesarean section or the incidence of cesarean delivery for dystocia. Similarly, Bofill et al.^[168] and Clark et al.^[169] observed no increase in the overall incidence of cesarean delivery in nulliparous women randomized to receive epidural bupivacaine analgesia, when compared with similar women randomized to receive intravenous opioid analgesia.

A 1994 meta-analysis suggested a strong association between epidural analgesia and an increased risk of cesarean section.^[170] However, a 1998 meta-analysis of randomized controlled trials did *not* support the hypothesis that epidural analgesia causes an increase in the cesarean delivery rate.^[171] A 1999 meta-analysis sponsored by the National Institute of Child Health and Human Development (NICHD) found that epidural analgesia with low-dose bupivacaine may increase the risk of oxytocin augmentation but not that of cesarean delivery.^[172]

Chestnut et al.^[173],^[174] performed two studies to assess the effect of the *timing* of epidural analgesia on the incidence of cesarean delivery. The first study included nulliparous women *already* receiving oxytocin for induction or augmentation of labor.^[173] Patients were randomized to receive intravenous nalbuphine or epidural bupivacaine when they had achieved a cervical dilation of at least 3 but less than 5 cm. Patients in the nalbuphine group could receive epidural analgesia once they achieved a cervical dilation of 5 cm or more, or 1 hour after a second dose of nalbuphine (as a rescue alternative). Attempts were made to minimize motor block in the epidural group. Early administration of epidural analgesia did not prolong the first stage of labor or increase the incidence of malposition of the vertex, instrumental vaginal delivery, or cesarean delivery. The overall incidence of cesarean delivery was 18 percent in the early epidural group and 19 percent in the late epidural group. Umbilical cord blood pH measurements were slightly lower in the late epidural group.

Chestnut et al.^[174] used a similar study design to determine whether early use of epidural analgesia affected obstetric outcome in nulliparous women in *spontaneous* labor.^[175] Early use of epidural analgesia did not increase the use of oxytocin augmentation, prolong the first stage of labor, or increase the incidence of malposition or instrumental delivery. There was no increase in cesarean delivery rate in the early epidural group (10 percent) versus the late epidural group (8 percent). Umbilical cord blood pH measurements were slightly lower in the late epidural group. The higher overall cesarean delivery rate in the first of these two studies (i.e., in women requiring induction or augmentation of labor) supports the conclusion that these parturients are at higher risk for cesarean delivery and should be considered separately in outcome studies.^[133],^[134]

What might cause the difference in outcome^[175] between the prospective studies of Thorp et al.^[164] and Chestnut et al.^[173],^[174] In the work of Chestnut et al., all patients ultimately received epidural analgesia, whereas in the study by Thorp et al., only one patient in the meperidine group ultimately received epidural analgesia. In the prospective study by Thorp et al.^[164] the authors assumed responsibility for the obstetric management decisions and obviously were not blinded to the anesthetic group. Their study patients were limited to an indigent population, while those of Chestnut et al.^[173],^[174] were evenly divided between indigent and private patients. Chestnut

et al. adjusted the epidural infusion to minimize the degree of motor block, but Thorp's group did not indicate the degree of maternal motor block or whether epidural analgesia was managed in such a way as to minimize excessive motor block.

RECOMMENDATIONS.

What can be concluded from these studies of epidural analgesia and the progress of labor? *First*, it is probably preferable to avoid institution of epidural analgesia during early, latent-phase labor in most patients. In general, epidural analgesia should not be instituted until the obstetrician is satisfied that the labor is established, that is, until the patient is having regular contractions and the cervix is dilating progressively. However, it is difficult to assign a specific cervical dilation as indicating the time to administer epidural analgesia; for some patients it will be 3 to 4 cm and for others, 4 to 6 cm. Psychoprophylactic techniques are probably most effective during the latent phase of labor and will allow many patients to forego supplemental analgesia during that period. However, physicians should recognize that some patients experience severe pain during latent-phase labor. This is especially true if the patient is receiving intravenous oxytocin. It is best to individualize decisions regarding timing of epidural analgesia. Thus, in some patients, early institution of epidural analgesia may be appropriate. In these situations, it may be possible to utilize intrathecal or epidural opioids and allow the patient to ambulate until labor has become more active. The American Society of Anesthesiologists and the ACOG have written a joint statement on pain relief in labor that notes in part, "There is no other circumstance where it is considered acceptable for a person to experience severe pain, amenable to safe intervention, while under a physician's care."^[176]

Second, it is preferable to use dilute solutions of local anesthetic rather than more concentrated solutions. For example, 0.125 percent or 0.25 percent bupivacaine will provide satisfactory analgesia in almost all parturients, and it is rarely necessary to give a more concentrated solution of bupivacaine for analgesia during labor. If a patient develops motor block, the local anesthetic solution can be made more dilute and supplemented with an opioid as needed.

Third, the obstetrician should recognize that a brief period of decreased uterine activity often follows the institution of epidural analgesia. In some patients, there is a brief period of decreased uterine activity followed by reestablishment of the contraction pattern and resumption of normal labor (Fig. 15-10) (Figure Not Available).^[177] This may actually be caused by the intravenous hydration given prior to epidural analgesia.^[178],^[179] In one study, a 1,000-ml fluid load decreased uterine activity for a short period of time, whereas an epidural block without a fluid load was associated with increased uterine

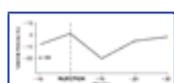

Figure 15-10 Effect of epidural injections of lidocaine with epinephrine on uterine activity levels in 65 cases. (From Lowenshon RI, Paul RH, Fales S, et al: *Intrapartum epidural anesthesia: an evaluation of effects on uterine activity*. *Obstet Gynecol* 44:388, 1974, with permission.)

activity.^[178] In some patients, epidural analgesia may accelerate labor, perhaps by decreasing maternal concentrations of catecholamines. At least one study has documented a favorable influence of epidural analgesia in patients with discoordinate uterine contractions and prolonged labor.^[180] However, in other patients, analgesia may seem to slow or to stop labor for more than a brief period. In such patients, the obstetrician should be willing to augment labor by giving oxytocin intravenously.

Fourth, there remains disagreement regarding whether it is advisable to add epinephrine to the therapeutic dose of local anesthetic. Some anesthesiologists add epinephrine to local anesthetic solutions to produce vasoconstriction in the area where the local anesthetic is injected. In this way, the blood absorbs smaller amounts of anesthetic over a longer time period. Thus, there is a decreased concentration of local anesthetic in the maternal blood, and less local anesthetic crosses the placenta to the fetus (Fig. 15-11). Also, the addition of epinephrine may result in a more solid block, especially if one is administering lidocaine. On the other hand, some studies have demonstrated that the addition of epinephrine to local anesthetic solution is more likely to decrease uterine activity than administration of local anesthetic without epinephrine (Fig. 15-12). Another study reported a similar effect of epinephrine on uterine activity but no significant effect of epinephrine on the duration of labor.^[181] Other investigations have also suggested that the addition of epinephrine to local anesthetic does not prolong the duration of labor.^[182]^[183]^[184]^[185] This is especially likely to be true if a very dilute concentration of epinephrine is administered.^[182]^[183]^[184]^[185]

Fifth, should epidural analgesia be continued or discontinued during the second stage of labor? We believe that it is inappropriate to withhold analgesia routinely during the second stage. Johnson et al.^[186] concluded: "Voluntary effort is decreased in some patients in the second stage of labor with spinal and peridural analgesia. Since this is not a consistent finding, and some patients actually exhibited increased capability for bearing

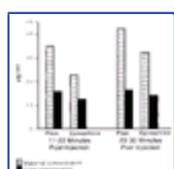

Figure 15-11 Histogram of mean maternal and cord plasma concentrations of lidocaine, 20 ml 2 percent solution with or without the addition of 1:250,000 epinephrine, in patients who were delivered 11 to 22 minutes or 23 to 30 minutes after administration of lidocaine by the lumbar epidural route. (From Thomas J, Climie CR, Long G, Nighjoy LE: *The influence of adrenaline*

down after the anesthesia, it must be an individual reaction without the actual loss of ability." We should like to emphasize that epidural analgesia during labor is not a generic procedure. For example, in one study^[150] maintenance of the infusion of local anesthetic until delivery did not prolong the second stage or increase the incidence of instrumental delivery, but it also did not reliably provide second-stage analgesia. In a similar study^[141] performed at the same institution, infusion of a different local anesthetic until delivery provided excellent second-stage analgesia, but it prolonged the second stage and increased the incidence of instrumental delivery. In the first study,^[150] the block during the second stage was clearly inadequate in most patients, while in the second study^[141] the block was probably excessive in some patients. Clearly, a dense epidural block may decrease the ability of some patients to push effectively. On the other hand, other patients will push more effectively in the presence of analgesia. In clinical practice, it seems best to individualize patient management. If the block is too dense and the patient cannot push effectively, then there should be diminution of the level and/or intensity of analgesia. In other patients, the block should be maintained or strengthened. The optimal approach is to provide a reasonable level of analgesia consistent with the parturient's ability to push effectively. Of course, it is also important that patients be actively coached in pushing.

Sixth, one should avoid arbitrary termination of the second stage. As noted earlier, the ACOG has redefined the "normal" limits of the duration of the second stage in patients with and without regional anesthesia.^[146] Indeed, in some patients with effective epidural analgesia, it may be appropriate to allow a second stage of more than 3 hours, provided that there is continued progress in descent of the vertex.

Seventh, it is important to recognize that risk to mother and infant of instrumental delivery performed under the ideal conditions provided by spinal or epidural anesthesia may differ from the risk of instrumental delivery performed without adequate anesthesia. Indeed, regional anesthesia may well allow for more complete cooperation by the patient, a more accurate application of the forceps, and a more gentle birth.

Finally, the weight of current evidence suggests that maternal-fetal factors and obstetric management are the most important determinants of the cesarean delivery rate.^{[159] [160] [161] [187] [188] [189]} Epidural analgesia during labor is not a generic procedure, and conclusions regarding the effect of one technique on the progress of labor may not be applicable to other techniques. We do *not* recommend withholding analgesia until the patient has achieved an arbitrary cervical dilation during the first stage of labor, and it is equally inappropriate to discontinue analgesia altogether during the second stage.

There remain several unresolved questions with regard to optimal management of epidural anesthesia during labor. *First*, does continuous infusion of local anesthetic affect labor differently than intermittent epidural bolus injection? Purported advantages of continuous epidural infusion during labor include (1) a more stable level of analgesia, (2) reduced risk of hypotension, (3) reduced risk of systemic toxicity, (4) reduced risk of total spinal block, and (5) convenience for the

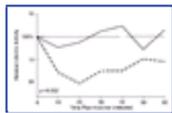

Figure 15-12 Mean values of uterine activity after epidural administration of lidocaine (solid line) or lidocaine with epinephrine (dotted line). (From Matadial L, Cibils LA: *The effect of epidural anesthesia on uterine activity and blood pressure. Am J Obstet Gynecol* 125:846, 1976, with permission.)

anesthesiologist.^[190] An infusion pump delivers a dilute solution of local anesthetic by continuous positive pressure. A potential disadvantage of continuous epidural infusion is that it tends to discourage individualization of the dose of local anesthetic in an individual patient. Thus, there is a tendency to give more local anesthetic than one would give if one were using the intermittent epidural bolus injection technique. For example, there have been at least five controlled comparisons of the continuous epidural infusion of bupivacaine versus intermittent epidural bolus injection of bupivacaine.^{[191] [192] [193] [194] [195]} In each study, patients in the continuous infusion group received more bupivacaine than did patients in the intermittent bolus group. It is unclear whether the increased dose of bupivacaine is clinically significant and represents a disadvantage. Furthermore, it is unclear whether the continuous epidural infusion technique has more or less effect on the progress of labor and method of delivery than does the intermittent epidural bolus injection technique. Altogether, the weight of evidence suggests that the continuous epidural infusion technique is advantageous, provided the anesthesiologist uses a dilute solution of local anesthetic.

Second, is it advantageous to add opioid to the solution of local anesthetic and thereby reduce the total dose of local anesthetic and the extent of maternal motor block? Chestnut and colleagues^[196] observed that the continuous epidural infusion of 0.0625 percent bupivacaine-0.0002 percent fentanyl produced first-stage analgesia similar to that provided by the infusion of 0.125 percent bupivacaine alone. Women who received bupivacaine and fentanyl experienced less intense motor block, but they did *not* have a shorter second stage or a lower incidence of instrumental delivery than did women who received bupivacaine alone. A legitimate criticism of that study is that the epidural infusion was discontinued at full cervical dilation in both groups. Had the infusion been continued until delivery, it is possible that there would have been a difference between groups in the method of delivery.

Vertommen et al.^[197] performed a multicenter randomized study of epidural bolus administration of 0.125 percent bupivacaine with 1:800,000 epinephrine, with and without sufentanil, in 695 parturients of mixed parity. There was no difference between the two groups in the duration of the second stage of labor (33 ± 24 minutes in the sufentanil group vs. 27 ± 21 minutes in the control group). Women in the sufentanil group had a decreased incidence of instrumental vaginal delivery (24 percent vs. 36 percent, $p < 0.01$). The authors attributed this reduction to the decreased total dose of bupivacaine (34 ± 17 vs. 42 ± 19 mg) and the decreased intensity of motor block in the sufentanil group. The authors did not specifically assess and report the quality of analgesia during the second stage of labor. In an accompanying editorial, it was noted that "no published study has shown that one can consistently provide effective analgesia *throughout the second stage of labor* without increasing the risk of instrumental delivery."^[198]

Third, should there be more frequent use of oxytocin during the second stage of labor? Goodfellow and colleagues^[199] noted a significant increase in maternal blood concentrations of oxytocin between the onset of full cervical dilation and crowning of the fetal head in patients without epidural anesthesia, but they did not observe a similar increase in patients with epidural anesthesia. Similarly, Bates and colleagues^[200] observed significantly less uterine activity during the second stage in patients with epidural anesthesia compared with patients without epidural anesthesia. Both groups of investigators recommended increased utilization of oxytocin during the second stage in order to increase the chance of spontaneous vaginal delivery.

Fourth, is there a role for delayed pushing during the second stage? Maresh and colleagues^[149] reported a study of 76 nulliparous women with epidural anesthesia who were randomly assigned to early pushing or late pushing in the second stage. There was a significant increase in the duration of the second stage but a nonsignificant decrease in the frequency of instrumental delivery in the late-pushing group. The increased second-stage duration was not associated with an increase in fetal heart rate abnormalities or a decrease in Apgar scores or umbilical cord blood pH. It is possible that patients become exhausted when asked to push too early during the second stage. Indeed, it may be preferable to allow the force of uterine contractions to deliver the vertex to a station at which maternal pushing might be effective.

Paracervical Block

Paracervical block analgesia, a simple, effective procedure when performed properly, is used most commonly by obstetricians. Usually, 5 to 6 ml of a dilute solution of local anesthetic without epinephrine (e.g., 1 percent lidocaine or 1 or 2 percent 2-chloroprocaine) is injected into the mucosa of the cervix at either the 4- and 8- or 3- and 9-o'clock positions; an Iowa trumpet prevents deep penetration of the needle (Fig. 15-13). The duration of analgesia depends on the local anesthetic used. Several manufacturers have stated that bupivacaine, the longest acting local anesthetic, is contraindicated for obstetric paracervical block. In the past, paracervical block enjoyed considerable favor, particularly when anesthesiologists were not available to provide major regional analgesia techniques. Disadvantages of the technique are that the block can only be applied during the first stage of labor and that it must be reapplied frequently during the course of a long labor. Furthermore, it has the widely recognized major disadvantage of fetal

Figure 15-13 Technique of paracervical block. Schematic coronal section (enlarged) of lower portion of cervix and upper portion of vagina shows relation of needle to paracervical region. (Modified from Bonica JJ: *Principles and Practice of Obstetric Analgesia and Anesthesia*. Philadelphia, FA Davis, 1967, p 234.)

bradycardia, which occurs in 2 to 70 percent of applications. It occurs within 2 to 10 minutes and lasts from 3 to 30 minutes. Although usually benign, it can be associated with fetal acidosis and occasionally with fetal death. ^[201] ^[202] ^[203]

There is no consensus regarding the mechanism of postparacervical block bradycardia. The theories include (1) high blood concentrations of local anesthetic in the fetus, (2) uterine artery vasoconstriction, and (3) postparacervical block increase in uterine activity. A high blood concentration is feasible, because the local anesthetic is injected close to the uterine artery. The anesthetic would traverse the wall of the uterine artery, pass directly to the fetus, and thus result in a high blood concentration and subsequent bradycardia. ^[201] Clinical support for this theory is that infants who suffer bradycardia frequently have higher anesthetic blood concentrations than do their mothers. ^[201] Alternatively, the bradycardia may result from uterine artery vasoconstriction secondary to a direct effect of the local anesthetic on the uterine artery. ^[204] ^[205] This effect has been demonstrated in vitro on human uterine arteries ^[204] (Fig. 15-14) and is supported by uterine blood flow studies in animals. ^[205] The fetal electrocardiogram (ECG) pattern during one of these episodes suggests hypoxia, a finding that supports the uterine artery vasoconstriction theory. ^[206] Furthermore, the high concentrations of local anesthetic required to produce vasoconstriction during the administration of a paracervical block can be achieved close to the uterine artery (Fig. 15-13). It is unlikely that such levels are obtained with other forms of regional anesthesia. The third theory is based on the possibility that local anesthetic injected directly into the uterine musculature increases uterine tone.

Some have suggested that manipulation of the fetal head, the uterus, or the uterine vasculature during institution of the block might produce reflex bradycardia. It is possible that no one theory is adequate to explain all cases of postparacervical block bradycardia. Regardless of etiology, the severity and duration of the bradycardia correlate with the incidence of fetal acidosis and subsequent neonatal depression. Freeman and colleagues ^[206] reported a significant fall in pH and a rise in base deficit only in those fetuses with bradycardia persisting more than 10 minutes. In summary, paracervical block should be used cautiously at all times and should not be used at all in mothers with fetuses in either acute or chronic distress.

Sterile Water Injection

A novel way to provide relief of severe lower back pain during the first stage of labor involves subcutaneous or intracutaneous injection of sterile water at four points on the lower back. ^[207] In a randomized controlled trial, the median reductions in the visual analogue scores were 4 to 5 compared to 1 in the placebo group.

Table 15-4 presents the frequency with which the various forms of analgesia are used during labor. The data are from a survey of 750 hospitals in the United States. ^[208]

ANESTHESIA FOR VAGINAL DELIVERY

Pain relief for vaginal delivery can be achieved in a number of ways. Some patients will require no anesthesia. For those who do, the goal is to match the patient's wishes with the requirements of the delivery without subjecting either mother or fetus to unnecessary risk.

Local Anesthesia

In the form of perineal infiltration, local anesthesia is widely used and very safe. Spontaneous vaginal deliveries, episiotomies, and perhaps use of outlet forceps can be accomplished with this simple technique. Local anesthetic toxicity may occur if large amounts of local anesthetic are used or in the unlikely event that an intravascular injection occurs. Usually, 5 to 15 ml of 1 percent lidocaine suffices. Philipson and colleagues^[209] demonstrated the rapid and significant transfer of lidocaine to the fetus after perineal infiltration. In 5 of 15 infants, the concentration of lidocaine at delivery was greater in the umbilical vein than in the mother (Table 15-5).^[209]

Pudendal Nerve Block

Pudendal nerve block is a minor regional block that also is widely used, reasonably effective, and very safe. The obstetrician, using an Iowa trumpet and a 20-gauge needle, injects 5 to 10 ml of local anesthetic just below the ischial spine. Because the hemorrhoidal nerve may be aberrant in 50 percent of patients,^[210] some physicians prefer to inject a portion of the local anesthetic somewhat posterior to the spine (Fig. 15-15). For those inexperienced at identifying the ischial spine, the bony prominence at the inner canthus of one's eye provides a reasonable facsimile of a small and somewhat sharp ischial spine. Although a transperineal approach to the ischial spine is possible, most prefer the transvaginal approach. One percent lidocaine or 2 percent 2-chloroprocaine is used.

The technique is satisfactory for all spontaneous vaginal deliveries and episiotomies and for some outlet or low-forceps deliveries, but may not be sufficient for deliveries requiring additional manipulation. For example, a breech delivery or a delivery necessitating more

Figure 15-15 A and B, Anatomy of the pudendal nerve and techniques of pudendal block.

than outlet forceps may require more pain relief, relaxation, and cooperation than pudendal block can ensure. Likewise, a pudendal block may not provide enough anesthesia for the successful and controlled release of shoulder dystocia. In these instances, as in any others that require significant manipulation, more extensive anesthesia will be required. Ideally, such requirements should be anticipated before the event.

More than with perineal infiltration, the potential for local anesthetic toxicity exists with pudendal block because of the proximity of large vessels close to the site of injection (Fig. 15-15). Therefore, aspiration before injection is particularly important. Furthermore, the potential for large amounts of local anesthetic to be used increases when perineal and labial infiltration are required in addition to the pudendal block. In these instances, it is important to monitor closely the amount of local anesthetic given.

Inhalation or Intravenous Analgesia

An anesthesiologist or nurse anesthetist administers inhalation or intravenous analgesia (stage I anesthesia), which provides varying degrees of pain relief and amnesia but maintains protective laryngeal and cough reflexes. Most often the obstetrician will add local infiltration or a pudendal block. The anesthesiologist will frequently question the patient to determine the level of anesthesia and to ensure that deeper planes of anesthesia are avoided. Such precautions are important because, if the patient becomes unconscious and passes beyond stage I, all of the hazards associated with general anesthesia are possible, including inadequate airway, hypoxia, and aspiration. Because continual assessment of the patient's state of consciousness is required and is sometimes difficult, only anesthesiologists or

nurse anesthetists should administer inhalation analgesia. Furthermore, this technique requires the use of the increasingly complicated anesthesia machine, misuse of which can prove disastrous. Most frequently, the anesthesiologist uses 40 or at most 50 percent nitrous oxide or, for intravenous analgesia, ketamine, 0.25 mg/kg. This latter agent may be particularly effective for the patient who cannot or will not tolerate an anesthetic face mask. Less commonly, the anesthesiologist may administer a subanesthetic concentration of a potent halogenated agent (e.g., sevoflurane) for a brief period.

Inhalation or intravenous analgesia alone will not be sufficient for performing episiotomies or repairing perineal lacerations. Therefore, these techniques usually require supplemental pudendal block or perineal infiltration. The combined effects of both techniques are additive and satisfactory for spontaneous vaginal deliveries, most outlet forceps deliveries, and even some manipulative deliveries. Inhalation or intravenous analgesia renders some patients amnesic of the event, a characteristic that is often undesirable.

Spinal (Subarachnoid) Block

A saddle block is a spinal block in which the level of anesthesia is limited to little more than the perineum, that is, the saddle area. Spinal anesthesia is reasonably easy to perform and usually provides total pain relief in the blocked area. Therefore, spontaneous deliveries, forceps deliveries, and episiotomies can be accomplished without pain for the mother. Likewise, complicated deliveries that require extensive manipulation can be effected in a controlled and pain-free manner. Although the ability to push may be compromised somewhat, the advantage of having a cooperative patient who is receptive to suggestion and able to cooperate because she is pain-free may outweigh the disadvantage of moderately diminished strength.

Usually spinal anesthesia is achieved by injecting 25 to 50 mg hyperbaric lidocaine or 5 to 7.5 mg hyperbaric bupivacaine into the subarachnoid space through a 24 to 27-gauge spinal needle. It is preferable to use a pencil-point needle of the smallest possible gauge, because these needles reduce the risk of spinal headache. Fentanyl 10 to 25 µg may also be added to the spinal anesthetic. Because the solution is hyperbaric relative to cerebrospinal fluid, the most important determinant of anesthesia level is gravity. The level is most easily controlled by varying the position of the patient. For example, the sitting position causes the level to fall toward the sacral nerve roots for a perineal block. Other factors may also contribute to the level of anesthesia: amount of drug, volume injected, speed of injection, and height of the patient. Less controllable factors include the Valsalva maneuver, coughing, and straining, any of which will cause the level to rise. One should avoid injecting the local anesthetic during a contraction, because a higher than expected level of anesthesia may occur. Finally, left uterine displacement is maintained by a wedge or by some other effective device placed under the right hip after the local anesthetic has been injected.

Because spinal anesthesia is sometimes administered by persons other than anesthesiologists and is technically easy to perform, the single most important fact to understand is that it is a major regional block; it is not a procedure to be taken lightly. All hazards associated with major blocks are possible, including hypotension and "total spinal." Although these complications can occur, they should not result in disaster if diagnosed early and treated appropriately. The person who administers spinal anesthesia must never leave the patient unattended without ensuring that another competent individual will assume responsibility for monitoring the

blood pressure and level of anesthesia. Usually, the level of the spinal block will be complete and fixed within 5 to 10 minutes. However, sometimes the level continues to creep upward for 20 minutes or longer.

Single-Dose Caudal and Lumbar Epidural Anesthesia

Single-dose epidural anesthesia techniques are used much less frequently than in the past. The relative difficulty and the large amounts of local anesthetic required are significant disadvantages for the caudal technique. Usually, when these techniques are used they are instituted during labor as continuous techniques and maintained or intensified for the delivery.

General Anesthesia

General anesthesia is rarely indicated for vaginal delivery. Whether given for a brief or a prolonged period of time, general anesthesia engenders considerable risk and should therefore not be used without strong indication. An unanticipated breech presentation, shoulder dystocia, or internal version and extraction of a second twin represent rare indications for general anesthesia. Also, general anesthesia may rarely be indicated for a difficult forceps delivery in a patient in whom major regional anesthesia is contraindicated. When general anesthesia is indicated, the technique specific for cesarean delivery is used, including administration by experienced and competent personnel, rapid sequence induction, and endotracheal intubation. For breech delivery or delivery of a second twin, one may administer a high concentration of a volatile halogenated agent (e.g., isoflurane, desflurane, or sevoflurane) to effect uterine and perhaps cervical relaxation. Equipotent doses of any of these three agents will provide equivalent uterine relaxation. ^[21] Table 15-6 lists the frequencies with which the various forms of anesthesia are used for vaginal delivery.

ANESTHESIA FOR CESAREAN DELIVERY

The patient can be either asleep or awake during cesarean delivery. For those who wish to be awake, either spinal anesthesia or lumbar epidural anesthesia is used most commonly. In the United States, general anesthesia is used for 8 to 11 percent of cesarean births (depending on size of hospital), and spinal and epidural anesthetics are used for approximately 90 percent (Table 15-7).^[208] Local anesthesia for cesarean delivery is possible but is only rarely used.^[212]

Either general or regional anesthesia should be safe for the infant; studies have reported Apgar scores and blood gas measurements as essentially the same for infants of mothers choosing either technique (Table 15-8).^[213]^[214]^[215],^[211] In recent years, some authors have suggested that Apgar scores and acid-base analysis evaluated brain stem activity, but not the higher centers. Therefore, neurobehavioral testing for the newborn was developed.^[216] The testing involves eliciting and observing the quality of the infant's responses to certain stimuli in the early postpartum hours. A trained person can accomplish the testing in approximately 15 minutes. Results indicate that infants of mothers who receive regional anesthesia achieve somewhat higher scores than those whose mothers receive general anesthesia, and infants do somewhat better when ketamine is the induction agent for general anesthesia than when thiopental is used.^[217] Regarding the choice of local anesthetic for regional anesthesia, infants were originally thought to do better after 2-chloroprocaine and bupivacaine than after lidocaine and mepivacaine.^[218] Recently, however, lidocaine has been "exonerated" and is associated with neurobehavioral scores equal to those observed when mothers have received 2-chloroprocaine or bupivacaine.^[69] When the Food and Drug Administration (FDA) appointed a committee to study neurobehavioral changes in newborns after anesthesia, the committee concluded that, although anesthetic agents can alter neurobehavioral performance, there was no evidence that they affect later development.^[41] Therefore, neurobehavioral considerations do not weigh heavily in the choice of anesthesia or anesthetic agent; the choice can be based on the preferences of the mother, the obstetrician, and the anesthesiologist as well as on the demands of the particular clinical situation.

General Anesthesia

Although outcomes for the neonate are similar after regional or general anesthesia, failure to intubate and aspiration continue to be major causes of maternal mortality.^[219]^[220]^[221]^[222]^[223] Because these two disadvantages of

general anesthesia are a considerable and significant threat to the mother, many anesthesiologists now prefer regional anesthesia over general anesthesia. Data from both the ASA Closed Claims study^[93] and the Centers for Disease Control and Prevention^[223] indicate maternal mortality rates are higher during general anesthesia than during regional anesthesia, perhaps as much as 17 times higher. To understand how these complications arise, the obstetrician should be aware of the sequence of events during general anesthesia. Furthermore, there may be times when the obstetrician must participate in difficult decisions concerning anesthetic management. Those decisions may affect the lives and well-being of both mother and infant.

Premedication

Premedication using sedative or opioid agents is usually omitted because these agents cross the placenta and can depress the fetus. Sedation should be unnecessary if the procedure is explained well.

Antacids

Use of a clear antacid is considered routine for all parturients prior to surgery. Additional aspiration prophylaxis using an H₂-receptor blocking agent and/or metoclopramide may be given to parturients with risk factors such as morbid obesity, diabetes mellitus, a difficult airway, or those who have previously received narcotics. As soon as it is known that the patient requires cesarean delivery, be it with regional or general anesthesia, 30 ml of a clear, nonparticulate antacid, such as 0.3 M sodium citrate,^[224] Bicitra,^[225] or Alka Seltzer, 2 tablets in 30 ml water,^[226] is administered to decrease gastric acidity and ameliorate the consequences of

aspiration, should it occur. The chalky white particulate

antacids are avoided because they can produce lung damage (Fig. 15-16).^[227]

Advantages and Disadvantages of General Anesthesia for Cesarean Delivery
<p>Advantages</p> <ul style="list-style-type: none"> • Patient does not have to be awake during a major operation. • General anesthesia provides total pain relief. • Operating conditions are optimal. <p>Disadvantages</p> <ul style="list-style-type: none"> • Patient will not be awake during childbirth, although there is a small risk of undesirable awareness. • There is a slight risk of fetal depression. • Intubation causes hypertension and tachycardia, which may be particularly dangerous in severely preeclamptic patients. • Intubation can be difficult or impossible. • Aspiration of stomach contents is possible.

Left Uterine Displacement

As during labor, the uterus may compress the inferior vena cava and the aorta during cesarean delivery; aortocaval compression is detrimental to both mother and fetus. The duration of anesthesia has little effect on neonatal acid-base status when left uterine displacement is practiced; however, when patients remain supine, Apgar scores decrease as time of anesthesia increases.^[228]

Regarding this latter point (i.e., anesthesia time or induction-to-delivery time), more recent data indicate that the induction-to-delivery time is not the crucial time. Rather, it is the uterine incision-to-delivery interval that is predictive of neonatal status.^[229] A uterine-incision interval of less than 90 seconds is optimal, whereas an incision-to-delivery interval of 90 to 180 seconds is less satisfactory; after 180 seconds, the incidence

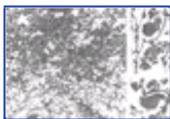

Figure 15-16 Lung after aspiration of particulate antacid. Note marked extensive inflammatory reaction. The alveoli are filled with polymorphonuclear leukocytes and macrophages in approximately equal numbers. Insets at right show large and small intra-alveolar particles surrounded by inflammatory cells (48 hours). Later, the reaction changed to an intra-alveolar cellular collection of clusters of large macrophages with abundant granular cytoplasm, in some of which were small amphophilic particles similar to those seen in the insets. No fibrosis or other inflammatory reaction was seen (28 days). (From Gibbs CP, Schwartz DJ, Wynne JW, et al: Antacid pulmonary aspiration in the dog. *Anesthesiology* 51:380, 1979, with permission.)

of newborn depression is significantly increased. Therefore, it seems that uterine manipulation and difficulty of the delivery are significant factors for the fetus during cesarean section.

Preoxygenation

Before patients become unconscious and paralyzed, it is best to wash all nitrogen from the lungs and replace it with oxygen. This is especially important in pregnant patients, because functional residual capacity is decreased and pregnant patients become hypoxemic more quickly than nonpregnant patients during periods of apnea.^[230] Therefore, before starting induction, 100 percent oxygen is administered via face mask for 2 to 3 minutes. In situations of dire emergency, four vital capacity breaths of 100 percent oxygen via a tight circle system will provide similar benefit.^[231] Thus, should untoward events occur, the patient can tolerate them for a longer period without becoming hypoxic.

Induction

The anesthesiologist rapidly administers thiopental (a short-acting barbiturate) or ketamine to render the patient unconscious. An appropriate dose of either agent has little effect on the fetus.^{[215], [232], [233], [234]}

Muscle Relaxant

Immediately after administration of thiopental or ketamine, the anesthesiologist gives a muscle relaxant to facilitate intubation. Succinylcholine, a rapid-onset,

short-acting muscle relaxant, remains the agent of choice in most patients.

Cricoid Pressure

In rapid-sequence induction, as the thiopental or ketamine begins to take effect and the patient approaches unconsciousness, an assistant applies pressure to the cricoid cartilage, which is just below the thyroid cartilage, and does not release the pressure until an endotracheal tube is placed, its position verified, and the cuff on the tube inflated.^[235], ^[236] Pressure on the cricoid closes off the esophagus and is extremely important in preventing aspiration should regurgitation or vomiting occur. It is a simple, safe, effective maneuver that should not be omitted.

Intubation

Usually, intubation proceeds smoothly. However, in approximately 5 percent of patients, it will be difficult or delayed. In some (0.3 percent of obstetric patients), it will be impossible. The incidence of failed intubation in obstetric patients is about seven times more common than in patients in the general operating room (i.e., 1:280 in obstetric patients vs. 1:2,230 in surgical patients).^[237] When the delay is prolonged or the intubation impossible, the situation becomes a crisis in which the critical factor is to deliver oxygen to the now unconscious and paralyzed patient. Also, because it is during this induction sequence (i.e., before the airway is secured with an endotracheal tube) that the patient is most at risk from aspiration, any delay increases the risk.^[93], ^[220] It is therefore particularly important during a difficult intubation that the person applying cricoid pressure not release that pressure until told to do so by the anesthesiologist.

The patient at risk for a difficult or impossible intubation can often be identified prior to surgery. Examination of the airway is a critical part of the preanesthetic evaluation. The most important factors to assess are (1) the ability to visualize oropharyngeal structures (Mallampati classification^[238]); (2) range of motion of the neck; (3) a receding mandible, which indicates the depth of the submandibular space; and (4) whether protruding maxillary incisors are present.^[239] When airway abnormalities are recognized by the obstetrician, patients should be referred for an early preoperative evaluation by the anesthesiologist.

Proper Tube Placement

Before the operation begins, the anesthesiologist must ensure that the endotracheal tube is properly positioned within the trachea. End-tidal carbon dioxide analysis is the preferred method to confirm that the tube is within the trachea.^[240] Of course, the anesthesiologist will also confirm that breath sounds are bilateral and equal. If the endotracheal tube is not in the trachea (and therefore is likely in the esophagus), the tube must be removed immediately and the entire situation reassessed. In some instances, the attempt will be repeated. Otherwise, the anesthesiologist will allow the patient to awaken (wherein lies the virtue of the short-acting drugs thiopental and succinylcholine), and another course of action will be chosen. Until the patient completely awakens, ventilation with bag and face mask and continuous application of cricoid pressure may be necessary. Once the patient is awake and breathing spontaneously, the anesthesiologist must choose between awake intubation or regional anesthesia. In most cases, if the endotracheal tube is incorrectly placed, the operation should not proceed until the airway is secure, because the patient cannot be allowed to awaken after the abdomen is opened. If the operation proceeds and ventilation cannot be accomplished, hypoxia, hypercarbia, and cardiac arrest can result; the fetus also will suffer.

When cesarean delivery is not urgent, the decision to

delay the operation and allow the mother to awaken is easy. However, if the operation is being done because of rapidly worsening fetal condition or maternal hemorrhage, allowing the mother to awaken may further jeopardize the fetus or mother. It is helpful if one continues fetal heart rate monitoring before and even during induction of anesthesia. In most situations, one can leave the fetal scalp electrode in place until delivery. At that time the circulating nurse can reach under the drapes and disconnect the scalp lead. Fetal heart rate monitoring may guide anesthetic and obstetric management in situations of failed intubation. Rarely, in situations of dire fetal compromise, the anesthesiologist and obstetrician may jointly decide to proceed with cesarean delivery while the anesthesiologist provides oxygenation, ventilation, and anesthesia by face mask ventilation with an additional person maintaining continuous cricoid pressure. In these emergency situations, it may be necessary to have additional trained personnel to provide assistance. After delivery, the obstetrician should obtain temporary hemostasis and then halt surgery while the anesthesiologist secures the airway by fiberoptic or blind nasal intubation.

The obstetrician and anesthesiologist should address these issues before they become emergent. Such instances should be the subject of combined obstetric/anesthesia conferences during which the concerns of all can be presented and discussed. An algorithm for management of failed intubation in the obstetric patient is shown in [Figure 15-17](#). Equipment to manage the difficult airway must be immediately available in the labor and delivery suite.^[241] The anesthesiologist performing a rapid-sequence induction is in a position comparable to the obstetrician confronted with the vaginal delivery of a breech presentation: the anesthesiologist has an unconscious and paralyzed mother whose airway is not yet established, and the obstetrician must deliver the largest part of the baby last. In both instances, one acts before the outcome is certain. In both instances, considerable clinical skill and judgment must be exercised.

Nitrous Oxide and Oxygen

Once the endotracheal tube is in place, a 50:50 mixture of nitrous oxide and oxygen is added to provide analgesia. Such a mixture is safe for both mother and fetus.^[242]

Volatile Halogenated Agent

Usually, in addition to the nitrous oxide, an analgesic quantity (low concentration) of a volatile halogenated agent (e.g., isoflurane, sevoflurane, or desflurane) will be added to provide amnesia and additional analgesia. These agents, in low concentrations, are not harmful to mother or fetus. Also, uterine relaxation does not occur, and bleeding is not excessive.^[211], ^[215], ^[243], ^[244] If one does not add a potent inhalation agent, there will be an unacceptably high incidence of maternal awareness and recall. Even with the use of one of these agents, maternal awareness and recall occasionally occur. Therefore, it is important that all operating room personnel use discretion in conversation and conduct themselves as if the patient were awake.

Postdelivery

Usually the concentration of nitrous oxide can be increased after delivery. In addition, the volatile halogenated

Figure 15-17 An algorithm for the management of failed intubation in the obstetric patient.

agent is continued, and an opioid is added to supplement the nitrous oxide and oxygen.

Oxytocin Administration

Ten to 30 U/L are infused intravenously. Bolus injections are avoided, because they can cause hypotension and tachycardia.^[245]

Extubation

Because the patient can aspirate while awakening as well as during induction, extubation is not done until the patient is awake and can respond appropriately to commands. Coughing and bucking do not necessarily indicate that the patient is awake, merely that she is in the second stage of the excitement stage of anesthesia. It is during this period of anesthesia that laryngospasm is most likely to occur should any foreign body, including the endotracheal tube or bits of stomach contents, stimulate the larynx. The patient must therefore be awake and conscious, not merely active, before extubation.

Recovery

The most important requirement of the recovery room is the presence of personnel trained appropriately and assigned no other duties than those required for the recovery process. The recovery room must contain adequate facilities such as suction, oxygen, and monitoring, and should provide care comparable to that provided patients who have received general or regional anesthesia for other surgical procedures. [3], [246] [247] [248] [249] [250]

Aspiration

Aspiration is a serious and often fatal complication of general anesthesia and therefore deserves specific attention. In most instances it can be prevented. When it cannot, the consequences depend in part on the volume and nature of the aspirate. The conventional wisdom is that patients are at risk when their stomach contents are greater than 25 ml and when the pH of those contents is less than 2.5. [251] There are several reasons why the pregnant patient is particularly at risk. The enlarged uterus increases intra-abdominal pressure and thus intragastric pressure. [252] The gastroesophageal sphincter is distorted by the enlarged uterus, making it less competent, possibly explaining the high incidence of heartburn that occurs during pregnancy. [253], [254] Concentrations of progesterone are increased during pregnancy. Progesterone is a smooth muscle relaxant, and thereby it delays gastric emptying and relaxes the gastroesophageal sphincter. Gastrin, the hormone that increases both acidity and volume of gastric contents, is increased during pregnancy, [255] and motilin, a hormone that speeds gastric emptying, is decreased during pregnancy. [256] Labor itself delays gastric emptying, [257] primarily when patients have received opioids. [258] Many patients undergo cesarean section after a prolonged labor, during which they may have received several doses of opioids. [42]

Not all cases of aspiration are the same. The severities of lung damage, morbidity, and mortality vary and depend on the type of material aspirated. A less acidic liquid (pH >2.5) significantly decreases Pa_O₂ physiologically but has little histologic effect. Liquids with a pH of less than 2.5 decrease Pa_O₂ further and cause a burn in the lungs that results in hemorrhage, exudate, and edema histologically. The type of aspiration that produces the most severe physiologic and histologic alterations is partially digested food. Pa_O₂ decreases more than with any other type of aspiration, and lung damage is considerably more destructive [259] (see Table 15-9).

The variability of the effects is important to the obstetrician and the anesthesiologist. Because the necessity of a cesarean delivery cannot always be predicted, oral intake of anything but small sips of clear liquids or ice chips should be prohibited during labor. [241] Eating food during labor is unnecessary and dangerous and should not be encouraged or allowed. [241] Acidic liquid can be neutralized safely and effectively with clear antacids or an H₂-receptor antagonist. [224] [225] [226], [260], [261] Partially digested food, however, causes significant hypoxia and lung damage even at a pH level as high as 5.9. [259] Therefore, the most important and critical preventive measure by the obstetrician is the advice not to eat before coming to the hospital, which should be accompanied by a thorough explanation of the necessity for such advice.

Regional Anesthesia

Ongoing hemorrhage is a firm contraindication to regional anesthesia. The blood volume of a hemorrhaging patient is too low for the vascular tree. One compensatory mechanism is vasoconstriction, which reduces the size of the vasculature, making it more commensurate with the blood volume. Major regional anesthesia produces sympathetic blockade, which not only hampers the compensatory mechanism but also dilates the vasculature and makes the discrepancy between volume and vasculature even greater.

Other contraindications to regional anesthesia include infection at the site of needle insertion, coagulopathy, patient refusal, and perhaps some varieties of heart disease. For example, most obstetricians and anesthesiologists have considered epidural anesthesia to be the anesthetic technique of choice for patients with mitral valvular disease, but have considered regional anesthesia to be contraindicated in other patients with aortic stenosis, pulmonary hypertension, and/or a right-to-left shunt. The latter group of patients cannot tolerate a decrease in systemic vascular resistance and/or a decrease

in venous return of blood to the right side of the heart. [266] Recently, there have been several reports of successful administration of epidural anesthesia to patients with aortic stenosis [267] and Eisenmenger syndrome. [268] However, it must be remembered that these reports represent small numbers of cases. Because regional anesthesia results in widespread sympathetic blockade, the pathophysiology of these forms of heart disease would most often dictate that regional anesthesia not be provided. If one chooses to give regional anesthesia to such patients, it is clear that single-dose spinal or epidural anesthesia is inappropriate. Rather, there should be slow, careful induction of epidural anesthesia performed by an anesthesiologist with experience in the use of epidural anesthesia in high-risk obstetric patients. Intrathecal or epidural *opioid* analgesia does not decrease systemic vascular resistance and cause hypotension and has emerged as an attractive choice of analgesia during labor. [269] [270] [271] Because neuraxial opioids provide inadequate somatic anesthesia, they are not appropriate for cesarean delivery unless combined with a local anesthetic.

Advantages and Disadvantages of Regional Anesthesia

Advantages

- The patient is awake and can participate in the birth of her child.
- There is little risk of drug depression or aspiration and no intubation difficulties.
- Newborns generally have good neurobehavioral scores.
- The mother can be given 100 percent oxygen.
- The father is more likely to be allowed in the operating room.

Disadvantages

- Patients may prefer not to be awake during major surgery.
- An inadequate block may result.
- Hypotension, perhaps the most common complication of regional anesthesia, occurs during 25 to 75 percent of spinal or epidural procedures.
- Total spinal anesthesia may occur.
- Local anesthetic toxicity may occur.
- Although extremely rare, permanent neurologic sequelae may occur.
- There are several contraindications.

The use of regional anesthesia in patients with fetal compromise depends on the severity of fetal condition and the presence or absence of preexisting epidural anesthesia. If the situation is severe and acute, most often one should not take the additional time necessary to perform a regional technique de novo. Also, if hypotension occurs, the risk to the already compromised fetus is increased. Lesser degrees of fetal compromise may well be compatible with regional anesthesia.^[272] For example, if an epidural catheter has been placed earlier, a partial level of anesthesia already exists, and there is hemodynamic stability, extension of epidural anesthesia may be appropriate for cesarean delivery. The anesthesiologist may give additional local anesthetic while the urethral catheter is inserted and the abdomen is prepared and draped. Often, there will be satisfactory anesthesia when the surgeon is ready to make the skin incision. If not, the ongoing fetal heart rate pattern will dictate whether a delay is acceptable. When partial but inadequate epidural anesthesia results, one may consider supplemental local infiltration of local anesthetic. Because the anesthesiologist may have already given a large dose of local anesthetic, the obstetrician should consult with the anesthesiologist to determine the proper choice and concentration of local anesthetic in order to avoid local anesthetic toxicity. For example, if the anesthesiologist has given lidocaine epidurally, and the patient has an area of inadequate anesthesia, the obstetrician might infiltrate the skin with 1 percent 2-chloroprocaine.

An improved fetal heart rate tracing may allow one to wait for satisfactory extension of epidural anesthesia, or it may allow the anesthesiologist to perform epidural or spinal anesthesia de novo. This must be done with caution, as there may be an increased risk of high spinal anesthesia when it is placed after an unsuccessful epidural anesthetic.^[106] Again, this illustrates the usefulness of continuing fetal heart rate monitoring before and during induction of anesthesia. In the absence of satisfactory epidural anesthesia and in the presence of ongoing acute fetal deterioration, rapid sequence induction of general anesthesia is usually indicated for cesarean section. However, one should not indiscriminately perform rapid sequence induction of general anesthesia. A history and/or suspicion of difficult intubation should prompt performance of either awake intubation or regional anesthesia, despite the presence of fetal compromise. One should not endanger the mother, however. As noted in the ACOG Committee Opinion on Anesthesia for Emergency Deliveries, "the risk of general anesthesia must be weighed against the benefit for those patients who have a greater potential for complications.... Cesarean deliveries that are performed for a nonreassuring fetal heart rate pattern do not necessarily preclude the use of regional anesthesia."^[274]

Finally, in healthy patients, the choice between epidural and spinal anesthesia will primarily rest with the anesthesiologist. With the recent availability of small-gauge

spinal needles with pencil-point tip design, the risk of headache is no different after spinal or epidural anesthesia.^[85] Most consider spinal block to be easier and quicker to perform, and most believe that the resulting anesthesia will be more solid and complete.^[276] On the other hand, hypotension is more rapid in onset. Perhaps the most significant advantage of spinal anesthesia is that it requires considerably less local anesthetic, and therefore the potential for local anesthetic toxicity is less. Either technique is satisfactory, however, and should provide safe, effective anesthesia for mother, newborn, and obstetrician.

If spinal or epidural anesthesia is used for cesarean delivery, excellent postoperative analgesia can be obtained by addition of narcotics to the local anesthetic solution.^[277] In general, the more lipid-soluble narcotics such as fentanyl or sufentanil provide fast onset of analgesia with minimal side effects but have a short duration of 2 to 4 hours. They are often used in combination with a local anesthetic in a continuous or patient-controlled epidural infusion to improve the quality of the block. In contrast, morphine is quite hydrophilic, which gives it a prolonged duration of up to 24 hours, and it can be given as a single dose at the time of cesarean delivery. Unfortunately, its water solubility gives it a long onset time and higher incidence of side effects. The most common side effects of spinal and epidural narcotics are itching and nausea. Respiratory depression is a rare but serious complication.^[277] , ^[278]

Several studies have shown that spinal or epidural opioids provide superior pain relief when compared with parenteral (intramuscular or intravenous PCA) narcotics with a trend toward earlier hospital discharge and lower cost.^[279] , ^[280]

Local Anesthesia

The obstetrician can use local anesthesia to perform a cesarean delivery but must be thoroughly familiar with the recommended maximal dosages of the anesthetic used because large amounts may be necessary (Table 15-2). The obstetrician should give a dilute solution of local anesthetic (e.g., 0.5 percent lidocaine or 1.0 percent 2-chloroprocaine) to allow for administration of a sufficiently large volume. It may be necessary to dilute a stock solution of 1 percent lidocaine or 2 percent 2-chloroprocaine to provide the recommended dilute solution. The patient must be familiar with the procedure and willing to cooperate. When the technique is used successfully, the operation must be done skillfully and with minimal tissue trauma. Such requirements are often difficult to meet during an emergency cesarean section, particularly one for severe fetal distress or massive hemorrhage. When a major operation proceeds with local anesthesia, the initial stages of the operation may be accomplished easily, but later the need may arise to progress more rapidly or to use maneuvers that require more tugging and pulling than anticipated. For example, the fetal head may be impacted in the pelvis, or a uterine vein may be lacerated. In these situations, the obstetrician must proceed with extreme haste, and a patient under local anesthesia may not be able to tolerate the manipulation. With an anesthesiologist in attendance, general anesthesia can be instituted immediately and the situation resolved. Therefore, the obstetrician must seriously consider all consequences before beginning an emergency cesarean delivery without an

anesthesiologist in attendance.

Occasionally local anesthesia is elected in the patient for whom a regional block is technically impossible or contraindicated (e.g., after back injury or surgery) so that the patient can be awake for the delivery of the infant. In these cases, after delivery of the infant general anesthesia is usually initiated, if necessary, for completion of the operation.

Key Points

Analgesia during labor can reduce or prevent adverse hormonal and metabolic stress responses to the pain of labor.

Use of parenteral opioids for labor analgesia can produce respiratory depression in the mother and newborn and delayed gastric emptying in the mother. However, when used appropriately, opioids are safe and effective.

Placental transfer of a drug between mother and fetus is governed by the characteristics of the drug (including its size, lipid solubility, and ionization), maternal blood levels and uterine blood flow, placental circulation, and the fetal circulation.

Regional analgesia is the most effective form of intrapartum pain relief currently available, and has the flexibility to provide additional anesthesia for spontaneous or instrumental delivery, cesarean delivery, and postoperative pain control.

Spinal opioids provide excellent analgesia during much of the first stage of labor, while decreasing or avoiding the risks of local anesthetic toxicity, high spinal anesthesia, and motor block. Patients can often ambulate, although most will need additional analgesia later in labor and during the second stage.

Side effects and complications of regional anesthesia

include hypotension, local anesthetic toxicity, total spinal anesthesia, neurologic injury, and spinal headache. Personnel providing anesthesia must be available and competent to treat these problems.

Epidural analgesia during labor is *associated* with an increased risk of prolonged labor and operative delivery, but whether there is a *cause-and-effect* relationship is controversial. Epidural analgesia is not a generic procedure, and use of a dilute solution of local anesthetic is less likely to result in prolonged labor and malposition of the fetal vertex.

General anesthesia is utilized for 8 to 11 percent of cesarean deliveries. Although safe for the newborn, general anesthesia can be associated with failed intubation and aspiration, the leading causes of anesthesia-related maternal mortality.

Aspiration of gastric contents causes the worst physiologic consequences when there are food particles present and/or pH is less than 2.5; therefore, patients should be encouraged not to eat during labor.

Regional anesthesia may be an appropriate choice for cesarean section for nonreassuring fetal condition, especially if there is a suspicion of a difficult maternal airway.
