Chapter 16 - Malpresentations

Susan M. Lanni
John W. Seeds

Near term or during labor, the fetus normally assumes a vertical orientation or lie and a cephalic presentation with the fetal vertex flexed on the neck ([Fig. 16-1](#)) . In about 5 percent of cases, however, deviation occurs from this normal lie, presentation, and flexion attitude, and such deviation constitutes a fetal malpresentation. The word "malpresentation" suggests the possibility of adverse consequences and is typically associated with increased risk to both the mother and the fetus. Malpresentation once led to a variety of maneuvers intended to facilitate vaginal delivery, and early in the 20th century such interventions included destructive operations leading, predictably, to fetal death. Later, manual or instrumental attempts to convert the malpresenting fetus to a more favorable orientation were devised. Internal podalic version followed by a complete breech extraction was once advocated as a solution to many malpresentation situations. However, internal podalic version along with most manipulative efforts to achieve vaginal delivery were associated with a high fetal or maternal morbidity or mortality rate and have been largely abandoned. In contemporary practice, cesarean delivery has become the recommended alternative to manipulative vaginal techniques when normal progress toward vaginal delivery is not observed.

This chapter examines malpresentations, possible etiologies, and the mechanics of labor and vaginal delivery unique to each situation.

CLINICAL CIRCUMSTANCES ASSOCIATED WITH MALPRESENTATION

Generally, factors associated with malpresentation include (1) diminished vertical polarity of the uterine cavity, (2) increased or decreased fetal mobility, or (3) obstructed pelvic inlet. The association of great parity with malpresentation is presumably related to laxity of maternal abdominal muscular support and therefore loss of the normal vertical orientation of the uterine cavity. Placentation either high in the fundus or low in the pelvis ([Fig. 16-2](#)) is another factor that diminishes the likelihood of a fetus comfortably assuming a longitudinal axis. Uterine myomata, intrauterine synechiae, and müllerian duct abnormalities such as septate uterus or uterus didelphys are likewise associated with a higher than expected rate of malpresentation. Because both prematurity and hydramnios permit increased fetal mobility, there is an increased probability of a noncephalic presentation if labor or rupture of membranes occurs. In contrast, conditions such as autosomal trisomies, myotonic dystrophy, joint contractures from various etiologies, arthrogryposis or oligohydramnios, and fetal neurologic dysfunction that result in decreased fetal muscle tone, strength, or activity are also associated with an increased incidence of fetal malpresentation. Furthermore, preterm birth involves a fetus that is small relative to the maternal pelvis and results in increased fetal mobility. In these cases, pelvic engagement and descent with labor or rupture of membranes can occur despite malpresentation. Finally, the cephalopelvic disproportion associated with severe fetal hydrocephalus or with a frankly contracted pelvis is frequently implicated as an etiology of malpresentation because normal engagement of the fetal head is prevented.

ABNORMAL AXIAL LIE

The fetal "lie" indicates the orientation of the fetal spine relative to the spine of the mother. The normal

474

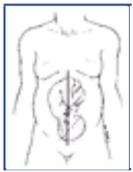

Figure 16-1 Frontal view of a fetus in a longitudinal lie with fetal vertex flexed on the neck.

fetal lie is longitudinal and by itself does not indicate whether the presentation is cephalic or breech. If the fetal spine or long axis crosses that of the mother, the fetus may be said to occupy a transverse or oblique lie (Fig. 16-3), resulting in a shoulder or arm presentation (Fig. 16-4). The lie may be termed unstable if the fetal membranes are intact and there is great fetal mobility resulting in frequent changes of lie or presentation.^[1]

Abnormal fetal lie is diagnosed in approximately 1 in 300 cases, or 0.33 percent.^{[2] [3] [4] [5] [6] [7] [8]} Prematurity is often a factor, with abnormal lie reported to occur in about 2 percent of pregnancies at 32 weeks, or six times the rate found at term.^[9] Persistence of a transverse, oblique, or unstable lie beyond 37 weeks requires a systematic clinical assessment and plan for management, because rupture of membranes without a fetal part filling the inlet of the pelvis imposes a high risk of cord prolapse, fetal compromise, and maternal morbidity if neglected.

Great parity, prematurity, contraction or deformity of the maternal pelvis, and abnormal placentation are the most commonly reported clinical factors associated with abnormal lie,^{[2] [5] [9]} although Cockburn and Drake^[3] found many cases that manifested none of these. In fact, any condition that alters the normal vertical polarity of the intrauterine cavity will predispose to abnormal lie.

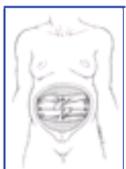

Figure 16-2 Either the high fundal or low implantation of the placenta illustrated here would normally be in the vertical orientation of the intrauterine cavity and increase the probability of a malpresentation.

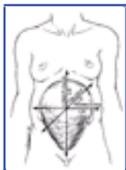

Figure 16-3 A fetus may occupy a longitudinal, oblique, or transverse axis, as illustrated by these vectors. The lie does not indicate whether the vertex or the breech is closest to the cervix.

475

Figure 16-4 This fetus lies in an oblique axis with an arm prolapsing.

Diagnosis may be by palpation or vaginal examination. Routine use of Leopold's maneuvers may assist detection, but Thorp et al.^[10] found the sensitivity of Leopold's maneuvers for the detection of malpresentation to be only 28 percent and the positive predictive value only 24 percent compared with immediate ultrasound verification. Others have observed prenatal detection in as few as 41 percent of cases before labor.^[9] A fetal loss rate of 9.2 percent^[9] with early diagnosis compares with a mortality of 27.5 percent when the diagnosis was delayed, indicating that early diagnosis improves fetal outcome.

Reported perinatal mortality for unstable or transverse lie (corrected for lethal malformations and extreme prematurity) varies from 3.9 percent^[11] to 24 percent,^[1] with maternal mortality as high as 10 percent. Maternal deaths are usually related to infection after premature rupture of membranes, hemorrhage secondary to abnormal placentation, complications of operative intervention for cephalopelvic disproportion, or traumatic delivery.^{[7] [9]} Fetal loss of phenotypically and chromosomally normal neonates from a pregnancy of gestational age such that viability is expected is primarily associated with neglect, prolapsed cord, or traumatic delivery.^[9] Cord prolapse occurs 20 times as often with abnormal axial lie as it does with a cephalic presentation.

Etiologic Factors in Malpresentation

Maternal

- Great parity
- Pelvic tumors
- Pelvic contracture
- Uterine malformation

Fetal

- Prematurity
- Multiple gestation
- Hydramnios
- Macrosomia
- Hydrocephaly
- Trisomies
- Anencephaly
- Myotonic dystrophy
- Placenta previa

MANAGEMENT

The normally grown infant at term cannot undergo a safe vaginal delivery from an axial malpresentation.^[4],^[7] Furthermore, a careful search for a potentially dangerous or compromising etiology of the malpresentation is indicated. A transverse/oblique or unstable lie late in the third trimester necessitates ultrasound examination to exclude a major fetal malformation and abnormal placentation. Elective hospitalization may permit observation and early recognition of cord prolapse.^[6],^[11] Phelan et al.^[12] reported 29 patients with transverse lie diagnosed at or beyond 37 weeks' gestation and managed expectantly. Eighty-three percent (24 of 29) spontaneously converted to breech (9 of 24) or vertex (15 of 24) before labor; however, the overall cesarean delivery rate was 45 percent, and there were two cases of cord prolapse, one uterine rupture, and one neonatal death. Such outcomes suggest that active intervention at or beyond 37 weeks or after confirmation of fetal lung maturity may be of benefit. External cephalic version with subsequent induction of labor, if successful, might diminish the risk of adverse outcome.

In cases of an abnormal lie, the risk of fetal death varies with the type of obstetric intervention. Fetal mortality of 0 to 10 percent has been reported for cesarean birth compared with 25 to 90 percent when internal podalic version and breech extraction are performed.^[3],^[4],^[7],^[9],^[13] A mortality rate of only 6 percent was reported for successful external version and vertex vaginal delivery.^[8],^[9] External cephalic version followed by induction of labor after 37 weeks in the case of abnormal lie is a reasonable alternative to both expectant management and elective cesarean delivery. Although disputed by some,^[3],^[14] external cephalic version has been found to be safe, with close monitoring, and effective in

476

the majority of cases.^[15] Using such a protocol, Edwards and Nicholson^[6] reported 86 of 96 cases delivered vaginally, with fetal compromise detected in only four and no fetal losses.

If external version is unsuccessful or unavailable, if spontaneous rupture of membranes occurs, or if active labor has begun with an abnormal lie, cesarean delivery is the treatment of choice for the potentially viable infant.^[1],^[3],^[14] There is no place for internal podalic version and breech extraction in the management of transverse or oblique lie or unstable presentation in singleton pregnancies because of the unacceptably high rate of fetal and maternal complications.^[2]

A persistent abnormal axial lie, particularly if accompanied by ruptured membranes, also alters the choice of uterine incision at cesarean delivery. Although a low transverse cervical incision has many surgical advantages, up to 25 percent of transverse incisions require vertical extension for delivery of an infant from an abnormal lie to allow access to and atraumatic delivery of the vertex entrapped in the muscular fundus.^[3],^[14] Furthermore, the lower uterine segment is often poorly developed. It makes no sense to perform a cesarean section to minimize birth trauma, then choose a transverse uterine incision if that incision makes fetal extraction more difficult. Therefore, when managing a transverse or oblique lie with ruptured membranes or a poorly developed lower segment, a vertical incision is more prudent. Intraoperative cephalic version may allow the use of a low transverse incision, as reported by Pelosi et al.,^[14] but ruptured membranes with oligohydramnios makes this difficult.

DEFLECTION ATTITUDES

"Attitude" refers to the position of the fetal head with relation to the neck. The normal attitude of the fetal vertex during labor is one of full flexion on the neck, with the fetal chin against the upper chest. Deflexed attitudes include various degrees of deflection or even extension of the fetal head on the neck (Fig. 16-5). Spontaneous conversion to a more normal flexed attitude or further extension of an intermediate deflection to a fully extended position will commonly occur as labor progresses due to resistance exerted by the pelvic bony and soft tissues. Although safe vaginal delivery is possible in most cases, experience indicates that cesarean delivery is the only appropriate alternative when arrest of progress is observed.

Face Presentation

A face presentation is characterized by a longitudinal lie and full extension of the fetal head on the neck,

Figure 16-5 The normal "attitude" (*top view*) shows the fetal vertex flexed on the neck. Partial deflexion (*middle view*) shows the fetal vertex intermediate between flexion and extension. Full deflexion (*lower view*) shows the fetal vertex completely extended, with the face presenting.

with the occiput against the upper back (Fig. 16-6). The fetal chin is chosen as the point of designation at vaginal examination. For example, a fetus presenting by the face whose chin is in the right posterior quadrant of the maternal pelvis would be called a *right mentum posterior* (RMP) (Fig. 16-7). The reported incidence of face presentation ranges from 0.14 to 0.54 percent,^[8] ^[19] ^[17] ^[19] ^[20] ^[21] averaging about 0.2 percent, or 1 in 500 live births overall. Reported perinatal mortality, corrected for nonviable malformations and extreme prematurity,

477

Figure 16-6 This fetus with the vertex completely extended on the neck enters the maternal pelvis in a face presentation. The cephalic prominence would be palpable on the same side of the maternal abdomen as the fetal spine.

varies from 0.6 percent^[22] to 5 percent,^[23] averaging about 2 to 3 percent.

All clinical factors known to increase the general rate of malpresentation (see box, [Etiologic Factors in Malpresentation, above](#)) have been implicated in face presentation, but Browne and Carney^[24] emphasized that as many as 60 percent of infants with a face presentation were malformed. Anencephaly, for instance, is found in about one third of cases of face presentation.^[5] ^[25] ^[26] Fetal goiter resulting from iodine deficiency or in cases of maternal Graves' disease with thyroid-stimulating immunoglobulin, as well as tumors of the soft tissues of the neck may also cause deflexion of the head. Frequently observed maternal factors include a contracted pelvis or cephalopelvic disproportion in 10 to 40 percent of cases.^[17] ^[20] ^[23] In a review of face presentation, Duff^[18] found that one of these etiologic factors was found in up to 90 percent of cases.

Early recognition is important, and diagnosis can be suspected anytime abdominal palpation finds the fetal cephalic prominence on the same side of the maternal abdomen as the fetal back (Fig. 16-8); however, face presentation is more often discovered by vaginal examination and confirmed by radiography or ultrasound. In practice, fewer than 1 in 20 infants with face presentation is diagnosed abdominally.^[22] In fact, only half of these infants are found to have a face presentation by any means prior to the second stage of labor,^[20] ^[22] ^[26] ^[27] and half of the remaining cases are undiagnosed until delivery.^[20] ^[23] Perinatal mortality may be higher, however, with late diagnosis.^[17]

Mechanism of Labor

Knowledge of the early mechanism of labor for face presentation is incomplete. Many infants with a face presentation probably begin labor in the less extended brow position. With descent into the pelvis, the forces of labor press the fetus against maternal tissues; either flexion or full extension of the head on the spine then occurs. The labor of a face presentation must include engagement, descent, internal rotation generally to a mentum anterior position, and delivery by flexion as the chin passes under the symphysis (Fig. 16-9). However, flexion of the occiput may not always occur. Borrell and Fernstrom^[28] have proposed that delivery in the fully extended attitude may be common.

The prognosis for labor with a face presentation depends on the orientation of the fetal chin. At diagnosis, 60 to 80 percent of infants with a face presentation are mentum anterior,^[5] ^[20] ^[22] ^[29] 10 to 12 percent are mentum transverse,^[5] ^[22] ^[29] and 20 to 25 percent are mentum posterior.^[5] ^[20] ^[22] ^[29] Almost all average-sized infants presenting mentum anterior with adequate pelvic dimensions will achieve spontaneous or easily assisted vaginal delivery.^[5] ^[22] ^[30] ^[31] Furthermore, most mentum transverse infants

Figure 16-7 The point of designation from digital examination in the case of a face presentation is the fetal chin relative to the maternal pelvis. *Left*, Right mentum posterior (RMP). *Middle*, Mentum anterior (MA). *Right*, Left mentum transverse (LMT).

Figure 16-8 Palpation of the maternal abdomen in the case of a face presentation should find the fetal cephalic prominence on the side away from the fetal small parts instead of on the same side as in the case of a normally flexed fetal head.

Figure 16-9 Engagement, descent, and internal rotation remain cardinal elements of vaginal delivery in the case of a face presentation, but successful vaginal delivery of a term size fetus presenting a face generally requires delivery by flexion under the symphysis from a mentum anterior position as illustrated here.

will rotate to the mentum anterior position and deliver vaginally, and even 25 to 33 percent of mentum posterior infants will rotate and deliver vaginally in the mentum anterior position.^{[5], [16], [20]} In a review of 51 cases of persistent face presentation, Schwartz et al.^[29] found that the mean birth weight of those infants in mentum posterior who did rotate and deliver vaginally was 3,425 g, compared with 3,792 g for those infants who did not rotate and deliver vaginally. Persistence of mentum posterior with an infant of normal size, however, makes safe vaginal delivery less likely. Overall, 70 to 80 percent^{[5], [20], [22], [23]} of infants with face presentation can be delivered vaginally, either spontaneously or by low forceps, while 12 to 30 percent require cesarean delivery. Manual attempts to convert the face to a flexed attitude or to rotate a posterior position to a more favorable mentum anterior are rarely successful and increase both maternal and fetal risks.^{[16], [22], [26], [32]} Internal podalic version and breech extraction as a remedy for face presentation is contraindicated. Campbell^[22] reported fetal losses of up to 60 percent with this maneuver. Maternal deaths from uterine rupture and trauma after version with extraction have also been documented. Spontaneous delivery or cesarean delivery are therefore the preferred routes for maternal safety as well.^{[16], [22], [26]}

Prolonged labor is a common feature of face presentation^{[5], [8]} and has been associated with an increased number of intrapartum deaths.^[17] Therefore, prompt attention to an arrested labor pattern is recommended. The choice between augmentation of a dysfunctional labor or primary cesarean delivery rests on an assessment

Figure 16-10 This fetus is a brow presentation in a frontum anterior position. The head is in an intermediate deflexion attitude.

of uterine activity, pelvic adequacy, and fetal condition. In the case of an average or small fetus, adequate pelvis, and hypotonic labor, oxytocin may be considered. However, worsening of fetal condition during labor is common. Salzmann et al.^[26] observed a 10-fold increase in fetal compromise with face presentation. Several other observers have also found that abnormal fetal heart rate patterns occur more often with face presentation.^{[16], [18]} Continuous intrapartum electronic fetal heart rate monitoring of a fetus with face presentation is considered mandatory, but extreme care must be exercised in the placement of an electrode, as ocular and cosmetic damage might result from this device. If external Doppler heart rate monitoring is inadequate and an internal electrode is considered necessary, placement of the electrode on the fetal chin is often recommended.

No absolute contraindication to oxytocin augmentation of hypotonic labor in the case of a face presentation exists, but an arrest of progress despite adequate labor or nonreassuring fetal heart rate pattern should call for cesarean delivery.^[8] Although cesarean delivery has been reported in up to 60 percent of cases of face presentation,^{[18], [27]} safe vaginal delivery may be accomplished in many, and a trial of labor with careful monitoring of fetal condition and progress is not contraindicated unless macrosomia or a small pelvis is identified. If cesarean delivery is warranted, care should be taken to flex the head gently both to accomplish elevation of the head through the hysterotomy incision as well as to avoid potential nerve damage to the neonate. However, forced flexion may also result in damage, especially with fetal goiter, or neck tumors.

Laryngeal and tracheal edema resulting from pressures of the birth process might require immediate nasotracheal intubation.^[33] Nuchal tumors or simple goiter, fetal anomalies that might have caused the malpresentation, require expert neonatal management.

BROWN PRESENTATION

An infant in a brow presentation occupies a longitudinal axis, with a partially deflexed cephalic attitude, midway between full flexion and full extension (Fig. 16-10).^[24] The frontal bones are the point of designation. If the anterior fontanel is on the mother's left side, with the sagittal suture in the transverse pelvic axis, the fetus would be in a left frontum transverse (LFT) position (Fig. 16-11). The reported incidence of brow presentation varies widely, from 1 in 670^[34] to 1 in 3,433,^[35] averaging about 1 in 1,500 deliveries. Brow

Figure 16-11 In brow presentation, the anterior fontanel (frontum) relative to the maternal pelvis is the point of designation. *Left*, Fetus in left frontum transverse (LFT). *Middle*, Frontum anterior (FA). *Right*, Left frontum anterior (LFA).

480

presentation will be detected more often in early labor before flexion occurs to a normal attitude. Less frequently, further extension results in a face presentation.

Perinatal mortality corrected for lethal anomalies and very low birth weight varies from 1 to 8 percent.^[36] In an examination of 88,988 deliveries, Ingolfsson^[37] found that corrected perinatal mortality rates for fetuses presenting by the brow depended on the mode of delivery. The highest loss rate, 16 percent, was associated with manipulative vaginal birth.^[37]

In general, factors that delay engagement are associated with persistent brow presentation. Cephalopelvic disproportion, prematurity, and great parity are often found and have been implicated in more than 60 percent of cases of persistent brow presentation.^[5], ^[35], ^[38], ^[39]

Detection of a brow presentation by abdominal palpation is unusual in practice. More often, a brow is detected on vaginal examination. As in the case of a face presentation, late diagnosis is more likely. Fewer than 50 percent of brow presentations are detected before the second stage of labor, with most of the remainder undiagnosed until delivery.^[34], ^[37], ^[38], ^[39] Frontum anterior is reportedly the most common position at diagnosis, occurring about twice as often as either transverse or posterior positions. Although the initial position at diagnosis may be of limited prognostic value, Skalley and Kramer^[39] reported the cesarean delivery rate to be higher with frontum transverse or frontum posterior than with frontum anterior.

A persistent brow presentation requires engagement and descent of the largest (mento-occipital) diameter or profile of the fetal head.^[40] This process is possible only with a large pelvis or a small infant or both. However, brow presentations convert spontaneously by flexion or further extension to either a vertex or a face presentation and are then managed accordingly.^[34], ^[35] The earlier the diagnosis is made, the more likely conversion will occur spontaneously. Fewer than half of infants with persistent brow presentations undergo spontaneous vaginal delivery, but in most cases a trial of labor is not contraindicated.^[5], ^[36]

Prolonged labors have been observed in 33 to 50 percent of brow presentations,^[5], ^[20], ^[35], ^[38], ^[39] and secondary arrest is not uncommon.^[34] Forced conversion of the brow to a more favorable position with forceps is contraindicated,^[34], ^[35], ^[39] as are attempts at manual conversion. One unexpected cause of persistent brow presentation may be an open fetal mouth pressed against the vaginal wall, splinting the head and preventing either flexion or extension^[28], ^[35] (Fig. 16-12).

In most brow presentations, as with face presentations, minimal manipulation yields the best results^[35], ^[41] if the fetal heart rate pattern remains reassuring. Ingolfsson^[37] concluded, however, that expectancy is justified only with a large pelvis, a small fetus, and adequate progress. If a brow presentation persists with a large baby, successful vaginal delivery is unlikely, and cesarean delivery may be most prudent.^[20]

Figure 16-12 The open fetal mouth against the vaginal sidewall may brace the head in the intermediate deflexion attitude as shown here.

481

Although radiographic or computed tomographic pelvimetry might be helpful, Cruikshank and White^[5] reported that while 91 percent of those cases with adequate pelvic dimensions converted to a vertex or a face and delivered vaginally, only 20 percent of those with some form of pelvic contracture did also. Therefore, regardless of pelvic dimensions, consideration of a trial of labor with careful monitoring of maternal and fetal condition may be appropriate. As in the case of a face presentation, oxytocin may be used cautiously to correct hypotonia, but prompt resumption of progress toward delivery should follow.

COMPOUND PRESENTATION

Whenever an extremity is found prolapsed beside the major presenting fetal part, the situation is referred to as a compound presentation ^[42] (Fig. 16-13). The reported incidence ranges from 1 in 377 to 1 in 1,213 deliveries. ^[5], ^[42] ^[43] ^[44] ^[45] The combination of an upper extremity and the vertex is the most common.

This diagnosis should be suspected with any arrest of labor in the active phase or failure to engage during active labor. ^[44] Diagnosis is made by vaginal examination that discovers an irregular mobile tissue mass adjacent to the larger presenting part. Recognition late in labor is common, and as many as 50 percent of persisting compound presentations are not detected until the second stage. ^[42] Delay in diagnosis may not be detrimental because it is likely that only the persistent cases require significant intervention.

Figure 16-13 The compound presentation of an upper extremity and the vertex illustrated here most often spontaneously resolves with further labor and descent.

Although maternal age, race, parity, and pelvic size have all been associated with compound presentation, ^[43], ^[44] prematurity is the most consistent clinical finding. ^[5], ^[42] It is primarily the very small fetus that is at great risk of persistent compound presentation. In late pregnancy, external cephalic version of a fetus in breech position may increase the risk of a compound presentation. ^[46]

Perinatal mortality with a compound presentation is typically elevated, with an overall rate of 93 per 1,000 reported by Cruikshank and White. ^[5] Higher losses of 17 and 19 percent have been reported when the foot prolapses. ^[43] As with other malpresentations, fetal risk can be directly related to the method of management. A fetal mortality rate of 4.8 percent has been noted if no intervention is required compared with 14.4 percent with intervention other than cesarean delivery. A 30 percent fetal mortality rate has been observed with internal podalic version and breech extraction. ^[43] There is probably some selection bias in these figures, because it is likely that more difficult cases were chosen for manipulative intervention. When intervention is necessary, cesarean delivery appears to be the only safe choice.

Fetal risk in compound presentation is specifically associated with birth trauma and cord prolapse. Cord prolapse occurs in 11 to 20 percent of cases. ^[5], ^[43], ^[44] and is the most frequent single complication of this malpresentation. Prolapse probably occurs because the prolapsed extremity splints the presenting part, resulting in an irregular fetal aggregate that incompletely fills the pelvic inlet. In addition to the hypoxic risk of cord prolapse, common fetal morbidity includes neurologic and musculoskeletal damage to the involved extremity. Maternal risks include soft tissue damage and obstetric laceration.

Despite these dangers, labor is not necessarily contraindicated with a compound presentation; however, the prolapsed extremity should not be manipulated. ^[42] ^[43] ^[44], ^[47] The accompanying extremity may retract as the major presenting part descends. Cruikshank and White ^[5] found that 75 percent of vertex/upper extremity combinations deliver spontaneously. Occult or undetected cord prolapse is possible, and therefore continuous electronic fetal heart rate monitoring is recommended.

The primary indications for surgical intervention are cord prolapse, nonreassuring fetal heart rate patterns, and failure to progress. ^[5] Cesarean delivery is the only appropriate clinical intervention, ^[42] since both version extraction and attempts to reposition the prolapsed extremity are associated with high fetal and maternal morbidity and mortality and are to be avoided. ^[43], ^[44] Breen and Wiesmeien ^[42] found that 2 percent of patterns with compound presentation required abdominal delivery, whereas Weissberg and O'Leary ^[44] reported cesarean delivery to be necessary in 25 percent of cases. Protraction of the second stage of labor has been noted

TABLE 16-1 -- BREECH CATEGORIES

Type	Overall Percent of Breeches	Risk (%)	
		Prolapse	Premature
Frank breech	4873 ^[31] , ^[46] , ^[48] , ^[54] , ^[70]	0.5 ^[68]	38 ^[48]
Complete	4.611.5 ^[31] , ^[48] , ^[54] , ^[70]	46 ^[68]	12 ^[48]
Footling	1238 ^[31] , ^[48] , ^[54]	1518 ^[68]	50 ^[48]

to occur more frequently with persistent compound presentation, and dysfunctional labor patterns are said to be common. ^[42] Again, as in other malpresentations, spontaneous resolution occurs more often and surgical intervention is less frequently necessary in those cases diagnosed early in labor. Persistent compound presentation is more likely with a small infant, as is the prognosis for successful vaginal delivery. Persistent compound presentation with a term-sized infant has a poor prognosis for safe vaginal delivery, and cesarean delivery is usually necessary.

BREECH PRESENTATION

The infant presenting as a breech occupies a longitudinal axis with the cephalic pole in the uterine fundus. This presentation occurs in 3 to 4 percent of labors overall, although it is found in 7 percent of pregnancies at 32 weeks and in 25 percent of pregnancies of less than 28 weeks' duration. ^[48] The three types of breech are noted in [Table 16-1](#) . The infant in the frank breech position is flexed at the hips with extended knees. The complete breech is flexed at both joints, and the footling breech has one or both hips partially or fully extended ([Fig. 16-14](#)) .

The diagnosis of breech presentation may be made by abdominal palpation or vaginal examination and confirmed by ultrasound. Prematurity, fetal malformation, müllerian anomalies, and polar placentation are commonly observed causative factors. High rates of breech presentation are noted in certain fetal genetic disorders, including trisomies 13, 18, and 21; Potter's syndrome; and myotonic dystrophy. ^[49] Thus, conditions that alter fetal muscular tone and mobility also increase the frequency of breech presentation.

Mechanism and Conduct of Labor and Vaginal Delivery

The two most important elements for the safe conduct of vaginal breech delivery are continuous electronic fetal heart rate monitoring and noninterference until spontaneous delivery of the breech to the umbilicus has occurred. Early in labor, the capability for immediate cesarean delivery should be established. Anesthesia should be available, the operating room readied, and appropriate informed consent obtained. Two obstetricians should be in attendance as well as a pediatric team. Appropriate training and experience with vaginal breech delivery are fundamental to success. The instrument table should be prepared in the customary manner, with the addition of Piper forceps and extra towels. There is no contraindication to epidural analgesia once labor is well established; many view epidural anesthesia as an asset in the control of the second stage.

The infant presenting in the frank breech position usually enters the pelvic inlet in one of the diagonal

Figure 16-14 The complete breech is flexed at the hips and flexed at the knees. The incomplete breech shows incomplete deflexion of one or both knees or hips. The frank breech is flexed at the hips and extended at the knees.

483

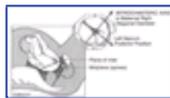

Figure 16-15 The breech typically enters the inlet with the bitrochanteric diameter aligned with one of the diagonal diameters, with the sacrum as the point of designation in the other diagonal diameter. This is a case of left sacrum posterior (LSP).

pelvic diameters ([Fig. 16-15](#)) . Engagement has occurred when the bitrochanteric diameter of the fetus has passed the plane of the pelvic inlet, although by vaginal examination the presenting part may only be palpated at -2 to -4 station (out of 5) relative to the ischial spines. As the breech descends and encounters the levator ani muscular sling, internal rotation usually occurs to bring the bitrochanteric diameter into the anteroposterior (AP) axis of the pelvis. The point of designation in a breech labor is the fetal sacrum and, therefore, when the bitrochanteric diameter is in the AP axis of the pelvis, the fetal sacrum will lie in the transverse pelvic diameter ([Fig. 16-16](#)) .

If normal descent occurs, the breech will present at the outlet and begin to emerge, first as a sacrum transverse, then rotate to a sacrum anterior. Crowning occurs when the bitrochanteric diameter passes under the pubic symphysis. An episiotomy in the midline to but not through the anal sphincter may facilitate delivery but should be delayed until crowning begins. Some argue that a mediolateral episiotomy offers more room and less risk of extension through the anal sphincter, but considerable skill and experience are required to repair a mediolateral episiotomy properly, and this incision is associated with greater blood loss and pain. Premature episiotomy will contribute to unnecessary blood loss and to the level of anxiety and perhaps a tendency to rush the delivery. As the infant emerges, rotation begins, usually toward a sacrum anterior position. This direction of rotation may reflect the greater capacity of the hollow of the posterior pelvis to accept the fetal chest and small parts. It is important to emphasize that operator intervention is not yet needed or helpful other than possibly to perform the episiotomy and encourage maternal expulsive efforts.

Premature or aggressive assistance may adversely affect the breech birth in at least two ways. First, cervical dilatation must be maximized and complete dilatation sustained for sufficient duration to retard retraction of the cervix and entrapment of the aftercoming fetal

Figure 16-16 With labor and descent, the bitrochanteric diameter generally rotates toward the anteroposterior axis and the sacrum toward the transverse.

484

Figure 16-17 The fetus emerges spontaneously (A), while uterine contractions maintain cephalic flexion. Premature aggressive traction (B) encourages deflexion of the fetal vertex and increases the risk of head entrapment or nuchal arm entrapment.

head. Rushing the delivery of the trunk may significantly diminish the effectiveness of this process. Second, the safe descent and delivery of the breech infant must be the result of expulsive forces from above to maintain flexion of the fetal vertex. Any traction from below in an effort to speed delivery would encourage deflexion of the

vertex and result in the presentation of the larger occipitofrontal fetal cranial profile to the pelvic inlet (Fig. 16-17). Such an event could be catastrophic. Rushed delivery also increases the risk of a nuchal arm, with one or both arms trapped behind the head above the pelvic inlet. Entrapment of a nuchal arm makes safe vaginal delivery much more difficult, as it dramatically increases the size of the aggregate object that must pass through the birth canal. Safe breech delivery of an average-sized infant, therefore, depends predominantly on maternal expulsive forces, and patience, not traction from below.

As the frank breech emerges farther, the fetal thighs are typically pressed firmly against the fetal abdomen, often splinting and protecting the umbilicus and cord. After the umbilicus appears over the maternal perineum, the operator may align his or her fingers medial to one thigh, then the other, pressing laterally as the

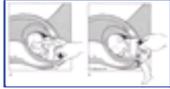

Figure 16-18 After spontaneous expulsion to the umbilicus, external rotation of each thigh (A) combined with opposite rotation of the fetal pelvis results in flexion of the knee and delivery of each leg (B).

485

Figure 16-19 When the scapulae appear under the symphysis, the operator reaches over the left shoulder, sweeps the arm across the chest (A), and delivers the arm (B).

fetal pelvis is rotated away from that side (Fig. 16-18). This results in external rotation of the thigh at the hip, flexion of the knee, and delivery of one and then the other leg. The dual movement of counterclockwise rotation of the fetal pelvis as the operator externally rotates the right thigh and clockwise rotation of the fetal pelvis as the operator externally rotates the fetal left thigh is most effective in facilitating delivery. The fetal trunk is then wrapped with a towel to provide secure support of the body while further descent results from expulsive forces from the mother. The operator primarily facilitates the delivery of the fetus by guiding the body through the introitus. The operator is not applying outward traction on the fetus that might result in deflexion of the fetal head or nuchal arm.

When the scapulae appear at the outlet, the operator may slip a hand over the fetal shoulder from the back (Fig. 16-19), follow the humerus and, with a lateral

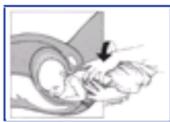

Figure 16-20 Gentle rotation of the shoulder girdle facilitates delivery of the right arm.

movement, sweep first one and then the other arm across the chest and out over the perineum. Gentle rotation of the fetal trunk counterclockwise assists delivery of the right arm, and clockwise rotation assists delivery of the left arm (turning the body "into" the arm). This accomplishes delivery of the arms by drawing them across the fetal chest in a fashion similar to that used for delivery of the legs (Fig. 16-20). Once both arms have been delivered, if the vertex has remained flexed on the neck, the chin and face will appear at the outlet, and the airway may be cleared and suctioned (Fig. 16-21).

With further maternal expulsive forces alone, spontaneous controlled delivery of the fetal head will often occur. If not, delivery may be accomplished with a

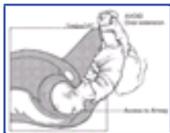

Figure 16-21 Following delivery of the arms, the fetus is wrapped in a towel for control and slightly elevated. The fetal face and airway may be visible over the perineum. Excessive elevation of the trunk is avoided.

486

simple manual effort to maximize flexion of the vertex using pressure on the fetal maxilla (not mandible; the Mauriceau-Smellie-Veit maneuver) along with suprapubic pressure (Crédé's maneuver) and gentle downward traction (Fig. 16-22). Although maxillary pressure will maximize cephalic flexion, the main force effecting delivery remains the mother.

Alternatively, the operator may apply Piper forceps to the aftercoming head to facilitate delivery. The application requires very slight elevation of the fetal trunk by the assistant, while the operator kneels and applies the Piper forceps directly to the fetal head in the pelvis. The position of the operator for applying the forceps is depicted in Figure 16-23, which also demonstrates how excessive elevation by the assistant may potentially cause harm to the neonate. Hyperextension of the fetal neck from excessive elevation of the fetal trunk, shown in Figure 16-23, should be avoided.

Piper forceps are characterized by absence of pelvic curvature. This modification allows direct application to the fetal head and avoids conflict with the fetal body that would occur with the application of standard instruments from below. The forceps are inserted into the vagina from beneath the fetus. The blade to be placed on the maternal right is held by the handle in the operator's right hand and the blade inserted with the operator's left hand in the vagina along the right maternal sidewall and placed against the left fetal parietal bone. The handle of the left blade is then held in the operator's left hand and inserted by right hand along the left maternal sidewall and placed against the right fetal parietal bone. Forceps application controls the fetal head and prevents extension of the head on the neck. Gentle downward traction on the forceps with the fetal trunk supported on the forceps shanks results in controlled delivery of the vertex (Fig. 16-24). Routine use of Piper forceps to the aftercoming head may

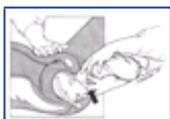

Figure 16-22 Cephalic flexion is maintained by pressure (heavy arrow) on the fetal maxilla (not mandible!). Often, delivery of the head is easily accomplished with continued expulsive forces from above and gentle downward traction.

Figure 16-23 Demonstration of INCORRECT assistance during the application of Piper forceps; the assistant hyperextends the fetal neck. Positioning as such increases the risk for neurologic injury.

be advisable both to ensure control of the delivery and to maintain optimal operator proficiency in anticipation of deliveries that may require their use.

Arrest of spontaneous progress in labor with adequate uterine contractions necessitates consideration of cesarean delivery. Any evidence of fetal compromise or

sustained cord compression on the basis of continuous

Figure 16-24 The fetus may be laid on the forceps and delivered with gentle downward traction as illustrated here.

487

electronic fetal monitoring also requires consideration of cesarean delivery. Vaginal interventions directed at facilitating delivery of the breech that is complicated by an arrest of spontaneous progress are discouraged, because fetal and maternal morbidity and mortality are both greatly increased. However, if labor is deemed to be hypotonic by internally monitored uterine pressures, oxytocin is not contraindicated. [50] [51] [52]

Mechanisms of descent and delivery of the footling and the complete breech are not unlike those of the frank breech described above, except one or both legs might already be extended and thus not require attention. The risk of cord prolapse or entanglement is greater and, hence, the possibility of emergency cesarean delivery increased. Furthermore, footling and complete breeches are not as effective a cervical dilator as either the vertex or the larger aggregate profile of the thighs and buttocks of the frank breech. Thus, the risk of entrapment of the aftercoming head is perhaps increased, and as a result primary cesarean delivery is often advocated for nonfrank breech presentations. However, the randomized trial of Gimovsky et al. found the vaginal delivery of the nonfrank breech to be reasonably safe as well. [53]

Management of the Term Breech

The reported perinatal mortality associated with breech presentation has varied from 9 to 25 percent, [54] [55] three to five times that of the nonbreech infant at term. [56] [57] [58] The excess deaths associated with breech presentation are largely due to lethal anomalies and complications of prematurity, both of which are found more frequently among breech infants. Excluding anomalies and extreme prematurity, the corrected perinatal mortality reported by some investigators approaches zero regardless of the method of delivery, whereas others find that even with exclusion of these factors the term breech infant has been found to be at higher risk for birth trauma and asphyxia. [59] [60] [61] In order to assess the safety of breech delivery, an appropriately controlled randomized trial with sufficient number of study patients must be conducted. To date, only two randomized trials have been reported. [59] [62] The remainder of reports surrounding the issue of safety of breech delivery is confined to cohort and observational types of studies, usually retrospective, and subject to significant risk of bias. Therefore, conclusions regarding safety of breech from a fetal standpoint will vary, but those reported are summarized in Table 16-2. Overall, consideration of a potential breech vaginal delivery often involves bias, and yet must be mutually agreed upon by the patient and the physician. A cooperative, compliant patient makes the most appropriate candidate for breech vaginal delivery.

At least a portion of the striking increase in the rate of cesarean deliveries over the past two decades is a

TABLE 16-2 -- INCIDENCE OF COMPLICATIONS SEEN WITH BREECH PRESENTATION

Complication	Incidence
Intrapartum fetal death	Increased 16-fold [63] , [67]
Intrapartum asphyxia	Increased 3.8-fold [65] , [67]
Cord prolapse	Increased 5- to 20-fold [48] , [55] , [68]
Birth trauma	Increased 13-fold [48]
Arrest of aftercoming head	8.8% [48]
Spinal cord injuries with extended head	21% [30] , [98]
Major anomalies	618% [55] , [63] , [67]
Prematurity	1633% [31] , [54] , [60] , [63] , [69] , [82] , [83]
Hyperextension of head	5% [97]

response to the risk of morbidity and mortality associated with the breech presentation. [62] [63] [64] [65] In 1980, Collea [48] observed that 29 percent of primary cesarean operations performed at his institution during a 12-month period were performed at least in part because of breech presentation. The National Institutes of Health Consensus Report in 1981 found that 12 percent of cesarean deliveries in 1978 were performed for breech presentation and that this indication contributed 10 to 15 percent to the overall rise in the rate of cesarean births. The overall rate of cesarean birth for breech in some institutions is as high as 94 percent, while in the United States generally the cesarean delivery rate for breech presentation increased from 11.6 percent to 79.1 percent between 1970 and 1985. [65] [66] However, even though greater risks appear to face the breech infant, [67] the method of delivery alone has not been conclusively shown to contribute to those risks. [68] [69] There remain many who believe that complete abandonment of vaginal delivery for the breech is not yet justified. [70] [71]

In some series, improved perinatal survival has been reported for breeches born by cesarean delivery, [55] [60] [67] [72] [73] and there is some evidence, though inconsistent, that the method of delivery may also impact on the quality of survival. In 1979, Westgren et al. [74] found functional neurologic defects by 2 years of age in 24 percent of breech infants born vaginally, but only in 2.5 percent of those breech infants of similar weights and gestational ages born by cesarean delivery. However, in comparing 175 breech infants having a 94 percent cesarean delivery rate with 595 historical controls having a 22 percent rate of abdominal delivery, Green et al. [65] found no significant differences in outcome. Faber-Nijholt et al. [75] reviewed neurologic outcomes in 348 infants born in breech position. Examinations were performed on 239 children from 3 to 10 years of age. No statistically significant differences were noted between neonates delivered by vaginal breech versus matched vertex controls, thus concluding breech outcomes

488

relate to degree of prematurity, impact of pregnancy complications, and presence of malformations as well as birth trauma or asphyxia. The benefit of elective cesarean delivery in the case of breech presentation therefore remains uncertain.

In the term breech, observational studies report increased neonatal morbidities including neonatal intensive care unit (NICU) admission, hyperbilirubinemia, bone fracture, intracranial hemorrhage, neonatal depression, [77] convulsions, and death. [78] However, Roman et al. found that emergent cesarean section was also associated with poor neonatal outcomes. On the other hand, in a review of outcomes of 705 singleton, non-malformed breech presentations, Irion et al. reported similar neonatal outcomes, and concluded that as a result of the increased maternal morbidity associated with cesarean birth there was no firm evidence to recommend elective cesarean delivery for the term breech neonate. [79] This opinion was supported by Brown et al. in their prospective case series, noting corrected perinatal mortality rate did not differ for neonates weighing greater than or equal to 1,500 g. [52]

Special Clinical Circumstances and Risks Preterm Breech, Hyperextended Head, Footling Breech

The various categories of breech presentation clearly demonstrate dissimilar risks, and management plans might vary among these situations. [80] [81] The premature breech, the breech with a hyperextended head, and the footling breech are categories that have high rates of fetal morbidity or mortality. Complications associated with incomplete dilatation and cephalic entrapment may be more frequent. For these three breech situations, in general, cesarean delivery appears to optimize fetal outcome and is therefore recommended.

Low birth weight (<2,500 g) is a confounding factor in about one third of all breech presentations. [54] [60] [63] [69] [82] [83] Whereas the benefit of cesarean delivery for

the 1,500 to 2,500 g breech infant remains controversial,^{[11], [35], [52], [55], [82], [84], [85], [86], [87], [88], [89]} some studies showed improved survival with abdominal delivery in the 1,000 to 1,500-g weight group.^{[60], [86]} A recent multicenter study of long-term outcomes of vaginally delivered 26 to 31-week pregnancies found no differences in rates of death or developmental disability within 2 years of follow-up.^[90] Traumatic morbidity is reportedly decreased in both weight groups by the use of cesarean delivery, including a lower rate of both intra- and periventricular hemorrhage.^[89] Although some advocate a trial of labor in the frank breech infant weighing over 1,500 g, others recommend labor only when the infant exceeds 2,000 g.^{[35], [63], [65], [91]} There are proportionately fewer frank breech presentations in the low-birth-weight group.^{[31], [60]} In fact, most infants weighing less than 1,500 g and presenting as a breech are footling.^[91] Although most deaths in the very-low-birth-weight breech group are due to prematurity or lethal anomalies,^{[82], [85], [91], [92]} cesarean delivery has been shown by some to decrease corrected perinatal mortality in this weight group compared with that in similar-sized vertex presentations.^{[60], [93]} Other authors suggest that improved survival in these studies relates to improved neonatal care of the premature infant when compared with the outcomes of historical controls.^[94] When vaginal delivery of the preterm breech is chosen or is unavoidable, however, conduction anesthesia and the use of forceps for the delivery of the aftercoming head appear to decrease fetal morbidity and mortality.^{[82], [95], [96]}

Premature rupture of the fetal membranes (PROM) is associated with prematurity and chorioamnionitis, both of which have been found to be independent risk factors for the development of cerebral palsy (CP). PROM is associated with a high rate of malpresentations because of the prematurity and decreased amniotic fluid. Knowing the association of chorioamnionitis with periventricular leukomalacia (PVL), a lesion found to precede development of CP in the premature neonate, Baud et al. correlated the mode of delivery with PVL, and subsequent CP in breech preterm deliveries. The authors found that in the presence of chorioamnionitis, delivery by elective cesarean section was associated with a dramatic decrease in the incidence of PVL.^[76]

Hyperextension of the fetal head has been consistently associated with a high (21 percent) risk of spinal cord injury if the breech is delivered vaginally.^{[30], [97], [98]} In such cases, it is important to differentiate simple deflexion of the head from clear hyperextension, given that Ballas et al.^[99] have shown that simple deflexion carries no excess risk. The issue of simple deflexion of the fetal vertex as opposed to hyperextension is similar to the relationships between the occipitofrontal cranial plane and the axis of the fetal cervical spine illustrated in Figure 16-5. Often, as labor progresses, spontaneous flexion will occur in response to fundal forces.

Finally, the footling breech carries a prohibitively high (16 to 19 percent) risk of cord prolapse during labor. In many cases, cord prolapse is manifest only late in labor, after commitment to vaginal delivery has been made.^{[60], [85]} Cord prolapse necessitates prompt cesarean delivery. Furthermore, the footling breech is a poor cervical dilator, and cephalic entrapment becomes more likely.

Near-Term Frank or Complete Breech

Controversy continues surrounding the method of delivery for the frank or complete breech, as the cesarean delivery rate for breech presentation generally increases to over 90 percent without a continued or proportionate drop in perinatal mortality.^{[62], [63], [64]} Maternal mortality

is clearly higher with cesarean delivery, ranging from 0.2 to 0.43 percent.^{[65], [80]} Maternal morbidity is also higher with abdominal delivery. Some institutions report a 50 percent incidence of postoperative maternal morbidity^{[68], [77]} compared with as little as 5 percent with vaginal delivery.^[68] In an attempt to balance both maternal and fetal risks, plans have been proposed to select appropriate candidates for a trial of labor.

Cheng and Hannah^[100] examined some of the English language literature regarding breech term deliveries between 1966 and 1992. They reviewed 82 reports, rejecting 58 because of study design inconsistencies or flaws. The remaining 24 presented outcomes according to intended mode of delivery (vaginal or abdominal). Among the studies reviewed, perinatal mortality was higher for the planned vaginal delivery groups, with an odds ratio (OR) of 3.86 (95 percent confidence interval [CI] = 2.22 to 6.69). Neonatal short-term morbidity caused by trauma was higher in the planned vaginal delivery group, with an odds ratio of 3.96 (95 percent CI = 2.76 to 5.67). Likewise, long-term infant morbidity was more frequent in the planned vaginal delivery group (OR = 2.88, with a 95 percent CI = 1.04 to 7.97), but this finding barely achieved significance and resulted from only four foreign studies. Unfortunately, most of the 24 reports constituting this review were retrospective, and many presented data gathered without the use of continuous fetal monitoring. One of the most influential reports with a relatively high rate of adverse outcome with vaginal delivery was from West Africa, where continuous fetal monitoring was not used. The significance of statistical summaries that encompass data from such widely disparate practice patterns is unclear. The authors acknowledged that differences in outcomes might be caused by factors other than the planned method of delivery because of selection bias in most of the studies.^[100]

In 1965, Zatuchni and Andros^[83] retrospectively analyzed 182 breech births. Of those reviewed, 25 infants had poor outcomes. These investigators concluded that scoring six clinical variables at the time of admission (Table 16-3) identified those patients destined to manifest

TABLE 16-3 -- ZATUCHNI-ANDROS SYSTEM

Factor	0	1	2

serious problems in labor and allowed prompt and appropriate intervention. The parturient herself could increase the score by presenting later in labor; other factors that affect the score are less modifiable. At least three subsequent prospective studies applied the Zatuchni-Andros system and found it to be both sensitive and accurate in selecting candidates for successful vaginal delivery.^{[101], [102], [103]} A Zatuchni-Andros score of less than 4 in these studies accurately predicted poor outcomes in patients with infants presenting as a breech. Furthermore, in applying the scoring system, only 21 to 27 percent of patients failed to qualify for a trial of labor.^{[101], [102]} Previous breech delivery, one of the items scored in the Zatuchni-Andros system, has a significant odds ratio for recurrence of breech (4.32, 95 percent CI = 4.08 to 4.59) after one breech delivery, and up to 28.1 (95 percent CI = 12.2 to 64.8) after three. This study did not, however, control for recurrent causes of breech presentation such as uterine malformations and abnormal placentation.^[104]

Because most reports of breech delivery are of level II to III evidence, their validity and, most importantly, universal applicability are called into question. Many data were gathered prior to electronic fetal heart rate monitoring becoming commonplace. Only one randomized trial (level I evidence) has examined term frank breech and method of delivery.^[69] Singleton term frank breech infants with an estimated fetal weight between 2.5 and 3.8 kg of mothers with radiographically adequate pelvimetry were prospectively randomized into two groups. One hundred fifteen patients were randomized to a vaginal delivery compared with 93 randomized to elective cesarean delivery. One hundred twelve of the 115 women had time for x-ray pelvimetry; three delivered vaginally before pelvimetry was possible. Fifty-two of 112 women in the planned vaginal delivery group were not allowed to labor because of inadequate pelvimetry, leaving 60 for a planned vaginal delivery. Intrapartum monitoring was used in all patients. Eighty-three percent of patients allowed to labor delivered vaginally without a perinatal loss.^[50] There were no maternal deaths, but 36 percent of patients experienced some postpartum morbidity.^[69] The authors found no significant difference in perinatal outcome and concluded that a trial of labor is a safe option with the frank breech of average size, flexed head, adequate pelvis, reassuring heart rate monitoring, and normal progress in labor. The small numbers of patients studied, however, make their acceptance of the null hypothesis inconclusive.

In a similar study, O'Leary^[105] allowed frank breeches estimated to be between 2.5 and 3.5 kg in women with a large pelvis to labor vaginally. He used radiographic pelvimetry, ultrasound, and the Zatuchni-Andros score and was attentive to the labor curve in selecting candidates for cesarean delivery. Results were similar to

those of Collea et al.^[50] Neither group of investigators found that oxytocin induction of labor was contraindicated if all other criteria were satisfied^[50],^[105] however, both groups concluded that augmentation of secondary arrest was not appropriate. Neither nulliparity nor multiparity was found to be an accurate prognostic indicator.^[31],^[106] In a similar study, Gimovsky et al.^[53] randomized 105 nonfrank term breech infants to cesarean section or trial of labor and found that 44 percent of those undergoing trial of labor achieved safe vaginal delivery with no differences in neonatal outcomes. Most cesarean deliveries were performed for arrested progress.

Flanagan et al.^[51] reported a nonrandomized, retrospective study in which 244 women with breech infants at term (the majority were frank, with some complete, and footling breeches) underwent a trial of labor. Of these, 72 percent delivered vaginally. Of those cesarean deliveries ultimately required, 44 were for abnormal labor (64 percent of those delivered by cesarean), 14 for fetal distress (20 percent), and 11 for cord prolapse (16 percent). The authors noted no increased trauma related to vaginal delivery. However, one child had a facial nerve paralysis with facial asymmetry. The authors surmised this injury may be a result of in utero compressive damage, not from trauma at the time of the vaginal delivery. The authors estimated that with the application of external version to a known breech population and a trial of labor for selected frank breech infants, the cesarean section rate for these pregnancies could be cut in half.^[51]

In conclusion, there appears to be a place for a trial of labor and attempted vaginal delivery of the uncomplicated term or near term frank breech of average size through a normal pelvis if there is normal progress in labor and fetal heart rate monitoring remains reassuring. The apparent safety of a trial of labor in selected cases, however, is not without dispute.^[100],^[107]

Radiographic pelvimetry has been included in the management of the breech presentation with little objective validation. Regardless, it is expected to predict successful vaginal delivery when adequate pelvic dimensions are present. There are at least four techniques for pelvimetry that are presently in common usage worldwide, including conventional plain film radiography using up to three films, computed tomography (CT) with up to three views (lateral, AP, and axial slice), magnetic resonance imaging (MRI), and digital fluorography, not presently used in the United States. MRI is the only technique not associated with radiation exposure, and CT pelvimetry using a single lateral view results in the lowest exposure dose.^[108] Air gap technique with conventional radiography will lower the radiation dosage. Current trends show a move towards the lower dose CT techniques of up to three images.^[109]

The clinician must possess the necessary training and experience to offer a patient with a persistent breech presentation a trial of labor. Furthermore, the relationship between the patient and the clinician should be well established and the discussions of risks and benefits must be objective and nondirective with accurate documentation of the discussion. If any of these factors are lacking, cesarean delivery becomes the safer choice. However, even if a clinician has made the choice that he or she will never prospectively offer a patient with breech presentation a trial of labor, the burden of responsibility to know and understand the mechanism and management of a breech delivery is not relieved. No one active in obstetrics will avoid the occasional emergency breech delivery. Regular review of principles, and practice with simulations using a mannekin and model pelvis with an experienced colleague, can increase the skills and improve the performance of anyone facing such an emergency.

Factors that impact on the decision to deliver a breech vaginally or by cesarean section are listed in the box, Management of the Breech. The obvious implication of the dramatically decreased experience in training programs with vaginal breech delivery is that inexperience itself will constitute an indication for cesarean delivery. Certainly, in no case should a woman with an infant presenting as a breech be allowed to labor unless (1) anesthesia coverage is immediately available, (2) cesarean delivery can be undertaken promptly, (3) continuous

fetal heart rate monitoring is used, and (4) the delivery is attended by a pediatrician and two obstetricians of whom at least one is experienced with vaginal breech birth.

Management of the Breech
Trial of labor may be considered if
Estimated fetal weight (EFW) = 2,000 to 3,800 g
Frank breech
Adequate pelvis
Flexed fetal head
Fetal monitoring
Zatuchni-Andros score 4
Rapid cesarean possible
Good progress maintained in labor
Experience and training available
Informed consent possible
Cesarean delivery may be prudent if
EFW <1,500 or >4,000 g
Footling presentation
Small pelvis
Hyperextended fetal head
Zatuchni-Andros score <4
Absence of expertise
Nonreassuring fetal heart rate pattern
Arrest of progress

Breech Second Twin

Approximately one third of all twin gestations present as vertex/breech (i.e., first twin is a vertex, and the second is a breech).^[110] The management alternatives in the case of the vertex/breech twin pregnancy in labor include cesarean delivery, vaginal delivery of the first twin and attempted external cephalic version of the second

twin, or internal podalic version and extraction of the second twin. Gocke et al. [111] examined the outcomes of management of 136 pairs of vertex/nonvertex twins weighing over 1,500 g and concluded that breech extraction of the second twin appeared to be a safe alternative to cesarean delivery. [111] Blickstein et al. [110] compared the obstetric outcomes of 39 cases of vertex/breech twins to the outcomes of 48 vertex/vertex twins. Although the breech second twin had a higher incidence of low birth weight and a longer hospital stay, the authors found no basis for elective cesarean delivery in this clinical circumstance. Laros and Dattel [112] studied 206 twin pairs and likewise found no clear advantage to arbitrary cesarean delivery because of a specific presentation. Fishman et al. [113] examined outcomes in 390 vaginally delivered second twins, 207 delivered as a vertex and 183 delivered breech. Ninety-five percent of the breech deliveries were total breech extractions. No significant differences were found between the vertex and breech infants even when stratified by birth weight. Any clinician uncomfortable with the prospective delivery of a singleton breech, however, would be unwise to consider a breech extraction of a second twin.

Vaginal delivery followed by external version is a viable alternative, using ultrasound in the delivery room to directly visualize the fetus. Often there is a transient decrease in uterine activity after the delivery of the first infant, which can be used to advantage in the performance of a cephalic version. Tchabo and Tomai [114] described an experience with 30 malpositioned second twins (12 transverse and 18 breech). Version after birth of the first twin was successful in 11 of the 12 transverse infants and in 16 of the 18 breech infants. These cases were all over 35 weeks' gestation, with intact membranes of the second twin after delivery of the first, no evidence of anomalies, and normal amniotic fluid volume.

Internal podalic version/extraction of the second twin can be facilitated by ultrasonic guidance. The goal is to insert a hand into the uterus, identify and grasp both fetal feet with membranes intact, and apply traction to bring the feet into the pelvis and out the introitus with maternal expulsive efforts remaining the major force in effecting descent of the fetus. Membranes are left intact until both feet are at the introitus. [115] Once membranes are ruptured, the delivery is subsequently managed as a footling breech delivery. If the operator has difficulty identifying the fetal feet, intrapartum ultrasound may be of assistance.

During breech extraction, and perhaps more often with a breech extraction of a smaller twin, the fetal head can become caught in the cervix. In such a case, with the operator's entire hand into the uterus the fetal head is cradled; as the hand is withdrawn, the head is protected. [116] This splinting technique has also been used for the safe extraction of the breech head at the time of cesarean delivery.

No randomized prospective trials involving preterm twins with vertex/nonvertex presentation have been performed. A small, prospective trial in the near-term gestation (>35 weeks) by Rabinovici et al. [119] found no difference in neonatal morbidity between vaginal delivery and cesarean birth. They did find increased maternal morbidity with cesarean delivery.

External Cephalic Version

External cephalic version is a third alternative to vaginal delivery or cesarean delivery for the breech infant. [15], [54], [56], [117], [118], [119], [120] Many have found that external cephalic version significantly reduces the incidence of breech presentation in labor and is associated with few complications such as cord compression or placental abruption. [15], [120] Reported success with external version varies from 60 to 75 percent, with a similar percentage of these remaining vertex at the time of labor. [15], [121], [122], [123], [124] Ylikorkala and Hartikainen-Sorri [120] found that while many infants in breech presentation before 34 weeks will convert spontaneously to a cephalic presentation, few will do so afterward. Repetitive external version applied weekly after 34 weeks was successful in converting over two thirds of cases and reducing their breech presentation rate by 50 percent. [120] In a randomized trial of external cephalic version in low-risk pregnancies between 37 and 39 weeks, Van Dorsten and colleagues [117] were successful in 68 percent of 25 cases in the version group, whereas only 4 of the 23 controls converted to a vertex spontaneously before labor. All those in whom external version was successful presented in labor as a vertex. [117] Van Veelan et al. [126] reported a prospective, controlled study of external cephalic version performed weekly between 33 weeks and term, and 48 percent of the study group were vertex in labor compared with only 26 percent of controls. Hanss [127] reported experience with 112 patients seen for external version, with a success rate of 49 percent, and a cesarean delivery rate of 17 percent among those with successful version compared with 78 percent among those patients with an unsuccessful version attempt.

492

Zhang et al. [15] reviewed English language reports between 1980 and 1991 that reported the outcomes of pregnancies after external cephalic version and concluded that it was a safe and effective intervention. The overall success rate among investigators in the United States was 65 percent, with an average cesarean delivery rate of 37 percent among those undergoing an attempted version compared with 83 percent among controls. Successful version was reported more often in parous than nulliparous women and more often between 37 and 39 weeks than after 40 weeks. [15]

Gentle constant pressure applied in a relaxed patient with frequent fetal heart rate assessments are elements of the method stressed by all investigators. [54], [56], [117] Methodology varies, although the "forward roll" is more widely supported than the "back flip" (Fig. 16-25). [117] The mechanical goal is to squeeze the fetal vertex gently out of the fundal area to the transverse and finally into the lower segment of the uterus.

Tocolysis, epidural anesthesia, and ultrasound during the procedure may also be helpful. A number of tocolytics have been reported; however, the most experience has been reported using intravenous ritodrine. Because of maternal side effects, however, this agent has fallen out of favor in this country. Other agents used are hexaprenaline, salbutamol, nitroglycerin, [128] and terbutaline. A randomized trial of 103 nulliparous patients found success rates with subcutaneous terbutaline were 52 percent compared to 27 percent in the control group. No adverse maternal effects resulting from the drug were found. [129] Robertson et al., [122] in a randomized trial including 58 patients at 37 to 41 weeks' gestation with breech presentation, found no benefit from -mimetic tocolysis. The success rate was 66.7 percent with tocolysis and 67.8 percent without tocolysis. [122] Factors associated with failure of version included obesity, deep pelvic engagement of the breech, oligohydramnios, and posterior positioning of the fetal back. [123] The use of epidural anesthesia for external cephalic version has also been controversial. Many believe that operators might apply excessive pressure to the maternal abdomen when epidural anesthesia is employed, which will make fetal compromise more likely, caused by either fetal heart rate decelerations or placental abruption. However, a randomized trial of 69 women using epidural anesthesia demonstrated a better than twofold increase in success of the procedure when epidural was employed. [130] Fetomaternal transfusion has been reported to occur in up to 6 percent of patients undergoing external version, [131] and thus Rh-negative unsensitized women should receive Rh-immune globulin. Quantitation of fetomaternal hemorrhage with the Kleihauer-Betke test will determine the number of ampules of Rh immune globulin to be administered.

In the case of the gravida with a previous cesarean delivery, external cephalic version has also been controversial. Studies of limited sample size have concluded that external cephalic version is safe for mother and fetus and results in increased vaginal delivery rates. Flamm et al. quoted a success rate of 82 percent in patients with a previous cesarean delivery. [132] In 1994, Schachter et al. used intravenous ritodrine tocolysis in a study of 11 patients with history of previous low cervical transverse cesarean section. No uterine dehiscences were found either clinically or at the time of cesarean delivery. Of the five patients that needed cesarean delivery, three had fetuses with newborn weights of greater than 4 kg; all patients in the vaginal delivery group had newborns weighing 3.5 kg. [133]

Of interest is the recent randomized trial of moxibustion of accupoint BL 67 (Zhiyin; beside the outer corner of the 5th toenail) to resolve breech presentation. Moxibustion is a traditional Chinese method that uses the application of heat generated by the combustion of

Figure 16-25 External cephalic version is accomplished by gently "squeezing" the fetus out of one area of the uterus and into another. Here, the "forward roll," often the most popular, is illustrated.

493

herbs to provide stimulation to the accupoints for a period of 1 to 2 weeks. The particular herb used is *Artemisia vulgaris* (mugwort), which is purported to work by stimulating fetal movements, which were found to be significantly increased in the intervention group. One of 130 patients in the treatment group required cephalic version, whereas 24 of 130 in the controls group required this procedure. Seventy-five percent of the treatment group, and 62 percent of the control group were cephalic at birth. [134] Such an approach is of uncertain value.

SHOULDER DYSTOCIA

Shoulder dystocia is diagnosed when, after delivery of the fetal head, further expulsion of the infant is prevented by impaction of the fetal shoulders within the maternal pelvis. Specific efforts are necessary to facilitate delivery (Fig. 16-26).

Although a difficult shoulder dystocia occurs infrequently, one does not soon forget the experience. Often, but not always, at the end of a difficult labor, the fetal head may be delivered spontaneously or by forceps, but the neck then retracts. The fetal head appears to be drawn back with the chin close to the maternal perineum or thigh, creating difficulty suctioning the infant's mouth. As maternal expulsive efforts are encouraged, the fetal head becomes plethoric, and the danger to the infant is apparent if delivery cannot be promptly accomplished.

Shoulder dystocia has been reported in 0.15 to 1.7 percent of all vaginal deliveries.^[135],^[136] All investigators have documented increased perinatal morbidity and

Figure 16-26 When delivery of the fetal head is not followed by delivery of the shoulders, the anterior shoulder has often become caught behind the symphysis as illustrated here. The head may retract toward the perineum. Desperate traction on the fetal head is not likely to facilitate delivery and may lead to trauma.

mortality with shoulder dystocia.^[135],^[136] Mortality varies from 21 to 290 in 1,000 when shoulder girdle impaction occurs, and neonatal morbidity has been reported to be immediately obvious in 20 percent of infants.^[135] In reviewing 131 macrosomic infants, Boyd et al.^[137] found that only half of all cases of brachial palsy occurring in macrosomic infants also carried a diagnosis of shoulder dystocia. Obviously, brachial palsy was noted in half of these cases without a clinical diagnosis of shoulder dystocia. Severe asphyxia was observed in 143 of 1,000 births with shoulder dystocia compared with 14 of 1,000 overall.^[137] Fetal morbidity is not always immediately apparent. McCall^[138] found 28 percent of infants born with shoulder dystocia to demonstrate some neuropsychiatric dysfunction at 5- to 10-year follow-up. Fewer than one half of these children had immediate morbidity. The neonatal morbidity of greatest concern is brachial plexus injury, resulting from trauma to cervical nerve root V and VI. Fortunately, most cases are transient, with full recovery observed in 90 to 95 percent of infants.^[139]

Although shoulder dystocia has traditionally been strongly associated with macrosomia, up to one half of cases of shoulder dystocia occur in neonates under 4,000 g.^[140],^[141] However, Acker et al.^[141] found that the relative probability of shoulder dystocia in the 7 percent of infants over 4,000 g was 11 times greater than the average, and in the 2 percent of infants over 4,500 g it was 22 times greater. With macrosomia or continued fetal growth beyond term, the trunk and particularly the chest grow larger relative to the head. Chest circumference exceeds the head circumference in 80 percent of cases.^[140] Arms also contribute to the greater dimensions of the upper body. Macrosomia shows the strongest correlation with shoulder dystocia of any clinical factor and occurs more often with gestational diabetes and twice as often in postdate pregnancies. Other clinical factors associated with shoulder dystocia appear to be related to macrosomia as well and include maternal obesity,^[137],^[142] previous birth of an infant weighing over 4,000 g,^[137],^[140],^[142],^[143] diabetes mellitus,^[142],^[143] prolonged second stage of labor,^[141],^[142],^[143] prolonged deceleration phase (8 to 10 cm),^[127] instrumental midpelvic delivery,^[144] and previous shoulder dystocia,^[143] which has been found to have a recurrence risk of almost 14 percent. Increased maternal age and excess maternal weight gain have been found by some but not all investigators^[137],^[142],^[143],^[144] to increase the risk of macrosomia and shoulder dystocia.^[143] Father's birthweight, and adult size during young adulthood have also been found to correlate with fetal weight in addition to the traditional determinants.^[145]

Macrosomia has been variously defined as a birth weight over either 4,000 g or 4,500 g.^[135],^[137],^[147],^[148] Male predominance is routinely observed, and the condition is associated with the clinical features described above. The

two most common complications observed with macrosomia are postpartum hemorrhage and shoulder dystocia.^[142] Golditch and Kirkman^[148] observed shoulder dystocia in 3 percent of deliveries of infants weighing between 4,100 and 4,500 g and in 8.2 percent of those over 4,500 g. Benedetti and Gabbe^[135] reported that fetal injury occurred in 47 percent of infants weighing over 4,000 g who were delivered from the midpelvis and had shoulder dystocia.

Clinical efforts to detect macrosomia prenatally could be helpful in anticipating problems with delivery of the shoulders. Such efforts, however, have been disappointing. Numerous sonographic markers have been assessed to determine their usefulness in predicting macrosomia. These include the estimation of fetal weight using a variety of fetal dimensions and the comparison of chest to head circumference. Most recently, the fetal abdominal diameter biparietal diameter difference (ADBPD) was evaluated retrospectively both in diabetic and in nondiabetic women.^[150] A difference of greater than or equal to 2.6 cm was found to predict shoulder dystocia with sensitivity and specificity of 100 and 46 percent, respectively, with positive and negative predictive values of 30 and 100 percent, respectively. Furthermore, a fetal abdominal circumference of 35 cm or greater has been found to identify more than 90 percent of macrosomic infants.^[151] Both of these studies are retrospective and limited by difficulty measuring the fetal abdominal outline at advanced gestational age caused by acoustic shadowing. Parks and Ziel^[142] found that of 110 macrosomic infants the diagnosis was made prenatally in only 20 percent. The clinical estimate of birth weight was more than 3 lb in error in 6 percent of cases. Numerous efforts in the literature repeatedly demonstrate the shortcomings of both clinical and ultrasonographic estimations of fetal weight, and have concluded that the best estimation is a combination of the two.

There is a growing trend to consider cesarean delivery of any infant with an estimated weight over 4,500 g or of any infant of a diabetic mother with an estimated weight over 4,000 g^[141],^[144] to avoid birth trauma, particularly brachial plexus injury. Any consideration of elective abdominal delivery on the basis of estimated fetal weight alone, however, must consider the technical error of the method. If 90 percent confidence is desired that the actual fetal weight is at least 4,000 g, the sonographic estimate by most current methods must exceed 4,600 g. This is a result of the expected methodologic error of ± 10 percent (± 1 SD). Furthermore, the fetal vertex is often too deeply engaged in the pelvis to allow accurate measurement of head circumference. Estimated fetal weight should be only one of several factors considered in the management of the laboring patient. In the obese diabetic patient with an estimated fetal weight over 4,500 g and showing poor progress in labor, cesarean delivery may be the most prudent course. However, in most other cases, the risks of cesarean to the mother, the accuracy of prediction of macrosomia, and the alternative of a carefully monitored trial of labor should be discussed. Gross et al.^[152] carefully reviewed the clinical characteristics of 394 mothers delivering infants over 4,000 g and concluded that, although birth weight, prolonged deceleration phase, and length of second stage were all individually predictive, no prospective model adequately discriminated the infant destined to sustain trauma from shoulder dystocia from the infant not so destined.^[152] Taking this one step further, identifying macrosomic fetuses for the ultimate prevention of neurologic injury has been the subject of reports that report a significant increase in annual cost for routine cesarean deliveries for macrosomia in the nondiabetic population, but improved ratios of cost per brachial plexus injury prevented per year in the diabetic

population. Ultrasound detection and elective cesarean delivery of the macrosomic infant of the nondiabetic has been predicted to result in \$4.9 million of expenditure to prevent one permanent neurologic injury, whereas one maternal death would result from cesarean delivery for every 3.2 neonatal nerve injuries prevented. ^[153] Elective cesarean delivery for fetuses of diabetic mothers (both gestational and pregestational) has also been controversial. Langer et al. found that 76 percent of shoulder dystocias could be prevented if a policy of elective cesarean delivery was instituted at an estimated weight of 4,250 g, ^[154] while Acker found that using a fetal weight threshold of 4,000 g, 55 percent could be prevented in the diabetic population. ^[141] While many clinicians will perform an elective cesarean delivery in a patient with diabetes mellitus and an estimated fetal weight of 4,000 to 4,500 g, ^[154] Keller expressed concern about the inaccuracy of ultrasound estimation of fetal weight in the gestational diabetic population, with 50 percent of shoulder dystocias occurring in fetuses who weighed less than 4,000 g. ^[156]

The occurrence of brachial plexus injury in the absence of shoulder dystocia has been described and attributed to in utero forces, such as the posterior shoulder impacting on the sacral promontory (although anterior injuries have been described as well), ^[157] malpresentations, ^[158] and dysfunctional labor, mostly precipitate labor. ^[141], ^[159] Interestingly, in neonates with brachial plexus injury without shoulder dystocia, there was a trend toward lower birth weight, more clavicular fractures, injuries to the brachial plexus of the posterior arm, and longer persistence of the condition than their counterparts in the shoulder dystocia-present group. ^[157]

The most effective preventive measure is to be familiar with the normal mechanism of labor and to be constantly prepared to deal with shoulder dystocia. Normally, after the delivery of the head, external rotation (restitution) occurs, returning the head to its natural perpendicular relationship to the shoulder girdle. The

fetal sagittal suture is usually oblique to the AP diameter of the outlet, and the shoulders occupy the opposite oblique diameter of the inlet (Fig. 16-27). As the shoulders descend in response to maternal pushing, the anterior shoulder emerges from its oblique axis under one of the pubic rami. If, however, the anterior shoulder descends in the AP diameter of the outlet and the fetus is relatively large for the outlet, impaction behind the symphysis can occur, and further descent is blocked. ^[136] Shoulder dystocia also occurs with an extremely rapid delivery of the head, as can occur with vacuum extraction or forceps or precipitous labor.

Successful treatment follows anticipation and preparation. Anticipation involves the prenatal suspicion of macrosomia by clinical and/or sonographic means. One must be aware of the clinical features that have been cited and consider a pregnancy at high risk for macrosomia and therefore for shoulder dystocia.

Such deliveries are best managed in a delivery room. Deliveries in bed increase the difficulty of reducing a shoulder dystocia because the bedding precludes fullest use of the posterior pelvis and outlet. Strong consideration for cesarean delivery is recommended when a prolonged second stage occurs in association with macrosomia.

Once a vaginal delivery has begun, the obstetrician must resist the temptation to rotate the head forcibly to a transverse axis. Maternal expulsive efforts should be used rather than traction. Gentle manual pressure on the fetal head inferiorly and posteriorly will push the posterior shoulder into the hollow of the sacrum, increasing the room for the anterior shoulder to pass under the pubis (Fig. 16-28). This pressure is not outward traction and must be symmetric. If the head is pressed asymmetrically, as if to "pry" the anterior shoulder out, brachial plexus injury is more likely.

If delivery is not accomplished, a deliberate, planned

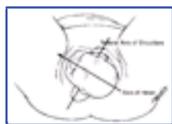

Figure 16-27 After delivery of the head, "restitution" results in the long axis of the head reassuming its normal orientation to the shoulders as seen here.

Figure 16-28 Gentle, symmetric pressure on the head will move the posterior shoulder into the hollow of the sacrum and encourage delivery of the anterior shoulder. Care should be taken not to "pry" the anterior shoulder out asymmetrically, as this might lead to trauma to the anterior brachial plexus.

sequence of efforts should then be initiated. One must not pull desperately on the fetal head. Fundal expulsive efforts, including maternal pushing and any fundal pressure, should be temporarily stopped. Aggressive fundal pressure prior to disimpaction or rotation of the shoulders will not facilitate delivery and may work against rotation and disimpaction.

The McRoberts maneuver ^[160] is a simple, logical, and usually successful measure to promote delivery of the shoulders. The McRoberts maneuver involves hyperflexion of maternal legs on the maternal abdomen that results in flattening of the lumbar spine and ventral rotation of the maternal pelvis and symphysis (Fig. 16-29). This maneuver may increase the useful size of the posterior outlet, resulting in easier disimpaction of the anterior shoulder. Gonik et al. ^[161] showed that the McRoberts maneuver significantly reduces shoulder extraction forces, brachial plexus stretching, and likelihood of clavicular fracture. In a retrospective review of shoulder dystocia, Gherman et al. found that the McRoberts maneuver was the only step required in 42 percent of 236 cases. ^[162] When shoulder dystocia occurs because of failure of the bisacromal diameter to engage, the Walcher position, which entails dropping the maternal legs down toward the floor with concurrent suprapubic pressure in a dorsal-caudal direction, has been advocated. Only then, while constant suprapubic pressure is being maintained, should the parturient be placed in the McRoberts position; this may allow for the disimpaction of the fetal shoulder from the symphysis by increasing the AP diameter of the inlet prior to increasing the outlet. ^[163] Additionally, the "all fours," or Gaskin maneuver, which differs from the knee-chest position, may relieve the dystocia. ^[164] Use of this maneuver is reasonable only in the setting of a mobile parturient

Figure 16-29 The least invasive maneuver to disimpact the shoulders is the McRoberts maneuver. Sharp ventral flexion of the maternal hips results in ventral rotation of the maternal pelvis and an increase in the useful size of the outlet.

with no significant motor blockade from regional anesthetic, and a stable and wide surface on which to assume this position in order to avoid the potential for injury during transition to this position.

If the shoulders remain undelivered, often only moderate suprapubic pressure is required to disimpact the anterior shoulder and allow delivery (Fig. 16-30). If this is not effective, the operator's hand may be passed

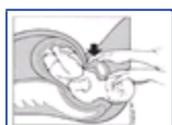

Figure 16-30 Moderate suprapubic pressure will often disimpact the anterior shoulder.

behind the occiput into the vagina, and the anterior shoulder may be pushed forward to the oblique, after which, with maternal efforts and gentle posterior pressure, delivery should occur (Fig. 16-31).^[131] Alternatively, the posterior shoulder may be rotated forward, through a 180-degree arc, and passed under the pubic ramus as in turning a screw (Wood's screw maneuver). As the posterior shoulder rotates anteriorly, delivery will often occur.^[165]

Many authorities have advocated delivery of the posterior arm and shoulder should the above methods fail. The operator's hand is passed into the vagina, following the posterior arm of the fetus to the elbow. The arm is flexed and swept out over the chest and the perineum (Fig. 16-32). In some cases, delivery will now occur without further manipulation. In others, rotation of the trunk, bringing the freed posterior arm anteriorly, is required.^[131],^[140] These maneuvers are highly likely to fracture the clavicle (up to 25 percent), humerus (up to 15 percent), or both or result in transient or permanent nerve injury (up to approximately 9 percent).^[165] Overall, similar rates of bone fracture were noted when any type of manipulation was performed to accomplish delivery of an impacted fetal shoulder.^[166] Deliberate fracture of the clavicle is possible and will facilitate delivery by diminishing the rigidity and size of

497

Figure 16-31 Rotation of the anterior shoulder forward through a small arc or the posterior shoulder forward through a larger one will often lead to descent and delivery of the shoulders. Forward rotation is preferred, as it tends to compress and diminish the size of the shoulder girdle, while backward rotation would open the shoulder girdle and increase the size.

the shoulder girdle. It is best if the pressure is exerted in a direction away from the lung to avoid puncture. Sharp instrumental transection of the clavicle is not recommended, since lung puncture is common with such a method, and infection of the bone through the open wound is a serious possible complication.

Two techniques rarely used in the United States for the management of shoulder dystocia include vaginal replacement of the fetal head with cesarean delivery (Zavanelli maneuver) and subcutaneous symphysiotomy. Sandberg reviewed the Zavanelli maneuver for both the vertex- and breech-presenting undeliverable fetuses. Cephalic replacement was successful in 84 of 92 vertex-presenting fetuses, and in 11 of 11 breech-presenting, podalic replacement was successful. Maternal risks included soft tissue trauma and sepsis, but the fetal risks were described as "minimal," with no fetal injuries attributed to the maneuver; this may be misleading because of the presence of a multitude of etiologies for permanent injury or death, likely from attempts at disimpaction, prolonged delivery time, and hypoxia.^[167] O'Leary and Cuva^[168] described 35 cases, 31 of which were considered successful and 1 of which needed a hysterotomy incision to allow manual disimpaction of the fetal shoulders and facilitate vaginal delivery when the fetal head could not be replaced into the vagina from below.

Subcutaneous symphysiotomy has been practiced in remote areas of the world for many years as an expedient alternative to cesarean delivery with very good results.^[169] In a case series of three symphysiotomies, the procedure was associated with death of all three neonates because of hypoxic complications but as a last resort. The procedure was concluded to be safe and

Figure 16-32 The operator here inserts a hand and sweeps the posterior arm across the chest and over the perineum. Care should be taken to distribute the pressure evenly across the humerus to avoid unnecessary fracture.

498

effective as long as attention is paid to the three main points in the procedure: lateral support of the legs, partial sharp dissection of the symphysis, and displacement of the urethra to the side with an indwelling urinary catheter.^[170] However, neither cephalic replacement nor symphysiotomy has been widely or often used in obstetric practice in the United States. Attempted implementation of either method by the inexperienced practitioner before the trial of more conventional remedies may increase risk to the child, the mother, and the clinician.

In summary, shoulder dystocia is not precisely predictable, but may be anticipated in the case of a variety of predisposing clinical conditions. Shoulder dystocia will, in most cases, respond to any or all of several prudent interventions. The specific method used to disimpact the shoulder is probably not as critical as the practice of a careful, methodical approach to the problem and the avoidance of desperate, potentially traumatic or asymmetric traction. The maneuvers used should be carefully described in the delivery note. There may not be any complication of labor and delivery where forethought is more important to a successful outcome than shoulder dystocia.

Key Points

The "fetal lie" indicates the orientation of the fetal spine relative to that of the mother. Normal fetal lie is longitudinal and by itself does not connote whether the presentation is cephalic or breech.

Cord prolapse occurs 20 times as often with an abnormal axial lie as it does with a cephalic presentation.

Fetal malformations are observed in more than half of infants with a face presentation.

Fetal malpresentation requires timely diagnostic exclusion of major fetal or uterine malformations and/or abnormal placentation.

With few exceptions, a closely monitored labor and vaginal delivery is a safe possibility with most malpresentations. However, cesarean delivery is the only acceptable alternative if normal progress toward spontaneous vaginal delivery is not observed.

External cephalic version of the infant in breech presentation near term is a safe and often successful management option. Use of tocolytics and/or epidural anesthesia may improve success.

Appropriate training and experience is a pre-requisite to the safe vaginal delivery of selected infants in breech presentation.

Shoulder dystocia cannot be precisely predicted or prevented but is often associated with macrosomia, maternal obesity, gestational diabetes, and a postdate pregnancy.

The clinician must be prepared to deal with shoulder dystocia at every vaginal delivery with a deliberate, controlled sequence of interventions.

Chapter 17 - Obstetric Hemorrhage

Thomas J. Benedetti

It is critical that the obstetrician be able to estimate rapidly the blood volume deficit in the pregnant patient. Although some have proposed that the pregnant woman fails to show the usual signs and symptoms of blood loss, there is little scientific evidence to support this hypothesis. This confusion may have arisen from an incomplete understanding of the physiologic responses to volume loss and lack of appreciation of normal volume expansion of pregnancy. The normal pregnant patient frequently loses 500 ml of blood at the time of vaginal delivery and 1,000 ml at the time of cesarean delivery. Appreciably more blood can be lost without clinical evidence of a volume deficit as a result of the 40 percent expansion in blood volume that occurs by the 30th week of pregnancy.

To understand why the pregnant patient does not exhibit early signs of volume loss, it is important to understand the normal physiologic responses to hemorrhage ([Fig. 17-1](#)). When 1,000 ml is rapidly removed from the circulatory blood volume, vasoconstriction occurs in both the arterial and venous compartments in order to preserve essential body organ flow. As illustrated [in Figure 17-1](#), when intravascular volume is lost, blood pressure is initially maintained by increases in systemic vascular resistance. As volume loss exceeds 20 percent, the fall in cardiac output accelerates and blood pressure can no longer be maintained by increases in resistance. Blood pressure and cardiac output fall in parallel after this point. In addition, if the volume loss has occurred more than 4 hours earlier, significant fluid shifts from the interstitial space into the intravascular space will partially correct the volume deficit. This movement of fluid, termed *transcapillary refill*, can replace as much as 30 percent of lost volume. In more chronic bleeding states, the final blood volume deficit may amount to as little as 70 percent of the actual blood lost.

CLASSIFICATION OF HEMORRHAGE

A standard classification for volume loss secondary to hemorrhage is illustrated in Table 17-1. Hemorrhage can be classified as one of four groups, depending on the volume lost. The determination of the class of hemorrhage reflects the volume deficit, which may not be the same as the volume loss. The average 60-kg pregnant woman has a blood volume of 6,000 ml at 30 weeks, and an unreplaced volume loss of less than 900 ml falls into class 1. Such patients rarely exhibit signs or symptoms of volume deficit.

A blood loss of 1,200 to 1,500 ml is characterized as a class 2 hemorrhage. These individuals will begin to show expected physical signs, the first being a rise in pulse rate and/or a rise in respiratory rate. Tachypnea is a nonspecific response to volume loss and, although a relatively early sign of mild volume deficit, is frequently overlooked. A doubling of the respiratory rate may be observed in this circumstance. If the patient appears to be breathing rapidly, the minute ventilation is usually twice its normal value. This finding should not be interpreted as an encouraging sign, but rather one of impending problems.

Patients with class 2 hemorrhage will frequently have orthostatic blood pressure changes and may have decreased perfusion of the extremities. However, this amount of blood loss will not usually result in the classic cold, clammy extremities. Rather, a more subtle test is needed to document this phenomenon. One can simply squeeze the hypothenar area of the hand for 1 to 2 seconds and then release the pressure. A patient with normal volume status will have an initial blanching of the skin, followed within 1 to 2 seconds by a return to the normal pink coloration. A patient who

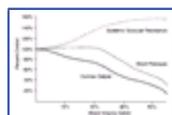

Figure 17-1 Relationships among systemic vascular pressure, cardiac output, and blood pressure in the face of progressive blood volume deficit.

has a volume deficit of 15 to 25 percent will have delayed refilling of the blanched area of the hand.

Narrowing of the pulse pressure is another sign of class 2 hemorrhage. A thorough understanding of blood pressure readings is necessary in order to interpret subtle volume changes in the pregnant patient. The blood pressure can be viewed as having three components: diastolic pressure, pulse pressure, and systolic pressure. The diastolic pressure reflects the amount of systemic vasoconstriction present, the pulse pressure indicates stroke volume, and the systolic pressure denotes the interrelationship between the level of vasoconstriction and the stroke volume. While pulse pattern is a good clinical approach to the assessment of stroke volume in a given patient, it is not a reliable method of monitoring stroke volume in larger groups of patients because of individual variations in the many factors that may alter stroke volume (age, aortic stiffness). However, monitoring this parameter in a given patient will provide earlier signs of hypovolemia and reduced blood flow than either systolic or diastolic pressure used individually.

When a patient loses blood, compensatory mechanisms

TABLE 17-1 -- CLASSIFICATION OF HEMORRHAGE IN THE PREGNANT PATIENT.

Hemorrhage Class	Acute Blood Loss	Percentage Lost
1	900	15
2	1,200-1,500	20-25
3	1,800-2,100	30-35
4	2,400	40

Adapted from Baker R: Hemorrhage in obstetrics. *Obstet Gynecol Annu* 6:295, 1997.

* Total blood volume = 6,000 ml.

In the usual clinical setting, very few episodes of volume loss occur without some infusion of intravenous fluids, usually crystalloid-containing solutions such as lactated Ringer's solution, or normal saline. Therefore, the amount of blood loss preceding physical signs and symptoms will usually exceed the values listed.

are activated that help ensure perfusion to vital body organs (brain, heart). The initial response, vasoconstriction, diverts blood away from nonvital body organs (skin, muscle, kidney). Blood loss results in sympathoadrenal stimulation, which causes a rise in diastolic pressure. Since the systolic pressure is usually maintained with small volume deficits (15 to 25 percent), the first blood pressure response seen with volume loss is narrowing of the pulse pressure (120/70 to 120/90 mm Hg). That is, pulse pressure changes from 50 mm Hg to 30 mm Hg. When pulse pressure drops to 30 mm Hg or less, the patient should be carefully evaluated for other signs of volume loss.

Class 3 hemorrhage is defined as blood loss sufficient to cause overt hypotension. In the pregnant patient, this usually requires a blood loss of 1,800 to 2,100 ml. These patients exhibit marked tachycardia (120 to 160 beats/min) and may have cold, clammy skin and tachypnea (respiratory rate of 30 to 50 breaths/min).

In class 4 patients, the volume deficit exceeds 40 percent. These patients are in profound shock and frequently have no discernible blood pressure. They may have absent pulses in their extremities and are oliguric or anuric. If volume therapy is not quickly begun, circulatory collapse and cardiac arrest will soon result.

The hematocrit is another clinical method frequently used to estimate blood loss. After acute blood loss, the hematocrit will not change significantly for at least 4 hours, and complete compensation requires 48 hours. Infusion of intravenous fluids can alter this relationship, resulting in earlier lowering of measured hematocrit. When significant hemorrhage is thought to have occurred, a hematocrit should always be obtained. If this result shows a significant fall from a previous baseline value, a large amount of blood has been lost. Measures should immediately be taken to evaluate the source of the loss and whether the hemorrhage is ongoing but unrecognized.

Cesarean delivery is a frequent cause of excessive blood loss. It must be remembered that narcotics, which are frequently used for pain relief in the immediate

postoperative period, can significantly reduce the ability of the sympathetic nervous system to effect vasoconstriction of the arterial and venous compartments. If these medications are given to a hypovolemic patient, serious hypotension can result. Signs and symptoms of hypovolemia should always be sought before the postoperative patient is given narcotic analgesics on the first postpartum day.

URINE OUTPUT"THE WINDOW OF BODY PERFUSION"

In hypovolemic patients, urine output must be carefully monitored. In many cases, the urine output will fall

505

before other signs of impaired perfusion are manifest. In contrast, adequate urine volume in patients who have not received diuretics strongly suggests perfusion to vital body organs is adequate.

There is reasonable correlation between renal blood flow and urine output. If the urine output is low, renal blood flow is often low as well. When there is a rapid decrease in renal blood flow, there is usually a reduction in urine output. In such cases, renal blood flow tends to shift from the outer renal cortex to the juxtamedullary portion of the renal cortex. Glomerular filtration rate is further reduced, but absorption of water and sodium is increased because there are fewer glomeruli and longer loops of Henle in this region. Urine will become more concentrated and will have a lower concentration of sodium and a higher osmolarity. With a gradual fall in renal blood flow, the urine sodium and osmolarity will often be affected before any significant fall in urine output. A urine sodium concentration of less than 10 to 20 mEq/L or a urine/serum osmolar ratio of greater than 2 usually indicates reduced renal perfusion.

BLOOD LOSS IN SEVERE PREECLAMPSIA

Major blood loss in a patient with severe preeclampsia may present a confusing picture. One must be aware of the altered hemodynamic status of these patients to appreciate the extent of the volume loss and to ensure appropriate fluid replacement. In severe preeclampsia, the blood volume has frequently failed to expand and is similar to that in a nonpregnant woman. These patients will not have the protective effect of the usual volume expansion of pregnancy and will show signs of blood loss earlier. In these cases, however, blood pressure can be a misleading indicator of volume. A blood pressure appropriate for a previously normotensive patient could indicate serious volume depletion in the preeclamptic woman. It is especially important to record serial pressures. If the blood pressure shows a significant drop during the immediate postoperative or postpartum period, a volume deficit should be suspected because hypertension usually persists for days to weeks in patients with severe preeclampsia.

When significant hemorrhage occurs in the woman with hypertension, it may be important to supplement the crystalloid fluid resuscitation with colloidal fluids pending the availability of the best colloid, whole blood. Albumin (5 percent) may be given in the ratio of 500 ml of albumin for every 4 L of crystalloid. This form of therapy will help compensate for the low albumin and total protein concentrations present in the patient with severe preeclampsia. It is not uncommon for these women to have total protein levels less than 5.0 g/dl with an albumin concentration below 2.5 g/dl. If crystalloid fluids are given alone, massive fluid accumulation in the already overexpanded extravascular space can occur and may result in cerebral as well as pulmonary edema. ^[1]

TREATMENT

Patients showing signs of class 2 or greater volume loss should receive crystalloid intravenous fluids pending the arrival of blood and blood products. The infusion rate should be rapid, between 1,000 and 2,000 ml in 30 to 45 minutes, or faster if the patient is obviously hypotensive. This infusion may serve as a therapeutic trial to help determine the amount of blood loss. If the physical signs and symptoms return to normal and remain stable after this challenge, no further therapy may be needed. If blood loss has been severe and the patient continues to bleed, however, this favorable response may be only transient. In this situation, typed and cross-matched blood should be given. The initial administration of a balanced salt solution will reduce the amount of whole blood needed to restore an adequate blood volume.^[2]

Blood and Blood Products

Whole Blood

The use of whole blood has been discouraged and in many instances discontinued by blood banking centers around the United States. In obstetrics, the main indication for whole blood rather than component therapy is massive blood loss requiring more than a 4,000-ml replacement (Table 17-2). New strategies and algorithms must now be developed to respond to clinical situations that, in the past, were treated with whole blood.

For many years, the anticoagulant cpda-1 has been used to preserve whole blood. This compound contains c, a calcium chelating agent; p, phosphate, to maintain adenosine triphosphate (ATP) levels; d, dextrose, food for red blood cells (RBCs) and for preservation of 2,3-diphosphoglyceric acid (2,3-DPG) levels; and a, adenine, to preserve ATP levels. Maintenance of ATP is essential to preserve the RBC sodium pump and cell shape, both of which affect cell survival. A by-product of the normal glycolytic pathway in the RBC, 2,3-DPG, causes a shift to the right of the oxyhemoglobin dissociation curve. This shift permits more oxygen to be dissociated from the hemoglobin molecule and released into the tissues. Despite these alterations, the useful life of a unit of whole blood is 35 days. Recently, a new system for red cell preservation has been developed. The red cell preservative Optisol is a crystalloid solution

TABLE 17-2 -- BLOOD REPLACEMENT

Product	Cost/Unit	Contents	Volume (ml)	Effect
Whole blood (WB)	\$97	Red blood cells (2,3DPG)	500	Increase volume (ml/ml)
		White blood cells (not functional after 24 hours)		Increase hematocrit 3%/unit
		Coagulation factors (50%V, VIII after 7 days)		
		Plasma proteins		
Packed red cells	\$97	Red blood cells same as whole blood	240	Same red blood cells as whole blood
				Less risk febrile, or WBC transfusion reaction
		White blood cells less than whole blood		
		Plasma proteins few		Increase hematocrit 3%/unit
Platelets	\$47	55 × 10 ⁶ platelets/unit, few white blood cells	50	Increase platelet count 5,000-10,000 /unit
				Give 6 packs minimum
Fresh frozen plasma	\$50	Clotting factors V and VIII, fibrinogen	250	Only source of factors V, XI, XII
				Increase fibrinogen 10 mg/dl/unit
Cryoprecipitate	\$30	Factor VIII 25% Fibrinogen von Willebrand factor	40	Increase fibrinogen 10 mg/dl/unit
Albumin 5%	\$54	Albumin	500	
Albumin 25%	\$54	Albumin	50	

containing sodium, dextrose, adenine, and mannitol. The clinical advantages of this system are improved flow characteristics of the red cells, extension of the shelf life of red cells from 35 days to 42 days, and the ability to extract larger volumes of fresh frozen plasma (FFP) from each unit of whole blood. The expansion of the shelf life is a particular advantage and should make the autologous blood donation available to more patients. The main disadvantage of this system is that its adoption by the blood bank eliminates the availability of whole blood for transfusion. The other consideration is for neonates in whom large volumes of adenine and mannitol may be toxic.

Massive Blood Transfusion

Massive transfusion is an ill-defined term but can generally be thought of as the need to replace a patient's entire blood volume in 24 hours or less.^[3] In a pregnant patient, this is usually 10 or more units of blood. Massive transfusion is a medical emergency that often requires the ultimate in surgical and medical skills. Administrative skills are also essential because usually a number of physicians from various medical specialties are involved in the care of such a patient. Events may be occurring rapidly and clinical circumstances changing from minute to minute. Clear lines of communication between the various health care providers must be maintained. During an acute hemorrhage requiring prolonged surgical management, such as a placenta accreta with bladder involvement or severe placental abruption, it is optimal to have one member of the obstetric team whose job is to coordinate blood replacement and to monitor laboratory results, which are the basis for choosing which components to replace. Communication between the surgeon and the anesthesiologist regarding volume and coagulation status is essential and may be compromised if all physicians are heavily involved in their own work.

The essentials of management of the patient requiring massive transfusion are maintenance of circulation, blood volume, oxygen-carrying capacity, hemostasis, colloid osmotic pressure, and biochemical balance. At the University of Washington, we have addressed the problem of massive obstetric bleeding by the institution of an Emergency Bleeding Protocol. This is a series of prearranged actions that are put in place once a member of the health care team initiates the protocol. The

attending anesthesiologist or obstetrician is usually this individual. Once activated, the protocol stipulates a designated on-call individual at the central blood center to be emergently notified. Two units of O-negative packed cells are immediately sent to the delivery suite from the hospital emergency supply and an order is sent to the blood center for immediate release of 4 units of uncross-matched packed red cells, 6 units of platelets, and 10 bags of cryoprecipitate. An emergency set of blood studies is done that includes coagulation studies, an arterial blood gas, and an additional tube for cross-match. An algorithm is used to guide transfusion of blood products once laboratory studies are available. (If platelets are $<100,000$, 6 units of platelets

are transfused; if fibrinogen is <125 mg/dl, 10 bags of cryoprecipitate are transfused; if international normalized ratio [INR] is >1.5 or massive bleeding is encountered, then 4 units of AB plasma are thawed and transfused.) Specified individuals are designated to keep track of orders and results. A flow sheet is used to keep track of products used, medications given, laboratory results, and intravenous fluids.

In the last 2 years, our ability to standardize the response to these uncommon but life-threatening situations has been well received by all the providers involved in these situations. A predictable series of responses to this acute emergency has served to reduce the level of provider stress and anxiety that accompanies emergency bleeding.

Metabolic derangements are frequently mentioned when massive transfusion is discussed. However, traditional formulas for using alkylating agents or calcium supplements are probably unnecessary. Hypocalcemia is a theoretical problem, but clinical syndromes from this problem are infrequently described and the possible complications of prophylactic calcium infusion may be more harmful than hypocalcemia. Hypocalcemia can be clinically important when it is combined with hyperkalemia and hypothermia, a triad that can lead to cardiac arrhythmias. Hypothermia can be a problem if the recently refrigerated blood is administered at a rate of 1 unit every 5 to 10 minutes. If this rate of administration is required, attempts should be made to warm the blood above 4°C before transfusion. Close attention should be paid to the electrocardiogram. If arrhythmias are noted, supplemental calcium should be considered.

Acid-base problems may arise in the event of massive transfusion. However, citrate toxicity is rarely a problem because the healthy liver can metabolize the citrate in a unit of blood in 5 minutes. Unless transfusion rates exceed 1 unit per 5 minutes or the liver is previously diseased, citrate toxicity should not be a problem. Although stored blood has an acid pH, acidosis is uncommon because the metabolism of citrate produces alkalosis. Prolonged acidosis is more often the result of hypoperfusion and shock rather than blood replacement. Blood gas measurement should guide the therapy with bicarbonate in this instance.

Packed Red Blood Cells

Packed red blood cells (PRBCs) are the most effective and efficient way to provide increased oxygen-carrying capacity to the anemic patient. Unless a patient has suffered massive blood loss, PRBCs and crystalloid will satisfy most clinical needs. Oxygen-carrying capacity may become impaired in the euvolemic patient when the hemoglobin level drops below 7 g/dl. If adequate volume replacement has not been accomplished, patients may exhibit orthostatic blood pressure changes or other signs of impaired oxygen-carrying capacity at hemoglobin levels above 7 g/dl. Because a unit of PRBCs has small amounts of white blood cells (WBCs) and isoagglutinins (anti-A and anti-B), its use reduces the incidence of nonhemolytic transfusion reactions compared with that of 1 unit of whole blood. However, care should be taken to administer PRBCs with normal saline rather than lactated Ringer's or dextrose solutions. These solutions can cause the blood to clot or the red cells to lyse.

Platelets

Platelets are necessary for the initial phase of hemostasis. They must be maintained at room temperature and agitated during storage. Platelet concentrates usually contain less than 100 ml of plasma and small numbers of RBCs and WBCs.

Platelet concentrates now exist in two forms: random donor concentrates and apheresis platelets. Pooled random donor platelets have been harvested by centrifuging units of whole blood. Although the usual dose is 4 to 6 units of pooled platelets, up to 8 units can be pooled into a single bag for transfusion. All units are the same ABO type and will expire 4 hours after pooling. Apheresis platelets are collected from a single donor and contain more plasma (200 to 400 ml) than the random pooled platelet concentrates. They can be collected as a random unit or for a specific recipient. As with the pooled donor concentrates, they expire 4 hours after release from the blood center.

A unit of platelets derived from a single unit of whole blood has a shelf life of 72 hours. Transfusion of a single unit of platelets can be expected to raise the platelet count between 5,000 and 10,000/l in a patient without antiplatelet antibodies and a normal sized spleen. The survival of transfused platelets can be as long as 3 to 5 days but will be shorter if disseminated intravascular coagulation (DIC) is present. A single unit of platelets should never be given: the smallest single dose of clinical value is 4 to 6 units. Platelets should be administered rapidly, over 10 minutes, with repeat laboratory evaluation performed 2 hours after infusion. For the obstetric patient, it is important that the platelets be ABO and Rh specific. Sensitization can be prevented by concomitant administration of Rh-immune globulin. One 300-g dose will prevent sensitization for 30 platelet packs. It must also be remembered that six packs of platelets have a volume effect if multiple doses are used. Each unit of random donor platelets carries the transfusion risk of a single unit of blood.

Platelet administration is frequently considered for patients with DIC, massive hemorrhage, severe preeclampsia, and idiopathic thrombocytopenic purpura (ITP). In each of these conditions, the absolute levels at which a platelet transfusion is indicated may vary depending

on the time course of the thrombocytopenia (more chronic forms will result in less hemostatic defects than acute loss), the need to perform a surgical procedure, the etiology of the inciting event producing thrombocytopenia, and the level of blood pressure elevation and the bleeding time. In general, platelet counts below 50,000/l will require transfusion prior to or during surgery. However, when the need for a cesarean delivery arises in patients with platelet counts ranging from 20,000 to 50,000 platelets, transfusion may be avoided or the amount reduced if the transfusion is delayed until the need becomes apparent. This is usually evident from bleeding from skin edges, as hemostasis in the uterus is primarily a function of uterine muscle contraction, not platelet function.

Cryoprecipitate

Prepared by warming fresh frozen plasma and collecting the precipitate, cryoprecipitate contains significant amounts of factor VIII, factor XIII, fibrinogen, and von Willebrand's factor. ABO compatibility is necessary only in infants because of their small size. In pregnant patients, whenever possible, Rh-compatible cryoprecipitate should be used. If this is not possible, RhoGAM should be administered within 72 hours of transfusion. One 20-ml unit of cryoprecipitate will contain 200 mg of fibrinogen. When attempting to calculate the expected rise in serum fibrinogen, one must take into account the anticipated recovery with transfusion and the plasma volume of the patient (approximately 4 L in a 70-kg pregnant patient). This should result in only a 5 mg/dl rise in fibrinogen per bag of cryoprecipitate transfused because only 75 percent of the fibrinogen remains in the intravascular space after transfusion. In the past, estimates were twice this level, and many patients were undertransfused with cryoprecipitate. This preparation should be used when significant hypofibrinogenemia must be treated. Multiple bags need to be pooled and suspended in normal saline.

Fresh Frozen Plasma

Fresh frozen plasma is the plasma harvested from a unit of whole blood. It is frozen within 8 hours of collection. FFP contains all coagulation factors in normal concentrations. It contains no platelets, leukocytes, or red blood cells. Transfusion of FFP need not be Rh compatible but should be ABO compatible. FFP has not been shown to transmit cytomegalovirus (CMV). Fresh frozen plasma should be administered when both volume replacement and coagulation factors are needed. The main clinical indication for this therapy is the massively hemorrhaging patient. If bleeding continues after the transfusion of 4 to 5 units of blood, a coagulation screen should be checked to see whether the replacement of clotting factors and platelets is indicated. If the prothrombin time (PT) or partial thromboplastin time (PTT) are at least 50 percent prolonged or the international normalized ratio (INR) is greater than 1.5, there is usually a 70 percent reduction in factor levels present. A 10 percent increase in factor levels will usually be required for significant change in coagulation status. The required dose of FFP in this instance will be 4 250-ml

units.

A second type of FFP has recently been introduced to the market. Manufactured by the Vitex Corporation, solvent/detergent-treated plasma is produced by pooling approximately 2,500 units of donor plasma. It is then batch treated with a solvent and a detergent, which together are very effective in destroying the lipid envelope viruses. These viruses include human immunodeficiency (HIV)-1, HIV-2, hepatitis B, hepatitis C, and human T-lymphotrophic virus (HTLV) types I and II. Coagulation factors are equivalent to FFP. The obvious advantage of this approach is the elimination of the risk of viral transmission of the previously mentioned viruses. Disadvantages are the exposure of many donors because of the pooled nature of the preparation. Disease transmission of nonlipid envelope viruses hepatitis A and parvovirus has been reported. The second disadvantage is cost, which is approximately three times that of FFP (\$125 vs. \$44). Physicians should check with their respective blood centers regarding the availability and policies regarding the use of this product.

Autologous Transfusion

Primarily as the result of fear of acquiring the acquired immunodeficiency syndrome (AIDS) virus from blood transfusion, interest in autologous blood transfusion for pregnant patients was heightened in past years. Autologous transfusion can be accomplished in two ways. In the most common approach, blood is collected and stored during the weeks before delivery. In the past this presented some logistic problems for the pregnant patient, since 3 weeks was the longest time that blood can be stored. Currently, blood storage has been extended to 35 days and, with the advent of a new solution for blood storage, another week can be added to the shelf life of donated blood (see prior section). Although predelivery autologous blood donation is generally safe for both mother and fetus, the low incidence of blood transfusion in patients at the time of childbirth and the safety of allogeneic transfusion has limited enthusiasm on the part of health care professionals. Studies have questioned the cost effectiveness of autologous transfusion in general.^[4] Since the incidence of transfusion in pregnant patients is significantly lower than the incidence

of transfusion in operative patients, predelivery autologous blood donation in pregnant patients is probably not cost effective.

The chance of acquiring HIV from a unit of donated and screened blood is now approximately 1 in 700,000. Furthermore, when blood transfusion is clinically indicated, there is usually the need for more blood than the patient is able to donate unless the blood is frozen, which dramatically increases the cost of the procedure. Antepartum patients inquiring about this practice should be carefully counseled that the chance of needing a blood transfusion is about 1 in 80 overall. It exceeds 1 percent when emergency cesarean delivery becomes necessary or if placenta previa exists.^{[5] [6] [7]} These data, coupled with the low risk of acquiring HIV from a donated unit of blood, makes the a priori risk of a low-risk patient needing a blood transfusion and subsequently acquiring HIV less than 1 in 20 million.

A second type of autologous donation, intraoperative blood salvage, can occur at the time of excessive blood loss. Intraoperative autotransfusion has been reported in obstetric patients at the time of ruptured ectopic pregnancy and after delayed cesarean hysterectomy. This technique has some limitations in the obstetric setting. Heavy bacterial contamination is a contraindication, and the use during cesarean delivery had been questioned because of the possibility of amniotic fluid, fetal debris, and bacterial contamination. Recently, a clinical report of 139 patients who were transfused with autologous blood has been published.^[8] In all cases, Cell Saver technology (Haemonetics, Braintree, MA) was used either at cesarean section or during severe obstetric hemorrhage. Blood salvage was begun after delivery of the infant and after amniotic fluid was removed from the operative field. Median volumes infused were 500 ml, but a few patients had volumes refused over 4,000 ml and in one case over 11,000 ml were refused. There were no differences in infections, respiratory, or coagulation abnormalities when the autologous transfused patients were compared to patients with similar conditions transfused with donor blood products. This technique may be useful in patients in whom anticipated blood loss is high. It may be acceptable to Jehovah's Witness patients and has the potential to add a significant margin of safety for these patients.

Transfusion Risks

PRBCs, fresh frozen plasma, cryoprecipitate, and platelets have the same risk of transmitting infectious diseases as a unit of whole blood. [See the box "Risks of Blood Transfusion"](#) for common risks of blood transfusion when blood is procured from volunteer donors. Significant progress has been made in historical and laboratory screening for common infectious diseases. The risks of serious complications from blood transfusion have fallen to very low rates. Blood obtained from paid sources can be expected to have higher rates of many of the complications listed in the box.

A. Viral infection	
HIV-1, HIV-2	1/700,000
Hepatitis B	1/140,000
Hepatitis C [*]	1/90,000
HTLV I and II	1/641,000
B. Bacterial contamination	
Red cells	1/500,000
Platelets	1/12,000
C. Reactions	
Acute hemolytic reaction	1/600,000
Delayed hemolytic reaction	1/1,000
Acute lung injury	1/5,000
<small>* In 1999, trials were begun to screen blood with a PCR test for HCV RNA. It is anticipated that there will be a significant reduction in the transmission of hepatitis C but reliable data are not currently available.</small>	

Transfusion Reactions

Transfusion of an incompatible blood component results in a hemolytic transfusion reaction. They are usually due to clerical errors or to misidentification of the patient or unit of blood. Naturally occurring antibodies in the ABO system are the usual causes. Hemolytic transfusion reactions may result in DIC or acute renal failure. The clinical signs of acute hemolytic transfusion reaction may include some or all of the following: severe anxiety, flushing, chest or back pain, fever, hypotension, tachycardia, or dyspnea. In an anesthetized patient, hemoglobinuria may be the first noticeable sign. A rapid diagnostic test is the discovery of reddish plasma after centrifugation of a red-top tube of blood. Upon recognition, the transfusion should be stopped, and the blood returned to the blood center along with a tube of the patient's blood. Treatment with fluids, diuretics, and transfusion support for bleeding are the cornerstone of therapy. A delayed hemolytic transfusion reaction can occur in patients who have been previously sensitized to an antigen through transfusion or pregnancy. This can result in a symptomatic or asymptomatic hemolysis

within a week after a transfusion. Although more common than acute hemolytic reactions, the consequences are generally less severe.

Fever after or during transfusion is usually, but not

always, related to sensitization of antigens on cell components, usually leukocytes. However, fever can also be the first sign of sepsis related to bacterial contamination of red cells or platelets. Some authorities recommend empiric antibiotic therapy in patients who develop fever within 6 hours of transfusion of RBCs or platelets. ^[1]

Transfusion-related acute lung injury is an acute respiratory distress syndrome occurring within 4 hours of transfusion. It is characterized by dyspnea and hypoxemia secondary to noncardiogenic pulmonary edema and is estimated to occur with a frequency of greater than 1 in 5,000 transfusions. The mechanisms of injury to the pulmonary capillaries are varied and involve lipid products from donor red cell membranes and neutrophil reactions. The estimate of mortality secondary to this entity is felt to be underreported, but greater than 90 percent of patients can be expected to recover.

ANTEPARTUM HEMORRHAGE

Abruptio Placenta

The premature separation of the normally implanted placenta from the uterus is called *abruptio placenta* or *placental abruption*. Diagnosis of placental abruption is certain when inspection of the placenta shows an adherent retroplacental clot with depression or disruption of the underlying placental tissue; however, this frequently is not found if the abruption is of recent onset. Clinical findings indicating placental abruption include the triad of external or occult uterine bleeding, uterine hypertonus and/or hyperactivity, and fetal distress and/or fetal death. Placental abruption can be broadly classified into three grades that correlate with clinical and laboratory findings.

Grade 1: Slight vaginal bleeding and some uterine irritability are usually present. Maternal blood pressure is unaffected, and the maternal fibrinogen level is normal. The fetal heart rate pattern is normal.

Grade 2: External uterine bleeding is mild to moderate. The uterus is irritable, and tetanic or very frequent contractions may be present. Maternal blood pressure is maintained, but the pulse rate may be elevated and postural blood volume deficits may be present. The fibrinogen level may be decreased. The fetal heart rate often shows signs of fetal compromise.

Grade 3: Bleeding is moderate to severe but may be concealed. The uterus is tetanic and painful. Maternal hypotension is frequently present and fetal death has occurred. Fibrinogen levels are often reduced to less than 150 mg/dl; other coagulation abnormalities (thrombocytopenia, factor depletion) are present.

Incidence

The reported incidence of placental abruption varies from 1 in 86 to 1 in 206 births.^{[12] [13] [14]} This variability reflects differing criteria for diagnosis as well as the increased recognition in recent years of milder forms of the disorder. Grade 1 placental abruption is found in about 40 percent, grade 2 in about 45 percent, and grade 3 in 15 percent of clinically recognized cases of placental abruption.^{[12] , [13]} Eighty percent of all cases will occur before the onset of labor.^[13]

Etiology

The primary etiology of placental abruption is unknown, but several reports have identified statistically significant correlations with common obstetric complications. Studies have suggested an increased incidence of abruption in patients with advanced parity or age, maternal smoking, poor nutrition, cocaine use, and chorioamnionitis.^{[15] [16] [17] [18] [19]} However, some of these data may have been subject to selection bias, as only populations of low socioeconomic status were evaluated. The U.S. Perinatal Collaborative project performed during the years 1959 and 1966 and a recent population-based study in Washington state failed to show a relationship between placental abruption and either maternal age or parity.^{[14] , [20]} However, a population-based study over 15 years in Norway was able to demonstrate a strong relationship between maternal age and placental abruption for all levels of parity.^[21]

Maternal hypertension (>140/90 mm Hg) seems to be the most consistently identified factor predisposing to placental abruption.^[22] This relationship is true for all grades of placental abruption but is most strongly associated with grade 3 abruption, in which 40 to 50 percent of cases are found to have hypertensive disease of pregnancy.^{[20] , [22]} Intrapartum hypertension significantly increases the risk of abruption, but one study failed to show a relationship between the antenatal detection of hypertension and placental abruption.

Blunt external maternal trauma is an increasingly important cause of placental abruption. Two conditions account for the majority of blunt abdominal trauma leading to placental abruption: motor vehicle collision and maternal battering. Historically, 1 to 2 percent of grade 3 abruptions have been attributed to maternal trauma.^{[23] , [23]} However, recent epidemiologic studies show an alarmingly high incidence of maternal battering in some populations.^[24] These data make it incumbent on the obstetrician to consider placental abruption when a history of trauma is elicited and vice versa. The

511

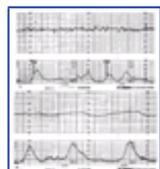

Figure 17-2 A, A fetal heart rate tracing at 37 weeks' gestation in a patient involved in an automobile accident in which the maternal abdomen struck the steering wheel. Fetal movements were present, and no periodic changes were observed. Uterine contractions were occurring every 2 to 3 minutes. B, Eight hours later, repetitive late decelerations are now present. An asphyxiated fetus was delivered, and evidence of grade 3 placental abruption was found at the time of delivery.

physical evidence of trauma may be minimal and yet still be associated with placental abruption that can progress from grade 1 to 3 within 24 hours. [Figure 17-2](#) illustrates fetal heart rate tracings 8 hours apart in a patient involved in an automobile accident.

Rapid decompression of the overdistended uterus is an uncommon cause of placental abruption. This may occur in patients with multiple gestations and those with polyhydramnios. There is an increased risk of placental abruption associated with multiple gestation.^[25] However, the timing of placental abruption in multiple gestations is difficult to ascertain. When rapid decompression

512

of the uterus is apparent, abruption is usually observed after the delivery of the first fetus. Delivery of the second twin follows soon after, before a retroplacental clot has time to form. Rapid decompression of the uterus should be avoided in a patient with polyhydramnios. Amniotic fluid should be slowly released by amniocentesis before the induction of labor or once spontaneous labor has been established.

In the past, folic acid deficiency, a short umbilical cord, and the supine hypotensive syndrome had been suggested as etiologies for placental abruption. Further evidence has shown, however, that these factors are unlikely causes of placental abruption.

Recent evidence has implicated the presence of acquired or inherited thrombophilias as a significant factor in the etiology of placental abruption. ^[29] In that study of Jewish women, mutations of one or more of three thrombophilic mutations (factor V Leiden mutation) were present in 60 percent of women who had suffered placental abruption. The presence of factor V Leiden mutation in the control population was much higher (17 percent) than in the comparable white United States population (5 percent). Furthermore, ethnic minority populations have even lower risk of this mutation. ^[26] Further study of this finding is necessary before definitive clinical recommendations can be made regarding screening and treatment.

The pathologic changes in the placental bed in patients with placental abruption show a high incidence of vascular abnormalities. Failure of transformation of uteroplacental arteries is the most common finding (60 percent). Anomalies in the vessels deep in the myometrium, including vessel occlusion with surrounding myometrial hemorrhage, were observed in 33 percent. ^[27] At the placental level, hemorrhage into the decidua basalis causes it to split, leaving a layer adherent to the myometrium. This decidual hematoma may then progress to cause further separation and compression of the adjacent placenta.

There is a significant recurrence rate for placental abruption. This figure has been reported to vary from 5 percent to 17 percent. ^[13], ^[17], ^[22] If a patient has suffered an abruption in two pregnancies, the chance for recurrence is 25 percent. In the largest series of placental abruption severe enough to result in fetal demise, the recurrence rate of severe placental abruption again resulting in fetal demise was 11 percent. Unfortunately, no published data are available to document a prospective plan of management that will reduce this unacceptably high risk. The following case illustrates one plan for such a patient.

Illustrative Case

A 32-year-old G5P4 presented at 6 weeks' gestation with the following history: She had suffered grade 3 placental abruption in her third pregnancy at 35 weeks' gestation and had undergone cesarean delivery for severe maternal coagulopathy with a dead fetus. She required 8 units of blood and blood products because of a significant intraoperative hemorrhage and contracted hepatitis C. In her next pregnancy she had an uncomplicated antenatal course and was last seen for a clinic visit at 33 weeks. She was a one-pack-a-day smoker, but all efforts to eliminate smoking from her life had been unsuccessful. At 35 weeks' gestation she presented with syncope followed by severe abdominal pain with a dead fetus. This was the same clinical presentation and gestation as the previous pregnancy. She underwent induction of labor and had a successful vaginal delivery but required 12 units of blood and blood products. In the fifth pregnancy the following management plan was developed: enrollment in a smoking cessation program; clinic visits every 2 weeks; antenatal testing beginning at 28 weeks; amniocentesis at 34 weeks' gestation, and delivery by repeat cesarean section with tubal ligation if pulmonary maturity was documented, and, if pulmonary maturity was not present, maternal administration of glucocorticoids with continuous fetal monitoring for 48 hours, followed by cesarean delivery. The patient was unable to comply with the smoking cessation program but maintained her clinic visits. At 34 weeks, amniocentesis demonstrated pulmonary maturity, and cesarean section and tubal ligation were accomplished without complication. Her 2,500-g male infant had an uncomplicated neonatal course. While this case resulted in a favorable outcome for both mother and fetus, it has been shown that grade 3 placental abruption and fetal death can follow normal antepartum testing by as few as 4 hours. ^[28]

Diagnosis and Management

Vaginal bleeding in the third trimester of pregnancy is the hallmark of placental abruption and should always prompt an investigation to determine its etiology. After appropriate physical and laboratory examination of the mother and fetus, ultrasound evaluation of the uterus, placenta, and fetus has become the standard of care (Fig. 17-3). The other common and potentially life-threatening cause of third-trimester bleeding, placenta previa, should be recognized in nearly all cases in which it is present. If ultrasound examination fails to show a placenta previa and if other local causes of vaginal bleeding (including cervical or vaginal trauma, labor, or malignancy) have been ruled out, placental abruption becomes the most likely diagnosis.

In the initial studies evaluating ultrasound, less than 2 percent of cases were definitively identifiable with ultrasound. Recent advances in ultrasound imaging and interpretation have improved this rate so that more than 50 percent of patients with confirmed placental abruption will demonstrate ultrasound evidence of hemorrhage. However, even complete placental abruption

Figure 17-3 A, Ultrasound study at 18 weeks' gestation demonstrating a hypoechoic area (A) representing retroplacental bleeding and an enlarged placenta (P). This patient had chronic hypertension. She presented with intermittent dark red vaginal bleeding and abdominal pain, a picture consistent with a chronic abruption. **E**, At delivery, the placenta revealed a large clot (small arrow) and fresh hemorrhage (large arrow). The fibrous bands bridging the clot are also consistent with chronic abruption.

may be missed by ultrasound examination during the acute phase of placental abruption.

Ultrasound can identify three predominant locations for placental abruption. These are subchorionic (between the placenta and the membranes), retroplacental (between the placenta and the myometrium), and preplacental (between the placenta and the amniotic fluid). Hematomas identified by ultrasound during the early phases of vaginal bleeding and pain are most likely to be hyperechoic or isoechoic compared with the placenta. As the hematoma resolves, it will become hypoechoic within a week and sonolucent within 2 weeks. ^[29] Because of the changing character of the hematoma, misinterpretation of a hematoma as uterine myoma, succenturiate placental lobe, chorioangioma, or molar pregnancy has been reported.

The location and extent of the placental abruption identified on ultrasound has definite clinical significance. Retroplacental hematomas carry a worse prognosis for fetal survival than subchorionic hemorrhages. The size of the hemorrhage is also predictive of fetal survival. Large retroplacental hemorrhages (>60 ml) are associated with a 50 percent or greater fetal mortality, whereas similar sized subchorionic hemorrhages are associated with a 10 percent mortality. ^[30]

Nearly half of all placental abruptions will result in delivery at less than 37 weeks' gestation. ^[21] Gestational age at the time of presentation is an important prognostic factor. In patients presenting at less than 20 weeks, 82 percent can be expected to have a term delivery despite evidence of placental abruption. If the presentation occurs after 20 weeks' gestation, only 27 percent will deliver at term.

Nearly 80 percent of patients who eventually prove to have a placental abruption will present with vaginal bleeding. The remaining 20 percent of patients fail to exhibit external signs of bleeding. These patients have a concealed abruption and are commonly given the diagnosis of premature labor. Such cases must be watched very carefully. On some occasions, the abruption may progress despite successful tocolysis, and fetal death may result. Other classic signs of placental abruption include increased uterine tenderness and tone. These findings are uncommon (17 percent) unless the abruption is grade 2 or 3. ^[13]

Once the diagnosis of placental abruption has been made, precautions should be taken to deal with the possible life-threatening consequences for both mother and fetus. At least 4 units of blood should be available for maternal transfusions. A large-bore (16-gauge) intravenous line must be secured and the infusion of a crystalloid solution begun. Blood should be drawn for hemoglobin and hematocrit determinations and coagulation studies (fibrinogen, platelet count, fibrin degradation products, PT, PTT). A red-topped tube should also be obtained and used to perform a clot test. This test, a "poor man's" fibrinogen assay, will often give critical information before the laboratory can document a coagulation defect. If a clot does not form within 6 minutes or forms and lyses within 30 minutes, a coagulation defect is probably present and the fibrinogen level is less than 150 mg/dl. Continuous fetal monitoring should be used to record fetal heart rate and document uterine activity.

In the patient with a term fetus in whom the diagnosis of grade 1 abruption is made, close observation for signs of fetal or maternal compromise is essential. If the fetus is known to be mature, controlled delivery should be accomplished by induction of labor while the mother and fetus are in stable condition.

The occurrence of a grade 1 placental abruption with a preterm fetus presents greater challenge. Often, a vicious circle is established in which a small placental abruption stimulates uterine irritability, further separating the placenta until fetal compromise becomes evident. In patients remote from term, and with both mother and fetus clinically stable, inhibition of uterine contractions with tocolytic agents has been described. However, there are no randomized studies demonstrating improved fetal or maternal outcome using tocolysis in this condition. In three separate reports totaling 92 patients, no adverse maternal complications were reported and significant prolongation of gestation (>1 week) was accomplished in over 50 percent of patients.^[31]^[32] No adverse fetal complications were reported, with mortality being attributable only to extreme prematurity. In the largest and most recent uncontrolled study, Towers et al. used tocolysis in over 70 percent of 131 patients presenting with placental abruption. In patients stable enough to receive tocolysis, approximately one third of patients delivered within the first 48 hours, one third delivered within 7 days, and one third delivered greater than 1 week from initial presentation. Fetal death was related to prematurity and there were no cases of intrauterine fetal demise of a fetus alive on hospital admission. Tocolysis in this setting does not appear to be hazardous to the fetus, but its benefit may be limited to 48 hours, as is the case with tocolysis in preterm labor not associated with placental abruption. The maternal safety of tocolysis cannot be ascertained from the current studies, but physicians should keep in mind that placental abruption accounts for 6 percent of all maternal mortality. Unproven therapies in the face of high-risk maternal conditions should be approached with caution and should be administered after careful consideration and counseling of risks and benefits to the mother and fetus. Any attempt to arrest preterm labor in known or suspected abruption should be weighed against the likelihood for survival, morbidity if the infant were delivered, and the severity of the abruption.

When tocolysis is used, magnesium sulfate has less adverse cardiovascular side effects than α -sympathomimetics. A comparison of other tocolytic agents or a comparison with observation alone has never been evaluated by a clinical trial. In many cases of placental abruption, delivery will be the treatment of choice. During labor, careful attention must be paid to several maternal and fetal parameters. Because 60 percent of fetuses may exhibit signs of intrapartum fetal distress, continuous fetal heart rate monitoring is essential. In a similar manner, continuous monitoring of maternal volume status is important. An indwelling Foley catheter will permit accurate assessment of maternal urine output. Serial maternal hematocrit determinations should be made regularly at intervals of 2 to 3 hours. The goal of therapy should be to maintain a maternal urine output of 1 ml/min and a hematocrit of at least 30 percent. An updated flow sheet at the bedside permits the clinician to follow maternal vital signs, urine output, laboratory values, and critical clotting parameters.

Placental abruption frequently stimulates the clotting cascade, resulting in DIC. Intravascular fibrinogen is converted to fibrin by activation of the extrinsic clotting cascade. In the usual clinical setting, platelets and clotting factors V and VIII are also depleted. Serial measurements of plasma fibrinogen provide valuable information regarding the coagulation status of the patient and will help estimate the volume of blood loss that has occurred.

The normal maternal fibrinogen concentration in the third trimester is 450 mg/dl. In grade 1 abruptions, there is often no alteration in this value and no evidence of DIC. However, when the fibrinogen value drops below 300 mg/dl, significant coagulation abnormalities are usually present. Most women with significant falls in fibrinogen will require blood transfusion to maintain a normal circulating volume. If the presenting fibrinogen level is less than 150 mg/dl, most patients will have already lost 2,000 ml of blood. The signs and symptoms of such blood loss may not be obvious because, as noted earlier, the normal hypervolemia of pregnancy protects the mother from a volume loss that a nonpregnant individual could not tolerate. In the case of grade 3 placental abruption, the mean blood loss is 2,500 ml or more.^[34] In patients with grade 2 and grade 3 abruption, rapid crystalloid infusion of at least 1,000 ml pending the availability of whole blood should be done. Two to 3 ml of crystalloid should be given for each 1 ml of blood lost to maintain euolemia.

If urine output fails to reach 30 ml/h despite adequate volume replacement, consideration should be given to inserting a central venous pressure (CVP) catheter to determine the adequacy of intravascular volume. This catheter may be inserted through a site in the arm rather than the neck or subclavian area because of the severe coagulopathy that is often present. The absolute level of CVP is less important than the response of the CVP to volume infusion, as long as the CVP is less than 7 cm H₂O in response to the preceding 250-ml aliquot. If this response has been achieved but the urine output is still inadequate, consideration should be given to replacing the CVP catheter with a pulmonary artery catheter. This circumstance is uncommon unless there is intrinsic heart disease or severe preeclampsia or the patient has already suffered critical renal ischemia and is in acute renal failure.

Considerable controversy remains regarding the appropriate method of delivery in patients with placental abruption. Concern exists for the fetal outcome in such cases. A number of patients present with a live fetus,

only to have that fetus die undelivered while awaiting vaginal delivery.^[43]^[45] Retrospective reviews show a trend for increased fetal survival in patients who have undergone cesarean delivery once the maternal condition has been stabilized. However, none of these reports surveyed a period in which intrapartum fetal monitoring was routine. Currently, the use of continuous electronic fetal monitoring in this situation is associated with excellent fetal survival, and cesarean delivery can be reserved for cases with fetal distress or other traditional obstetric indications.^[43] The cesarean section rate associated with placental abruption is 50 to 75 percent, depending on the clinical aggressiveness of the physicians managing the patient.^[35]

The management of mothers with severe coagulopathy and/or fetal demise requires a thorough knowledge of the natural history of severe placental abruption. This information is best found in the classic paper of Pritchard and Brekken. Several important clinical observations first noted in 1967 are still important today. They observed that only 38 percent of patients with placental abruption severe enough to result in fetal demise will show DIC. They documented that patients destined to have severe placental abruption will show evidence of hypofibrinogenemia within 8 hours of initial symptoms. They did not observe any recovery from low fibrinogen levels in patients with severe hypofibrinogenemia without blood product transfusion. They also documented the time course for recovery from hypofibrinogenemia to be 10 mg/dl/h after delivery of the fetus and placenta.

Restoration of a normal blood volume and coagulation status is the sine qua non of treatment in these patients. It is important to remember that rather than exhibit shock out of proportion to the total blood loss, patients with severe placental abruption often appear resistant to the development of hypotension. They may have a blood pressure that appears quite normal. However, this is a false interpretation because 50 percent of patients will exhibit hypertension once adequate volume replacement has been accomplished. Adequate volume status in this situation is best achieved by ensuring a urine output of at least 30 ml/h.

After euolemia has been achieved and appropriate coagulation factors administered, attention can be given to effecting delivery. Some clinicians believe that if placental abruption has progressed to fetal death and severe coagulopathy, cesarean delivery will result in the quickest resolution of maternal problems. However, operating in the presence of a coagulopathy can result in prolonged operative times secondary to surgically uncontrollable bleeding. Pritchard and Brekken observed that bleeding from all cut surfaces at the time of cesarean delivery occurred with fibrinogen levels of less than 150 mg/dl. Hemorrhage after vaginal delivery was not correlated with fibrinogen levels unless there were extensive vaginal lacerations or uterine atony. In their study, Pritchard and Brekken did not administer coagulation products unless they were performing laparotomy or there were extensive vaginal lacerations. In current obstetric practice, administration of coagulation factor replacement along with PRBCs is the treatment of choice in patients with DIC. Even in the face of a severe coagulopathy, induction to delivery times exceeding 18 hours may result in equal or better maternal outcome as long as maternal volume status and coagulation status can be maintained.^[44]

As soon as adequate volume status is accomplished and blood products are available, induction of labor should be initiated. This can usually be accomplished with oxytocin. Many patients are already experiencing some uterine activity, oftentimes hypertonic in nature. Pritchard and Brekken noted that frequently there is generalized increased uterine tone without rhythmic uterine contractions being clinically detectable. It is important to judge the progress of labor in this instance by serial cervical exams with particular attention being given to cervical effacement. In patients with severe placental abruption, rapid cervical dilatation usually occurs only after complete effacement. Care must be taken not to prematurely abandon a vaginal trial because of the lack of early cervical dilatation.

Contrary to popular belief, the uterus does not need to be evacuated before coagulation status can be restored. Administering blood and blood products and delaying attempts at vaginal delivery for a few hours until hematologic parameters have improved is associated with good maternal outcome. There are now two reported cases of severe placental abruption with maternal coagulopathy in the second trimester in which blood and blood product administration completely reversed the syndrome, and live fetuses were subsequently delivered.^[36]^[37]

When cesarean delivery is necessary, extravasation of blood into the uterine muscle to produce red to purple discoloration of the serosal surface will be found in 8 percent of patients. This finding, known as a Couvelaire uterus, has been feared to result in a high incidence of uterine hemorrhage secondary to atony. However,

atony is the exception rather than the rule, and most patients with a Couvelaire uterus demonstrate an appropriate response to the infusion of oxytocin. Hysterectomy should be reserved for cases of atony and hemorrhage unresponsive to conventional uterotonics.

Neonatal Outcome

Increased perinatal mortality has been uniformly associated with placental abruption, with some groups reporting as high as 25 to 30 percent combined fetal and neonatal deaths.^[38], ^[39] Recent studies have shown a greater risk for adverse long-term neurobehavioral outcome

516

in infants delivered after placental abruption.^[40] In a case-control study of low-birth-weight infants, 40 infants born after placental abruption were compared with 80 infants matched for gestational age at delivery. There was a significant association between abruption and abnormal neonatal outcome (death or cerebral palsy). The chance of a completely normal neonatal outcome tended to decrease in relationship to the severity of the abruption, but small numbers of patients in each group limited the statistical significance of this finding. The most significant obstetric finding in this group was the high incidence of abnormal fetal heart rate tracings (45 percent) and emergency cesarean delivery (53 percent) compared with the control group (10 percent and 10 percent, respectively).

Placenta Previa

Placenta previa is defined as the implantation of the placenta over the cervical os. There are three recognized variations of placenta previa: total, partial, and marginal (Fig. 17-4). In total placenta previa, the cervical os is completely covered by the placenta. This type presents the most serious maternal risk, as it is associated with greater blood loss than either marginal or partial placenta previa. The frequency of total placenta previa has been reported to be as low as 20 percent^[41] and as high as 43 percent.^[42] Partial placenta previa is defined as the partial occlusion of the cervical os by the placenta and occurs in 31 percent of diagnosed cases. A marginal placenta previa is characterized by the encroachment of the placenta to the margin of the cervical os. It does not cover the os. The differentiation of the latter two degrees of placenta previa is dependent on the dilatation of the cervix and the method of diagnosis (ultrasound or direct examination).

A leading cause of third-trimester hemorrhage, placenta

Figure 17-4 Three variations of placenta previa.

previa presents classically as painless bleeding. Bleeding is thought to occur in association with the development of the lower uterine segment in the third trimester. Placental attachment is disrupted as this area gradually thins in preparation for the onset of labor. When this occurs, bleeding occurs at the implantation site, as the uterus is unable to contract adequately and stop the flow of blood from the open vessels.

The incidence of placenta previa is stated to be 1 in 200 live births.^[42], ^[43] Significant epidemiologic risk factors are maternal age above 35 years (rate ratio, 4.7) and black or other minority races (rate ratio, 1.3). Whether the increased risk for older mothers is related to parity or to an independent risk factor is still uncertain. The most important obstetric risk factor in the development of placenta previa is previous cesarean delivery. The risk for placenta previa occurring in the pregnancy following a cesarean delivery has been reported to be between 1 and 4 percent.^[41], ^[44] ^[45] ^[46] ^[47] There is a linear increase in placenta previa risk with the number of prior cesarean deliveries. In patients with four or more cesarean deliveries, the risk of placenta previa approaches 10 percent.^[44]

The timing of the diagnosis of placenta previa has undergone significant change in the last decade. Whereas third-trimester bleeding was a common presentation for placenta previa, most cases of placenta previa are now detected antenatally prior to the onset of significant bleeding. The common practice of second-trimester ultrasound for detection of fetal anomalies has led to this change. However, because most cases of placenta previa diagnosed in the second trimester will resolve, management of placenta previa diagnosed in the second trimester will differ from the same diagnosis in the third trimester. At 17 weeks' gestation, evidence of placental tissue covering the cervical os will be found in 5 to 15 percent of all patients.^[42] More than 90

517

percent of these patients will have a normal ultrasound by 37 weeks' gestation.^[48] This phenomenon has been termed *placental migration*. It is unlikely that the placenta actually separates and reattaches throughout the second and third trimesters. The changes in architecture secondary to differential growth of the lower uterine segment during the second and third trimesters probably account for this observation. Location of the placenta with reference to the cervix will influence the likelihood of resolution of placenta previa with advancing gestation. Total placenta previa diagnosed in the second trimester will persist into the third trimester in 26 percent of cases, while marginal or partial placenta previa will persist in only 2.5 percent of cases.^[49]

In patients diagnosed prior to 24 weeks' gestation, a repeat ultrasound should be scheduled between 24 and 28 weeks' gestation to confirm the resolution of the radiographic diagnosis of placenta previa. However, if patients have vaginal bleeding during this time period, they should be managed as presumed cases of placenta previa. Placenta previa should be suspected in all patients presenting with bleeding after 24 weeks' gestation.

Changes in the antenatal course of placenta previa were documented by Wing et al. in their prospective randomized study.^[50] Of 139 patients admitted with placenta previa diagnosed after 24 weeks, 23 percent experienced no bleeding episodes by 36 weeks. An additional 12 percent had an initial bleeding episode after 35 weeks and were delivered shortly after delivery. Therefore, at least one third of patients with placenta previa persisting after 24 weeks will suffer no significant bleeding episodes before 35 weeks. A small percentage of patients (5 percent) will present with bleeding so severe as to necessitate immediate delivery.

Patients with third-trimester bleeding should be treated in a manner similar to that outlined in the section on abruptio placenta (e.g., maternal stabilization, fetal monitoring). However, blood studies do not need to be as extensive as those ordered for patients with placental abruption. DIC is rare in cases of placenta previa and tests for maternal coagulation abnormalities do not need to be routinely performed. Once fetal and maternal status have been stabilized, ultrasound evaluation should be performed to establish or reconfirm the diagnosis. (Fig. 17-5).

Once the diagnosis of placenta previa is made, management decisions depend on the gestational age, amount of bleeding, fetal condition, and presentation. In the patient who is unequivocally at 37 weeks' gestation with evidence of uterine activity or with persistent bleeding, delivery is the treatment of choice. In previous years, a double setup examination was the initial step in this process. With the early diagnosis of placenta previa and rapid and reliable ultrasound availability and interpretation, this technique is now unnecessary in the majority of cases.

In uncommon patients, vaginal delivery may still be considered. Patients with marginal or partial placenta previa who present in labor with minimal bleeding are ideal candidates. It can also be considered for patients with previable gestations or intrauterine fetal demise. Appropriately conducted labor in these selected instances can be safe for both mother and fetus.^[51]

When double setup examination is elected, it should be done in an operating room with full preparation made to perform emergency cesarean delivery should excessive vaginal bleeding follow the examination. In performing a double setup examination, the patient should be prepared and draped for cesarean delivery. The

Figure 17-5 This ultrasound examination at 34 weeks' gestation in a patient with painless vaginal bleeding revealed placenta previa (P) covering the cervical os (Cx). The maternal

anesthesiologist should be present and the operating room team ready. The patient should first undergo a careful speculum examination, which may reveal placental tissue in the cervical os. If the diagnosis of placenta previa cannot be made with a speculum examination, the obstetrician should next examine the vaginal fornices. Fullness in the fornices suggests the presence of the placenta extending down toward the cervix. Finally, examining fingers should be carefully introduced into the cervical os to detect the placenta.

For the patient who is remote from term (24 to 36 weeks' gestation), expectant management is the treatment of choice. The essence of this approach is maintenance of the fetus in a healthy intrauterine environment without jeopardizing maternal condition. Maternal blood loss should be replaced in order to maintain the maternal hematocrit between 30 and 35 percent. This RBC volume will provide a margin of safety in the event of a large hemorrhage. Even an initial blood loss in excess of 500 ml can be expectantly managed with adequate volume replacement.

Although obstetricians are most concerned about maternal hemorrhage, they must remember that fetal blood can also be lost during the process of placental separation. Rh-immune globulin should be given to all at-risk patients with third-trimester bleeding who are Rh-negative and unsensitized. A Kleihauer-Betke preparation of maternal blood should also be performed in all Rh-negative women. This test will detect the occasional patient with a fetomaternal hemorrhage of greater than 30 ml. Thirty-five percent of infants whose mothers require antepartum transfusion will themselves be anemic and require transfusion when delivered. [42]

Twenty percent of patients with placenta previa will show evidence of uterine contractions. Because a vaginal examination to document cervical dilatation is absolutely contraindicated, it is difficult to make a firm diagnosis of preterm labor. Although no controlled studies are available to show the efficacy of tocolytic therapy in such cases, some studies document that it can be safely attempted. [42], [52] The choice of agents in this situation is controversial. If -mimetics are used in the presence of maternal hypovolemia, serious maternal hypotension can result (Fig. 17-6). In addition, the use of -mimetics will produce maternal tachycardia, making the evaluation of maternal volume status more difficult. Nonetheless some authors have reported the use of these agents for tocolysis in patients with placenta previa without excessive complications. [53], [54], [55]

Because of the reduced risk of cardiovascular complications, magnesium sulfate has become the agent of choice for the treatment of patients in preterm labor with placenta previa at many institutions. Infusion of a 6-g loading dose followed by 3 g/h or more are often necessary to control uterine irritability because of the increased maternal glomerular filtration rate. Once the patient has been stabilized on magnesium sulfate, the use of oral tocolytics has been advocated by some, although no conclusive studies demonstrate improved outcome with oral tocolytic therapy for any indication. Patients may occasionally require more than 1 week of continuous intravenous tocolytic therapy. Such treatment is considered justified since, before 33 weeks' gestation, each day that the fetus remains in utero reduces its stay in the neonatal intensive care nursery by 2 days. [56] The use of antenatal corticosteroids to accelerate fetal pulmonary maturity is effective in reducing the incidence of neonatal respiratory distress syndrome, intracranial

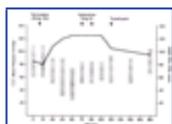

Figure 17-6 Blood pressure and heart rate response to terbutaline administration in a bleeding patient with placenta previa. Hypotension, which developed acutely, was somewhat resistant to ephedrine and crystalloid administration.

hemorrhage, and neonatal death. [57], [58] Given a high incidence of respiratory distress syndrome in the infants of mothers requiring delivery after failed expectant management (24 to 41 percent), [42], [59] antenatal steroids should be given in patients presenting between 25 and 33 weeks. Data on safety of repeated weekly doses of steroids are concerning enough that this practice is currently not recommended outside of investigational protocols.

If the mother responds to conservative management, she should be treated with bed rest, preferably in the hospital setting. Blood should always be available for maternal transfusion in the event of sudden hemorrhage. The length of maternal hospitalization in this instance is presently undergoing reevaluation. An initial study suggested that continued hospitalization until delivery was more cost effective than rest at home when total expenses for both mother and baby are calculated. [59] An additional reason for continued hospitalization was the observation that one half of all patients requiring early delivery because of failed expectant management do so because of excessive bleeding with or without uterine contractions.

Two recent studies have challenged this management plan. [60], [61] In those retrospective studies, no significant advantage for either cost or morbidity was found with conservative hospital management until delivery. [59] Wing et al. showed that between 40 and 50 percent of patients presenting with bleeding placenta previa will be candidates for conservative management. Conservative management consisted of hydration, indicated blood transfusion, and magnesium sulfate tocolysis when uterine activity was apparent when the amniotic membranes were intact and the fetus exhibited a reactive nonstress test. After a 72 hour period of observed stability, patients with adequate resources (24-hour phone contact and 24-hour ability to rapidly return to the hospital) are candidates for home treatment. Treatment at home should include bed rest with bathroom privileges. In 15 percent of cases, the placenta previa will resolve radiographically in an average of 4 weeks. Treated conservatively, nearly 30 percent of patients with persistent placenta previa will progress to term without further bleeding. Approximately 70 percent of patients so treated can be expected to have at least one further episode of bleeding. However, only 10 percent will have a third episode. In patients with more than two episodes of significant bleeding, hospital treatment until delivery appears to be the safest strategy.

Approximately 25 to 30 percent of patients can be expected to complete 36 weeks' gestation without labor or repetitive bleeding forcing earlier delivery. In these patients, amniocentesis should be performed and, if the analysis of amniotic fluid documents pulmonary maturity, a cesarean delivery planned.

When encountering a patient with placenta previa, the possibility of a placenta accreta or one of its variations, placenta percreta or placenta increta, should be considered (Fig. 17-7). [62] In this condition, the placenta forms an abnormally firm attachment to the uterine wall. There is absence of the decidual basalis and incomplete development of the fibrinoid layer. The placenta can be attached directly to the myometrium (accreta), invade the myometrium (increta), or penetrate the myometrium (percreta). Antenatal diagnosis with ultrasound has been demonstrated by some authors. [63], [64] However, in the largest reported series a false-positive diagnosis was reported in 20 percent of patients. Ultrasound findings most predictive of placenta accreta are thinning and distortion of the uterine serosa-bladder interface. Color Doppler imaging can also aid the detection of bladder invasion as illustrated in Figure 17-8.

Prior cesarean delivery and other uterine surgery are the factors most often associated with placenta accreta. In patients without prior uterine surgery who have placenta previa, the incidence of placenta accreta will be 4 percent. In patients with previous cesarean delivery who have placenta previa, the incidence of placenta accreta is approximately 10 to 35 percent. [44], [47] In patients with multiple cesarean deliveries and placenta previa the risk of accreta is 60 to 65 percent. At least two thirds of the patients with placenta previa/placenta accreta will require cesarean hysterectomy. [42], [65], [66] However, in cases where uterine preservation is highly desired and no bladder invasion has occurred, bleeding after placental removal has been successfully controlled with a variety of surgical techniques. Packing of the lower uterine segment with subsequent removal of the pack through the vagina within 24 hours [66] has been successful. Interrupted circular suture of the lower uterine segment on the serosal surface of the uterus has

Figure 17-7 Uteroplacental relationships found in abnormal placentation.

also been reported to be successful.^[67] Predelivery placement of catheters for angiographic embolization of pelvic vessels is another technique recently described.^[68],^[69]

Complete placenta accreta suspected or confirmed before attempted placental removal may permit other treatment options. Bleeding may be minimal unless the placenta has partially separated. If no cleavage plane is identified and a placenta accreta is suspected, one should first make preparations for the possibility of major postpartum blood loss. At least 4 units of blood should be on hand and an anesthesiologist present in the delivery room. If vaginal delivery has occurred, the patient should be in a suite in which a laparotomy can be performed, and surgical instruments for hysterectomy should be sterilized and ready. Whenever possible, the obstetrician should discuss the likely diagnosis with the patient and review possible treatment options.

If uterine preservation is not important, or if maternal blood loss is excessive, hysterectomy offers the best chance for survival and will minimize morbidity.^[70] If uterine preservation is important, four treatment options are available:

1. *Placental removal and oversewing the uterine defects.* After removing as much of the placenta as possible, the bleeding defects are oversewed and the patient treated with oxytocics and antibiotics (this option is probably most useful when there is significant bleeding from a partially separated placenta with only a focal accreta).
2. *Localized resection and uterine repair.*
3. *Curettage of the uterine cavity, and leaving the placenta in situ.* For the patient who wishes to maximize her chances for uterine preservation and who is not actively bleeding, the placenta may be left in situ. The umbilical cord should be ligated and cut as close to its base as possible. The patient should then be treated with antibiotics. This approach has been successful when bleeding has not necessitated more aggressive surgical procedures.^[71] Some authors have advocated treatment with methotrexate in this instance, but there is presently no consensus on whether this therapy is any more effective than observation.
4. In rare cases, placenta accreta invades the maternal bladder. In this instance, it is probably best to treat in a manner similar to abdominal pregnancy and avoid placental removal. However, this may not obviate the need for eventual hysterectomy and partial cystectomy.^[72],^[73]

Third-Trimester Fetal Bleeding

A rare but important cause of third-trimester bleeding is that associated with rupture of a fetal vessel. Vasa previa is a condition in which the fetal vessels traverse the membranes in the lower uterine segment and cover the cervical os and occurs in approximately 1 in 1,000 to 1 in 5,000 pregnancies. With a velamentous insertion of the umbilical cord, its vessels often run between the chorion and amnion without the protection of Wharton's jelly. In other instances, a succenturiate placenta will have vascular communications between placental cotyledons. The classic presentation is spontaneous rupture of membranes, laceration of a fetal vessel, and rapid fetal death.

Ultrasound imaging now makes it possible to diagnose this condition in some instances, prior to the onset of fetal bleeding. The diagnosis of a succenturiate placental cotyledon or the discovery of an anomaly of the umbilical cord insertion should prompt the use of color Doppler examination of the membranes over the cervix. Both transabdominal and transcervical imaging have been used for this purpose. When umbilical arterial

waveforms are documented at the same rate as the fetal heart rate, diagnosis is confirmed. When this occurs, careful observation and timing of elective cesarean section upon documentation of fetal pulmonary maturity should be considered.

When the fetal vessel ruptures, often acute vaginal bleeding is associated with an abrupt change in the fetal heart rate. The fetal heart rate pattern often shows an initial fetal tachycardia followed by bradycardia with intermittent accelerations. Short-term variability is frequently maintained.

One must have a high index of suspicion to make the correct diagnosis. In most instances, one must make the diagnosis rapidly and institute definitive therapy and delivery to optimize fetal outcome. The fetal mortality in this condition has been reported to be greater than 50 percent.^[74]^[75] [Figure 17-9a](#) and [Figure 17-9b](#) illustrate the fetal heart rate tracing of a successfully treated case of spontaneous rupture of a velamentous insertion of the fetal vessel.

On occasion when the fetal heart rate is not abnormal and the source of the bleeding is in question, an examination of the blood passed vaginally can be performed. Adult oxyhemoglobin is less resistant to alkali than fetal oxyhemoglobin. There are three tests for fetal hemoglobin using alkaline denaturation: Apt, Ogita, and Loendersloot.^[76] All take from 5 to 10 minutes to perform. They all have good sensitivity for detection of pure fetal blood. However, when the blood is mixed with amniotic fluid, the Apt and the Loendersloot tests were not able to identify fetal blood at concentrations less than 60 percent. The Ogita test was able to detect fetal blood at levels of only 20 percent and requires less sample than the other tests.

To perform the Ogita test, one drop of sample is added to five drops of alkali (0.1 mole potassium hydroxide) and shaken for 2 minutes. Ten drops of precipitation solution (400 ml of 50 percent saturated ammonium sulfate and 1 ml of 10-mole hydrochloric acid) are added. The mixture is dropped on a filter paper with a capillary tube to make a 20-mm ring. Fetal hemoglobin will form a colored ring at the periphery of the deposited sample within 30 seconds.

In most cases, there is rarely time to perform this test. In the acute situation, the diagnosis is based on clinical findings unless there has been prior ultrasound suspicion of vasa previa.

POSTPARTUM HEMORRHAGE

Acute blood loss is the most common cause of hypotension in obstetrics. Hemorrhage usually occurs immediately preceding or after delivery of the placenta. Excessive blood loss most commonly results when the uterus fails to contract after the delivery of its contents. Effective hemostasis after separation of the placenta is dependent on contraction of the myometrium to compress severed vessels. Failure of the uterus to contract can usually be attributed to myometrial dysfunction and retained placental fragments. Factors predisposing to myometrial dysfunction include overdistention of the uterus as in multiple pregnancy, fetal macrosomia, hydramnios, oxytocin-stimulated labor, uterine relaxants, and amnionitis. At term, approximately 600 ml/min of blood flows through the placental site. However, blood loss from severe uterine atony can easily exceed this rate because blood is lost from the entire intrauterine surface when the uterus fails to contract.

Prevention

Reduction of excessive blood loss after vaginal birth or cesarean delivery can be aided by recognizing high-risk factors for postpartum hemorrhage (Table 17-3) and by applying proven methods to limit bleeding. Some techniques with demonstrated effectiveness have still not found their way into general use by many obstetric practitioners, including active management of the third stage of labor and spontaneous delivery of the placenta at time of cesarean delivery. Dilute solutions of oxytocin in addition to gentle cord traction reduces cesarean delivery associated blood loss by 31 percent compared with manual removal of the placenta.^[77] Similarly, umbilical cord clamping within 30 seconds of delivery and gentle cord traction followed by administration of intramuscular or dilute solutions of intravenous oxytocin before delivery of the placenta reduce postpartum blood loss and postpartum transfusion requirements.^[78] Administration of oxytocin before delivery of the placenta is associated with a reduction in the length of the third stage of labor (mean 5 minutes) and a low incidence of manual removal of the placenta (2 percent) compared with physiologic management of the third stage of labor (15 minutes and 2.5 percent, respectively).^[79] When the placenta is retained for 30 minutes

TABLE 17-3 -- RISK FACTORS FOR OBSTETRIC HEMORRHAGE OF > 1,000 ml

Factor	Risk Increase
Placental abruption	12.6
Placenta previa	13.1
Multiple pregnancy	4.5
Obesity	1.6
Retained placenta	5.2
Induced labor	2.2
Episiotomy	2.1

Figure 17-9a Fetal heart rate tracing after rupture of a velamentous insertion of the cord. *A*, Normal fetal heart rate tracing in early labor at term showing accelerations but no other changes. *B*, Just before panel 118, bright red vaginal bleeding is noted. Shortly thereafter, the fetal heart rate is noted to be 80 to 90 beats/min.

or longer, randomized studies have shown that injection of the umbilical cord with either saline or oxytocin has no significant benefit in effecting spontaneous delivery of the placenta. In the absence of significant maternal hemorrhage, an additional 30 minutes of expectant management can be allowed because half of the retained placentas will deliver spontaneously during this time, avoiding the need for manual removal, anesthesia, and excessive blood loss.

Spontaneous delivery of the placenta after administration of oxytocin is also associated with reduced blood loss during cesarean section. Randomized trials have shown that both the risk of endometritis and the mean blood loss are significantly lower when the placenta is delivered spontaneously. Blood loss was reduced by 30 percent and postpartum endometritis reduced sevenfold when compared to manual removal of the placenta.^[79]

Upon encountering postpartum hemorrhage, manual digital exploration of the uterus should be quickly accomplished to rule out the possibility of retained placental fragments (Fig. 17-10). If retained tissue is not detected, manual massage of the uterus should be started (Fig. 17-11). Simultaneously, pharmacologic methods should be employed to control uterine bleeding. Initial therapy includes the administration of a dilute solution of oxytocin, usually 10 to 20 units of oxytocin in 1,000 ml of physiologic saline solution. The solution can be administered in rates as high as 500 ml in 10 minutes without cardiovascular complications. However, an intravenous bolus injection of as little as 5 units of oxytocin may be associated with maternal hypotension,

523

Figure 17-9b *C*, In the delivery room, the fetal heart rate tracing shows the characteristic bradycardia-tachycardia heart rate response as the fetus attempts to compensate for acute blood loss. An emergency cesarean delivery was performed, and the infant was anemic. After rapid volume infusion and resuscitation, the infant survived and is developing normally. *D*, Examination of the placenta showed a velamentous insertion of the umbilical cord and a lacerated fetal vessel as a result of spontaneous rupture of the membranes. In this case, the unprotected fetal vessels passed over the cervical os, a vasa previa.

further stressing an already compromised maternal cardiovascular system.

When oxytocin fails to produce adequate uterine contraction, most clinicians now administer synthetic 15-methyl-F₂-prostaglandin (Prostin, Upjohn). Although ergovine (0.2 mg intramuscularly) has been a standard second-line drug for many years, the efficacy and safety of prostaglandin medications in this instance have

obviated the need to use ergonovine in most instances. Initial studies with prostaglandin medications for postpartum hemorrhage were performed with the naturally occurring F_2 -prostaglandin compound, which required direct intrauterine injection. The total dose used was 1 to 2 mg diluted in 10 to 20 ml of saline. ^[80] Subsequently, clinical trials of the synthetic 15-methyl- F_2 -prostaglandin produced promising results. ^[82] This

524

Figure 17-10 Digital exploration of the uterus and removal of retained membranes. A sponge has been wrapped around the examiner's fingers.

compound should be given in 0.25-mg doses in the deltoid muscle every 1 to 2 hours. As many as five doses may be administered without adverse effect. Experience at the University of Washington would support these observations, as the routine availability of this agent in the delivery unit has arrested a number of otherwise uncontrollable hemorrhages.

A recent uncontrolled report of a newer agent, misoprostol, for the control of refractory hemorrhage may represent a promising new medical option. O'Brien et al. used 1,000 g of misoprostol per rectum in patients with refractory uterine bleeding prior to the administration of 15-methyl- F_2 -prostaglandin. ^[81] Control of uterine bleeding was reported in all cases and no further uterotonic medications were necessary. Further studies are necessary to determine the exact place and safety of misoprostol during postpartum hemorrhage from uterine atony.

When pharmacologic methods fail to control hemorrhage from atony, surgical measures should be undertaken to arrest the bleeding before it becomes life threatening. However, before a laparotomy, a careful inspection of the vagina and cervix should be made to confirm that the uterus is the source of the bleeding.

If the uterus is found to be contracted appropriately

Figure 17-11 Manual compression and massage of the uterus to control bleeding from uterine atony.

and no placental fragments are retained within the uterus, a laceration of maternal soft tissues is the likely cause of continued vaginal bleeding. Careful inspection of the cervix and vagina will often indicate the source of the bleeding. [Figure 17-12](#) [Figure 17-13](#) [Figure 17-14](#) [Figure 17-15](#) illustrate second-, third-, and fourth-degree lacerations of the perineum and techniques for their repair. Adequate exposure for the repair of such lacerations is critical and, if needed, assistance should be summoned to aid in retraction.

Figure 17-12 Repair of an anterior periurethral laceration. Either running or interrupted sutures can be used. An indwelling catheter is placed before the repair is made.

525

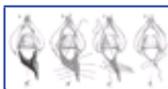

Figure 17-13 Repair of a second-degree laceration. A first-degree laceration involves the fourchet, the perineal skin, and the vaginal mucous membrane. A second-degree laceration also includes the muscles of the perineal body. The rectal sphincter remains intact.

In cervical laceration, it is important to secure the base of the laceration, which is often a major source of bleeding. However, this area is frequently the most difficult to suture. Valuable time can be lost trying to expose the angle of such a laceration. A helpful technique to use in these cases, especially when help is limited or slow in responding, is to start to suture the laceration at its proximal end, using the suture for traction to expose the more distal portion of the cervix until the apex is in view ([Fig. 17-16](#)). This technique has the added advantage of arresting significant bleeding from the edges of laceration.

When uterine bleeding is not responsive to pharmacologic methods and no vaginal or cervical lacerations are present, surgical exploration may be necessary. Laceration of uterine vessels during the birth process will

Figure 17-14 Repair of the sphincter after a third-degree laceration. A third-degree laceration extends not only through the skin, mucous membrane, and perineal body, but includes the anal sphincter. Interrupted figure-of-eight sutures should be placed in the capsule of the sphincter muscle.

526

Figure 17-15 Repair of a fourth-degree laceration. This laceration extends through the rectal mucosa. *A*, The extent of this laceration is shown, with a segment of the rectum exposed. *B*, Approximation of the rectal submucosa. This is the most commonly recommended method for repair. *C*, Alternative method of approximating the rectal mucosa in which the knots are actually buried inside the rectal lumen. *D*, After closure of the rectal submucosa, an additional layer of running sutures may be placed. The rectal sphincter is then repaired.

occasionally be found. On occasion, bleeding will be similar to that from uterine atony, but the uterus will appear contracted. On other occasions, substantial episodic hemorrhage followed by periods of relatively little blood flow will occur. Hayashi et al. have recently documented 3- to 8 cm-longitudinal lacerations of the inner myometrium as a cause of bleeding refractory to the usual techniques. ^[83] Hysterectomy specimens have demonstrated longitudinal laceration of the lower uterine segment myometrium to depths of 3 to 10 mm. They have termed this condition inner myometrial laceration. It appears to be an incomplete type of uterine rupture. It is often difficult to diagnose this condition before the hysterectomy is performed. When the uterine arteries and the cardinal ligaments are clamped and cut in this condition, the uterine cavity will often be entered because of the attenuated nature of the myometrium in these areas.

If hemorrhage is secondary to atony, vascular ligation will often be necessary to control bleeding. Hypogastric artery ligation, a technique recommended for many decades to control postpartum hemorrhage, has fallen out of favor because of the prolonged operating time, technical difficulties associated with its performance, and an inconsistent clinical response. Instead, a stepwise progression of uterine vessel ligation should be rapidly accomplished. Ligation of the ascending branch of the uterine arteries should be attempted as a first step if hemorrhage is unresponsive to oxytocin or prostaglandin ^[84], ^[85] (Fig. 17-17A) and (Fig. 17-17B). The uterine artery should be located at the border between the upper and lower uterine segment and suture ligated with 0 or No. 1 chromic suture. The suture should be placed 2 cm medial to the uterine artery and the needle driven from the anterior surface of the uterus posteriorly and tied. Because the suture is placed high in the lower uterine segment, the ureter is not in jeopardy and the bladder usually does not need to be mobilized. In approximately 10 to 15 percent of cases of atony, unilateral ligation of the uterine artery is sufficient to control hemorrhage. Bilateral ligation will control an additional 75 percent. ^[85]

If bleeding continues, attention should next be paid to interrupting the blood flow to the uterus from the infundibulopelvic ligament (Fig. 17-17C). There are a number of techniques to accomplish this. The easiest involves ligation of the anastomosis of the ovarian and uterine artery, high on the fundus, just below the uterovarian ligament. A large suture on an atraumatic needle can be passed from the uterus, around the vessel, and tied. If bilateral uterovarian vessel ligation does not stop the bleeding, temporary occlusion of the infundibulopelvic

527

Figure 17-16 Repair of a cervical laceration, which begins at the proximal part of the laceration, using traction on the previous sutures to aid in exposing the distal portion of the defect.

ligament vessels may be attempted. This can be accomplished with digital pressure or with rubber-sleeved clamps. It may be an especially useful technique if the patient is of low parity and future childbearing is of great importance. If this appears to control hemorrhage, ligation of the infundibulopelvic ligament can be performed by passing an absorbable suture from anterior to posterior through the avascular area inferior to and including the ovarian vessels. Although the ovarian blood supply may be decreased, successful pregnancy has been reported after all major pelvic vessels were ligated to arrest postpartum hemorrhage. ^[72], ^[73]

There are two recently described surgical techniques for the control of hemorrhage secondary to uterine atony: hemostatic suturing and the B-Lynch surgical technique. ^[87], ^[88] Both of these techniques use surgical tamponade of the uterus to control bleeding. Neither has been subjected to randomized trials, but reports of cessation of hemorrhage secondary to atony is reported to be successful in clinical circumstances in which usual medical and surgical treatments have failed to control hemorrhage. These techniques may be considered prior to hysterectomy in women of low parity in whom preservation of childbearing is desired.

A prerequisite to successful use of the B-Lynch or brace suture technique is the control of uterine bleeding with manual compression of the uterus. Assessment of bleeding should be done by direct visualization through the vagina by placing the patient in a supine frogleg position during the operation. It is important to confirm cessation of bleeding with manual compression both before performing the B-Lynch procedure and after the procedure has been performed. Technical details of the procedure can be found in the original article.

Another hemostatic suturing technique recently described involves placing multiple 2- to 3-cm² sutures in the myometrium using a through-and-through suture of No. 1 chromic. With this procedure, segments of the anterior and posterior uterine wall are sewn together and tied tightly, compressing the intervening myometrium. This technique can be used in the upper portion of the uterus to control bleeding from atony or in the lower uterine segment to control bleeding from lowlying placental implantation.

Selective Arterial Embolization

Arterial embolization is currently an increasingly common therapeutic option for various types of obstetric hemorrhage. The radiographic approach to obstetric hemorrhage has a number of advantages over the surgical approach: anesthetic and surgical risks are reduced, specific vessels can be identified and selectively occluded, and hysterectomy can be avoided. In addition to embolization, transient transcatheter uterine artery balloon occlusion can aid in the management of surgical cases where extreme hemorrhage has been a common occurrence. The obstetric conditions in which arterial embolization have been successfully employed include postpartum bleeding from atony, bleeding from pelvic vessel laceration, postcesarean hemorrhage, and bleeding associated with extrauterine pregnancy. In the absence of coagulopathy, the success rate of arterial embolization has been reported to be greater than 90 percent.

Procedure-specific complications occur in less than 10 percent of cases. Postprocedure fever and pelvic infection are most commonly reported. Much less common, but potentially more serious, is reflux of embolic material to nontargeted pelvic structures. Currently, there are no procedure-related deaths described in obstetric patients.

In order to maximize the full potential of this technique, a close working relationship between the obstetric team and the interventional radiologists must exist. Preoperative identification of patients at high risk for life-threatening hemorrhage is the responsibility of the obstetrician. Such conditions will include, but not be limited to, placenta accreta, cervical pregnancy, and abdominal pregnancy. Prophylactic catheterization of the anterior division of the internal iliac arteries can be

528

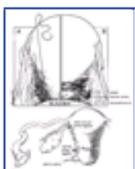

Figure 17-17 Ligation of the uterine artery. A and B, This anterior view of the uterus demonstrates the placement of a suture around the ascending branch of the uterine artery and vein as described by O'Leary and O'Leary. Note that 2 to 3 cm of myometrium medial to the vessels has been included in the ligature. The vessels are not divided. C, View of sutured uterus: ligated uterine artery, and ligated utero-ovarian artery.

done in less than 10 minutes with fluoroscopy. However, radiation exposures of 2 rad/min should be expected. Whether this potential fetal risk is justified by the opportunity to avoid life-threatening hemorrhage is a decision that must be made in consultation with the patient. ^[90] ^[91] ^[92] ^[93] ^[94]

Pelvic Hematoma

Blood loss leading to cardiovascular instability is not always visible. In some instances, traumatic laceration of blood vessels may lead to the formation of a pelvic hematoma. Pelvic hematomas may be divided into three main types: vulvar, vaginal, or retroperitoneal.

Vulvar Hematoma

This type of hematoma results from laceration of vessels in the superficial fascia of either the anterior or posterior pelvic triangle. The usual physical signs are subacute volume loss and vulvar pain. The blood loss in this case is limited by Colle's fascia and the urogenital diaphragm. In the posterior area, the limitations are the anal fascia. Because of these fascial boundaries, the mass will extend to the skin and a visible hematoma will result (Fig. 17-18) and (Fig. 17-19).

Treatment in these cases requires the volume support outlined previously. Surgical management calls for wide linear incision of the mass through the skin and evacuation of blood and clots. As this condition is often the result of bleeding from small vessels, the lacerated vessel

529

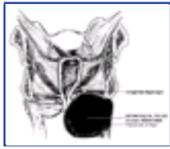

Figure 17-18 Vulvar hematoma, showing anatomic landmarks.

will not usually be identified. Once the clot has been evacuated, the dead space can be closed with sutures. The area should then be compressed by a large sterile dressing and pressure applied. Efforts to pack the cavity are usually futile and only serve to create further bleeding. An indwelling catheter should be placed in the bladder at the start of the surgical evacuation and left in place for 24 to 36 hours. Compression can be removed after 12 hours.

Vaginal Hematoma

Vaginal hematomas may result from trauma to maternal soft tissues during delivery. These hematomas are frequently associated with a forceps delivery but may occur spontaneously. They are less common than vulvar hematomas. In this instance, blood accumulates in the plane above the level of the pelvic diaphragm (Fig. 17-20). It is unusual for large amounts of blood to collect in this space. The most frequent complaint in such cases is severe rectal pressure. Examination will reveal a large mass protruding into the vagina.

Vaginal hematomas should be treated by incision of the vagina and evacuation. Figure 17-21 shows an ultrasound of a vaginal hematoma recognized 3 weeks postpartum. Even with delayed recognition of a vaginal hematoma, evacuation should be undertaken. The accumulated blood will take many weeks to reabsorb and the patient's discomfort will usually be intolerable for such a long period of time. As with vulvar hematomas, it is uncommon to find a single bleeding vessel as the source of bleeding. The incision need not be closed, as the edges of the vagina will fall back together after the clot has been removed. A vaginal pack should be inserted to tamponade the raw edges. The pack is then removed in 12 to 18 hours.

Figure 17-19 Photograph of vulvar hematoma before evacuation.

530

Figure 17-20 Vaginal hematoma showing anatomic landmarks.

Retroperitoneal Hematoma

Retroperitoneal hematomas are the least common of the pelvic hematomas but are the most dangerous to the mother. Symptoms from a retroperitoneal hematoma may not be impressive until the sudden onset of hypotension or shock. A retroperitoneal hematoma occurs after laceration of one of the vessels originating from the hypogastric artery (Fig. 17-22). Such lacerations may result from inadequate hemostasis of the uterine arteries at the time of cesarean delivery or after rupture of a low transverse cesarean delivery scar during

Figure 17-21 Abdominal ultrasound image of larger vaginal hematoma, approximately 3 weeks postpartum. B, bladder; U, uterus; H, hematoma.

a trial of labor. In these patients, blood may dissect up to the renal vasculature.

Treatment of this life-threatening condition involves surgical exploration and ligation of the hypogastric vessels on both the lacerated side and on the contralateral side if unilateral ligation does not arrest the bleeding. On occasion, it may be possible to open the hematomas and identify the bleeding vessel.

Umbrella Pack

The use of an umbrella pack to control bleeding after hysterectomy is a valuable technique in desperate situations (Fig. 17-23). This technique may be needed after cesarean hysterectomy complicated by persistent bleeding from the vaginal cuff. Such hemorrhage may be encountered after massive blood loss secondary to the washout of platelets or as a result of DIC. In either instance, it may be impossible to control the generalized oozing from the vaginal cuff except with pressure. The umbrella pack will often permit one to tamponade the bleeding surfaces until coagulation factors and platelets can be given and, in addition, enables the surgeon to close the abdomen without the fear of continued blood loss.

The pack itself should be a bag or sack of nonadhesive material. A small plastic bag serves the purpose very well. The bag can be inserted through the vagina or at laparotomy. When abdominal placement is possible, the bag should be filled with 2-in gauze packing through the vagina to ensure an orderly packing that will facilitate removal at a future time. The bag should be filled with enough gauze to occlude the open vaginal

531

Figure 17-22 Retroperitoneal hematoma as a result of laceration of one of the branches of the hypogastric artery. Evacuation of the hematoma is illustrated in the accompanying panel.

Figure 17-23 Abdominal placement of an umbrella pack to control hemorrhage from the vaginal cuff. A, Vaginal route for insertion of gauze packing. The pack is pulled downward over the vaginal cuff (B) and is secured (C).

532

cuff completely and present enough resistance to prevent expulsion when a weight is attached to the end of the pack.

Once the pack is in true pelvis and the gauze has been inserted, a 1,000-ml intravenous bag should be tied to the umbrella pack and traction applied. Traction should be maintained for 24 hours. After 24 hours, the traction may be relieved, but the bag should be left in place for an additional 12 hours. After 36 hours, the gauze packing should be removed by pulling on the tail that has been left protruding through the vagina. After the gauze has been evacuated, the bag should be removed.

Two major complications of this procedure include infection and urinary obstruction. The latter can be obviated by the use of an indwelling Foley catheter. The danger of infection is an ever-present one but is usually of secondary importance in the acute events surrounding such massive bleeding. Prophylactic antibiotics should be used in these cases. Since the publication of this technique in the first edition of this textbook, three cases of successful use of the umbrella pack in obstetric patients have been published.^[95], ^[96]

Inversion of the Uterus

Occasionally, the third stage of labor is complicated by partial delivery of the placenta followed by rapid onset of shock in the mother. These events characterize uterine inversion. Hypotension usually results before significant blood loss has occurred. The inexperienced obstetrician may mistake an inversion of the uterus for a partially separated placenta or aborted myoma.

Uterine inversion is an uncommon but life-threatening event. Since 1970, the reported incidence has been 1 in 2,000 deliveries.^[97] Inversion of the uterus is termed incomplete if the corpus does not pass through the cervix, complete if the corpus passes through the cervix, and prolapsed if the corpus extends through the vaginal introitus. Uterine inversion usually occurs in association with a fundally inserted placenta. Although previous studies have implicated the use of excessive cord traction and the Crede maneuver as causes of uterine inversion, recent studies have failed to document this association.^[97]

Treatment of uterine inversion should include fluid therapy for the mother and restoration of the uterus to its normal position. This latter is best accomplished using the technique illustrated in [Figure 17-24](#) and should be attempted immediately upon recognition of the inversion. Separation of the placenta before replacement of the uterus will only increase maternal blood loss.^[98] If possible, the uterus should be replaced without removing the placenta. Initial efforts to replace the uterus should be made without the use of uterine-relaxing

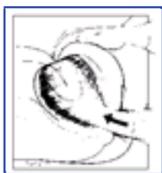

Figure 17-24 Manual replacement of an inverted uterus.

agents. If initial efforts fail, the use of either -mimetic agents or magnesium sulfate should be tried. The choice of these agents depends on the maternal vital signs. In the case of severe maternal hypotension, magnesium sulfate is probably the best choice. These agents have been reported to be safe and associated with an 85 to 90 percent success rate in patients failing initial replacement without pharmacologic therapy. In 10 to 15 percent of remaining cases, general anesthesia should be employed.^[99] Subacute inversion of the uterus occurs when the corpus has protruded through the cervix, and the cervix and lower uterine segment have subsequently contracted, thereby trapping the corpus. In this instance, general anesthesia is necessary for restoration of the uterus to its proper anatomic position.

Occasionally, it is impossible to reposition the subacutely inverted uterus vaginally and laparotomy is necessary. [Figure 17-25](#) shows the surgical technique used to correct this problem. Initially, a combination of vaginal pressure and traction from above on the round ligaments should be attempted. However, this maneuver may not always be successful, and one may have to resort to a vertical incision on the posterior aspect of the lower uterine segment in order to replace the uterus.

Once the uterine inversion has been corrected, the anesthetic agents used for uterine relaxation should be discontinued and oxytocic agents given to produce uterine contraction. If oxytocin fails to contract the uterus, prostaglandin F₂ should be used. The same dosage and intervals used to arrest postpartum hemorrhage with uterine atony are appropriate in this circumstance.

533

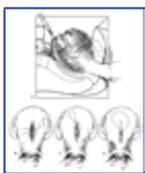

Figure 17-25 Surgical restoration of an inverted uterus. Note the incision on the posterior aspect of the uterus and subsequent repair.

Coagulation Disorders

Continued bleeding in the third stage of labor that is unresponsive to usual treatment should cause the clinician to consider uncommon but serious maternal coagulation disorders.

Von Willebrand's Disease

Von Willebrand's disease (VWD) is a hemorrhagic disorder that affects both men and women. This coagulopathy is inherited in an autosomal dominant pattern and is characterized by the following laboratory abnormalities: prolonged bleeding time, decreased factor VIII activity, decreased factor VIII-related antigen, and decreased von Willebrand factor. The latter is a plasma factor that is essential for proper platelet function and aggregation.

VWD is quite variable in its clinical course, severity, and laboratory abnormalities, even in the same patient. It is therefore possible for a patient with this disorder to go undetected throughout pregnancy until bleeding

534

problems develop postpartum. The usual increase in factor VIII coagulant activity associated with pregnancy may also mask VWD. Only those patients with very low

levels (<5 percent) before gestation fail to exhibit this rise.

When VWD is diagnosed before parturition, factor VIII activity should be monitored serially and transfusion with cryoprecipitate given to keep the factor VIII activity near term at 40 percent. If factor VIII levels are inadequate, the patient should be given one bag of cryoprecipitate per 10 kg body weight 24 hours before the planned induction of labor or cesarean delivery. This infusion will immediately restore the factor VIII activity level, but it will take 24 hours for the associated platelet defect to be corrected. If one suspects this disorder in a patient with unexplained postpartum hemorrhage, coagulation studies should be ordered and a hematologist consulted. However, since time is often limited, it would be prudent to notify the blood bank that cryoprecipitate may be needed emergently. In this situation, at least 6 units of cryoprecipitate are required, to be given every 12 hours for the next 3 to 5 days. ^[100]

Amniotic Fluid Embolism/Anaphylactoid Syndrome of Pregnancy

Amniotic fluid embolism (AFE) is a rare but frequently fatal obstetric emergency clinically recognized in approximately 1 in 8,000 to 1 in 80,000 births. The mortality rate for mothers suffering from AFE is 50 to 60 percent, ^[101] ^[102] ^[103] but an additional 30 percent (75 percent of survivors) can be expected to have long-term neurologic deficits. ^[104] The definitive diagnosis of AFE has traditionally been thought to require demonstration of fetal squames and lanugo in the pulmonary vascular space. However, in the most comprehensive study of this syndrome to date, only 73 percent of patients dying from this syndrome had this finding. ^[103] Based on mounting clinical and experimental evidence, Clark et al. ^[104] have suggested renaming this clinical syndrome the *anaphylactoid syndrome of pregnancy* to emphasize that the clinical findings are secondary to biochemical mediators rather than pulmonary embolic phenomenon.

The classic clinical presentation of the syndrome has been described by five signs that often occur in the following sequence: (1) respiratory distress, (2) cyanosis, (3) cardiovascular collapse, (4) hemorrhage, and (5) coma. In the previously mentioned paper, Clark et al. ^[104] described a more heterogenous clinical presentation.

The most important new findings are the certainty of fetal distress accompanying this syndrome and the high incidence of maternal coagulopathy. In many cases, fetal distress is the initial presenting symptom, rapidly followed by maternal distress (see Table 17-4).

The cardiorespiratory effects of acute intravascular

TABLE 17-4 -- INCIDENCE: SIGNS AND SYMPTOMS OCCURRING IN > 50% OF PATIENTS WITH AFE

Sign or Symptom	No. of Patients	Percentage
Hypotension	43	100
Fetal distress	30	100
Pulmonary edema/ARDS	28	93
Cardiac arrest	40	87
Cyanosis	38	83
Coagulopathy	38	83
Dyspnea	22	49
Seizure	22	48

From Clark S, Morgan M: Amniotic fluid embolism. *Anesthesia* 34:20, 1979, with permission.

injection of amniotic fluid have been studied in pregnant ewes. ^[105] The initial response to the intravascular injection of amniotic fluid was hypotension. A 40 percent decrease in mean arterial pressure was followed by a 100 percent increase in mean pulmonary artery pressure. Little change occurred in the left atrial pressure or the pulmonary artery wedge pressure. A 40 percent fall in cardiac output was associated with the rapid rise in pulmonary artery pressure. These changes resulted in a two- to threefold increase in pulmonary vascular resistance and a two- to threefold decrease in systemic vascular resistance. In contrast to these findings in sheep, intravascular injection of amniotic fluid in rhesus monkeys failed to produce cardiovascular changes similar to the syndrome observed in humans. ^[103]

Classic teachings have emphasized the role of uterine hyperstimulation as a predisposing factor in this syndrome. More recent data ^[103] have shown this to be an erroneous conclusion. Uterine hyperstimulation was found in less than 10 percent of patients prior to the occurrence of AFE. Uterine tetany did occur in 50 percent of patients concomitant with respiratory distress. This most likely represents the uterine response to maternal hypoxemia rather than the event precipitating the AFE. Equally incorrect is the hypothesis that oxytocin administration is a risk factor for the development of the syndrome. There is no higher frequency of oxytocin use in patients suffering AFE than in laboring patients without this complication.

Only scanty information is available on which to base the treatment of the initial syndrome. Early airway control usually necessitating endotracheal intubation has been stressed in the few patients surviving the full-blown syndrome. ^[106] ^[107] Once maximal ventilation and oxygenation have been achieved, attention should be paid to restoration of cardiovascular equilibrium. Central monitoring of fluid therapy with a pulmonary artery catheter is very helpful if the patient can be stabilized long enough to allow time for its placement. Pulmonary arterial blood may be aspirated and stained

for the presence of fetal squames, lanugo hair, and mucin. However, these are found in only 50 percent of patients with the syndrome, and there are known falsepositives. The treatment of shock in the early phase of the syndrome unaccompanied by massive blood loss has not been well studied. Recent data would suggest that the hypotension results from myocardial failure and that efforts should be used to provide myocardial support. ^[104] These would include inotropic agents such as dopamine, as well as volume therapy. ^[108] Other investigators have observed reduced systemic vascular resistance and have used vasopressor therapy such as ephedrine or levarterenol with success. ^[107] If the patient survives the initial cardiorespiratory collapse, there is a high likelihood that coagulopathy will develop if it has not been previously clinically apparent. DIC results in the depletion of fibrinogen, platelets, and coagulation factors, especially factors V, VIII, and XIII. The fibrinolytic system is activated as well. ^[109] Most patients will have profound hypofibrinogenemia, with values less than 200 mg/dl being the rule. PT and PTT will also be abnormal in nearly all patients. Platelet counts are more variable, with 60 percent having values less than 100,000/l. Supportive coagulation and volume therapy (blood, fresh frozen plasma, or cryoprecipitate) should be administered as soon as they are available.

The neonatal outcome in patients suffering this catastrophe is better than the maternal outcome. If the fetus is alive at the time of the event, nearly 80 percent will survive the delivery. Unfortunately, 50 percent of the survivors will incur neurologic damage. ^[103] The two main factors influencing neonatal outcome are the presence or absence of maternal cardiac arrest and the time from arrest to delivery in the latter group. In general, fetal outcome is improved when maternal cardiac arrest does not occur. The shortest arrest to delivery time is associated with the best neonatal outcomes in the presence of maternal cardiac arrest.

Disseminated Intravascular Coagulation

DIC results from the loss of local control of the body's clotting mechanisms. Normally, there are four essential elements in the maintenance of local control of the hemostatic system: vascular integrity, platelet function, the coagulation system, and clot lysis. ^[110] The body must maintain vascular integrity for the survival of the organism. To minimize blood loss, any break in this system initiates the entire hemostatic cascade.

Platelets play an essential role in initiating and localizing clot formation. Platelets circulate until they encounter a break in vascular integrity. They then adhere to the damaged endothelium and release adenosine diphosphate (ADP), recruiting additional platelets to form an adhesive mass of platelets. Once the platelet plug extends past the site of damaged endothelium, platelets interact with the normal vessel wall and produce prostacyclin. This substance inhibits further platelet aggregation and localizes the platelet plug to the site of injury.

Platelets also localize the formation of fibrin by the coagulation cascade. Coagulation factors circulate in an inactive form. Aggregated platelets and injured tissue provide a phospholipid surface on which the coagulation factors can act. Once the factors are activated, fibrin is produced. The action of the coagulation cascade is

limited to a localized area by a decrease in the amount of activated factors. These factors are reduced by (1) the reticuloendothelial system, (2) dilution by rapid blood flow, and (3) neutralization by a circulating protein (antithrombin 3). ^[110]

Once a clot has formed, the reestablishment of normal circulation depends on the orderly removal of the clot. Clot lysis is usually a localized process that must proceed in a timely fashion, since rapid lysis would lead to rebleeding. Clot lysis is limited in two ways. Since the coagulation cascade and lytic processes both depend on factor XII, they are triggered simultaneously. Second, activated plasminogen or plasmin is inactivated by antiplasmin, which circulates in concentrations 10 times that of plasminogen. The orderly progression of clot lysis is facilitated by the incorporation of plasminogen directly into the clot, protecting it from rapid neutralization by antiplasmin. Activation of plasminogen within the clot can then proceed at a local level.

During DIC, the body is forming and lysing fibrin clots throughout the circulation rather than in the localized physiologic process. Therefore, the loss of localization of the clotting process is the main defect in DIC. The lytic process may be activated as well but occurs only in response to the activation of the clotting system.

In obstetrics, DIC causing hemorrhage may involve any of the four mechanisms involved in the localization process. However, it is uncommon for DIC to be initiated by a failure of vascular integrity. Similarly, a platelet abnormality leading to diffuse platelet aggregation is an unlikely cause of hemorrhage in obstetrics. However, activation of the coagulation cascade by the presence of large amounts of tissue phospholipid is a common stimulus for DIC in obstetrics. Such conditions include abruptio placenta, retained dead fetus, and amniotic fluid embolism. These tissue phospholipids contribute to the utilization of large amounts of clotting factors and lead to a consumption coagulopathy. Once this widespread coagulation has taken place, the lytic process is called into action. The degradation of large amounts of fibrin produces fibrin split products, or fibrin degradation products (FDPs). These factors have their own physiologic activity and, when present in large amounts, contribute to bleeding by inhibiting fibrin cross-linking and producing platelet dysfunction.

The platelet count and fibrinogen level are the most

clinically useful tests in evaluating the patient with DIC. They may be repeated on an hourly to every 2-hour basis to provide an accurate reflection of the activity of the coagulation process. PT and PTT are usually abnormal during DIC but are less helpful in evaluating the ongoing severity of the disorder. Because platelets and fibrinogen have a half-life of 4 to 5 days, they are not immediately replaced by the body's own mechanisms and will give an accurate reflection of ongoing consumption as well as the effectiveness of factor replacement.

The sine qua non of successful management of DIC is treatment of the initiating event. Once the cause has been located and treated, the process should resolve. However, depleted factors must be restored to permit orderly repair of injured tissues. Successful therapy involves the replacement of essential factors faster than the body is consuming them. These factors are platelets, coagulation factors derived from fresh frozen plasma or cryoprecipitate, and fibrinogen supplied by cryoprecipitate of fresh frozen plasma. Monitoring replacement therapy should be initiated 20 minutes after the intravenous administration of these products. The obstetrician should attempt to achieve a platelet count of more than 100,000/l and a fibrinogen level of greater than 100 mg/dl. In obstetric conditions complicated by hemorrhage, heparin has no use and will only cause the bleeding to worsen.

Key Points

The rapid assessment of volume loss is dependent on basic vital signs and physical findings.

Blood product use should be based on objectively determined needs rather than predetermined formulas.

An action plan should be developed for situations in which massive blood transfusion is anticipated or arises unexpectedly.

In patients with abruptio placentae, cesarean delivery usually should be performed for obstetric or fetal indications, not maternal coagulopathy.

Expectant management of patients with abruptio placentae or placenta previa can be safely accomplished in many patients.

In patients with postpartum hemorrhage secondary to uterine atony, dilute solutions of oxytocin (intravenous) and 15-methyl-F₂-prostaglandin (intramuscular) should be the first two drugs administered.

The maternal risks from heterologous blood transfusion have decreased significantly in the last 5 years.

The clinical presentation of amniotic fluid embolism is more heterogenous than previously described.

When uterine inversion is encountered, the uterus should be replaced and reinverted before placental removal is attempted.

Oxytocin should be given before placental expulsion and separation to minimize postpartum blood loss.

Chapter 18 - Cesarean Delivery

Richard Depp

The terms *cesarean section*, *cesarean delivery*, and *cesarean birth* may be used to describe the delivery of a fetus through a surgical incision of the anterior uterine wall. This definition does not include nonsurgical expulsion of the embryo/fetus from the uterine cavity or tubes following uterine rupture or ectopic pregnancy. *Cesarean section* is a tautology; both words connote incision. Therefore, *cesarean birth* and *cesarean delivery* are preferable terms.

Cesarean birth has become the most common hospital-based operative procedure in the United States, accounting for more than 22 percent of all live births in 1999.^[1]^[2]^[3] The increase has been attributed to the liberalization of indications for "fetal distress," cephalopelvic disproportion/failure to progress, breech presentations, as well as elective repeat cesarean delivery.^[4] In many medical centers, the present overall rate would be significantly higher were it not for a recent change in attitude facilitating acceptance of vaginal birth after cesarean birth.^[5]

The cesarean delivery-associated maternal mortality rate is approximately 20 per 100,000 births in the United States.^[6] Taken as an isolated endpoint, it is an infrequent complication. Cesarean delivery has many possible immediate untoward consequences: an increased risk for postpartum infectious morbidity despite antibiotic prophylaxis, an increased risk of significant blood loss and need for transfusion with potential problems associated with blood and blood product replacement, and an increased risk of anesthetic complications. There are no reliable data regarding the cumulative long-term maternal morbidity associated with cesarean birth.

Despite a dramatic impact on society, little attention has been focused on the cumulative consequences of this major surgical procedure with its implications not only for the current pregnancy but also for future reproduction. The increase in cesarean birth rates noted in the 1980s has had a dramatic impact on the reproductive future of women. As the percentage of laboring patients presenting with a prior cesarean birth has increased, there has been an associated increase in more difficult repeat cesarean deliveries and complications, including a higher incidence of placenta previa, placenta accreta, symptomatic uterine rupture, hemorrhage, requirement for transfusion, and need for unplanned hysterectomy.

This chapter presents indications for cesarean delivery and peripartum hysterectomy, surgical techniques and procedural complications, and issues surrounding candidacy for and management of a trial of labor (TOL) after a prior cesarean birth (VBAC).

HISTORY OF CESAREAN DELIVERY

Terms

The origin of the term *cesarean section* is likely the product of two separate reports in 1581 and 1598, the former making reference to *Cesarean* and the second to *Sections*. The origin of the term *cesarean* is somewhat uncertain. The hypothesis that Julius Caesar was the product of a cesarean birth is unlikely to be true in view of the probability of fatality associated with the procedure in ancient times and the observation that his mother, Aurelia, corresponded with him during his campaigns in Europe many years later. The term may have as its origin in the Latin verb *cadere*, to cut; the children of such births were referred to as *caesones*. It is also possible that the term stems from the Roman law known as Lex Regis, which mandated postmortem

540

operative delivery so that the mother and child could be buried separately; the specific law is referred to historically as Lex Cesare. ^[7]

In 1876, Eduardo Porro, an Italian professor, recommended hysterectomy combined with cesarean birth to control uterine hemorrhage and prevent systemic infection. ^[8] ^[9] ^[10] The Porro procedure combined subtotal cesarean hysterectomy (see the section Peripartum Hysterectomy, below) with marsupialization of the cervical stump. ^[9] Fortunately, the need for such an extreme procedure was soon minimized by the proposal to close the uterine incision with sutures. The introduction of suture material, which enabled the surgeon to control bleeding, was of monumental importance in the evolution of the procedure. In 1882, Max Sänger from Leipzig published a monograph based largely on experience from surgeons in the United States who had used internal sutures, explaining the principles and technique of cesarean delivery, including aseptic preparation, with special emphasis on a two-step uterine closure using silver wire and silk and careful attention to hemostasis. ^[11] ^[12] The use of silver wire stitches were developed by 19th century gynecologist J. Marion Sims, who invented his sutures to repair vaginal tears (fistulas) that had resulted from traumatic childbirth. Sänger thought that this approach would obviate the growing tendency for cesarean hysterectomy caused by fear of hemorrhage and infection. It is interesting to note that Sänger attributed much of the early development of suture material to American frontier surgeons, including Frank Polin of Springfield, Kentucky, who in 1852 had reported the use of silver wire sutures in surviving patients who had undergone cesarean delivery. ^[13]

The low transverse incision was trialed between 1880 and 1925 and was noted to reduce the risk of infection, as well as uterine rupture, in subsequent pregnancies. ^[6]

Death from peritonitis remained a major threat. Approximately 30 years later, extraperitoneal cesarean delivery was first described by Frank ^[14] (1907) and subsequently modified by Latzko ^[15] (1909) as a technique to reduce the risk of peritonitis in high-risk patients. Subsequently, Krönig ^[16] (1912) realized that extraperitoneal cesarean birth not only minimized the effects of peritonitis but also allowed access to the lower uterine segment through a vertical midline incision, which could then be covered with peritoneum, an approach that led to the modern-day low vertical procedure. Later, Beck ^[17] (1919) and DeLee and Cornell ^[18] (1922) modified the Krönig approach and popularized it in the United States. Finally, Kerr ^[19] (1926) developed the low transverse incision, which is most commonly employed throughout the world today. The need for an extraperitoneal procedure was essentially eliminated by the development of modern antibiotics.

As the risk-versus-benefit considerations changed, obstetricians became more confident in the use of cesarean section and began to argue against delaying surgery. Surgeons such as Robert Harris of the United States, Thomas Radford of England, and Franz von Winckel of Germany recommended cesarean delivery as an early solution to labor disorders to improve outcome. In turn, maternal and perinatal mortality rates were reduced as cesarean birth became viewed as one of several approaches to improve perinatal outcome. ^[6]

CESAREAN BIRTH RATES

The Changing Rate of Cesarean Birth

The early onset of a change in the overall cesarean delivery rate is dramatically demonstrated by data from the Chicago Lying-In Hospital, which had a fivefold increase in the cesarean rate from 0.6 percent in 1910 to 3 percent in 1928.^[20] In the ensuing years, the reported rate of cesarean delivery in the United States increased in dramatic fashion, from 4.5 percent in 1965 to 16.5 percent in 1980, finally peaking at 24.7 percent in 1988.^[21] Cesarean delivery rates have also increased worldwide during the past 20 years.^[22],^[23] In a recent survey of obstetricians in London, 31 percent of female obstetricians and 8 percent of their male counterparts said they would prefer to deliver by cesarean section. The leading reason for this choice was fear of perineal injury with vaginal birth, followed by fear of damage to the baby, and the desire for an electively scheduled procedure.^[24] However, the increase in international rates does not approach the high rates seen in the United States.

NICHD Task Force on Cesarean Childbirth

Cesarean births increase health care costs, pose considerable additional risk for maternal mortality and morbidity and, with few exceptions, provide only marginal proven fetal benefits. In 1979, the National Institute of Child Health and Human Development (NICHD) established a task force on cesarean childbirth and in 1980 sponsored a consensus development conference to consider the issue of cesarean delivery in the United States.^[25] The task force recommended that efforts be made to diminish the impact of elective repeat cesarean delivery and the diagnosis of "dystocia" because these indications were the two major causes of the increase in cesarean birth rates that were likely to be susceptible to reduction.

Although an immediate slowing of the rate of increase of cesarean births was not readily apparent, the widespread dissemination of the consensus document

did provide the medical community with reassurance that an attempt to reduce the escalating cesarean rate was a reasonable goal. The cesarean rate ultimately peaked at 24.7 percent in 1988.^[1],^[26] Both the total cesarean rate and the primary rate have decreased since then to approximately 22.8 and 14.5 percent, respectively, in 1993.^[2] Unfortunately, cesarean rates in some institutions continue to exceed 30 percent.

Is There an "Ideal" Cesarean Rate?

It is probably not possible to define an "ideal" cesarean rate. The desired rate will vary from institution to institution on the basis of multiple factors. Quilligan^[27] has suggested that it may be better to define a range of values for each indication: failure to progress/cephalopelvic disproportion (2 to 4 percent); repeat cesarean delivery (2 to 6 percent); breech and abnormal lie (1.3 to 3.5 percent); nonreassuring fetal heart rate (FHR) (1.5 to 3 percent); and third-trimester bleeding (1 percent). Tertiary centers with associated higher rates of preterm birth and placenta previa can be expected to have higher cesarean rates. Recently, the U.S. Department of Health and Human Services, as part of its Healthy People 2000 program, identified a number of health-related objectives, including (1) reduction of the primary cesarean delivery rate to 12 percent and (2) increase of the number of VBACs to greater than or equal to 35 per 100 women who have had a prior cesarean section.^[2],^[28]

In 1997, the American College of Obstetricians and Gynecologists (ACOG) appointed a task force on cesarean delivery rates to determine the factors that contribute to the cesarean delivery rates in the United States.^[29] The task force noted that the highest variation in primary cesarean delivery rates occurred among nulliparous women with a singleton fetus in a cephalic presentation without other complications. The task force also observed that patients with a prior cesarean varied in the frequency with which they were offered a trial of labor and how often the trial of labor was successful. Using data from the National Center for Health Statistics, the task force established two benchmark rates based on the 25th to 75th percentiles of state rankings for these two patient groups. The task force advised that the targets for these two categories be set at the 25th percentile for primary cesarean delivery rates and the 75th percentile for VBAC rates. For nulliparous women at 37 weeks with a singleton fetus and a cephalic presentation, the national 1996 cesarean delivery rate was 17.9 percent. The group recommended a benchmark rate of 15.5 percent, at the 25th percentile. For multiparous women with one prior low transverse cesarean delivery at 37 weeks' gestation or greater with a singleton fetus and a cephalic presentation, the national 1996 VBAC rate was 30.3 percent. The task force recommended a benchmark rate of 37 percent, at the 75th percentile. The task force emphasized that in examining the cesarean rate of obstetricians or the institutions in which they practice it is essential that the rate be adjusted for the risk factors in the patient population. The task force proposed that using case-mix adjusted cesarean delivery rates and these benchmarks would be helpful in evaluating practice patterns and developing strategies to lower the rate of cesarean sections.^[29]

Causes of Increased Cesarean Birth Rate

At least 90 percent of the increase between 1980 and 1985 was attributable to three factors: repeat cesarean deliveries (48 percent), dystocia (29 percent), and "fetal distress" (16 percent). There are many complex and interrelated reasons (Table 18-1) for the increase in the cesarean birth rate.^[2]

Medical Advances

Early liberalization of the indications for cesarean delivery rose out of the increased availability of effective antibiotics, safer blood banking, and a greater tendency for obstetrics to be practiced in facilities delivering large numbers of patients. Even socioeconomic factors have played a role.

TABLE 18-1 -- CAUSES OF INCREASED CESAREAN RATE

Medical advances diminishing maternal risks
Labor- and delivery-related factors
Repeat cesarean birth ¹
Continuous electronic fetal monitoring ²
Dystocia diagnosis liberalized ³
Epidural analgesia/anesthesia

Macrosomia (>4,000 vs. >4,500 g)
Decreased use of forceps/vacuum ^[30]
Maternal factors
More older childbearing women/delay in childbirth ^[21]
More nulliparous women with attendant risk
Increasing maternal risk
Fetal factors
Fetus as a patient
Breech presentation ^[21]
VLBW fetus
Active genital herpes
Postterm pregnancy
Multiple gestation (especially with nonvertex)
Failed induction for fetal indication
Physician factors
Fear of malpractice litigation
Physician compensation (possible)
Physician convenience (possible)

* Data from Taffel et al.,^[21] Notzon et al.,^[22] and Placek et al.^[30]

Delay in Childbirth

The widespread availability of contraceptive and sterilization techniques has resulted in women giving birth at an older age. ^[21]

More Older and Often Nulliparous Patients

Older and often nulliparous patients constitute an increasing proportion of laboring women. In the United States between 1980 and 1985, the number of births in patients at least 30 years of age increased from 20 to 25 percent of all deliveries. ^[21] It is well known that the cesarean delivery rate increases with advancing age (Table 18-2) as a result of increased likelihood of dystocia and medical complications such as preeclampsia and gestational diabetes.

Dystocia Diagnosis Liberalized

The diagnostic criteria for dystocia accepted by some have been liberalized, and forceps deliveries have fallen into relative disfavor in some medical centers. For the interval 1972 to 1980, Placek et al. ^[30] reported a decline in forceps deliveries from 37 to 18 percent, which parallels the increase in the cesarean delivery rate from 7 to 17 percent. ^[30]

Fetus as a Patient

Historically, cesarean delivery had been performed primarily to reduce the likelihood of maternal morbidity and mortality. In the mid-1970s, the eventual health status of the fetus-neonate began to play a larger role in the decision process. Widespread use of techniques such as continuous electronic fetal monitoring, ultrasound evaluation of the fetus, and fetal karyotype determinations by amniocentesis or chorionic villus sampling resulted in a change in emphasis to "quality of survival" for newborns, not simply survival. The fetus became viewed more as a person and eventually a patient (see Chapter 11).

TABLE 18-2 -- TOTAL CESAREAN BIRTH RATES (%) BY AGE OF MOTHER

Age (years)	1980 [*]	1989 [*]	1991

Nonreassuring FHR Indications

Despite dramatic advances in perinatal medicine, the widespread use of electronic fetal monitoring, and a significant increase in the cesarean birth rate in the last two decades, there has been no reported reduction in the rate of cerebral palsy. There is consensus that continuous electronic fetal monitoring (EFM) does not reduce the risk of newborn morbidity related to metabolic acidosis or cerebral palsy more than intermittent auscultation. ^[31] ^[32] ^[33] ^[34] Since cesarean delivery for this indication commonly follows the observation of subtle EFM changes in FHR variability or late decelerations, both of which are not detectable by auscultation, the association of subtle findings with later developmental problems may indicate a preexisting fetal abnormality, not likely to benefit from a cesarean delivery. The previously "normal" fetus, except in extreme conditions (i.e., severe prolonged decelerations arising from cord prolapse or placental abruption), is likely to have sufficient physiologic adaptability to adjust to the stress responsible for the relatively subtle fetal heart rate patterns that are not detectable by intermittent auscultation (see Chapter 14). Support for this notion is provided by the obvious contrast between the relatively high frequency of significant FHR alterations but infrequent occurrence of cerebral palsy. The fetus with prior developmental abnormality is more likely to demonstrate nonreassuring FHR patterns during labor than is its neurologically normal peer.

Breech as an Indication

Vaginal breech deliveries have been abandoned by many clinicians in favor of cesarean delivery (see Chapter 16). Most breech presentations are now delivered by cesarean birth, with rates in some medical centers as high as 79 and 92 percent.^[21],^[35] Hannah and her colleagues recently published a large prospective randomized trial comparing planned cesarean delivery with planned vaginal birth for term frank or complete breech presentations. Perinatal mortality, neonatal mortality, and serious neonatal morbidity were all significantly lower in the planned cesarean group.^[36] This study certainly supports current patterns of practice. It should be remembered that extraction of a breech at cesarean delivery requires skills very similar to those used in a vaginal birth, including avoidance of hyperextension of the fetal head.

Fear of Litigation

Unfortunately, obstetric practice in the United States is adversely influenced by the high rate of malpractice litigation. Medicolegal pressures have forced a liberalization of indications. Concern regarding potential malpractice

543

action for failure to intervene at an alleged "standard" time increased dramatically in the 1980s, particularly among physicians in traditional private practice. Statistics to support this concept indicate that private nulliparous patients are more likely than clinic patients to undergo cesarean delivery if dystocia or malpresentation or so-called fetal distress is diagnosed.^[37]

The practice of obstetrics has become more defensive. Many American obstetricians have concluded that one of the best ways to reduce malpractice vulnerability is to "liberalize" indications for cesarean delivery. Obstetricians harbor a fear that they may be criticized in hindsight for failure to perform an earlier cesarean delivery that "may have" resulted in a better outcome. The result is a more defensive approach to practice, including a lower threshold for resorting to cesarean delivery.^[38] Unfortunately, there are few data to support a benefit to this strategy.

The magnitude of "fear of litigation" as a contributing factor to the current cesarean rates can be inferred from a survey of British and American obstetricians, designed to determine the perceived reason for the rise in cesarean rates. Litigation was the leading reason given by 84 percent of American obstetricians but only 42 percent of British obstetricians.^[39] Some physicians have used cesarean delivery as an answer to all potential problems; an extreme was reached in 1985, when the following was asked: "If an informed patient opts for prophylactic cesarean section at term, can it be denied?"^[40],^[41] Tort reform is the only likely solution to this particular problem.

Prior Cesarean Birth

As the indications were expanded, it is not surprising that "prior cesarean delivery" became an ever-increasing indication for cesarean birth. Approximately 25 percent of all cesarean deliveries were for the indication of prior cesarean birth in 1970.^[1],^[2] The percentage of all cesarean procedures attributable to this indication peaked at 37.2 percent in 1997.

Determinants of Rate Variation

Physician Factors

The etiology of differences in cesarean birth rates reported by different centers is as yet unresolved. For instance, Blumenthal et al.^[42] noted a significant difference between the incidence of dystocia in public versus private patients and concluded that the difference was probably the result of differences in indications used by physicians in the two groups. Although it has been suggested that physician convenience or economic gain may be operative in the decision to perform a cesarean delivery in private patients, Phillips et al.^[43] were unable to demonstrate the predictable distribution of nonscheduled cesarean births that would support this hypothesis. Furthermore, this author's experience with a large number of private physicians in many centers suggests that this is not a major contributor. Rather, it is the fear of not performing a cesarean that is often the main culprit. Furthermore, the difference in compensation for cesarean and vaginal deliveries is small, and, in most cases well deserved, often following long or difficult labors.

Regional Differences

There are surprisingly dramatic regional differences in total cesarean rates in all hospitals as well as in teaching hospitals.^[1],^[2],^[43],^[44] In 1993, the cesarean rate in the South was 25.9 percent, significantly higher than rates in the West (19.3 percent), Midwest (20.8 percent), and Northeast (23.4 percent).^[1],^[2] Regional variations also exist among teaching hospitals.

Teaching Versus Nonteaching Hospitals

Women delivering in a teaching hospital are less likely to have a cesarean delivery than are those delivering in hospitals without resident programs. In 1990, the estimated rate in all hospitals with resident programs was 20.3 percent compared with an overall national rate of 23.5 percent; the estimated rate for nonteaching hospitals was 24.7 percent (odds ratio [OR], 0.77; 95 percent confidence interval [CI], 0.770.78; $p = 0.0001$). Of all cesarean deliveries conducted in teaching hospitals, 64.8 percent were primary and 35.2 percent were repeat.^[44] The hypothesized basis for the lower rate in teaching hospitals includes routine consultation prior to performing nonelective cesareans, routine review conferences, and around-the-clock availability of physicians to manage labor, minimizing any tendency for physician time pressures to influence the decision process.

Obstacles to Rate Reduction

There is an ongoing need to continue to reduce the current cesarean birth rates. Despite an awareness that there is a potential problem, we may have entered a cycle that will make major rate reduction difficult. Respected clinicians vary greatly in their acceptance of procedures such as midforceps or vaginal delivery of the breech, whether it be a singleton or one of a multiple gestation. Many physicians recently trained in obstetrics have had insufficient exposure to operative vaginal procedures to develop a "comfort" level and consequently often opt for a procedure with which they are familiar, cesarean delivery. In 1999, residents completing their training in obstetrics and gynecology in the

544

United States performed, on average, 169 cesarean deliveries, 31 forceps deliveries, and 27 vacuum deliveries.^[46] Furthermore, increasing concern has been raised about the safety of VBAC, leading to provider and patient preference for a repeat cesarean delivery.

BENEFITS AND RISKS OF CESAREAN BIRTH

Maternal Mortality

Maternal mortality as a result of cesarean delivery fortunately is an infrequent occurrence, but the overall rate is estimated to be severalfold higher than that following vaginal delivery. Approximately 300 maternal deaths occur annually in the United States in just over 4 million deliveries of all types per year, an overall rate less than 10 per 100,000 live births. Not surprisingly, the reported incidence of maternal mortality following cesarean delivery can vary greatly from series to series, particularly in single-institution reports. Maternal mortality following cesarean birth has been assessed in two publications^[6],^[47] with a sufficient number of cesarean deliveries (400,000 and 121,000) to provide meaningful estimates. On the basis of these two reports, mortality can be estimated to range from 6.1 to 22 per 100,000 live births. Approximately one third to one half of maternal deaths of these patients can be attributed directly to the cesarean procedure itself.

Perinatal Morbidity and Mortality

The hypothesis that cesarean birth offers a major opportunity to improve perinatal outcome has, with few exceptions, not been proven. It is more likely that the improvement in perinatal mortality is the product of widespread changes in perinatal care. There are no well-documented prospective trials demonstrating benefit to the fetus or to the mother that would justify the extent of the increase in the primary cesarean delivery rate over the past two decades.

There has been a heated international debate regarding the role of cesarean birth in reducing perinatal mortality. O'Driscoll and Foley^[48] do not attribute improvements in perinatal outcome to liberalization of cesarean indications. Cesarean delivery rates have remained stable at the National Maternity Hospital in Dublin, Ireland, at less than 5 percent between 1965 to 1980, whereas rates in the United States have increased from slightly less than 5 percent in 1965 to more than 15 percent in 1980. Because the perinatal mortality rate at the National Maternity Hospital has progressively fallen from 42.1 to 16.8 per 1,000 births despite a low cesarean delivery rate, one is forced to consider that, although liberalization of cesarean delivery indicators may contribute to better perinatal outcome, it is likely to be less important than the overall improvement in obstetric and neonatal care.

Leveno et al.^[50] subsequently countered that the data of O'Driscoll and Foley^[48] are limited by their emphasis on mortality rather than morbidity. They suggested that their more liberal use of cesarean delivery (18 percent in 1983) was "associated with" decreased intrapartum deaths and neonatal seizures when compared with the National Maternity Hospital in Dublin.^[48],^[49]

O'Driscoll and Foley, in their response to the critique by Leveno et al., indicated that in order to compare uncommon events, a larger number of births would be required. They compared data from more than 24,000 births with a 5.1 percent cesarean rate at the National Maternity Hospital with those from more than 22,000 deliveries with a 17.8 percent cesarean rate at Parkland Hospital. Despite the dramatic difference in cesarean rates, they could detect no difference in perinatal mortality.^[51] During the study years (1982 to 1984), the incidence of neonatal seizures was similar in the two institutions. Caution was also raised regarding the precision of the diagnosis and etiology of seizures between the two institutions.

It is most likely that the decline in perinatal mortality is attributable to major advances in prenatal care (ultrasound, antepartum testing, amniotic fluid surfactant determinations, and so forth), as well as dramatic improvements in neonatal intensive care including the availability of surfactant implemented in the same time frame. Porreco^[52] provided data to suggest little, if any, impact arising from cesarean birth. They divided unselected patients into two groups, one with management minimizing the use of cesarean delivery and the other with routine management. The cesarean rate in the first group (5.7 percent) was considerably less than that of the routine group (17.6 percent). Despite the dramatic difference in cesarean rates, the perinatal mortality and morbidity rates were not significantly different between the two groups.^[52]

Cesarean Delivery as a Strategy To Reduce Cerebral Palsy

Scheller and Nelson^[53] from the NICHD, in a review of the literature of the past 25 years, concluded that there is no evidence to support the hypothesis that the increased cesarean delivery rate has had a favorable impact on the rate of neurologic disorders or on cerebral palsy. When comparing the occurrence rates of cerebral palsy in nations with a broad range of cesarean rates (7 to 22 percent), the reported cerebral palsy rates in all countries were within a very narrow range of 1.1 to 1.3 per 1,000 in neonatal survivors with birth weights more than 2,500 g.^[53] Furthermore, there is no evidence

that continuous electronic fetal monitoring provides an advantage over periodic auscultation or reduces the rate of cerebral palsy.^[31]^[32]^[33],^[54]

INDICATIONS FOR CESAREAN DELIVERY

Overview of Indications

In general, cesarean delivery is used when labor is contraindicated or vaginal delivery is unlikely to be accomplished safely or within a time frame necessary to prevent the development of fetal and/or maternal morbidity in excess of that expected following vaginal delivery.

Indications for cesarean delivery can be categorized (Table 18-3) in several ways. Some indications strictly benefit the fetus, whereas others are largely done for maternal benefit to avoid maternal hemorrhage, reduce the potential spread of malignancy, avoid the repeated need for additional procedures such as abdominal cerclage in future pregnancies, and prevent uterine rupture. Some indications will benefit *both* mother and fetus. Some indications are well accepted even though selectively applied on a subjective basis. Placenta previa and conjoined twins are universally accepted as indications for cesarean birth. On the other hand, several indications such as a breech presentation or a VLBW fetus are controversial.

Fetal Indications

Fetal indications for cesarean birth are in large part designed to minimize neonatal morbidity and possibly long-term consequences of profound intrapartum metabolic or mixed metabolic acidemia and/or delivery-related trauma (including significant fetal thrombocytopenia) or transmission of infection.^[55] Accepted indications, often used selectively, include the following: "significant" nonremediable and nonreassuring FHR patterns, especially when associated with progressive loss of variability; various categories of breech presentation at risk for head entrapment and/or cord prolapse; the VLBW fetus; and active genital herpes. The

 Universally accepted if selective/subjective criteria present.
 Of a critical degree commonly associated with change in FHR variability.

decision to use cesarean delivery may be selective, based on the results of ultrasound or cordocentesis studies (i.e., major fetal congenital anomalies such as hydrocephalus, gastroschisis, or omphalocele). In such cases, a planned, controlled delivery with predictable access to pediatric surgical support may be desirable. However, at this time, there is no proven benefit in performing a cesarean delivery for gastroschisis or omphalocele.^[56]

"Significant" Nonreassuring FHR Observations

Approximately 1 to 3 percent of all laboring patients undergo cesarean delivery for a nonremediable and nonreassuring FHR pattern (see Chapter 14). Some clinicians unfortunately continue to designate this indication as "fetal distress," a term not recommended by the ACOG.^[56] The cesarean delivery rate and the precise criteria for "fetal distress" vary considerably from hospital to hospital and among individual practitioners. In large part, that variation reflects the subjective nature of the interpretation of continuous FHR. In 1978, Haddad and Lundy^[57] estimated that approximately 50 percent of cesarean births performed for such nonreassuring

FHR patterns in their hospital were not justified on independent peer review.

Infection as a Risk

The impact of vaginal delivery as a risk factor for transmission of infections such as human immunodeficiency virus (HIV) and herpes simplex virus (HSV) is organism/problem specific ([see Chapter 40](#)).

Maternal-Fetal Indications

Placental abnormalities such as placenta previa or placental abruption in which hemorrhage poses a significant risk to both mother and fetus ([see Chapter 17](#)), as well as labor "dystocia," are indications for which cesarean delivery offers a potential benefit to both mother and fetus. When extreme, each can pose one or more maternal risks, including hemorrhage, uterine rupture and infection, and fetal metabolic acidosis.

Dystocia is a term used to describe indications for cesarean birth arising from one or more of the "three Ps": relatively large fetus (passenger), relatively small "passage" (pelvis), or relatively insufficient or inefficient uterine contractions (power). Some add a fourth "P," the fearful physician. Included in dystocia are failure to progress (FTP), relative cephalopelvic disproportion (CPD), and absolute CPD on the rare occasion when the latter can be diagnosed ([see Chapter 13](#)). Some include failed inductions under this designation. CPD is almost always a relative term; the CPD diagnosis is made only after application of a number of diagnostic and therapeutic measures including oxytocin. In most instances it involves a normal-sized fetus. ^[58]

Maternal Indications

There are only a few indications for cesarean delivery that are solely maternal. They include mechanical obstructions of the vagina from large vulvovaginal condylomata, advanced lower genital tract malignancy, and placement of a permanent abdominal cerclage with a desire for future pregnancies.

Gabbe: *Obstetrics - Normal and Problem Pregnancies, 4th ed.* , Copyright © 2002 Churchill Livingstone, Inc.

HOSPITAL REQUIREMENTS FOR CESAREAN DELIVERY

The requirements for hospitals offering cesarean delivery appear in several publications. ^[59] ^[60]

Facility and Personnel Requirements

Any hospital that provides labor and delivery services should be equipped to perform an "emergency" cesarean delivery. In the past, it was recommended that a hospital offering obstetric services should provide the professional and institutional resources to respond to "acute obstetric emergencies" (i.e., a cesarean delivery) within 30 minutes, when indicated (see below), from the time a decision is made until the procedure is begun. ^[60] The nursing, anesthesia, neonatal resuscitation, and obstetric personnel required must be either in the hospital or readily available. In its 1999 Practice Bulletin, the ACOG has recommended that, if a VBAC-TOL is considered, a physician capable of monitoring the labor and performing an emergency cesarean delivery should be "immediately" available. ^[3] Will adverse outcomes be prevented if patients are delivered "immediately"? Data from a prospective study by Porter suggests that factors other than time to delivery are important in determining neonatal outcome associated with uterine rupture. ^[62] Porter described 26 cases of uterine rupture in VBAC-TOL patients laboring in large metropolitan hospitals, all with 24-hour in-house anesthesia. Six infants (23 percent) suffered either neonatal death or significant neurologic sequelae. The mean time from decision to delivery was 19 minutes for cases with a poor neonatal outcome and 41 minutes for those with a good result. Patients who demonstrated a brady-cardia were delivered in less than 20 minutes, and one third still had a poor outcome.

At this time, there is no consensus standard that defines an acceptable time interval for performance of a cesarean delivery. In the presence of certain subjective, judgment-dependent, "clinically significant" nonreassuring

FHR patterns that fulfill criteria and pose significant risk of profound fetal metabolic acidemia requiring rapid intervention, prolapse of the cord, symptomatic uterine rupture, and certain cases of obvious and symptomatic placental abruption and persistent hemorrhage secondary to placenta previa, an immediate response is warranted. Under most circumstances (i.e., protraction and arrest disorders of labor) cesarean delivery is not necessary within a 30-minute time frame. Indeed, in certain large units, triage may be necessary to determine priority of access to the operating room, anesthesiologists, and other resources.

Porreco and Meier^[63] evaluated the likelihood of need for an urgent cesarean birth that would activate the 30-minute recommendation in patients with and without a prior cesarean birth. The need for a delivery within 30 minutes was similar in patients with no prior cesarean delivery (1.9 percent [two cases]) and in those with a previous low transverse incision (1.4 percent). The two patients with a prior low transverse incision who required an urgent cesarean birth were found to have an intact scar at the time of surgery. The Canadian Consensus Conference on Cesarean Childbirth (four prospective studies) made similar observations, noting the probability of urgent cesarean delivery to be only 2.7 percent among 11,819 births. ^[64] Symptomatic uterine dehiscence occurred in only 0.22 percent of births.

SURGICAL PRINCIPLES AND OPERATIVE PROCEDURE

Skin Preparation

An abdominal incision interrupts the body's first line of defense against infection. The primary objective of skin preparation for cesarean delivery is to reduce the risk of wound infection by decreasing the bacterial flora of the patient's abdominal wall along the anticipated incision site. It is impossible to sterilize skin. The preparation of the patient's intended incision site in the operating room ordinarily includes mechanical removal of obvious foreign material, application of soap or detergent scrub to remove surface dirt and oil, plus application of a topical antimicrobial agent to reduce the bacteria to a minimal level at the site and adjacent skinfolds and/or umbilicus.^[65] In surgical patients, the duration and choice of the scrub have not been demonstrated to reduce the rate of wound infection significantly in either clean or clean-contaminated (cesarean delivery) wounds.^[66]^[67]^[68] There is great variation in the duration of the clinical skin scrub among both physicians and hospitals. Some apply a surgical scrub for up to 5 minutes, whereas others simply scrub the intended site for approximately 30 seconds and apply a bactericidal solution. Overall, the rate of wound infection is approximately 6 to 8 percent whether the skin preparation is sprayed or mechanically scrubbed. It is likely that simple application by painting or spraying is as effective, if not more effective, than the traditional approach of long-term mechanical scrubbing.^[69]^[70] There are also data that suggest that a rapid alcohol preparation followed by application of iodine-impregnated sterile drapes may safely reduce skin preparation time to 1 to 2 minutes.^[71]

Bacteria such as *Staphylococcus aureus*, which may be normal inhabitants of the hair follicle, may be reduced in the preparation process, but are not totally eliminated.^[72] Fortunately, "transient" flora are easier to remove from the skin than are the "resident" flora that are attached to the skin by adhesion or adsorption and require friction for removal. Under ordinary circumstances, the number of flora in any one area is relatively stable. The relative risk of infection with skin incisions varies, to some extent, according to the site of the incision; the availability of moisture, which promotes bacterial colonization; and the presence of lipid secretion by sebaceous glands. The indigenous "resident" flora of the skin are mainly diphtheroids and gram-positive rods, including aerobic *Corynebacterium* and anaerobic *Propionibacterium*. Gram-negative organisms can proliferate in moist areas such as under a panniculus or air-tight dressing.^[73] The aerobic corynebacteria diphtheroids are the most common organisms in areas of moist skin. These diphtheroids seldom cause clinical infection and are actually important in the ecology of skin by suppressing *Staphylococcus epidermidis* and *S. aureus*.

In contrast to the normal resident skin flora whose numbers are normally stable, "transient" flora are deposited on the skin and in the incision/wound from the environment and, as a consequence, vary greatly in type and number. Other factors that determine whether a wound infection will occur include host resistance, virulence of the organisms deposited on the skin/incisional wound, presence and amount of tissue destruction, size and reactivity of the suture material, vascularity of the incision site, and length of the procedure. In the case of cesarean delivery, leakage of cervical and vaginal secretions into the pelvis and transmittal to the skin incision site are also contributing factors.

Preparation of the vagina prior to cesarean delivery is seldom an issue with the possible exception of cases in which a cesarean hysterectomy is planned. Preparation of the vagina is intended to reduce postoperative infection. However, if the clinician decides to use prophylactic antibiotics, it is doubtful that there is any additional benefit to be gained from preoperative preparation of the vagina with an antiseptic preparation. Should a cesarean hysterectomy be planned, simple irrigation of the vagina with a saline solution will dilute the concentration

of bacteria in the vagina and may provide additional benefit.

Hair Removal

In general, the only reason to remove hair from the intended operative site is to eliminate hair that will mechanically interfere with the surgeon's approximation of the wound edges and with adhesion and removal of postoperative dressings.^[74] Hair is sterile.^[75] Removal of hair with a razor may increase wound infection rates by creating breaks in the skin for bacterial entry. Should shaving be required, it is best done in the operating room. Alexander et al.^[76] have shown that clipping the hair the morning of surgery results in a significantly lower infection rate than does clipping the hair the evening prior to surgery or shaving at any time.

Suture Selection

Sutures may be synthetic or nonsynthetic in origin. The latter are derived from gut, cotton, or silk. Sutures can be further divided into absorbable and nonabsorbable types (Table 18-4). The *United States Pharmacopeia* categorizes suture materials as nonabsorbable if tensile strength is maintained for more than 60 days. In turn, synthetic suture types are braided or monofilament. The braided absorbable sutures are either coated (Vicryl or Dexon Plus) or noncoated (Dexon S).

Synthetic sutures offer the benefits of decreased tissue reactivity, prolonged and predictable strength, and low coefficients of friction. Monofilament synthetic sutures elicit somewhat less tissue reaction than their braided counterparts: both are less reactive than their nonsynthetic absorbable and nonabsorbable counterparts. The larger the gauge of the suture, the greater the likelihood of adhesion formation.^[77] Knot security is maintained for several weeks longer with synthetic absorbable sutures than with chromic cat gut.

The ideal suture ties easily and offers knot security, minimal tissue inflammatory reaction, and tensile strength compatible with the inherent healing properties of the tissue to be reapproximated. It is also desirable that the suture be flexible, pliable, and easy to handle, resistant to infection, and reabsorbed at a predictable rate. The selection of the suture material to be used should also be based on how rapidly the particular tissue heals. For instance, chromic cat gut, a suture material that maintains tensile strength for a relatively short time, is often appropriate for visceral organs like the bladder, peritoneum, and vagina, surfaces that generally heal quickly, particularly in pregnancy.^[78] In contrast, skin and fascia heal more slowly; thus, the suture selected should provide more long-term tensile strength. For example, fascia regains only 25 percent of its original strength after 20 days of healing, and the fascial layer is subject to dehiscence if not closed properly. Nonabsorbable synthetic sutures such as polypropylene (Prolene) and polybutester (Novafil) are strong and dependable and are frequently used to repair fascia and for mass closure. Monofilament nylons, braided absorbable (Vicryl) Maxon, and polydioxanone (PDS) are also useful.^[79]

Each suture type has definite advantages and disadvantages. When using the synthetic sutures, it is recommended that the clinician add two more knots with longer tails to ensure knot security because these sutures may slip when knots are not properly tied. Manufacturers have introduced coated synthetic sutures (Dexon Plus, coated Vicryl) that have less memory and lie more easily. Should the clinician desire to maintain tensile strength in fascial and subcuticular tissue over longer intervals (e.g., patients who have diabetes mellitus, are infected, or on corticosteroid therapy), the newer synthetic monofilament absorbable sutures such as polyglyconate (Maxon) and PDS may be preferable because they support the tissues in the wound adequately for more than 6 weeks.

Nonabsorbable monofilament sutures such as Prolene and Novafil may be the suture of choice for closing the patient at risk of infection because they do not allow bacteria to invade and colonize the interstices of the braided polyfilament sutures. This feature is particularly

TABLE 18-4 -- CATEGORIES OF SUTURE MATERIAL POTENTIALLY AVAILABLE FOR CESAREAN DELIVERY AND/OR PERIPARTUM HYSTERECTOMY

	Absorbable	Nonabsorbable
Nonsynthetic	Plain gut	Silk
	Chromic gut	Cotton
Synthetic	Polyglycolic acid (Dexon)	Polypropylene monofilament (Surgilene, Prolene)
	Polyglactin (Vicryl) 910	Braided (Dacron, Mersilene)
	Polydioxanone (PDS)	Gore-Tex (Polytetrafluoroethylene)
	Polyglyconate (Maxon)	Nylon (Ethibond)
	Monocryl	

important for infected abdominal wall fascia, where tensile strength is crucial and chronic inflammation least desirable.

ABDOMINAL INCISIONS

Selection of Incision Type

The surgeon may choose either a vertical or a transverse skin incision (Fig. 18-1) when performing a cesarean delivery. The ultimate choice hinges on factors such as the urgency of the procedure, the presence of prior abdominal scars, and associated nonobstetric pathology, if any. To some degree the decision will be based on the surgeon's past experience and on consumer pressures favoring a low transverse incision.^[83], ^[84] The midline vertical, transverse Maylard, and transverse Pfannenstiel incisions are the three most commonly used types. Transverse Cherney and paramedian vertical incisions are seldom used.

There has been a significant increase recently in the use of transverse incisions as opposed to the traditional low vertical incision. The obstetrician, comfortable with several types of incision, is able to make a selective decision for each patient. The choice should be based on the relative simplicity and speed of the various incisions, the desired exposure, the estimated fetal weight, the anticipated cosmetic results, and the risk factors for infection or dehiscence. In general, vertical incisions allow

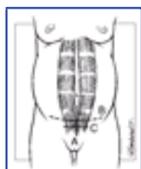

Figure 18-1 The obstetrician most commonly uses one of three abdominal incisions: (A) midline, (B) Maylard, and (C) Pfannenstiel. Hatched lines indicate possible extension. (Modified from Baker C, Shingleton HM: *Incisions. Clin Obstet Gynecol* 31:701, 1988.)

more rapid access to the lower uterine segment, have less blood loss, provide greater feasibility for incisional extension around the umbilicus, and allow easier examination of the upper abdomen. In pregnancy, speed of entry through a midline vertical incision is facilitated by the common occurrence of diastasis of the rectus muscles.

Transverse incisions are somewhat more time consuming; the difference in time of entry between the two incision types is approximately 30 to 60 seconds in the hands of an experienced clinician. Transverse incisions are preferred cosmetically, are generally less painful, have been associated with a lower risk of subsequent herniation, and yet provide equal, if not better, visualization of the pelvis. Some argue that there is a lower incidence of postoperative pulmonary complications when a transverse incision is used, particularly in patients with preexisting pulmonary problems such as obstructive lung disease.^[82] Whether a transverse incision is less subject to dehiscence and herniation remains controversial.^[83], ^[84]

A number of surgical principles are relevant regardless of the incision selected. The surgeon and surgical assistant should apply traction at right angles to the intended incision site in a symmetric manner so that the incision is developed in a uniform vertical plane through its length and depth. The "Allis" test may be used to determine if the abdominal incision will be large enough; if a 15-cm-long Allis clamp fits easily between retractors placed at the ends of the incision, little difficulty will be encountered in delivering the fetus.^[85] There is no reason to disturb the fat from the adjacent fascia unless there is difficulty in exposing the fascial edges. Such efforts will simply increase the risk of postoperative seromas and develop unnecessary dead space.

The Pfannenstiel and Maylard incisions are the most commonly used transverse incisions for cesarean delivery. The Maylard incision is quicker, provides better lateral pelvic and midabdominal visualization, requires less dissection and retraction of the anterior abdominal wall during the procedure, and makes a repeat procedure somewhat easier than the Pfannenstiel.

The Maylard incision (Fig. 18-1) differs from the Pfannenstiel incision in that it involves transverse incision of the anterior rectus sheath and the rectus muscles bilaterally.^[86] In the nonobese patient, the skin incision is ordinarily at least 3 to 4 cm above the symphysis. Should there be a large panniculus, the incision may be made considerably higher to avoid placement of the incision on the undersurface of the panniculus. The superficial inferior epigastric vessels, generally located in the lateral one third of the incision, may be individually ligated if necessary. Incision of the rectus muscles is accomplished by placing two fingers or clamps beneath each rectus muscle and lifting the muscles

in such a way as to allow surgical incision with either a knife or cutting cautery between the fingers or clamps. In most cesarean procedures, pelvic exposure is sufficient if only the medial two thirds of the rectus muscles are incised. This avoids the necessity to ligate the deep inferior epigastric vessels, as may be necessary in more extensive gynecologic cases. Nonetheless, the surgeon should palpate for these vessels. Should extension of the incision be necessary, these vessels should be isolated and ligated to avoid hematoma formation. Those favoring a Cherney modification believe it is preferable to partial transection of the rectus muscles, a technique required with the Maylard incision.^[87] After separation of the rectus muscles from the pubic symphysis, the transversalis fascia and peritoneum are then incised transversely, as opposed to the Pfannenstiel incision in which they are incised vertically.

The Pfannenstiel incision (Fig. 18-1) is a curvilinear incision that is best suited for the nonobese patient. The incision is generally made approximately 3 cm above the symphysis pubis within the pubic hair line at its midpoint. The determination of its lateral extension should, to some extent, be a function of the estimated fetal size. Symmetry of the incision can be facilitated by traction of the skin in a cephalad direction during incision that, when released, will result in a curvilinear incision. The incision is generally extended to the lateral border of the rectus muscles at a point 2 to 3 cm inferior and medial to the anterior superior iliac crests. The inferior and superior margin of the fascial incision is elevated to facilitate blunt dissection of the fascial sheath from the underlying rectus muscles. Individual perforating blood vessels between muscle and fascia will require ligation or coagulation to achieve adequate hemostasis. Sharp separation of the muscles from the median raphe, which is facilitated by upward traction on the anterior rectus sheath, is extended superiorly to the level of the umbilicus. Once the rectus muscles are adequately exposed, they are retracted laterally to reveal the underlying transversalis fascia and peritoneum, which is entered via a midline vertical incision in a manner similar to that of a low vertical abdominal incision.

Abdominal Entry

Surgeons vary in their choice of technique for incising the fascia. Some prefer initial entry by scalpel with subsequent extension with scissors. Others use the scalpel for the entirety of the incision because it is theoretically less traumatic. Once the surgeon becomes familiar with this technique, it allows somewhat faster entry than

does scissors. Nonetheless, either technique is appropriate. The site of initial peritoneal entry chosen should be approximately halfway between the umbilicus and symphysis so as to avoid bladder injury, particularly in patients undergoing a repeat cesarean procedure; the peritoneum should be "tented" between two hemostats or pickups and palpated to ascertain that there is no adherent bowel omentum, or even bladder. The peritoneal cavity may be entered using a scalpel or scissors. Should the planned peritoneal incision be in a vertical direction, the peritoneal incision is first extended superiorly for greater exposure and then inferiorly to a point just above the superior pole of the bladder.

SPECIAL CONSIDERATIONS

Skin Incision in the Obese Patient

The obese patient is at significant additional risk for wound complications. Reported wound complication rates are 4 and 29 percent in nonobese and obese patients, respectively.^[88] Should the patient be massively obese, it may be better to use an incision that does not involve the underside of the panniculus, an area that is more heavily colonized with bacteria and is difficult to prepare surgically, to keep dry, and to inspect in the postoperative period. The objective is to enter the abdomen directly over the lower uterine segment. The surgeon may choose either a vertical midline incision, which is developed periumbilically both above and below the umbilicus or, alternatively, a transverse incision closer to the umbilicus. The actual selection of the site of incision, whether it be vertical or transverse, can be made by retracting the panniculus in a caudad direction so as to place the incision directly overlying the uterine segment.

In closing the fascia of an obese patient, placement of the sutures in the fascia should be at least 1.5 to 2 cm lateral to the cut margin of the fascia, with successive bites approximately 1.5 cm apart along the longitudinal axis of the incision. Should there be major risk factors other than obesity, the clinician may consider use of (1) Smead-Jones monofilament polypropylene internal retention sutures or (2) interrupted or figure-of-eight sutures using either polyglycolic acid or other delayed absorption sutures like monofilament polyglyconate or polydioxanone.

It is also acceptable to use a running continuous large-gauge monofilament polypropylene suture on a large needle in closing the fascial incision. This technique offers the theoretical advantages of distributing tension equally over the continuity of the incision line and increasing the speed of wound closure, thus minimizing the risk of foreign material within the wound. Sutures should not be locked, a technique that reduces vascularization and potentially slows wound healing. Shepherd et al.^[89] encountered no wound dehiscences using a mass closure technique in over 200 high-risk

gynecology patients. Some advocate placement of a clip on the short end of the suture to avoid knot disruption. Subcutaneous sutures may be used and the skin closed with suture staples, left in place for 7 to 10 days. Subcutaneous closure will reduce the risk of wound disruption in women with 2 cm or more of subcutaneous fat.^[90]

Placenta Previa and Accreta

Although the incidence of placenta accreta has been reported to be approximately 1 in 2,500 deliveries, the incidence increases to approximately 4 percent in patients with a placenta previa.^[91] This association is particularly marked in the patient with a previous cesarean birth. Under such circumstances, the incidence of placenta accreta may approach 25 percent.^[92] For this reason the physician contemplating a cesarean delivery for placenta previa, particularly a repeat procedure, should consider the possibility of hysterectomy.

Selection of Lower Uterine Incision

The most commonly used uterine incisions ([Table 18-5](#) and [Fig. 18-2](#)) are the low transverse incision originally advocated by Kerr^[93] and the low vertical incision originally proposed by Krönig.^[19] A low transverse (Kerr) incision is used in more than 90 percent of all cesarean births. The low transverse incision has the following advantages over a vertical incision: less risk of entry into the upper uterine segment, greater ease of entry, less bladder dissection, less operative blood loss, less repair, easier reperitonealization, and less likelihood of adhesion formation to bowel or omentum. Importantly, in subsequent pregnancies the obstetrician can feel more comfortable offering a VBAC trial because there is less likelihood of uterine rupture.^[93]

TABLE 18-5 -- SURGICAL CONSIDERATIONS IN SELECTION OF UTERINE INCISION FOR CESAREAN DELIVERY

Low Segment Incisions	Transverse	Vertical

Uterine rupture (subsequent)	+	-
Lateral extension into uterine vessels	-	+
Extension inferiorly	+	-
Intraoperative bleeding	+	-
Subsequent adhesions	+	-

+, Advantage to uterine incision type; -, disadvantage.

A vertical incision (classic or low vertical) may be advantageous if the patient has not been in labor and the lower uterus is narrow and poorly developed or if the fetus is not in a cephalic presentation, particularly a back-down transverse lie or preterm breech. Should a transverse incision be performed under such circumstances, there is a greater likelihood of lateral extension of the incision into the vessels of the broad ligament. However, individualization is reasonable. For instance, the author generally prefers a vertical incision for a transverse lie. However, a low transverse incision is certainly feasible if the lower uterine segment is well developed, as may be the case when the patient presents in active labor with advanced cervical dilatation. Other possible indications for a vertical incision include leiomyomata

obstructing exposure to the lower segment and structural uterine anomalies.

The classic uterine incision involves the upper active uterine segment. Its primary advantage is the rapidity of entry into the uterus. Furthermore, some physicians believe that the incision is useful in the presence of an anterior placenta previa, reducing the potential for maternal and fetal hemorrhage. ^[94] Despite these advantages, this incision is used in no more than 10 percent of cases. A classic incision may be used when it is not possible to expose the lower uterine segment or when a hysterectomy is planned. More commonly encountered complications associated with classic incisions include subsequent adhesion formation and greater risk of uterine rupture with later pregnancies. ^[95] Patients who have had a prior classic incision should consider an appropriately timed elective repeat cesarean birth because of the risk of uterine rupture even before labor has started.

The theoretical advantages of the low vertical (Krönig) incision over the classic incision are similar to those of the low transverse incision. However, unlike the classic incision, there may occasionally be a caudad (inferior) extension of the incision into the cervix and vagina or even into the bladder. Although the low vertical (Krönig) incision is theoretically limited to the lower uterine segment, it often involves the upper segment.

PERFORMING THE CESAREAN DELIVERY

Development of Bladder Flap

After placement of a bladder catheter and entry into the peritoneal cavity, the obstetrician should palpate the uterus to determine the degree and direction of uterine rotation. In most instances, the uterus is dextrorotated such that the left round ligament may be visualized more anteriorly and closer to the midline than is

552

Figure 18-2 Uterine incisions for cesarean delivery. *A*, Low transverse incision. The bladder is retracted downward, and the incision is made in the lower uterine segment, curving gently upward. If the lower segment is poorly developed, the incision can also curve sharply upward at each end to avoid extending into the ascending branches of the uterine arteries. *B*, Low vertical incision. The incision is made vertically in the lower uterine segment after reflecting the bladder, avoiding extension into the bladder below. If more room is needed, the incision can be extended upward into the upper uterine segment. *C*, Classic incision. The incision is entirely within the upper uterine segment and can be at the level shown or in the fundus. *D*, J incision. If more room is needed when an initial transverse incision has been made, either end of the incision can be extended upward into the upper uterine segment and parallel to the ascending branch of the uterine artery. *E*, T incision. More room can be obtained in a transverse incision by an upward midline extension into the upper uterine segment.

the right. Some obstetricians insert moistened laparotomy pads into each lateral peritoneal gutter prior to making the uterine incision to absorb amniotic fluid and blood escaping from the incision, particularly when there is a strong suspicion of amnionitis. The uterovesical peritoneum (serosa) is grasped in the midline and undermined with Metzenbaum scissors inserted between the peritoneum and underlying myometrium to develop bluntly a retroperitoneal space bilaterally to the lateral margins of the lower uterine segment. The peritoneal reflection is then incised bilaterally in an upward direction and the vesicouterine fold is grasped with forceps and the bladder lifted anteriorly, allowing blunt separation of the bladder from the underlying lower uterine segment. Should adherent adhesions be noted in a repeat procedure, sharp dissection may be necessary to free-up the posterior aspect of the bladder. Once the dissection is complete in the midline, the fingers may be carefully swept laterally in each direction to free the bladder more completely. After the bladder flap is adequately developed, a universal retractor or bladder blade is used to retract the bladder anteriorly and inferiorly to facilitate exposure of the intended incision site. Use of a Richardson retractor to retract the superior margin of a transverse abdominal incision may help to facilitate exposure.

Low Transverse Cesarean Incision

The lower uterine segment incision ([Fig. 18-2A](#)) is begun 1 to 2 cm above the site of the original upper margin of the bladder. A small midline incision is first made with a scalpel through the lower uterine segment to the fetal membranes. Continuous suction should be available to facilitate visualization of the operative field and to evacuate amniotic fluid should the incision perforate through the fetal membranes. Care should be taken to avoid laceration of the fetus, which is an occasional complication, especially when the lower uterine segment is thin or when expeditious delivery of the fetus is required.

After suctioning, the incision may be extended laterally and slightly upward (cephalad) to the lateral margin of the lower uterine segment so as to maximize

553

incisional length and avoid extension into the uterine vessels. Extension of the incision may be accomplished by either of two methods: (1) sharp dissection, taking care to avoid fetal fingers and toes; or (2) blunt dissection by spreading the incision with each index finger. Blunt splitting of the uterine incision, particularly if the lower uterine segment is thin, will result in more rapid entry; however, there is potential for unpredictable extension with this method, particularly if the lower segment is not fully effaced. The choice is largely a function of training and theoretical concerns regarding unintended extension. The relative merits of the two approaches were recently addressed in a prospective randomized study that could detect no difference in the incidence of unintended extension, estimated blood loss, or length of surgery between the two approaches. Rather, the frequency of unintended extensions correlated with the stage of labor (1.4, 15.5, and 35.0 percent for no labor, first stage of labor, and second stage, respectively).^[96]

Low Vertical Incision

Should the fetus present as a breech or transverse lie, particularly back-down, there is often advantage to a low vertical ([Fig. 18-2B](#) and [Fig. 18-3](#)) uterine incision, particularly if the lower uterine segment is not well developed. The bladder is displaced downward to expose the lower uterine segment more inferiorly so that the low vertical incision will be less likely to extend into the upper segment. Once the anticipated site is exposed, an incision is made at the inferior margin of the lower segment and extended cephalad with either bandage scissors or knife. Should it be necessary to extend the incision into the upper active uterine segment, it should be noted in the operative report.

Although vertical cesarean incisions are traditionally categorized into low vertical and classic types, the performance of a true low vertical incision that does not enter the upper contractile portion of the uterus is actually uncommon. The clinical implication is that the low vertical incision poses considerably less risk in a subsequent VBAC trial than would be the case with a classic incision; nonetheless, the risk of rupture is probably somewhat greater than that of a low transverse incision.

Classic Cesarean Incision

The initial incision ([Fig. 18-2C](#)) is made with a scalpel 1 to 2 cm above the bladder reflection. Once the fetus or membranes are visualized, the incision is extended cephalad with bandage scissors, the size of the incision varying with the estimated size of the fetus. The patient should also be advised of this occurrence and its importance to future pregnancies should a VBAC trial be considered.

Management of the Anterior Placenta

Should the placenta be located in the anterior lower uterine segment, entry can be accomplished by one of three methods. First, the clinician can simply dissect through the placenta; this carries the risk of short-term fetal hemorrhage. Second, the placenta can be separated from the lower uterine segment, facilitating lateral

Figure 18-3 Low vertical incision. A, Ideally, a vertical incision is contained entirely in the lower uterine segment. B, Extension into the upper uterine segment, either inadvertently or by choice, is common.

of the fetus. Finally, a classic uterine incision can be used.

Delivery of the Fetus

Upon completion of the incision, the retractors are removed and a hand is inserted into the uterine cavity to elevate and flex the fetal head through the uterine incision. Initial efforts to deliver the presenting part through the uterine incision will indicate the adequacy of the uterine incision. Should the head be deeply wedged within the pelvis, it can be dislodged by an assistant applying upward pressure vaginally. Once the occiput presents into the incision, moderate fundal pressure may facilitate expulsion. On occasion the head may be delivered with shorthanded Simpson forceps or vacuum. Once delivery of the fetal head is completed, the nose and oropharynx are suctioned with a bulb syringe. If meconium is present, suction can be accomplished with continuous wall suction. When suctioning is complete, expulsion of the remainder of the newborn is facilitated by moderate uterine fundal pressure. The cord is then doubly clamped and cut, and the infant is transferred to the resuscitation team.

Umbilical cord blood gas data may be collected routinely or selectively in high-risk circumstances, such as fetal growth restriction, preterm birth, breech presentations, amnionitis, the presence of thick meconium, cesarean delivery for nonreassuring FHR findings, or unanticipated low Apgar scores. To facilitate collection of an adequate arterial sample, the umbilical cord is first clamped close to the placenta so as to maintain filling of the umbilical arteries and vein and then clamped close to the newborn. It is then doubly clamped in each location so as to isolate a 10- to 15-cm segment of cord for umbilical arterial and venous blood sampling.

Operative Techniques for the Preterm Fetus

The uterine incision to be used for the delivery of the preterm fetus is best selected after entry into the maternal abdomen. At least 50 percent of cases will require a low vertical or classic incision for indications such as malpresentation or a poorly developed lower uterine segment. Among 174 VLBW cesarean births at Los Angeles County Women's Hospital, a low transverse incision was performed in 31 percent of cases, a low vertical incision in 47 percent, and a classic uterine incision in 22 percent.^[97] Using ultrasound, Morrison^[98] prospectively evaluated the width of the lower uterine segment in the absence of labor and found its transverse dimension to be 0.5, 1.0, and 4.0 cm at 20, 28, and 34 weeks, respectively. Thus, without significant labor, the lower uterine segment will probably not be sufficiently developed to provide an adequate transverse dimension for removal of the fetus. The complications of performing a low transverse incision in the absence of adequate development of the lower uterine segment include difficult removal of the fetus, lateral extension of the incision into the broad ligament and uterine vessels, and downward extension of the incision into the cervix and the vagina. Boyle and Gabbe observed that 1.3 percent of low transverse cesarean incisions required a T or J extension ([Fig. 18-2D and E](#)) for malpresentation, usually of a preterm fetus, for a poorly developed lower uterine segment, or when the fetal head was deeply arrested in the midpelvis. Estimated blood loss was significantly greater in these cases.^[99] It is noteworthy that intraoperative complications including injury to the bladder, broad ligament laceration, and uterine artery laceration are more common in preterm than in term cesarean births. The complication rate is independent of incision type.^[100]

Cesarean Delivery of the Breech Presentation

Should an elective cesarean section be planned for a breech presentation, it is desirable, prior to performing the procedure, to confirm that the breech has not converted spontaneously to a vertex or to a more unfavorable transverse lie. The lie of the fetus can be verified by palpation prior to making the uterine incision. In the case of a transverse lie, the vertex or the buttocks of the breech can often be guided into a position underlying the planned site of the uterine incision. Should the lower uterine segment be well developed, a transverse or vertical uterine incision can be used. However, a vertical incision is often preferable should the cervix be long and closed, the lower uterine segment poorly developed, or the breech converted to a back-down transverse lie.

The head of a preterm breech infant may be trapped if the incision is not large enough.^[97] Although cesarean delivery is often elected in an attempt to minimize fetal trauma, the actual delivery mechanism via the cesarean incision is essentially identical to that of the vaginal route. Should the fetus present as a nonfrank breech or back-up transverse lie, the first step is to identify and grasp a foot and extract the leg through the incision until the second foot can be identified. The surgeon should conduct the delivery process in such a way as to minimize hyperextension of the fetal neck and compression of fetal organs. The mechanism for delivery of the breech is discussed elsewhere (see Chapter 16). However, should there be evidence of head entrapment, the first action should be to extend the abdominal incision and to enlarge the uterine incision. Occasionally, it may be necessary to incise perpendicular to a transverse incision

(inverted T-shaped incision) or to extend the transverse incision upward parallel to the uterine artery (J incision) ([Fig. 18-2D and E](#)). Both the inverted T and J incisions are more subject to uterine rupture with subsequent pregnancies.

Manual Versus "Spontaneous" Placental Expulsion

Following delivery of the fetus, 20 to 40 units of oxytocin can be administered in an isotonic crystalloid solution. Subsequent removal of the placenta is commonly done manually. McCurdy et al.^[101] compared the manual option to spontaneous delivery of the placenta in a prospective randomized trial. The manual group demonstrated a significantly higher measured blood loss (967 vs. 666 ml) and a surprisingly higher incidence of endometritis (23 vs. 3 percent). Additional data suggesting a benefit for awaiting "spontaneous expulsion" are provided in a 1964 report from Queenan and Nakamoto^[102] that demonstrated a reduction in Rh sensitization in the "spontaneous" group. Following its removal, the placenta should be inspected for possible missing cotyledons.

Repair of the Uterine Incision

Closure of the uterine incision may be aided by manual delivery of the uterine fundus through the abdominal incision.^[103] Delivery of the uterine fundus through the abdominal incision facilitates uterine massage and observation of uterine tone, as well as routine examination of the adnexa and tubal ligation. The fundus may be covered with a moistened laparotomy pad and the uterine incision inspected for obvious bleeding points, which are controlled with either Ring forceps or Allis clamps until suture closure can be accomplished. The uterine cavity may then be inspected and wiped clean with a dry laparotomy sponge to remove fetal membranes and placental fragments.

The primary disadvantages of uterine exteriorization are possible peritoneal discomfort and nausea and/or vomiting in patients under inadequate regional anesthesia. Some have hypothesized that exteriorization may temporarily kink and occlude the uterine blood supply, resulting in a delayed onset of bleeding at the incision site. If possible, such a complication must be quite unusual. A prospective randomized study by Magann et al.^[104] addressed the cumulative impact of delivery of the placenta and uterine exteriorization and confirmed that blood loss associated with "spontaneous" placental separation was significantly less than that associated with manual removal. When blood loss (uterus exteriorized vs. in situ) was compared, no difference was detectable between the spontaneous separation/expulsion and manual removal groups.

Midline placement of a ring forceps or Allis clamp may be used to elevate the lower portion of the low transverse uterine incision, facilitating visualization of the field and approximation of the incision. Although Allis clamps can be routinely placed at the angles of the incision to control bleeding and to identify the end of the incision, routine placement of more than the one midline clamp in the absence of bleeding simply clutters the field. The perimeter of the uterine incision is then inspected to

locate bleeding vessels and to localize the true margins of the uterine incision. Control of uterine bleeding is facilitated by oxytocin administration and uterine massage. Oxytocin administration is particularly important following classic cesarean birth. If bleeding is encountered along the margins of the incision, a ring forceps or Allis clamp should be placed at the site of bleeding. If the incisional margin is not carefully identified, on occasion the posterior wall of the lower uterine segment may balloon anteriorly and be confused with the lower margin of the transverse incision, potentially resulting in complete closure of the uterine cavity (i.e., superior edge of the inferior incision margin sutured to the posterior uterine wall).

Reapproximation of the lower uterine incision may be performed in either one or two layers (Fig. 18-4) using 0 or double 0 chromic suture or similar absorbable synthetic suture such as Vicryl, the second layer inverting the first. The initial suture should be placed lateral to the angle of a transverse incision or inferior to the lower margin of a vertical incision. Subsequent stitches may be run in a continuous or continuous-locking manner to the opposite end of the incision. The sutures may be placed through the entire myometrium. Some have stressed the importance of avoiding incorporation of decidua in the suture for concern of later development of endometriosis in the scar; however, this is a remote possibility.^[105] Although many routinely use a continuous-locking suture, there is questionable advantage to routine suture locking along the entire margin, except at sites of obvious oozing. Locking sutures potentially increase the likelihood of tissue ischemia and potentially may limit wound healing. It has been traditional to place a second continuous layer (Lembert or Cushing) of chromic or similar suture to invert the first layer, with either vertically or horizontally stitches, the latter requiring more frequent placement of the needle upon the needle holder. If the low transverse uterine segment is well effaced and hemostasis adequate, it is reasonable to reapproximate the uterine margins with a single suture layer. Hauth et al.^[106] have, on the basis of a prospective ($n = 906$) randomized trial comparing traditional two-layer with single-layer closure, reported that the single-layer closure significantly decreased operating

556

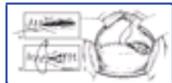

Figure 18-4 Closure of low transverse incision. *A*, The first layer can be either interrupted or continuous. A continuous locking suture is less desirable, despite its reputed hemostatic abilities, because it may interfere with incision vasculature and, hence, with healing and scar formation. *B*, A second inverted layer created by using a continuous Lembert's or Cushing's stitch is customary but is really needed only when apposition is unsatisfactory after application of the first layer. Inclusion of too much tissue produces a bulky mass that may delay involution and interfere with healing. *C*, The bladder peritoneum is reattached to the uterine peritoneum with fine suture.

time (39.2 vs. 44.8 minutes), had no increase in postoperative complications and, surprisingly, required fewer additional hemostatic sutures (beyond that expected in one or two layers) per patient. Uterine scar dehiscence or rupture does not appear to be increased with a single layer of closure. Tucker et al.^[107] compared the outcomes of 149 women with a single-layer closure with 143 women with two-layer closure and found no complete uterine ruptures in any of the 292 trials of labor. Partial scar separation was detected in approximately 2 percent of patients in each group.

Closure of a classic cesarean incision (Fig. 18-5) involving the more thickened upper segment most often will require a two-layer closure. Should the uterine wall be unusually thick, it may be necessary to use a third layer. Repair of the incision can be done in several ways. A common method is to use continuous 0 or 1 chromic cat gut suture in layers, the first layer approximating the inner one half of the uterine wall thickness in a continuous or continuous-locking manner. A second and occasionally a third layer is then used to approximate the uterine musculature. It may be desirable to bury the knot (at the superior end of the incision) of the outer suture line. The operative record should state the type of uterine incision, and the patient should be informed about the incision and its impact on care in subsequent pregnancies, including the advisability against a future attempt at a VBAC.^[95]

Reapproximation of the Visceral (Bladder Flap) and Parietal Peritoneum

Most obstetricians no longer close the visceral (bladder flap) and parietal peritoneum, a principle long accepted in the surgical literature. Unrepaired mesothelial surfaces spontaneously reapproximate within 48 hours and demonstrate healing with no scar formation at 5 days. Clinically, this approach is associated with a reduced need for postoperative analgesia and quicker return of

Figure 18-5 Repair of a classic incision. Three-layer closure of a classic incision, including inversion of the serosal layer to discourage adhesion formation. The knot at the superior end of the incision of the second layer can be buried by medial to lateral placement of the suture from within the depth of the incision and subsequent lateral to medial reentry on the opposing side with resultant knot placement within the incision.

557

bowel function.^[108], ^[109] Furthermore, this approach does not promote adhesion formation.^[110] ^[111] ^[112] ^[113]

Abdominal Closure

Once the uterine incisional reapproximation is completed, the incision should once again be inspected for bleeding points, which can be individually ligated, coagulated, or controlled with figure-of-eight sutures. Before closing the abdomen, the uterus, fallopian tubes, and ovaries should be examined for unsuspected pathology. Some routinely examine the appendix. When surgical sterilization or ovarian cystectomy is required, it is accomplished before replacing the uterus into the abdominal cavity. If used, laparotomy pads are removed and the abdominal contents, lateral gutters, and cul-de-sac are inspected and, where indicated, suctioned. The pelvis and lower abdomen may be irrigated, especially if there is coexistent chorioamnionitis or if there has been heavy spillage of meconium outside the operative field. The operating team should confirm that the needle and sponge counts are correct.

There is no need to reapproximate the parietal peritoneum or rectus muscles. The rectus fascia may be closed with either interrupted or continuous (nonlocking) sutures. Suture choice is important in fascial healing. If the suture is absorbed too rapidly, tensile strength may be reduced, thus increasing the likelihood of wound breakdown. Chromic suture should be avoided when possible. Selection of a suture for its duration of strength is particularly important for patients at risk for wound dehiscence. Unlike their chromic counterparts, synthetic braided sutures maintain tensile strength throughout fascial healing. They are predictably broken down by hydrolysis. In contrast, gut suture has less tensile strength and is degraded less predictably. Local infection may also result in more rapid loss of strength. If the surgeon is dealing with a patient at risk for wound breakdown from chronic corticosteroid therapy, for example, delayed absorbable material such as PDS or polyglyconate (Maxon) or permanent material such as nylon or polypropylene (Prolene) may have merit.

Once an appropriate suture is chosen, care should be taken in selecting the site of suture placement for fascial closure. In most instances of wound dehiscence, the suture remains intact but has cut through the tissue in which it has been placed. One study indicates that this problem is responsible for up to 88 percent of disrupted wounds.^[114]

Large bites using larger gauge suture material are less likely to transect tissue than are small bites with narrow-gauge suture material. Suture entry and exit sites should be well beyond the 1-cm inner zone of collagenolysis at the margin of the wound. Should sutures be placed within this inner zone, there is greater tendency for them to pull through, leading to dehiscence and possible evisceration. Sutures should be placed at approximately 1-cm intervals approximately 1.5 cm from the incision line.

It is acceptable to use a running suture in closing the fascia in patients with a clean incision. Fagniez et al.^[115] were not able to demonstrate a difference in dehiscence rates in a randomized prospective trial of 3,135 patients using a running versus interrupted polyglycolic acid suture in midline incisions. Approximation of fascia should allow maintenance of adequate blood flow; unnecessarily tight sutures will cause hypoxia and potentially interfere with predictable wound healing.^[116], ^[117] Should a patient be at high risk for wound dehiscence, it is preferable that the fascia not be closed with continuous suturing, particularly on a vertical incision. If the patient is at high risk for abdominal distention and wound breakdown, a mass or Smead-Jones (Fig. 18-6) closure is preferable. This closure is mechanically more

sound and allows for a 30 percent increase in abdominal girth.

It is generally not necessary to reapproximate the subcutaneous tissue unless the patient is markedly obese, in which case subcutaneous closure may reduce wound disruption. No difference in the rate of dehiscence was noted between obese patients who underwent peritoneal closure and those who did not in one large randomized trial.^[119] Skin may be closed with staples or a subcuticular stitch. Steristrip adhesive tape (3M Surgical Products, St. Paul, MN) can be used to

Figure 18-6 Modification of far-near, near-far Smead-Jones suture. Suture passes deeply through lateral side of anterior rectus fascia and adjacent fat, crosses the midline of the incision to pick up the medial edge of the rectus fascia, then catches the near side of the opposite rectus sheath, and, finally, returns to the far margin of the opposite rectus sheath and subcutaneous fat. (Modified from American College of Obstetricians and Gynecologists: *Prolog. In Gynecologic Oncology and Surgery. Washington, DC, ACOG, 1991, p 187.*)

reduce tension on subcuticular sutures. If staples are used, they may be replaced with Steristrips 3 or 4 days after surgery to decrease scarring.

INTRAOPERATIVE COMPLICATIONS

The patient undergoing cesarean delivery is at risk for many of the same intra- and postoperative complications as is the patient having a vaginal delivery. Management problems more commonly associated with cesarean delivery, as well as conditions such as uterine atony and placenta accreta, which are also discussed in [Chapter 17](#) , are briefly reviewed in this section.

Although injury to bladder, bowel, or ureters is uncommon, many competent obstetricians, despite careful surgical technique, will encounter complications. When they occur, the primary responsibility is to identify the injury and its extent, to repair the injury, and to obtain consultation should injuries be extensive or unusually complex.

Uterine Lacerations

Lacerations of the lower uterine incision are more common when a low transverse incision is used in the presence of a macrosomic fetus or a noncephalic presentation. Fortunately, these lacerations are usually easily sutured as long as they only extend laterally to the margin of the myometrium or inferiorly into the vagina. Care must be taken to avoid ligation of the ureters. In most circumstances, the lateral apex of the extension can be identified and the suture placed just lateral to that point. Should there be extension into the broad ligament in proximity to the ureters, on occasion it may be necessary to open the broad ligament and identify the ureters before suture placement. Rarely, there may be an advantage to retrograde placement of an 8-Fr ureteral catheter into the ureters. This can be accomplished transurethrally or by performing a vertical incision in the dome of the bladder to visualize the ureteral orifices. The bladder can then be repaired with an initial continuous 20 chromic suture followed by a second imbricating layer of 20 suture.

Bladder Injuries

Injury to the bladder is an infrequent but recognized complication of cesarean delivery. More widespread use of the transverse abdominal incision has increased the likelihood of bladder dome injury upon entering the abdomen. Although the risk of bladder injury can be minimized by preoperative catheterization of the bladder and careful entry into the peritoneal cavity, it is not always possible to avoid injury during a repeat procedure. When the bladder is more adherent than usual, sharp dissection of the "webbing" between the bladder base and the lower uterine segment and vagina, as opposed to blunt dissection with a sponge stick or gauze-covered finger, will reduce, but not eliminate, the incidence of unplanned cystotomy.

Bladder injury may also occur at the time of uterine rupture, particularly in patients with a prior cesarean delivery. Although rates as high as 10 to 14 percent have been reported, the incidence has decreased somewhat in women attempting VBAC. ^[118] ^[119] ^[120] Should hysterectomy be required, cystotomy as a complication of cesarean hysterectomy has been noted to occur in as many as 4 to 5 percent of procedures. ^[121] , ^[122] In most cases, the injury occurs at the bladder base. To some extent, if hysterectomy is anticipated, mobilizing the bladder from the lower uterine segment and upper vagina prior to making the uterine incision will diminish this risk.

Should a bladder laceration be encountered, the bladder may be repaired with a two-layer closure with 20 or 30 chromic. Surgeons may differ significantly in their surgical approach to repair. Controversies focus on the use of continuous versus interrupted sutures, on whether it is important to avoid including the mucosa in the suture line, and on the duration of catheter drainage. The issues are probably of little significance when the cystotomy is in the dome of the bladder. However, a cystotomy in the bladder base is more likely to present problems, because the bladder base is thinner and receives less blood flow. There is also a possibility of laceration into the trigone and injury to the ureteral orifices. Should the trigone be lacerated, there may be an advantage to inserting a ureteral catheter under direct visualization. After the bladder has been repaired, a catheter can be left in place for 7 to 10 days. ^[120] , ^[123]

Ureteral Injury

Although one does not frequently think of ureteral injury during cesarean delivery, this complication has been reported in up to 1 in 1,000 procedures. ^[120] Ureteral injury is also increased with cesarean hysterectomy, with rates of 0.2 to 0.5 percent being documented. ^[121] , ^[122] In most instances, injury occurs during efforts to control bleeding arising from lateral extension of the uterine incision. Opening the anterior leaf of the broad ligament while controlling blood loss with direct pressure will often facilitate more accurate suture placement, which will diminish the potential for ureteral injury. Unfortunately, the injury often goes unrecognized intraoperatively.

Gastrointestinal Tract Injury

Injuries to the bowel are also rare, but nonetheless are reported to occur in approximately 1 in 1,300 cesarean sections. ^[100] Prior abdominal surgery and pelvic/abdominal infection leading to adhesion formation are common risk factors. Sharp scalpel incision limited to a site of transparent peritoneum will reduce inadvertent bowel or bladder injury.

Should adhesions require lysis to gain access to the lower uterine segment, they should be sharply dissected with scissors tips pointed away from the bowel. Small defects in bowel serosa can be closed simply with interrupted silk sutures on an atraumatic needle. If these defects are very small, no closure may be necessary. Full-thickness lacerations should be repaired in a double-layer closure, using a transverse closure of a longitudinal laceration, to minimize the possibility of narrowing the bowel lumen. The mucosa can be closed with running or interrupted 3-0 absorbable sutures such as chromic or polyglactin. The muscular and serosal layers are then closed with a similar-sized interrupted silk suture.

In the event that there are multiple full-thickness small bowel injuries or the colon or sigmoid is entered, consultation with a gynecologic oncologist or general surgeon is appropriate. The small bowel may require resection and reanastomosis. Primary closure of a small laceration (<1 cm) of the colon is indicated using a double-layer closure as described above. More extensive injury associated with fecal contamination should be treated with copious lavage and may require a temporary colostomy. In either case, gram-negative aerobic and anaerobic antibiotic coverage should be provided. This is commonly provided by combination therapy with an aminoglycoside and either clindamycin or metronidazole (i.e., clindamycin/gentamicin) and/or cephalosporin with metronidazole. Some have recommended broad-spectrum monotherapy, which has the advantages of lower toxicity, lower drug costs, and lower cost of administration, including eliminating the need for monitoring of aminoglycoside blood levels. Ampicillin/sulbactam (3.0 g intravenously every 6 hours) is a reasonable first-line choice, with combination therapy reserved for patients with documented penicillin allergy. ^[124]

Uterine Atony

Initial efforts to control uterine atony include uterine massage and medical therapy with (1) intravenous oxytocin, 20 to 40 units/L; (2) methergotamine, 0.2 mg, or ergonovine administered intramuscularly; or (3) 15 methylprostaglandin F₂ (Hemabate), which can be administered either intramuscularly or directly into the myometrium. Should the initial dose of prostaglandin be insufficient, successive dosages of 250 µg, up to a total dose of 1.0 to 1.5 mg, can be used. Should medical treatment fail, the surgeon must decide between ligation of the uterine arteries (see Fig. 17-17), hypogastric artery ligation, and hysterectomy. Uterine or hypogastric artery ligation may be the desirable approach should the patient be stable cardiovascularly and desirous of future pregnancy. Hypogastric artery ligation can be accomplished by ligation of the ascending branch, which can usually be found at the inferior and lateral extreme of the low transverse incision ascending retroperitoneally within the broad ligament (Fig. 18-7). Unfortunately, even hypogastric artery ligation is actually successful in less than one half of the cases.^[125] Should uterine or hypogastric artery ligation also fail to control the hemorrhage, it may be necessary to proceed to hysterectomy.

Placenta Accreta

Placenta accreta is now the most common indication for postcesarean hysterectomy. Approximately 25 percent of patients having a cesarean delivery for placenta previa in the presence of a prior uterine incision subsequently require cesarean hysterectomy for placenta accreta. The risk of placenta accreta appears to increase with the number of prior incisions. This obstetric complication may be rising because of the growing number of previous cesarean sections.^{[128], [129]}

If the accreta is focal and the patient desires future pregnancies, it may be possible to excise the site of trophoblastic invasion, oversewing bleeding areas with several figure-of-eight sutures. If that is not possible, hysterectomy should be initiated. A complete hysterectomy will usually be required because a placenta accreta commonly involves the lower uterine segment and, in such cases, a supracervical hysterectomy will not be effective in controlling the bleeding.

Drainage of the Abdominal Incision

The purpose of a drain is to remove the bacterial growth media that can act as a site of infection and reduce potential spaces within the wound. There are few indications for prophylactic drainage, because cesarean delivery is a relatively "short" procedure and operative time and tissue devitalization are ordinarily not an issue. Prophylactic drainage is most commonly used in situations in which there is an expectation of fluid accumulation in association with likely contamination of the wound, particularly in obese patients.^[130] Therapeutic drainage is seldom, if ever, indicated with cesarean delivery or cesarean hysterectomy unless there

Figure 18-7 Hypogastric artery ligation. Approach to the hypogastric artery via the peritoneum, parallel and just lateral to the ovarian vessels, exposing the interior surface of the posterior layer of the broad ligament. The ureter will be found attached to the medial leaf of the broad ligament. The bifurcation of the common iliac artery into its external and internal (hypogastric) branches is exposed by blunt dissection of the loose overlying areolar tissues. Identification of these structures is essential. *A and B*, To avoid traumatizing the underlying hypogastric vein, the hypogastric artery is elevated by means of a Babcock clamp before passing an angled clamp to catch a free tie. (Adapted from Breen J, Cregori CA, Kindzierski JA: *Hemorrhage in Gynecologic Surgery*. Hagerstown, MD, Harper & Row, 1981, p 438.)

is a coincidental abscess. Should an abscess be encountered, a continuous suction drain should be inserted via a separate stab wound at a site away from the incision.^[131] In some instances in which there is a suspicion of heavy contamination, particularly in morbidly obese patients, it may be better to plan secondary wound closure as opposed to drainage.

POSTMORTEM CESAREAN DELIVERY

If clinically possible, a postmortem cesarean delivery should be started within 4 to 5 minutes after initiation of cardiopulmonary resuscitation for cardiac arrest. Delivery will increase the effectiveness of cardiopulmonary resuscitation by diminishing uterine compression of the inferior vena cava in the supine position.

If a postmortem cesarean delivery is contemplated, successful perinatal outcome will depend on knowledge of preexisting fetal status and realization that maternal demise can be reliably anticipated in the near future. There are a number of determinants that favorably affect outcome: (1) a gestational age compatible with fetal survival, (2) delivery within 10 minutes of cessation of maternal circulation, (3) prompt availability of appropriately trained staff and equipment, and (4) access to personnel capable of neonatal resuscitation.

Unfortunately, in many instances it is not possible to provide one or more of the above, and for this reason outcome is most often poor. Katz et al. ^[132] described 269 cases of postmortem cesarean births between 1879 and 1986 in the English literature. Only 188 newborns survived. In recent history, normal survival following postmortem cesarean birth has been primarily limited to instances in which the baby was delivered within 5 minutes after maternal death. The likelihood of a normal outcome decreases to approximately 10 to 15 percent in the 6- to 15-minute interval and to less than 15 percent at 16 or more minutes after death. The current consensus is that postmortem cesarean delivery may be performed at any time that a viable fetus or the potential for one exists, even without the consent of a family member.

There are limited data with which to assess the ability of modern life-support equipment to maintain the mother for an extended period. A 1988 case report described a mother supported for 10 weeks to gain time for fetal maturation. ^[133]

PREOPERATIVE AND INTRAOPERATIVE FLUID GUIDELINES

Extracellular (interstitial and intravascular) water constitutes approximately one third of total body water and 20 percent of total body weight. Ordinary daily physiologic fluid needs are approximately 2,000 to 2,500 ml.^[134] In the pregnant patient, daily physiologic fluid losses are estimated to be 1,000 ml in excess of urinary output and include urinary output (800 to 1,500 ml), insensible loss (800 ml) from both skin and lungs, and stool loss (200 ml). Insensible loss in the laboring patient can be considerably greater.

Because insensible fluid loss increases significantly in the laboring patient, the woman about to undergo a cesarean delivery for CPD may be quite dehydrated. She may have had insufficient fluid intake since the onset of labor and have increased fluid loss because of the physical exertion and rapid breathing movements associated with labor. The bleeding patient or the patient about to receive epidural anesthesia is particularly sensitive to the effects of dehydration.

There will be little problem with dehydration if intravenous fluid intake has been maintained at 100 to 125 ml/h during labor. Should this not be the case, fluid losses can be estimated based on the average hourly need (100 to 125 ml) times the cumulative number of hours since the time of last fluid intake. Adjustments, which may vary from center to center, should be made for ice chips and other fluid intake. An additional intravenous fluid load is required prior to the administration of epidural anesthesia.

Intravenous Fluids Commonly Used

1. Sodium chloride (0.9 percent isotonic saline) is an isotonic solution commonly used to expand plasma volume as well as to correct mild degrees of hyponatremia.
2. Lactated Ringer's solution is also an isotonic solution containing multiple electrolytes in a concentration similar to that found in human plasma. This solution is also used to expand plasma volume and may be preferable to isotonic saline during the first 24 postoperative hours.
3. Sodium chloride 0.45 percent is a hypotonic (half-normal) solution that is useful in the provision of postoperative fluid needs after the first 24 hours when volume expansion is no longer needed.

Fluid and Electrolyte Replacement

Should the patient be only mildly hypovolemic in the first 24 hours, normal isotonic saline or Ringer's lactate solution in 5 percent dextrose is preferable to more hypotonic solutions because there is greater retention of fluids in the intravascular space providing volume expansion. In contrast, infusion of a 5 percent dextrose in water solution (D₅ W) will result in distribution of fluid evenly throughout all water spaces, two thirds being in the intracellular space. Should hypovolemia be more significant, particularly in association with low intravascular colloid osmotic pressure, administration of an albumin-containing solution may minimize the effects of loss of fluids into the interstitial space. Under such circumstances, it may on occasion be advisable to use a central venous pressure line or a Swan-Ganz catheter.

Special Considerations for Preoperative Fluids

Some patients such as those with vomiting, diarrhea, or fever may require additional fluids. The presence of a fever may increase the need for intravenous fluid replacement, generally on the order of 15 percent above basal levels for every degree centigrade above normal body temperature.^[130]

Intraoperative Fluids

Fluid needs during surgery are generally determined by the anesthesiologist or nurse anesthetist and are largely directed to the replacement of estimated blood loss, insensible losses, and urinary output. In general, isotonic solutions are used to maintain adequate circulating blood volume. Actual blood or plasma replacement is rarely needed during cesarean delivery.

Intraoperative fluid requirements, apart from blood replacement, range from 500 to 1,000 ml/h, up to a maximum of 3 L in a 4-hour interval under ordinary surgical conditions. Such replacement is associated with a low incidence of renal failure and pulmonary edema in instances in which there has been obstetric hemorrhage.^[135]

Gabbe: *Obstetrics - Normal and Problem Pregnancies, 4th ed.* , Copyright © 2002 Churchill Livingstone, Inc.

POSTOPERATIVE COMPLICATIONS

Maternal Morbidity and Mortality

The previously noted increase in risk for maternal morbidity and mortality is in part a result of the complications leading to the cesarean delivery as well as the risk associated with any surgical procedure. Nonetheless, even when morbidity and mortality arising from the indication leading to cesarean delivery have been excluded, maternal morbidity and mortality remain severalfold

562

higher for cesarean delivery than for vaginal delivery. ^[6], ^[47], ^[136]

In a review of approximately 400,000 cesarean births performed between 1965 and 1978, maternal death occurred in 1 in 1,635 (mortality rate was 6.1 per 100,000) procedures; approximately one half of the deaths were attributable to the procedure. ^[6], ^[47] In another series, Sachs et al. ^[47] reviewed 121,000 cesarean births performed in Massachusetts from 1976 to 1984; 7 (5.8 per 100,000) of 27 total deaths (22 per 100,000) arose as a result of the procedure itself. Lower rates have been described, the most remarkable being a study from the Boston Hospital for Women reporting no maternal mortality in 10,231 cesarean deliveries. ^[137]

Major sources of morbidity and associated mortality relate to complications of maternal sepsis, anesthesia, and thromboembolic disease and its complications. Each has been discussed in Chapters 15 and 40. Much has been done in recent years to reduce the impact of anesthesia-related mortality largely through increased availability of qualified anesthesia personnel and the implementation of rigid protocols, including routine use of antacids prior to cesarean delivery, as well as routine protocols for intubation. Other common causes of morbidity arising from cesarean delivery include hemorrhage and injury to the urinary tract. ^[138], ^[139] It is important to remember that data describing morbidity for a primary cesarean delivery do not include the consideration of long-term consequences such as the possible need for repeat cesarean births, the increased likelihood of placenta accreta, and the need for unplanned hysterectomy.

Endomyometritis

Postpartum infection is the most frequent complication arising from cesarean delivery, and indeed primary cesarean delivery is the greatest risk factor, with rates up to 20-fold that associated with vaginal delivery. Should prophylactic antibiotics not be used, the incidence of postcesarean endomyometritis varies from as low as 5 to 10 percent to as high as 70 to 85 percent, with a mean of 35 to 40 percent in most series. ^[140] ^[141] ^[142] The rate is largely dependent on socioeconomic status and on whether the cesarean delivery is a primary procedure. The lowest incidence occurs in middle- and upper-income women undergoing a scheduled cesarean delivery; the highest in the young indigent patient undergoing primary cesarean delivery after an extended labor and prolonged membrane rupture. Age and socioeconomic status may influence the incidence of infection because they reflect general health and host immunocompetence. The other major risk factors include length of labor, duration of membrane rupture, and number of vaginal examinations and presence of prior chorioamnionitis. These factors exert their effects by influencing the size of the bacterial inoculum. Other weaker risk factors include length of surgery, preoperative hematocrit, intraoperative blood loss, duration of internal fetal monitoring, experience of the surgeon, and type of anesthesia.

Prior to the advent of modern broad-spectrum antibiotics with activity against both anaerobic and aerobic gram-negative bacilli, the incidence of severe complications arising from endomyometritis was as high as 4 to 5 percent. ^[143], ^[144] When blood cultures were obtained, the frequency of associated bacteremia was approximately 10 percent. ^[140] Prophylactic antibiotics at the time of cesarean delivery reduce the postoperative infection rate to approximately 5 percent. ^[143] With the advent of modern antibiotics, the incidence of life-threatening complications, including pelvic abscess, septic shock, and septic pelvic thrombophlebitis, is now less than 2 percent.

The microbiology, clinical diagnosis, laboratory aids, treatment, and approaches to reduce the rate of endometritis are detailed [in Chapter 40](#) .

Wound Complications

Risk Factors for Poor Wound Healing and Wound Infection

Identifiable medical risk factors that increase the likelihood of poor wound healing include diabetes mellitus and malnutrition. Surgical risk factors to be considered are the duration of surgery, the use of drains, the suture material chosen, and the closure technique employed. Postoperative factors include asthma, pulmonary complications and associated coughing, and vomiting. ^[145] ^[146] In rare cases, other risk factors such as ascites, long-term corticosteroid therapy, anemia, and even prior irradiation may exist.

Wound infection rates following cesarean delivery vary, according to the patient population evaluated, from 2.5 to as high as 16.1 percent. ^[145] Determinants include local wound conditions and patient host resistance. Infection rates will vary according to whether the cesarean delivery is performed as an elective repeat (clean procedure) procedure with intact membranes or follows labor, particularly with ruptured membranes (clean contaminated procedure). Risk factors for wound infection interact in a complex manner, making it difficult to determine the independent contribution of any one factor. Clean procedures are generally associated with a wound infection rate of approximately 2 percent, whereas the corresponding rate for a clean contaminated case is on the order of 5 to 10 percent. Should chorioamnionitis (contaminated procedure) be present, the wound infection rate will approximate 20 percent.

Many studies demonstrate a substantial increase in wound infections with increasing duration of membrane

563

rupture, long labors, and more frequent vaginal examinations. ^[147] ^[148] ^[149] ^[150] Amnionitis and possibly meconium passage are additional risk factors. Up to 75 percent of amniotic fluid cultures done at the time of primary cesarean delivery are positive, with an average of 3.5 organisms, 44 percent being highly virulent bacteria. ^[151] Flora isolated from amniotic fluid and wound infections exist in a synergistic system of aerobes and anaerobes similar to the situation with endometritis. *S. aureus*, *Escherichia coli*, *Proteus mirabilis*, *Bacteroides* species, and group B streptococci are common isolates; clostridial species are infrequent. ^[152] Even in the absence of ruptured membranes, patients in preterm labor with unrecognized chorioamnionitis may have pathogens consistent with bowel flora. ^[153]

Methods To Reduce Wound Infection

Some determinants of wound infection (diabetes mellitus, amnionitis, obesity, and alcoholism) are to a large degree beyond the control of the obstetrician. However, the obstetrician who knows the potential risk factors does have the option to use a number of measures selectively in an attempt to reduce the risk of wound infection and wound breakdown. These measures include (1) hair removal at the incision site (as opposed to shaving pubic and abdominal hair) if the abdomen is prepared the night prior to surgery; (2) preoperative skin preparation, including careful cleansing of the umbilicus and abdomen prior to surgery; (3) sterile technique; (4) wound hemostasis; (5) selective use of prophylactic antibiotics; (6) avoidance of reactive (plain gut) or unnecessary suture material, particularly in the patient at risk for a wound infection or breakdown; (7) closed-system drainage if the patient is obese or the wound is "wet" in the absence of an obvious bleeder as opposed to open Penrose drains; (8) skin closure with suture rather than a skin stapler; and (9) delayed wound closure if the wound is grossly contaminated by bowel contents.

Although it is difficult to determine the magnitude of preventable wound infections, Emmons et al.^[154] suggest that the approximately 25 percent of wound infections that are associated with *S. aureus* represent a potentially preventable condition that presumably arises from exogenous sources. Sixty consecutive wound infections (5.4 percent) were studied among 1,104 women undergoing cesarean delivery. Wound infections caused by cervical-vaginal flora were associated with prolonged labor, particularly with greater duration of continuous electronic FHR monitoring; with more frequent vaginal examinations; and with organisms isolated from the endometrium at cesarean section. In contrast, women with wound infections caused by *S. aureus* had neither prolonged labor nor *S. aureus* isolated at cesarean delivery.^[154]

When closing the wound, a balance must be maintained between adequate hemostasis and significant tissue devitalization. Excessive use of electrocautery may result in unnecessary tissue damage and reduced host resistance. Seroma or hematoma formation reduces tissue oxygenation and phagocyte penetration. Tissues should be carefully reapproximated without major tension. Unnecessarily tight placement of sutures may interfere with adequate tissue oxygenation, which is essential to bacterial phagocytosis.^[155]

Morbid obesity is a risk factor for wound infection, regardless of the degree of contamination and length of procedure.^[156] Adipose tissue is relatively fragile and tends to heal poorly. As a result, careful handling of the subcutaneous tissue is important. However, there is uncertainty as to the best surgical approach. Gallup^[84] recommends a midline incision, a superficial closed suction drain, a nonabsorbable monofilament fascial closure with a Smead-Jones technique, and avoidance of subcutaneous suture. Others favor a transverse incision^[157] and the use of subcutaneous sutures.^[90]

Diagnosis and Management of Wound Infection

The diagnosis of a wound infection is generally the result of daily inspection of the wound. Suspicion may be heightened should the patient, previously treated for endometritis, be unresponsive to antibiotic therapy. If fever develops, careful inspection of the wound will often lead to early diagnosis and treatment. Diagnosis of a wound infection is relatively obvious in the febrile patient if the wound is unusually tender, inflamed, and indurated or if drainage of purulent material is observed on palpation. The bacteriology and laboratory approach to diagnosis are discussed [in Chapter 40](#).

Should an infection be found, the involved wound must be opened to allow drainage and debrided to clean the wound margins. A culture for anaerobic and aerobic organisms may be obtained and systemic antibiotics used to cover the anticipated organisms within the wound. Culturing tissue debris from the wound improves the likelihood of anaerobic organisms. Once the wound is opened, drained, irrigated, and possibly debrided to remove adherent purulent material, the wound can be packed with wet-to-dry dressing three times daily until there is a healthy margin of red granulation tissue. When the infection is controlled, the patient and surgeon must then decide between the inconvenience for the patient associated with healing by secondary intention versus the risk of recurrent infection should primary closure be elected.^[158]

Fascial Dehiscence

Dehiscence of a wound through the fascia is infrequent, occurring in approximately 5 percent of wound infections.^[159] Dehiscence

564

Figure 18-8 Ultrasound of infected bladder flap hematoma marked by cursors (+). The patient presented approximately 1 week after cesarean delivery with fever. She responded to antibiotics. Note that the full bladder (B) enhances visualization of the hematoma (H). The arrow designates the endometrial cavity of the uterus (U).

is suggested by the presence of a large amount of discharge from the wound. If loops of small bowel protrude through the incision, the small bowel should be immediately covered with wet sterile dressings. The wound should be opened and inspected and emergency closure performed in the operating room under sterile conditions. If a dehiscence is confirmed, the wound should be cleansed, debrided, and closed with either Smead-Jones or retention sutures ([Fig. 18-6](#)).

Radiologic Imaging as Potential Diagnostic Aid

Resistance to antibiotic therapy, as evidenced by a persistent spiking febrile response, may be an indication for sonography or other imaging techniques ([Fig. 18-8](#) to [Fig. 18-10](#)) to rule out retained uterine products, seromas, hematomas, or abscesses in the abdominal wall, pelvis, or occasionally the uterine incision. Whereas sonography offers immediate evaluation of the pelvis in the patient resistant to therapy, computed tomographic (CT) scanning may be preferable in some cases because it allows complete assessment of the entire peritoneal cavity and may identify fresh hemorrhage within a fluid collection as well as ovarian vein thrombosis. Sonography with a 5- or 7-MHz short-focus transducer also allows detailed examination of the abdominal wall for seromas, hematomas, and abscesses.

By the first postpartum day, the uterus will be at or below the level of the umbilicus. On ultrasound, the uterine wall thickness will vary from 3 to 6.5 cm, being slightly thicker in multiparous patients than in primiparas.^[22] The uterine wall ordinarily appears homogenous with an occasional subtle irregularity.^[159] The endometrial cavity often presents as a stripe whose anteroposterior diameter varies from 0.5 to 1.3 cm.^[160] The uterine incision may present a variable sonographic appearance following cesarean section.^[161] Strong echoes may arise from the suture material. It is not unusual to see small seromas and hematomas of the uterine incision under the bladder flap. Should a significant fluid collection be observed around the uterine incision in a

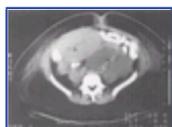

Figure 18-9 CT scan of pelvis 6 days after a cesarean section showing left-sided broad ligament hematoma (H). The uterus (U) is displaced to the right. The patient responded to antibiotics. 565

Figure 18-10 Magnetic resonance imaging (MRI) scan of abdominal wall abscess. This patient presented 1 week after a cesarean delivery with fever and an abdominal mass. The differential diagnosis included an intraperitoneal infection with extension or a wound abscess. This MRI shows a wound abscess (A) above fascia that extended to the abdominal wall (arrow). The abscess responded to drainage and antibiotics.

febrile patient, an abscess should be considered (Fig. 18-8).

When a postpartum abdominal ultrasound examination is performed, the patient should have a full bladder. This will facilitate displacement of the normal anteverted uterus posteriorly, positioning the endometrial cavity at right angles to the sound waves and improving visualization.^[162] In addition, bladder filling will frequently push any gas-filled loops of bowel out of the pelvis, thus facilitating visualization of the cul-de-sac, adnexa, and uterus. Transvaginal scanning may be helpful if the abdomen is distended, the incision site interferes with adequate abdominal imaging, or the patient is unable to tolerate the pressure of abdominal scanning.

Sonographic findings suggesting endometritis may include a dilated fluid- or gas-filled uterine cavity and fluid in the cul-de-sac. Sonographic evidence of an empty uterus will eliminate the possibility of retained products. However, an abnormal scan may represent either the normal retention of blood or retained products of conception.^[163] Abscesses may present with characteristic fluid and gas collections, shaggy walls, and internal echoes in association with cul-de-sac fluid accumulations indicating peritonitis. If gas is detected on sonogram, gas-forming organisms such as *E. coli* or *Clostridium perfringens* may be present. CT scanning may be used to diagnose ovarian vein thrombophlebitis (see Fig. 40-4).^[164]

Urinary Complications

Urinary tract infections rank second to endomyometritis as a cause of postcesarean febrile morbidity. The reported incidence varies from as low as 2 percent to as high as 16 percent.^{[165], [166]} In one study, approximately 7 percent of postoperative clean-catch urine specimens had at least 10^5 bacteria per milliliter in culture. One percent of patients had both bacteriuria and endomyometritis.^[167] Urethral catheterization contributes to 80 percent of nosocomial urinary tract infections in hospitalized patients, particularly when indwelling catheters are used. The incidence is increased with longer duration of catheter use, in diabetic patients, and in patients who are critically ill.^[164] Attention to detail in terms of proper preparation and insertion of the catheter and the use of a closed drainage system have decreased this risk.

Gastrointestinal Complications

Most patients undergoing cesarean delivery have little if any gastrointestinal problems postoperatively. However, anesthesia and narcotics employed to treat postoperative pain may contribute to bowel dysfunction. As a result, an occasional patient may have postoperative nausea or mild transient abdominal distention in the first 24 hours.

Ileus should be suspected if prolonged nausea or vomiting together with signs such as abdominal distention, absence of bowel sounds, and failure to pass flatus are persistent. Distended loops of bowel with or without airfluid levels on radiography will provide confirmatory evidence. In most instances, simply withholding oral intake, providing adequate fluid replacement, and being observant are sufficient. If the ileus is persistent, nasogastric suction may be required.

Actual mechanical bowel obstruction may initially present as an ileus, but is commonly associated with peristaltic rushes and high-pitched bowel sounds in conjunction with symptoms of nausea, vomiting, and abdominal distention. Once again, some patients will respond to conservative management, including restriction of oral intake and placement of a nasogastric tube or possibly even a long tube. The key to success is maintenance not only of fluids and electrolytes but also of hematocrit and serum protein. Should conservative therapy fail, surgical consultation and possible exploration may be required.

Thromboembolic Disorders

The risk of thrombosis increases during pregnancy because of both higher levels of coagulation factors and diminished fibrinolysis. These changes peak near term and immediately after delivery. Deep venous thrombophlebitis (DVT) of the lower extremities occurs in approximately 0.24 percent of all deliveries.^{[168], [169]} The risk of DVT after cesarean delivery is approximately three to five times greater than after vaginal delivery.^[170] Compounding risk factors include obesity, inability to ambulate, advanced maternal age, and higher parity. Should the DVT go untreated, approximately 15 to 25 percent of patients will develop pulmonary emboli, and 15 percent will sustain a fatal pulmonary embolus (PE). However, if recognized early and treated appropriately, the risks of PE and death are reduced to 4.5 and 0.7 percent, respectively.^{[169], [171]}

Classic symptoms for DVT include unilateral leg pain, tenderness, and swelling. A 2-cm difference in leg circumference between the affected and normal limb is generally required for diagnosis. Other clinical signs include edema, a palpable cord, and a change in limb color. A positive Homan's sign (calf pain on passive dorsiflexion of the foot) or a positive Lowenberg test (pain distal to the site of rapid inflation of a blood pressure cuff to 100 mm Hg) suggests DVT.

Unfortunately, the first sign of DVT may be the occurrence of a PE, which can present with symptoms of tachypnea (90 percent), dyspnea (80 percent), pleuritic chest pain with or without splinting (>70 percent), apprehension (~60 percent), tachycardia (40 percent), and cough (>50 percent).^{[172], [173]} Other findings include atelectatic rales, a friction rub, accentuated second heart sound, and a gallop. Patient evaluation is complicated in the postcesarean delivery patient, since splinting from incisional pain and tachypnea are not unusual findings. Doppler studies have a sensitivity of 90 percent for popliteal, femoral, or iliac thromboses, but only 50 percent for calf involvement because of abundant collateral vessels. Impedance plethysmography (IPG) is sensitive in approximately 95 percent of proximal thromboses, but is not as effective as Doppler for pelvic vessel thrombosis and will generally identify most cases, especially above the calves. Should Doppler and IPG be inconclusive, ascending venography, the most accurate of the three tests, should be performed. IPG can be used as a first-line test postpartum in the nonlactating mother. Should PE be suspected, a baseline arterial blood gas, chest radiograph, and electrocardiogram, as well as prothrombin time and partial thromboplastin time, should be obtained. Oxygen therapy should also be administered. Once the diagnosis has been established, heparin therapy should be started. The diagnosis and treatment of a PE are discussed in Chapter 30.

Septic Pelvic Thrombophlebitis

Approximately 0.5 to 2 percent of patients with endomyometritis or wound infection will develop septic pelvic thrombophlebitis, a more common complication of cesarean birth than of vaginal delivery. In large part, this is a result of the higher rate of endomyometritis in patients undergoing cesarean delivery.^[174] Largely a diagnosis of exclusion, septic pelvic thrombophlebitis occurs most commonly on the right side and may be suspected should there be fever and unilateral pain. Although tenderness about the incision site may make detection difficult, occasionally one will be able to palpate a tender, rope-like abdominal mass extending laterally and cephalad from the uterus. Sonographic examination of the lower abdomen and pelvis or CT scan may be of assistance in the diagnosis (see Fig. 40-4).

POSTOPERATIVE MANAGEMENT

Postoperative Analgesia

Analgesia should be provided in a dose and at a frequency that will neither obtund nor cause respiratory depression and yet allow the patient (1) to avoid the consequences of extremes in analgesic blood levels resulting in unnecessary pain and (2) to cooperate with normal postoperative management. The patient receiving inadequate analgesia may, in an effort to protect her wound, maintain a shallow breathing pattern without deep breaths and, hence, develop atelectasis. ^[175]

Commonly used analgesics include meperidine (50 to 75 mg) or morphine (10 mg, depending on maternal size), administered intravenously or intramuscularly every 3 to 4 hours. Intrathecal or epidural narcotic administration used with agents such as morphine can also be used for postoperative anesthesia, which may last as long as 30 hours following delivery, providing an advantage to a patient who has undergone a regional block (see Chapter 15). ^[176]

Ambulation

Early ambulation is important in reinstatement of inflation of the most dependent alveoli and the prevention of pulmonary complications, particularly in the patient who has had general anesthesia. Early ambulation also promotes the return of normal urinary and bowel activity. Under most circumstances, the uncomplicated patient can be allowed to sit up within 8 to 12 hours following the procedure, even after epidural anesthesia. The patient generally can ambulate within the first day after surgery, and by the second day can shower without fear of injury to the incision.

Oral Intake

Active bowel sounds are commonly not observed until the second postoperative day. Nonetheless, in most instances the patient will easily tolerate oral fluids the day after surgery. Only rarely, when the patient has been septic or there has been extensive intra-abdominal manipulation, will there be a need to withhold oral fluids, even though the patient may have diminished bowel sounds and not pass gas. Most clinicians feel comfortable in providing clear liquids and ice chips with only a small amount of liquid as soon as nausea subsides to relieve complaints of a dry mouth. The progression of the diet also varies according to clinician. Some advance the patient rapidly to a regular diet, whereas others institute a progression to a full liquid diet by 48 hours, awaiting the return of normal bowel sounds and passage of flatus to indicate return of colonic function. Few wait beyond the third postoperative day to institute a regular diet.

Bladder Management

The urinary catheter is ordinarily removed within 12 to 24 hours following surgery unless there have been intraoperative complications.

Postoperative Wound Care

The incision is generally covered for the first day with a light dressing, until the wound is sealed. The dressing is removed after the first postoperative day.

Laboratory Studies

Blood loss arising from an uncomplicated cesarean delivery is approximately 1,000 ml. ^[177] As a consequence of blood loss as well as intra- and postoperative hydration, the postoperative hematocrit may be expected to drop by approximately 2 to 3 percentage points during the initial 2 days following surgery, independent of hydration status.

Postoperative Fluids

The normal postpartum period is generally characterized by mobilization of the physiologic accumulation of fluid during pregnancy. As a consequence, large volumes of intravenous fluids are seldom required after cesarean delivery. In the low-risk patient, fluid replacement needs during a 24-hour interval are generally only 1,000 ml above urinary output. Three liters of a salt-containing solution will thus generally suffice during the first 24 hours unless urinary output falls below 30 ml/h. Under certain circumstances there may be increased requirements for fluids: following prolonged labor, febrile illness, vomiting and diarrhea, or even prior use of diuretics or salt restriction. More complex patients may have additional needs. Potassium is ordinarily not required during the first 24 hours by uncomplicated patients because of intracellular potassium release from cell destruction. After the first 24 hours, intravenous fluid replacement with 5 percent dextrose in 0.45 percent sodium chloride is commonly used, unless volume expansion is an issue. If it is anticipated that the patient will require prolonged intravenous fluids, potassium may be administered as 60 to 80 mEq/day. Should the patient be oliguric, potassium is generally not given until the patient has a normal urinary output.

Average Length of Stay

Depending on postoperative morbidity/complications and availability of care at home, hospital discharge may occur as early as the second to as late as the fifth postoperative day. The average length of stay is approximately 3 days. The length of hospitalization associated with cesarean birth, like those associated with vaginal delivery, has declined dramatically. ^{[1], [2], [29]}

Discharge Management

Reduction in the length of stay, from over 6 to 7 days to fewer than 4, has had a dramatic impact on many patient-related programs. Table 18-6 provides an example of a typical management guideline that may be used by third-party payors as they extend their efforts to "manage care." ^[178] Elective cesarean patients are no longer admitted the night before the intended procedure. It is noteworthy that their goal for length of stay for a cesarean birth is 2 days. One would hope that the managed care payers will divert some of the savings from profit to patient support and medical supervision of the mother and newborn at home.

The mother's activities at home for the first week should be limited to personal care and to care of the newborn. By the third to fourth week, the patient can generally resume most activities at home.

REDUCING THE CURRENT CESAREAN BIRTH RATE

Possible Strategies To Reduce the Rate

National Strategies

A number of national strategies have been proposed to reduce the current cesarean birth rate: (1) equalize the reimbursement for vaginal and cesarean deliveries; (2) publish physician-specific cesarean rates; (3) publish

TABLE 18-6 -- TYPICAL MANAGED CARE GOALS FOR CESAREAN DELIVERY (S-350)

Protocol:	(CPT-4:58611, 59510, 59514, 59515, 59525) (ICD-9:74.0, 74.1, 74.4, 74.9) (ICD-9:054.11, 641, 642.5, 642.6, 652.2-652.6, 652.9, 653, 654, 654.2, 654.7, 654.8, 658.2, 658.3, 660, 662.2, 663)
Day 1:	Preadmission patient education and home care assessment. Operating room for cesarean delivery, parenteral fluids and medications, possible PCA or epidural analgesics
Day 2:	Clear liquids to advanced diet as tolerated. Discontinue passive cutaneous analgesics (PCA) or epidural analgesics. Discontinue IV and Foley if not done previously. Parenteral or oral medications. Ambulatory. Flatus present. Possible discharge
Day 3:	Afebrile, ambulatory, oral medications, regular diet. Discharge
Note:	Although most patients recover and may require no more than 36 hours as inpatients postoperatively, the variability in the hour of surgical delivery makes it uncertain how many patients may be able to go home on the first postpartum day. Some who deliver early in the day of delivery may do so

Data from Doyle and Schibanoff.^[178]

hospital-specific cesarean rates; and (4) address physician malpractice concerns through legislation. The ACOG has indicated, with regard to the first strategy, that there is little or no evidence that the decision to perform a cesarean delivery or to offer a trial of labor is in any way motivated by a differential in payment. They recommend that financial incentives should not be used by payors to influence physician or patient decisions relative to the mode of delivery; rather, the decision should be based on standard obstetric indications and maternal fetal safety.^[179]

Hospital Administrative Strategies

Bottoms et al.^[180] concluded that cesarean delivery for dystocia and repeat cesarean deliveries should be points of primary review. If primary indications can be more tightly controlled, the number of candidates for repeat cesarean section will be reduced accordingly. Each hospital review committee should examine its institutional and individual physician cesarean rates. It is important that the review target each indication, since variation in total rate among physicians may not be associated with the same indication. Peer review conference screening should support the concept that, with the exception of a failed induction, cesarean delivery conducted on patients while still in the latent phase of labor should be an infrequent indication for cesarean birth. The validity of such a program is evident in a trial conducted in one hospital that evaluated the effects of selected clinical criteria and review mechanisms. Second opinions were required; VBAC-TOL was the preferred clinical approach; and peer review was implemented. After implementation of the program, the cesarean rate decreased from 17.5 percent in 1985 to 11.5 percent in 1987, a time when cesarean rates were rising.^[181]

Clinical Strategies

Table 18-7 summarizes potential clinical strategies to reduce the current cesarean rate. The strategy most likely to have a significant impact is one that strongly encourages VBAC-TOL.

Indications Susceptible to Reduction

In 1993, 921,000 (22.8 percent) of approximately 4 million births were by cesarean delivery.^[1], ^[2] Of all cesarean deliveries, approximately 336,000 (36 percent) were associated with a prior cesarean birth and 585,000 (64 percent) were primary cesarean births.^[1], ^[2] The primary cesarean delivery rate of 16.3 percent is the lowest since 1985 but is still approximately four times the rate in 1985 of 4.2 percent.^[1], ^[2]

Reduction in the overall rate will occur only if a strategy is developed for each indication category. For example, O'Driscoll et al.^[182] attributed much of their

TABLE 18-7 -- POTENTIAL APPROACHES TO REDUCE CESAREAN BIRTHS

success in maintaining a low cesarean rate to a lower rate of dystocia secondary to aggressive utilization of oxytocin, greater use of VBAC-TOL, and liberal criteria for vaginal breech deliveries. Brief mention will be made regarding the above clinical problems associated with cesarean birth with increased emphasis on VBAC-TOL as a strategy to reduce current cesarean rates.

Dystocia (Failure to Progress)/Cephalopelvic Disproportion

There is likely to be significant room for improvement in the current cesarean delivery rate for the clinical entity referred to as "dystocia," the most common indication for primary cesarean birth in the United States. The term includes a broad range of problems, including relative CPD and FTP encountered in the latent and active phases of labor (see Chapter 13). In 1993, of all women who had a cesarean section, 17.4 percent had an abnormal labor and 17 percent had CPD.^[1],^[2] There is also some basis for a special designation for "failed induction," since a diagnosis of CPD/FTP is more common following labor induction.^[183],^[184]

Determination of the cause of failure to achieve more vaginal deliveries is complex; as a result, any single strategy to reduce the impact of dystocia for cesarean delivery is unlikely to meet with major success.^[25],^[26] Although failure to make sufficient progress in the active phase of the first stage (cervical dilatation) or the second stage (descent) has been attributed to deficiencies in uterine "power"/activity, "excess size" of the "passenger," or "relative-small size" of the "pelvic-passage," FTP may also potentially be the result of different "physician" approaches to the management of the latent and active phases of labor (see Safety of Active Labor Management as a Strategy, below).

Prior Cesarean Birth

A reduction in the cesarean birth rate can be achieved only by using VBAC-TOL as an approach to address and lower the self-perpetuating contribution of the indication of previous cesarean birth.^[185] Few changes within the specialty of obstetrics and gynecology offer greater potential impact to more women than that of VBAC-TOL, since elective repeat cesarean delivery is estimated to be largely responsible for the increase in cesarean deliveries. The cesarean birth rate rose 44 percent between 1978 and 1984, and 47 percent of the rise was attributable to the performance of elective repeat cesarean deliveries.^[1],^[2],^[4] The total cesarean rate in the United States peaked in 1988 at 24.7 percent; of these, 36.3 percent (351,000) were repeat cesarean deliveries. In the 1989 to 1991 interval, the cesarean rate appeared to reduce or plateau. Changing VBAC-TOL rates appear to be largely responsible, increasing 47 percent from 1988 (12.6 percent) to 1989 (18.5 percent). The VBAC rate peaked in 1996 at 28.3 percent.

Breech Presentation

There is some potential for improvement in the current rate of cesarean deliveries. The management of both term and preterm breech presentations remains controversial. Nonetheless, the combination of fear of litigation and ever-decreasing opportunities to train residents in the proper approach to the management and technique for vaginal delivery has resulted in a continuing drift in practice toward cesarean births. In the United States, residents completing their training in obstetrics and gynecology perform, on average, eight breech deliveries including the delivery of the second twin.^[46] The cesarean rate for breech presentations in this country increased from 67.2 percent in 1980 to 80.4 percent in 1985.^[29] Given the recent report from Hannah and the Term Breech Trial Collaborative Group,^[36] this rate is likely to be maintained or to increase.

Nonreassuring FHR and the Medicolegal Environment

Under better circumstances, physicians could reduce the impact of FHR-based indication for cesarean delivery. Some of the blame for the current increase in cesarean delivery is attributed to continuous electronic fetal monitoring and inappropriate overinterpretation of FHR data. However, it is likely that the root cause is physician fear of malpractice litigation. Most FHR alterations, including some rather dramatic (in a visual sense) variable decelerations, are likely to reflect only a temporary decrease in fetal oxygenation, as opposed to so-called fetal distress, a diagnosis lacking a consensus for diagnostic criteria. It is well known that such a diagnosis is associated with a high false-positive rate. There is fairly widespread fear of the medicolegal consequences of not performing a cesarean delivery in the presence of a nonreassuring FHR strip, despite the presence of indicators that ordinarily should provide reassurance. In a less litigious environment, the physician in doubt could gain reassurance that labor can be allowed to continue by a favorable response to fetal scalp or fetal acoustic stimulation or alternatively from a reassuring fetal capillary pH value. The goal is avoidance of rather severe fetal metabolic (cord arterial pH < 7.00) or mixed acidosis as a means to reduce newborn morbidity and mortality.^[186],^[187] Temporary fetal hypoxemia, without associated metabolic or mixed metabolic acidosis, poses little risk for significant newborn morbidity. Defensive medicine will continue to impact upon this indication. Although cesarean delivery

for this indication is not a major contributor to the overall cesarean delivery rate, it is nonetheless likely that the impact of this indication can be reduced if tort reform can be enacted.

Active Management of Labor as a Reduction Strategy

Although the original intent of the active approach to the management of labor was to decrease the incidence of prolonged labor, in some centers its application has been associated with a significant reduction in the cesarean rate for dystocia.^[182],^[188],^[189],^[190],^[191] Unfortunately, this has not been observed in all studies.^[192] The active management of labor relies on utilization of strict criteria for the diagnosis of the active phase of labor and on a protocol using relatively high doses of oxytocin should there be diminished cervical dilatation in the first stage or inadequate descent in the second stage of labor. The benefits of the program are likely to accrue from avoidance of the clinical trap of overly aggressive management of the latent phase of labor as well as early intervention with oxytocin in patients with either protraction or arrest disorders. Patient education and one-on-one supervision by a personal nurse is also important (see Chapter 13).^[182],^[188]

VAGINAL BIRTH AFTER CESAREAN BIRTH

Despite early reports in the 1960s that VBAC-TOL was both feasible and safe, the American obstetrician was initially reluctant to accept a significant modification in obstetric practice.^[193] As late as 1987, more than 90 percent of women with a prior cesarean delivery had a repeat procedure.^[4]

Benefits and Risks of VBAC-TOL

VBAC-TOL is successful in 60 to 80 percent of acceptable candidates.^{[194] [195] [196] [197]} If applied to all patients presenting with a prior cesarean procedure (8.2 to 8.5 percent), there is a potential to increase the rate of overall vaginal delivery by approximately 5 percent. Furthermore, there is evidence from a large multicenter trial that VBAC-TOL reduces the incidence of postpartum infection, the need for postpartum transfusion, and maternal length of stay; as a result, there is significant cost savings.^[197], ^[198] Adding further impetus is the observation that the associated perinatal mortality rate (7 per 1,000 live births) of the VBAC-TOL study group is not higher than that of the overall rate (10.1 per 1,000 live births).^[197]

The potential financial savings arising from a successful national VBAC program was estimated at approximately \$500 million in 1985, assuming a repeat cesarean birth rate of only 6 percent and 3.4 million births.^[199] Data compiled for 1996 by the Health Insurance Association of America on 40,967 vaginal deliveries and 10,305 cesarean sections across the country reveal average charges of \$11,450 for a cesarean delivery and \$7,090 for a normal vaginal delivery, including both the hospital and physician components.^[198]

Evolution of VBAC-TOL Acceptance

Cesarean rates appeared to have plateaued by 1991. One of the most important contributing factors has been a rejection of the historical dictum "once a cesarean section, always a cesarean section," which had been in practice since the early 1900s. It is logical that such an approach would eventually disappear. First, the clinical environment has changed dramatically since this policy was advocated. At that time only 2 percent of births resulted in a cesarean delivery; most often the procedure was performed following a diagnosis of cephalopelvic disproportion; and the procedure commonly used was a classic uterine incision. The advent of the low cervical segment incision together with better control of postcesarean infections has decreased the risk of uterine incision dehiscence during subsequent pregnancies. Second, there was a need to control rapidly rising national health care costs. Third, elective repeat cesarean delivery was the indication most responsible for the recent increase in cesarean births.

Although obstetricians in western European countries have encouraged VBAC-TOL, the concept did not begin to gain momentum in the United States until after 1981, when the NICHD Conference on Child Birth concluded that vaginal delivery after cesarean birth is an appropriate option.^[25]

Initial reports indicated that successful VBAC could be achieved in 50 to 80 percent of patients with a prior low transverse uterine incision and in as many as 70 percent of women for whom the indication for the prior cesarean delivery was "failure to progress in labor."^[5], ^{[204] [205] [206]} Although uterine rupture was an infrequent possibility, it was noted to be rarely "catastrophic." Maternal and perinatal mortality rates for VBAC-TOL were no higher than those for elective repeat cesarean births.^[5], ^{[207] [208] [209] [210] [211] [212]} Acceptance has become more widespread as numerous positive reports, documenting the efficacy and safety of VBAC under a wide variety of clinical settings, have been published.^[5], ^[195], ^{[207] [208] [209] [210] [211] [212]} Later reports documented no increase in maternal or fetal risk for candidates who had more than one prior cesarean.^[209], ^[210], ^[213]

In 1988, the ACOG published *Guidelines for Vaginal Delivery After a Previous Cesarean Birth*, recommending

VBAC-TOL as an option that should be selected based on available evidence available at that time.^[6] They further recommended that "each hospital develop its own protocol for management of VBAC-TOL patients; and a woman with one prior cesarean delivery with a low transverse incision should be counseled and encouraged to attempt labor in the absence of a contraindication, such as a prior classical uterine incision." At the time there were insufficient data to provide a complete cost-benefit analysis for patients presenting with a prior low vertical incision, more than one fetus, a breech presentation, or estimated fetal weight greater than 4,000 g. The 1988 Committee Opinion indicated that the use of oxytocin to augment labor does not confer greater risk in a VBAC-TOL in a patient with a prior low transverse incision than would be the case in a general obstetric population; however, it did acknowledge that some physicians would not choose to use oxytocin in VBAC-TOL.^[6] Epidural anesthesia was considered appropriate. Suggested 1988 guidelines include the following:

1. Repeat cesarean birth should be by specific indication.
2. Women with two or more prior cesarean deliveries should not be discouraged from attempting a VBAC-TOL.
3. Normal patient activity should be encouraged during the latent phase of labor. There is no need for restriction prior to the onset of the active phase of labor.
4. Professional and institutional resources should be available to respond to "intrapartum obstetric emergencies" such as performing a cesarean delivery within 30 minutes from the time the decision is made until the "surgical procedure is begun."
5. A physician capable of evaluating labor and performing a cesarean delivery should be "readily available."

As noted earlier, ACOG has recently modified its recommendations. VBAC after one prior low transverse cesarean delivery is encouraged, and after two it may be allowed recognizing the increased risk of uterine rupture.^[213] The ACOG advises that the use of prostaglandin gel or oxytocin require close monitoring. Patients with a true low vertical incision are candidates for VBAC. The major change has been the recommendation that the obstetrician be "immediately available" to provide emergency care.^[3]

VBAC Trends

VBAC-TOL Rates

Acceptance of the VBAC-TOL concept has not been uniform. Approximately 40 to 50 percent of eligible

Data from Miller et al.^[21]

women who are offered a VBAC-TOL choose the alternative, to have a repeat cesarean delivery.^{[214] [215] [216] [217]} A meta-analysis of 29 studies involving 8,770 VBAC-TOLs reflects wide variation in approach as evidenced by "remarkable variation in the percentage of patients accepted for trial of labor, ranging from 1681%." Of interest, regression analysis indicated that the acceptance and success rates were not significantly associated.^[218] Table 18-8 summarizes the dramatic change in acceptance of the validity of the VBAC-TOL concept at a large university hospital in the 10-year interval from 1983 to 1992. Although the percentage of all patients with a prior cesarean delivery increased, the effect was neutralized by an increase in use of TOL (68 to 79 percent). The increase was especially evident in patients with two or more prior cesareans.^[211]

Evaluating the VBAC-TOL Data

U.S. Preventive Task Force Scoring System

Typically, under such an approach a Medline database search is conducted for reports of studies published in a predetermined time interval in one or more languages. The selected studies are evaluated, and the quality of the evidence obtained is then assessed on the basis of a scoring system (Table 18-9) scale. The evidence was graded (Table 18-9) according to the three categories of (A) "good" evidence, (B) fair evidence, and (C) insufficient evidence; but the recommendation can be made on other grounds.

Meta-Analysis as a Tool To Evaluate Infrequent Endpoints

Meta-analysis is a statistical tool that provides access to pooled data from multiple similar selected nonrandomized

TABLE 18-9 -- U.S. PREVENTIVE SERVICES TASK FORCE SCORING SYSTEM FOR EVIDENCE QUALITY

Score	Required Evidence
I	At least one properly designed randomly controlled trial
II-1	Well-designed controlled trial without randomization
II-2	Well-designed cohort or case-control analytic studies, preferably from more than one medical center or research group
II-3	Multiple time series with or without the intervention. Dramatic results in uncontrolled experiments
III	Opinion of respected authorities, based on clinical experience, descriptive studies, or reports of expert committees

Adapted from Rosen MG, Dickinson JC, Westhoff CL: Vaginal birth after cesarean: a meta-analysis of morbidity and mortality. *Obstet Gynecol* 77:465, 1991.

studies deemed appropriate by the reporting investigators. This approach provides the most readily available means with which to accumulate sufficient data to evaluate the impact of selected uncommon risk factors or endpoints. Odds ratios for each of the outcomes of interest can be calculated for each individual study, as well as for the pooled data. In the case of VBAC-TOL data, an odds ratio that is far from 1.0 (i.e., 0.5 or 2.5) indicates a strong relationship between the TOL group and the outcome analyzed. In contrast, an odds ratio that is close to 1 indicates a weak relationship. Similarly a narrow confidence interval indicates that the summary odds ratio is a precise estimate of the effect, whereas a wide confidence interval or one that includes the null hypothesis value (1.0) indicates that the observed odds ratio is not a precise effect estimator, which is most often observed when the outcome is a rare event. When outcome measures are rare, the odds ratio for any one particular outcome may appear to reveal a substantial difference between the various birth routes (TOL vs. VBAC vs. elective repeat cesarean delivery); however, when such outcomes are rare, the risk difference between the birth routes will be small. The primary limitation of meta-analysis is that both physician and patient choice are involved in each study and likely to be inconsistent from study to study.

Relevant VBAC-TOL Comparison Groups

To best determine the most appropriate prospective clinical management for patients presenting with a prior cesarean birth, the elective repeat cesarean group is the appropriate reference group with which to evaluate the safety of VBAC-TOL. Prospectively, the outcome of the elective group should be compared with the outcome of all patients undergoing TOL. In hindsight, after completion of the TOL, the TOL group may be subdivided into (1) successful TOL (VBAC) and (2) failed TOL.

Preexisting Conditions as Predictors of VBAC-TOL Success

One of the first questions to be raised by a patient when considering a VBAC-TOL is, what is the likelihood for a successful vaginal birth according to the indication for the prior cesarean birth? The overall VBAC success rate for all candidates is 60 to 80 percent (Evid. Qual. II-2 and II-3).^{[195] [196] [197] [198]} Obstetric history regarding preexisting conditions is helpful in the prediction of VBAC success. Women who have previously given birth vaginally or women whose prior cesarean delivery was for nonrecurring conditions are more likely to succeed (Evid. Qual. II-3).^{[199] [200] [201] [202]} Despite providing some assistance, there is no system to predict the specific patient who will achieve a VBAC success; even x-ray pelvimetry cannot predict success (Evid. Qual. II-1 and II-3).^{[221] [222]} Furthermore, success rates vary because of nonclinical variables and patient self-selection, which influences (Evid. Qual. Level II-2 and II-3) VBAC-TOL attempt rates.^{[215] [223] [224]}

Recurring Versus Nonrecurring Indications

The likely success of a VBAC trial will depend to some degree on whether the indication for the prior cesarean is a recurring or nonrecurring one. Patients with a non-recurring indication (breech presentation, so-called fetal distress-nonreassuring FHR pattern, and conditions such as placenta previa, abruption, or maternal hemorrhage) are more likely (82 to 86 percent) to achieve success than is the patient who has undergone a prior cesarean for a potentially recurring condition (70 percent) such as dystocia (failure to progress and/or CPD), approximating the success rate for the so-called low-risk nulliparous patient.^{[205] [218] [225]}

Rosen used meta-analysis of 29 individual studies reported between 1982 and 1989 (Table 18-10) to evaluate the association between preexisting conditions and achievement of vaginal delivery (successful VBAC) for the entire subset; the effect of not attempting a VBAC-TOL is included.^[218] VBAC-TOL success rates are similar (63 to 85 percent) among the subsets. However, when each subset is considered as a whole, a trial was offered apparently less often or when offered was refused more frequently when the prior indication was dystocia (OR, 0.5) and when oxytocin was used (OR, 0.3). The odds ratios of achieving vaginal delivery (when one

condition is compared with all other preexisting conditions) are listed in [Table 18-10](#) in decreasing order.

TABLE 18-10 -- META-ANALYSIS OF 29 STUDIES (RANGE, 624 FOR EACH INDICATOR) INVOLVING 8,770 VBAC-TOL

Preexisting Indicator in Prior Pregnancy	No. of Studies	Average Success Rate (%)	Odds Ratio*	95% CI	Studies Analyzed (Cases)
Previous breech	17	85	2.1	1.82.3	17 (1,720)
Prior vaginal delivery	12	84	2.1	1.72.5	12 (834)
Prior cesarean	6	75	0.7	0.50.9	6 (1,015)
Dystocia	24	67	0.5	0.50.6	24 (3,582)
Oxytocin used	10	63	0.3	0.30.4	10 (2,289)

Data from Rosen and Dickinson.^[219]

* Cephalopelvic disproportion, failure to progress.
Odds ratio for a successful trial of labor after cesarean with various preexisting indications.
Used in current pregnancy.

Prior Breech

Sixteen of 17 studies selected for meta-analysis indicate that the highest success rate (OR, 2.1; 95 percent CI, 1.8 to 2.3) with the current trial of labor is achieved when the prior indication for cesarean is breech presentation, indicating that the chance of achieving vaginal delivery was more than twice as great for a woman who had had a prior cesarean for a breech than if she had had a cesarean for all other reasons.^[219] Only one study found no association.^[201]

Prior Vaginal Delivery

Although all patients have a relatively high rate of successful VBAC attempt, the success rate is increased to over 80 percent for women who have had a prior vaginal birth.^{[125], [226], [227]} An early report was unable to demonstrate a significant impact of prior vaginal birth on an already high overall success rate (>80 percent).^[206] It may be that the impact of a prior vaginal birth exerts its effect only in patient populations in which VBAC trial management was less aggressive. Eleven of 12 available studies selected for meta-analysis indicate that a prior vaginal delivery improves the likelihood (OR, 2.1; 95 percent CI, 1.7 to 2.5) of a successful trial of labor.^[219] Only one selected study indicated that a prior vaginal delivery did not improve the likelihood.^[228] Two studies have examined the issue in greater detail, controlling for the order of these deliveries, and determined that vaginal delivery following the prior cesarean is a stronger predictor of success than vaginal delivery before the prior cesarean.^{[118], [208]}

More Than One Prior Cesarean (Multiple Prior Cesarean Births)

In 1999, the ACOG Practice Bulletin for vaginal delivery after a previous cesarean birth specified that "Women with two previous low-transverse cesarean deliveries and no contraindications who wish to attempt VBAC may be allowed a trial of labor. They should be advised that the risk of uterine rupture increases as the number of cesarean deliveries increases."^[3] The safety of VBAC-TOL in women having had two or more cesareans is now well established; they can be managed in a manner similar to that for patients with only one prior incision, with few complications.^{[5], [193], [201], [208], [209], [210], [211], [213], [214], [220], [229]} Meta-analysis of six studies, providing data ([Table 18-10](#)) on 1,015 women who had more than one prior cesarean before a trial of labor, indicates that such patients have historically been 30 percent less likely (OR, 0.7; 95 percent CI, 0.5 to 0.9) to be successful than all other trials of labor.^[219] A report by Miller et al.^[211] ([Table 18-11](#)) emphasizes the importance of inclusion of patients with two or three prior cesareans if reduction of the total cesarean rate is to be considered a serious goal. They constitute approximately 1.8 and 0.5 percent of the entire obstetric patient population, respectively, and are highly likely (75 and 79 percent, respectively) to achieve vaginal delivery. Although uterine rupture is more likely in this group (OR, 3.06), there is no appreciable increase in perinatal mortality.^[211]

Currently available data on the outcome of TOL with three or more prior cesareans are limited; however, VBAC success rate was 79 percent in one study.^[211] As noted by the ACOG, women with more than two prior procedures should be informed that they may possibly be at greater risk for uterine rupture if they choose TOL. However, they should not be discouraged from attempting a VBAC-TOL. As many as 33 percent of such patients will accept the VBAC-TOL option, and approximately 80 percent of those who do so will be successful.^[211]

Prior Dystocia (CPD/FTP)

Absolute cephalopelvic disproportion is virtually never present. Inherent clinical biases would suggest that patients with a previous cesarean delivery for dystocia

TABLE 18-11 -- USE AND SUCCESS RATES OF A VBAC-TOL ACCORDING TO THE NUMBER OF PRIOR CESAREAN BIRTHS

	No. of Prior Cesareans			
	One	Two	Three	Total
No. of prior cesareans	13,594	2,936	792	17,332
Percent total population	8.2	1.8	0.5	10.5
Trial of labor (TOL) (%)	80	54	30	73
Success (VBAC) (%)	83	75	79	82
Percent potential reduction in total cesarean rate	5.5	0.8	0.1	6.4

Data from Miller et al.^[211]

* Success rate with 2 prior cesareans was 75.3%, significantly lower than with 1 prior cesarean (OR, 0.612; 95% CI, 0.540.69; $p < 0.001$).

(FTP or CPD and failed induction) would not only be less likely to achieve a VBAC-TOL, but also would not attempt a trial as often. Meta-analysis of 24 studies involving 3,582 trials in women with a prior cesarean for dystocia ([Table 18-10](#)) indicates that if such women attempt a trial, they achieve a 67 percent VBAC-TOL success rate. However, when the entire group with prior dystocia is considered, they have the lowest success rate for vaginal delivery (OR, 0.5 to 50 percent of the rate of success [11 to 16 fewer vaginal deliveries per 100 cases]) achieved by all other women presenting with a history of prior cesarean for other indications (95 percent CI, 0.5 to 0.6).^[219] A more recent multicenter study (Evid. Qual. II-2) indicates that the patients with prior dystocia (CPD, FTP) who attempted a trial were successful in approximately two of three trials.^[197] One study in which 58 patients received oxytocin therapy prior to cesarean delivery for "failure to progress" in the first term pregnancy labors is particularly instructive.^[29] Despite the seeming importance of a well-managed initial pregnancy labor trial, 40 (69 percent) of the 58 women achieved vaginal delivery in their subsequent VBAC trial.

Impact of Dystocia-Related Factors

The likelihood of VBAC success is increased in the absence of a prior dystocia diagnosis. Similarly, success is increased by the presence of factors predicting the absence of dystocia, such as absolute fetal weight less than 4,000 g, smaller relative fetal weight than the index pregnancy, and response to oxytocin stimulation within 2 hours.^[227] Should oxytocin be required, the absence of a prior CPD diagnosis increases the likelihood of VBAC success.^[228] Furthermore, if the issue is indirectly assessed by evaluating other factors possibly related to dystocia, such as the length of the labor prior to the primary cesarean, the fetal birth weight, and the extent of dilatation at the time of the prior cesarean, there is no improvement in predictability, as described below.^[230]

Length of Labor Preceding Prior Cesarean

Two studies reported a tendency for a shorter labor immediately prior to the primary cesarean in women who are successful in a subsequent VBAC-TOL.^[230],^[231]

Fetal Birth Weight

One might hypothesize a linkage between fetal birth rate and VBAC success. Jarrell et al.^[228] reported a lower trial success rate in women with prior CPD delivering a newborn weighing more than 3,900 g. In contrast, Phelan et al.^[204] in a report involving 140 trials of labor with "macrosomic" (> 4,000 g) infants, reported that 67 percent of the women delivered vaginally. A statistically significant association between a higher average birth weight and a higher failure rate could not be identified in a subsequent meta-analysis of 10 selected studies providing sufficient data to determine average birth weights (average birth weight ranged from 3,123 to 3,642 g) of VBAC-TOL candidates.^[218]

Cervical Dilatation upon Admission for Current Pregnancy

Cervical dilatation greater than 4 cm upon admission has been reported to increase the likelihood of a successful trial of labor significantly in one study but not in the other.^[230],^[231]

Extent of Cervical Dilatation During Prior Primary Cesarean

Should the history indicate that the prior cesarean was for "failure to progress" following a failed induction or in a patient who did not enter the active phase of labor, one might anticipate the success rate to be similar to that of the general VBAC-TOL population. In contrast, should the history indicate that the patient entered the second stage and despite adequate contractile activity and pushing was unable to deliver, one

575

could reasonably hypothesize such a patient to be less likely to achieve success. Despite the possible rationality of the thought process, the data are not supportive. Two studies found no association between the extent of dilatation at the time of the primary cesarean and subsequent success in the present trial of labor.^[230],^[232] Most recently, Jongen et al. reported that 80 percent of 103 women who underwent VBAC-TOL after a prior cesarean delivery for failure of descent in the second stage had a successful trial.^[234]

Considerations in Management of VBAC-TOL

Management of the patient undergoing a VBAC-TOL is similar to that of patients attempting to achieve a vaginal delivery.^[3],^[233] As a consequence, it is appropriate to use oxytocin and epidural anesthesia as one would in other labors. Potential problems such as suspected fetal macrosomia will be encountered and management will be no different from that in normal labor. The major difference will arise from some heightening of concern for uterine dehiscence and/or rupture. Even that concern need not be extreme; the risk is low and, should dehiscence or rupture occur, in most cases the outcome is favorable for both the mother and fetus.

Prior Uterine Incision

Prior Lower Uterine Segment Incision

The presence of a preexisting incision confined to the lower uterine segment engenders minimal risk of uterine rupture, and the risk does not appear to be modified by the route of delivery.^[211],^[212] Only in hindsight (i.e., should there have been a failed TOL) does the 95 percent confidence interval (1.4 to 5.4) exceed and not overlap the reference value of 1.0, indicating increased risk.

Prior Low Vertical Incision

A prior low vertical uterine incision, limited to the lower, more passive, noncontractile portion of the uterine segment, is not a contraindication for a VBAC-TOL.^[60],^[212] Candidacy for a TOL in a patient with a prior low vertical scar is somewhat controversial. Low vertical incisions are not necessary as often, and most investigators have excluded women with low vertical scars from their reported series of patients. As a consequence, the available data are limited, and the data reported are possibly biased, since they are not the product of prospective studies. Some clinicians believe that it is not possible to confine a vertical incision to the lower uterine segment. Some consider any uterine incision that extends into the upper, more contractile portion of the myometrium to be a contraindication to subsequent labor.^[235] The theoretical concern does not appear to be warranted. Rosen et al.,^[212] in a meta-analysis of 170 VBAC patients with a prior low vertical incision, reported that the combined risk of dehiscence and rupture (two cases) was not different from that of VBAC patients with a prior low transverse incision.

Prior Classic Incision

It is likely that we will continue on occasion to be confronted with patients who have had a prior classic incision. A TOL should be strongly discouraged in such cases.^[60] Fortunately, classic cesarean incisions are uncommon, and as a result the need to conduct a repeat cesarean in this population subset will make only a small contribution to the overall repeat cesarean rate. Patients with prior classic incision have an associated 12 percent (SE 6 percent) risk (3 cases in 26 women who underwent unplanned TOL) of symptomatic uterine rupture during labor.^[212],^[236] Since approximately one third of ruptures occur prior to labor, it is currently recommended that women who have a prior classic cesarean delivery be delivered by repeat cesarean procedure upon achieving fetal pulmonary maturity prior to the onset of labor. Such patients should be warned of the hazards of an unintended labor and the signs of possible uterine rupture.^[237]

Known Versus Unknown Incision Type

In an era when prior medical records are not always readily available, it is reassuring that the overall risk of dehiscence or rupture is low even among women undergoing a TOL with an unknown prior cesarean incision type. In large part this is a function of observation that 90 to 95 percent of women with unknown scars will have had a low transverse incision.^[202] Some believe that if the extent of an incision is unknown or poorly documented, a TOL is probably not a reasonable approach.^[238] However, this is not very practical and is probably unnecessary. Meta-analysis reveals no statistically significant difference in rates ($p = 0.95$) between those with versus those without known incision types.^[212]

Oxytocin Usage in VBAC Trial

Use of oxytocin is contraindicated only if the patient has a prior classic incision; the indications for use of oxytocin are the same as those for patients without a history of one or more prior cesarean births.^[212],^[238] Oxytocin use should be in general accordance with the guidelines described [in Chapter 13](#) and ACOG Technical Bulletin No. 218.^[239] Its use during a VBAC-TOL for augmentation does not increase risk and is not associated

with an increase in perinatal mortality.^[60],^[240] Some discussion of theoretical questions relating to benefits and risks justifying this conclusion is worthwhile.

Does the Use of Oxytocin Provide Clinical Benefit?

If oxytocin is not used selectively, a significant number of VBAC-TOLs will end up as repeat cesarean procedures. However, when VBAC-TOL patients receiving oxytocin are compared with those not receiving oxytocin, failure is significantly higher in the oxytocin group. Unfortunately, it is not possible to predict prospectively which patient will derive benefit. If there is an early response to oxytocin, one can expect a greater probability of success. In contrast, if a patient fails to progress within approximately 2 hours, cesarean delivery becomes considerably more likely.^[227]

Benefit accrues from its use when employed for either induction or augmentation; vaginal delivery can be accomplished in 60 and 68 percent, respectively.^[241] Meta-analysis of 10 selected studies indicates that the success rate among TOL patients requiring oxytocin is approximately one third the rate of success in patients not receiving oxytocin (OR, 0.3; 95 percent CI, 0.3 to 0.4).^[219] Only 1 of the 10 studies suggested a higher, but not significantly higher, success rate following the administration of oxytocin.^[201] Although the data are not available, selection bias may explain the discrepancy; oxytocin augmentation is seldom used unless there is recognition of delayed progress in either cervical dilatation in the first stage or descent in the second stage, and induction may be indicated in patients with an unfavorable cervix.

Are There Contraindications to Oxytocin Usage?

With the exception of a prior classic uterine incision, currently there are no absolute contraindications to the use of oxytocin in an appropriate VBAC-TOL candidate. Each case must be considered on the basis of the clinical presentation and a judgment made regarding the relative benefits and risks of its use under the circumstances of the case.

Spontaneous Versus Induced Uterine Contractions as Risk Factors

Uterine contraction patterns, whether spontaneous or oxytocin induced, may demonstrate hypercontractility (tachysystole or tetany); on occasion there may be associated FHR decelerations. Hypercontractility, if persistent, may potentially increase fetal risk, a risk that is independent of the presence of a prior uterine scar.

Does Oxytocin "Significantly" Increase the Risk of Uterine Rupture and Perinatal Mortality in a VBAC-TOL?

Initial concern that oxytocin usage would significantly increase the risk of uterine rupture/dehiscence has not been confirmed. First, the risk is quite low. Its use is not associated with an increase in perinatal mortality.^[58] However, a case-control study found that "excessive (overuse of)" oxytocin infusion rates increased the risk for rupture or dehiscence.^[242] Although it is known that use of oxytocin is "associated" with an increase in risk of uterine rupture, this risk must be interpreted in an overall clinical context that may include other factors also associated with rupture. Use and duration of administration do not significantly increase the risk above that expected in the absence of oxytocin.^[5],^[92],^[199],^[212],^[241] Meta-analysis of selected studies indicates that the use of oxytocin during a VBAC-TOL does not appear to influence the risk of a dehiscence or rupture ($p = 0.7$), nor does it increase perinatal mortality rates.^[212] In a recent large series, Miller et al.^[211] report that oxytocin was used in only 68 percent of 118 cases of uterine rupture (74 percent of 69 ruptures in women with one prior cesarean and 67 percent of 39 ruptures in women with two prior cesarean deliveries). The risk of rupture may be increased in patients who receive oxytocin in the latent phase of labor or have dysfunctional labor.^[242]

Prostaglandin Gel and Misoprostol Usage

Although the use of prostaglandin E₂ gel for cervical ripening is extensive and is likely to have been employed in many prior VBAC candidates, reported data are limited. Three authors have reported experience with prostaglandin E₂ gel for cervical ripening.^[243]^[244]^[245] At this point, its use appears justified. In contrast, misoprostol has been associated with an increased risk of uterine rupture and should not be used in VBAC-TOL patients.^[246]

Possible Fetal Macrosomia

Prospective management of potential fetal macrosomia presents a significant clinical dilemma in any labor. Estimated fetal weight (EFW) of more than 4,000 g is not a contraindication to a TOL.^[60],^[212] Although clinicians might strategically reduce exposure to litigation by routine repeat cesarean delivery when the EFW is greater than 4,000 g, the strategy is flawed. It incorrectly assumes that fetal weight can be predicted reliably and ignores data that indicate that vaginal delivery can be accomplished safely in a large proportion of patients.^[204] The decision to perform a cesarean in all patients with an EFW of more than 4,000 g would result in many cesarean deliveries for actual weight less than 4,000 g

and with little or no improvement in outcome. The 1999 ACOG Practice Bulletin states that whether a trial of labor should be encouraged in the patient with an estimated fetal weight of more than 4,000 g "is controversial" as it is for patients with multiple previous cesarean deliveries, an unknown uterine scar, breech presentation, twin gestation, and a postterm pregnancy as well.^[3]

The only way to address the question conclusively is to review retrospectively the outcomes of VBAC-TOLs in which the birth weight is known to be in excess of 4,000 g. Flamm and Goings^[247] reviewed the outcomes of 1,776 patients who attempted a TOL in eight California hospitals; 301 newborns weighed at least 4,000 g. Fifty-eight percent of newborns weighing 4,000 to 4,500 g and 43 percent of those with birth weights of at least 4,500 g delivered vaginally. Of interest, when the outcomes of the 301 "macrosomic" TOLs were compared with the outcomes of the 1,475 TOLs with birth weights less than 4,000 g, there was no significant difference in maternal or perinatal morbidity or mortality. This clinical issue should be explored further.

Fetal Monitoring

In most cases, a significant alteration in FHR pattern is the presenting sign (Fig. 18-11); on occasion, an alteration (increased frequency and/or intensity) in uterine contraction pattern (if monitored externally) or a loss of intrauterine pressure (if monitored with an internal pressure catheter) is the presenting sign.^[199] The clinical detection and management of a possible uterine rupture will involve interpretation and reaction to a nonreassuring FHR observation (i.e., a sudden prolonged deceleration, late decelerations, or repetitive "significant" variable deceleration of a degree requiring intervention under the circumstances of the case). Although repetitive "significant" variable decelerations or a prolonged deceleration occur all too frequently in non-VBAC-TOL, detection of these findings during a VBAC-TOL strategically may justify a heightened response. It would appear prudent to proceed more rapidly to cesarean delivery under such circumstances than would be the case in the absence of a prior uterine incision. Undoubtedly, such a recommendation will result in some cesarean deliveries in which there is no rupture. However, the occurrence of a significantly nonreassuring FHR observation in a VBAC candidate is so infrequent as to have little impact on the overall cesarean rate of only one institution.

Intrauterine Pressure Catheters

One of the primary justifications for early recommendations by some that intrauterine pressure catheters be used was the potential to detect intrauterine pressure changes (abrupt change in intrauterine activity or pressure) associated with uterine rupture. Unfortunately, use of intrauterine pressure catheters does not reliably assist in the diagnosis of rupture.^[248],^[249]

Epidural Anesthesia

On the basis of available information, there appears to be little reason to withhold epidural anesthesia in a VBAC-TOL.^[5],^[195],^[206]^[207]^[208],^[220] The experience to date

suggests that the use of epidural anesthesia does not delay the diagnosis of uterine rupture and does not decrease the likelihood of a successful VBAC-TOL. ^[60], ^[206] Although there was natural concern that the use of epidural anesthesia in the first and second stages of labor may obscure symptomatology (pain, tenderness) of an otherwise painful uterine rupture and delay its diagnosis, the safety of epidural anesthesia in patients with a prior low transverse cesarean incision is now well established. Regional anesthesia does not appear to obscure the symptoms associated with uterine rupture. ^[195], ^[250], ^[251], ^[252] Furthermore, only a minority of patients experience pain and bleeding. ^[195], ^[206] Even in the unanesthetized patient, uterine or scar tenderness, a sign of uterine rupture, occurs in only 25 percent of cases. ^[253]

Routine Uterine Exploration

The relative merits of routine uterine exploration of the lower uterine segment following a successful VBAC is a subject of some controversy, an area where reasonable people may disagree reasonably. Advocates of routine exploration argue that failure to identify a defect does not allow for rational consideration of risk and benefits should a subsequent VBAC trial be considered. It is their belief that should routine exploration detect a "significant defect" that is connected with the peritoneal cavity, laparotomy should be performed either to repair the defect or to perform a hysterectomy. The logic supporting an approach not involving routine exploration is based on two observations. It is not clear how such information would modify future pregnancy management. If active bleeding is suspected, a laparotomy must be performed regardless of pelvic findings. Most agree it is not necessary to repair a small defect dehiscence unless there is significant bleeding or the patient develops significant symptomatology, because these asymptomatic scar dehiscences will heal well. ^[3] If a small defect is detected and there are no supporting signs or symptoms, the patient can be followed expectantly with careful observation of vital signs and serial hematocrit determinations. ^[61], ^[214] Second, should routine exploration occur in a patient with a "uterine window" (the lower uterine segment is intact, but very thin), there is the possibility that the exploration could disrupt an intact but thin lower segment. Although disruption

578

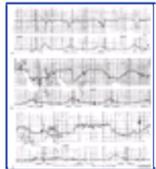

Figure 18-11 A, The patient is a 37-year-old gravida 7 para 3 AB3 woman at 41 weeks' gestation who presented for induction of labor. She had had two prior vaginal deliveries but her last baby was born at 33 weeks by low transverse cesarean section for nonimmune hydrops caused by a cardiac malformation. The patient's induction was begun with prostaglandin gel. Her cervix changed from fingertip dilated, 50 percent effaced, to 1 cm dilated, 70 percent effaced with a cephalic presentation at -2 station. Oxytocin was then begun at 1 milliunit/min. The patient progressed well, and epidural anesthesia was administered at 4 to 5 cm dilatation, 90 percent effaced, and 0 station. The patient was at 6 cm dilatation with a tracing demonstrating normal heart rate variability and variable decelerations. **B**, 30 minutes after the above tracing was recorded, the fetal heart rate pattern changed to severe variable decelerations. **C**, The tracing then demonstrated prolonged decelerations at 90 bpm. The patient was taken to the operating room for an emergency cesarean delivery. Uterine rupture had occurred along the site of the previous uterine incision. A female fetus weighing 3,200 g with Apgar scores of 7 and 8 was delivered. The umbilical arterial pH was 7.17 and the venous pH 7.22. The uterine incision had not extended and was easily closed. The baby did well.

of such a window would be unlikely to result in a significant problem, should abdominal exploration not be performed, one can easily predict an unnecessary sense of anxiety and anticipation by the patient in the ensuing hours until the clinician is confident that the patient will not develop signs or symptoms that would require abdominal exploration.

The ACOG VBAC Practice Pattern

In 1995, the ACOG published its first of a series entitled *Practice Patterns* on management of VBAC-TOL candidates. ^[214] It was revised in 1999. ^[3] The Practice Patterns are intended to serve as an acceptable clinical guideline to assist practitioners and patients in making decisions regarding appropriate care. They do not offer an exclusive course of management, but provide a detailed analysis, including meta-analysis, of factors that should help to determine a reasonable course of action to be chosen after taking into consideration available resources, patient risk factors, and desires of the patient. The relative merits of available data were evaluated using the U.S. Preventative Task Force Scoring System (Table 18-12) and the evidence (based on the highest level of data available) was graded (Table 18-13 and Table 18-14) according to the following categories: (A) "good" evidence; (B) fair evidence; and (C) insufficient evidence, but the recommendation can be made on other grounds.

Candidacy for VBAC-TOL

Most patients with a prior cesarean birth are candidates (Table 18-12, Evid. Level A). ^[61], ^[194], ^[195], ^[197] The only established contraindication is a prior classic incision (Evid. Level A). ^[214], ^[241] Patients with more than one prior cesarean may be selectively offered a VBAC-TOL (Evid. Level B). ^[194], ^[220], ^[254], ^[255], ^[256] Clinical conditions for which there are insufficient data to make a conclusive recommendation are noted in Table 18-12. Limited data (Evid. Level B) support a VBAC-TOL for patients with a prior low vertical incision.

Uterine Dehiscence and Uterine Rupture

Unfortunately, many studies do not define or differentiate between uterine rupture and dehiscence, and as a result most available data do not reliably specify the risks of rupture vs. dehiscence. Dehiscence has a distinctly different clinical connotation from "uterine rupture," which historically has been associated with prolonged oxytocin use in multiparous patients or following obstetric manipulations such as internal version or extraction. ^[257], ^[258] Despite this limitation, the combined threat of uterine dehiscence and rupture during a TOL is not sufficiently high (when compared with the elective repeat cesarean group) to deny women the well-accepted advantages of vaginal delivery.

TABLE 18-13 -- THE ACOG VBAC PRACTICE PATTERN SUMMARY

Clinical Issue	Conclusion from Trial	Evidence Level: Quality
Success rate	6080%	A:II-2
Benefits of VBAC-TOL	Outweigh risks	A:II-2

Candidates		
Prior LT C/S	Encourage trial	A:II-2
2 LT C/S	Do not discourage	B:II-2
Contraindications	Prior classic incision	C:III
Clinical problems		
Suspect macrosomia (in nondiabetic)	Not disqualified from VBAC trial	B:II-2
Multiple gestation	Insufficient data	C:II-2; II-3
Breech presentation	Insufficient data	C:II-2; II-3
Nonsubspecialty hospital	Appropriate site	A:II-3

LT C/S, low transverse uterine incision with no contraindications.

Definitions (Dehiscence Versus Rupture)

Uterine incisional dehiscence is commonly used to describe the occult or asymptomatic scar separation or thinning that is occasionally observed at surgery in patients with a prior low transverse incision. A useful operational definition of *dehiscence* is a uterine scar separation that does not penetrate the uterine serosa, does not produce hemorrhage, and does not cause major clinical problems.^[5] Dehiscence is most often detected among women who have experienced a failed TOL. Some patients may develop dehiscence during labor that on occasion may lead to the need for repeat cesarean. The first indication may be observation of a scar defect, a separation, or only a near-transparent uterine "window" at the time of a cesarean procedure. Incomplete ascertainment of uterine dehiscence is likely in women having a successful VBAC-TOL.

Uterine rupture, on the other hand, is symptomatic and may have presenting signs that require acute intervention. Since dehiscence is uncommon (2 percent) and rupture is relatively rare (<1 percent), most reported studies provide limited statistical power to detect small changes in the risk of dehiscence or rupture among relevant prior cesarean birth comparison groups.^[219] It is, however, unlikely that there is a major increased risk, since dehiscence or rupture is infrequent in all groups.

Combined Risk for Uterine Dehiscence and Rupture

Patients with a prior cesarean delivery who attempt a VBAC-TOL are at no higher risk, antepartum or early intrapartum, for uterine scar disruption (dehiscence and rupture) than are those having an elective repeat cesarean delivery.^[5], ^[212], ^[248], ^[259], ^[260] A recent meta-analysis that assessed the relative impact of VBAC-TOL on the combined risk of true rupture and asymptomatic dehiscence detected no difference ($p = 0.5$) in the combined risk between patients undergoing a VBAC-TOL (1.8 percent of 2,771) and those undergoing an elective repeat cesarean procedure (1.9 percent of 3,611).^[212] However, in hindsight the risk of dehiscence or rupture in the subset that had a failed TOL was 2.8 times that following an elective repeat cesarean ($p < 0.01$). The use of oxytocin did not ($p > 0.1$) influence the risk.

Risk for Dehiscence

Asymptomatic dehiscence is found incidentally in up to 2 percent of prior cesarean patients.^[219] The rate is similar in patients with a prior low transverse and low vertical incision.^[219] In a series of more than 2,600 patients, dehiscence was noted in only 1.5 percent of 1,465 patients having a successful VBAC-TOL versus 5.1 percent of 331 patients undergoing cesarean delivery for a failed VBAC-TOL. The difference may be partially a function of incomplete ascertainment in the VBAC success group. Nonetheless, these rates were not significantly different from the dehiscence rates in control patients who did not plan a TOL.^[5] A study ([Table 18-15](#)) involving more than 17,000 patients presenting with a prior cesarean, 12,000 of whom underwent a TOL, may give a more accurate assessment of the true prevalence of dehiscence; the status of the scar was routinely assessed visually or manually, and scar defects were categorized as either dehiscence or rupture. Among 17,332 women, there were 193 (1.1 percent) uterine dehiscences and 117 (0.7 percent) ruptures, for a combined risk in all women of 1.8 percent. The trial-related

* Thirteen non-TOL cases diagnosed at emergency cesarean for FHR indications immediately after admission; nine discovered at nonemergent cesarean. One prior cesarean = 0.5%; two prior cesareans = 1.3%; three prior cesareans = 1.1%.

risk of uterine rupture was 0.5 percent with one prior cesarean, 1.3 percent with two prior cesareans, and 1.1 percent with three or more prior cesareans. ^[211]

Risk for Uterine Rupture

Two series, one involving more than 11,000 and one more than 17,000 women with prior cesarean births, provide data specific for risk of rupture. ^{[195], [197], [211]} In one series, the overall risk (Table 18-15) of rupture (117 cases) was 0.7 percent (0.5 percent for those not undergoing a trial and 0.7 percent for those attempting a trial) in all women presenting with a prior cesarean. ^[211] In the two other reports summarizing experience from Kaiser-Permanente Hospitals in California, the overall incidence of rupture during the past decade was 0.5 percent ([10 of 5,733] in the interval between 1984 and 1988 and 0.8 percent [39 of 5,022] during the 1990 to 1992 interval). ^{[195], [197]}

Prospective Risk Scoring for Uterine Dehiscence or Rupture

Unfortunately, there are insufficient data for factors other than prior uterine incision type to provide a basis for prospectively identifying the specific patient who is likely to develop uterine rupture. Despite this limitation in prospective clinical care, VBAC-TOL continues to be viewed in a positive manner, largely because of the likelihood of VBAC success, the associated reduction in cesarean deliveries, and reduction in morbidity arising from cesarean delivery.

Certain risk factors, including exposure to "excessive amounts" (dose not defined) of oxytocin, dysfunctional labor, and a history of two or more prior cesarean procedures (Evid. Qual. II-2), have been "associated" with uterine rupture. ^[242] It is noteworthy that in one case-control study of 70 patients with prior cesarean delivery, the term *excessive amounts* of oxytocin was, in the authors' judgment, injudicious initiation (overutilization) of oxytocin during the latent phase of labor without delay following failure of uterine contractions to respond to hydration; the majority of such patients received oxytocin before they had confirmed dysfunctional labor (at 1 to 4 cm dilatation). ^[242] The frequency and relative impact of a number of possible clinical risk factors, using elective repeat cesarean delivery as a reference, is summarized from a meta-analysis of more than 6,000 VBAC-TOLs in Table 18-16.

Maternal Morbidity and Mortality

Maternal Mortality

Because maternal mortality is a rare complication, estimation of relative risk between prior cesarean comparison groups is difficult. In one review of American studies involving 5,400 patients published prior to 1980, there were no maternal deaths arising from uterine rupture, even those involving classic uterine scars. ^[261] A 1985 summary report of 6,258 women undergoing a TOL over a span of more than 30 years (1950 to 1984) indicated that 5,356 (86 percent) were successful with no maternal mortality, comparing favorably with an expected mortality rate of approximately 1 death per 1,000 cesarean deliveries. ^[199] Even the increased use of oxytocin during VBAC has not increased the risk of morbidity or mortality. ^{[5], [212], [226]} Other more recent studies support the prior observations of no significant increase in maternal mortality or morbidity. ^{[195], [212], [255], [262]} A meta-analysis (Table 18-17), summarizing maternal morbidity (dehiscence, rupture, fever) and mortality data from 11,417 VBAC-TOLs and 6,147 elective repeat cesareans reported in 31 VBAC studies between 1982 and 1989, confirms low maternal mortality and morbidity rates for both the elective repeat cesarean and TOL groups. ^[212] There were only two deaths among

* Meta-analysis of 11 VBAC studies with more than 6,000 VBAC-TOL (1982-1989). Standard error is 6%, or 60 per 1,000 births. Relative risk versus elective repeat cesarean delivery.

all TOLs and elective repeat cesarean deliveries. As one would expect, the observed maternal deaths derived from 10 studies were associated with postoperative surgical complications such as pulmonary embolus or following an obstetric complication such as placenta accreta. McMahon recently compared maternal morbidity in women undergoing VBAC-TOL with a group having an elective cesarean delivery. The higher rate of morbidity in the VBAC group was attributable to those patients who had had unsuccessful TOL. ^[263]

Maternal Febrile Morbidity

Mothers with successful TOLs (Table 18-17) have the lowest febrile morbidity, whereas those with a failed TOL (labor plus cesarean) have the highest (p < 0.001). ^[212] Because such a large percentage of women undergoing a trial of labor following a prior cesarean have a subsequent vaginal delivery, most women undergoing a VBAC-TOL will have less febrile morbidity and are thus likely to require a shorter hospital stay and fewer days lost from employment and family care responsibilities.

The perinatal risk for patients considering VBAC is no higher than that for patients delivering by elective repeat cesarean birth. [195], [197], [208], [212], [254], [262] The overall uncorrected perinatal death rate arising from more than 5,500 women presenting with a prior cesarean birth (Table 18-18) was 1.4 percent (14 per 1,000) in a meta-analysis of 10 studies. [212] The uncorrected total

* Ten studies involving more than 5,000 births for perinatal endpoint.

Reference group.

Excludes antenatal death <750 g, congenital anomalies.

§ Includes <750 g, congenital anomalies.

perinatal death rate for the subset of women undergoing a TOL was 2.1 times that of women who underwent an elective repeat cesarean ($p < 0.001$); however, when unrelated causes, such as antepartum fetal death (prior to labor), very low birth weight (< 750 g) and congenital anomalies incompatible with life, were excluded, this difference in perinatal mortality disappeared. The corrected perinatal mortality rate was 3 per 1,000 following a TOL and 4 per 1,000 following elective repeat cesarean (OR, 0.8; $p = 0.9$). When the perinatal outcome of "true" uterine ruptures was compared (only antepartum deaths excluded) with the outcome with no ruptures, there were 3 (13.6 percent) deaths after 22 ruptures and 28 (0.5 percent) after no rupture in 5,463 trials. Oxytocin use during a TOL did not influence perinatal mortality rate (OR, 1.5; 95 percent CI, 0.5 to 4.4).

Perinatal Morbidity and Mortality Arising from Dehiscence or Rupture

Intrapartum fetal deaths arising in the subset of patients who experience dehiscence of a low transverse uterine incision are uncommon. Although uterine rupture does occur infrequently, it is rarely catastrophic because of the availability of modern fetal monitoring, anesthesia, and obstetric support services. Data associated with rupture of a classic fundal incision are less reassuring. No maternal deaths were reported in an early review of published American VBAC studies involving 5,400 patients prior to 1980; fetal deaths were observed in 17 (56.7 percent) cases in which there was dehiscence or rupture of a fundal incision. [261] In contrast, lower uterine segment dehiscence occurred in 25 instances (0.46 percent), with no maternal deaths and only 3 (12 percent) fetal losses; the overall fetal mortality risk was 0.37 percent. Most fetal deaths arising from uterine dehiscence occurred either prior to admission or prior to the advent of widespread employment of continuous electronic FHR monitoring. More recent data suggest that maternal and perinatal outcomes are generally good following uterine rupture. However, uterine rupture under certain circumstances can have serious sequelae. Two reports have summarized the outcomes of 20 uterine ruptures. There were no maternal deaths in either reports, but only 14 of 20 (70 percent) had good perinatal outcomes. There were four perinatal deaths and four cases with newborn neurologic sequelae. Unfortunately, three of the four perinatal deaths involved women who were laboring at home without fetal monitoring. [248], [262] Table 18-19 summarizes the risks of uterine rupture and related perinatal deaths from a series of more than 17,000 women according to the number of prior cesarean births.

Newborn Depression as Morbidity Endpoint

The uncorrected odds ratio for a 5-minute Apgar score of 6 or less following a VBAC-TOL was 2.1 ($p < 0.001$) versus the elective repeat group (Table 18-18). However, the absolute risk for the same score is low in both groups (2 percent in VBAC-TOL vs. 1.6 percent in the elective repeat group). These outcome data are flawed, since they include newborns weighing less than 750 g and those with serious congenital anomalies. [212] Should there be a failed TOL, the risk for a low Apgar score is 2.6 times that following an elective repeat cesarean section ($p = 0.03$). However, should the TOL

* In women undergoing a trial of labor.

Incidence of uterine rupture with two or more prior cesarean births was 1.7%, significantly greater than with one prior cesarean (OR, 3.06; 95% CI, 1.954.79; $p < 0.001$).

succeed, there is no greater risk than after a repeat cesarean delivery ($p = 0.2$). Use of oxytocin does not increase the risk (OR, 1.6; 95 percent CI, 0.8 to 3.2; $p = 0.2$).

Documenting the Medical Record

Unknown Uterine Incision

Although it is highly likely that a prior uterine incision of unknown type involved the lower uterine segment, the best strategy is to make a reasonable effort to document the nature of the prior incision.^[6] The medical records office of the prior hospital in many cases can provide the necessary information. In those instances when the clinician is unable to determine the nature of the prior incision, the inability per se should not serve as a contraindication to a TOL.

The Operative Report

A description of the extent of a vertical uterine incision (low vertical vs. classic) in the cesarean operative report can be important in deliberations regarding the decision to pursue a VBAC-TOL in future pregnancies.

Timing of Elective Repeat Cesarean Delivery

Should the patient refuse a VBAC-TOL or have a recurring indication for cesarean delivery, the clinician has four possible options to determine when elective cesarean delivery should occur. According to the ACOG, fetal maturity may be assumed and amniocentesis need not be performed if the criteria of one of the four options in Table 18-20 are met.^[23], ^[26] The criteria do not preclude use of menstrual dating, particularly if one of the four confirm menstrual dates in a patient with normal menstrual cycles and no immediately recent use of oral contraceptives. Ultrasound is considered confirmatory if there is agreement between menstrual-gestational age and crown-rump age at 6 to 11 weeks or by the average gestational age determined by multiple measurements at 12 to 20 weeks within 1 week and within 10 days, respectively.

TABLE 18-20 -- FETAL MATURITY ASSESSMENT PRIOR TO ELECTIVE REPEAT CESAREAN DELIVERY

Option 1 (FHR)	One or more of the following is present for the stated duration:
	For 20 weeks: FHR by nonelectronic fetoscope
	For 30 weeks: FHR by Doppler
Option 2 (hCG)	For 36 weeks: positive serum or urine pregnancy test
Option 3 [†] (Ultrasound)	At 612 weeks' gestation: Ultrasound crown-rump length supports gestational age of 39 weeks
Option 4 [†] (Ultrasound)	At 1220 weeks, multiple ultrasound measures confirm gestational age of 39 weeks as determined by clinical history and physical examination
Option 5	Await spontaneous onset of labor
Option 6	Fetal pulmonary maturity documented by amniotic fluid surfactant assessment

Data from ACOG.^[26]

Adapted from American College of Obstetricians and Gynecologists, Committee Opinion: Fetal Maturity Assessment Prior to Elective Repeat Cesarean Delivery. No. 98. September 1991.

* Does not preclude use of menstrual age with agreement within 7 days (option 3) or 10 days (option 4).

Desire for Permanent Sterilization as an Indication for Repeat Cesarean

Approximately 42 percent of patients refuse the VBAC option.^[21] The decision to attempt a VBAC-TOL is often clouded by other clinical factors such as the need for a postpartum tubal ligation. Some would argue that a patient's desire for a permanent sterilization is not an appropriate indication for a repeat cesarean procedure. In most cases, such a view is appropriate; the morbidity of vaginal delivery and subsequent postpartum tubal ligation is less than that of a repeat cesarean. In one study, 13 percent of successful VBAC patients had a postpartum tubal ligation with only minor prolongation of their hospital stay.^[26]

Many patients, however, will find such an argument unattractive, particularly if the prior cesarean for dystocia was performed after a long labor including extended pushing. Unfortunately, ligation may not be feasible immediately postpartum following a successful VBAC. Other reasons for refusal are fear of "another long labor" resulting in a cesarean; concern about the likely need for one anesthesia for the cesarean/vaginal delivery and another for the tubal ligation; a preference not to reinstate contraception; and concern that they cannot easily take time away from family or professional activities, even for an outpatient tubal ligation. More predictable access to tubal ligation immediately following a successful VBAC could potentially blunt the influence of many of the above. This access will vary according to hospital resources, particularly at night and on weekends.

Indication for Repeat Cesarean Delivery

Nearly two thirds of all repeat cesarean procedures are performed without a trial of labor. The most common indications are listed in Table 18-21.^[21]

TABLE 18-21 -- MOST COMMON INDICATIONS FOR REPEAT CESAREAN DELIVERY WITHOUT LABOR IN 17,322 WOMEN WITH PRIOR CESAREANS

Indication	Occurrence (%)
Elective repeat	47

Malpresentation	20
FHR indication	14
Macrosomia	5
Placenta previa	3
Multiple gestation	2

Data from Miller et al.^[21]

* 21% in women with 1 prior cesarean delivery; 56% in women with two prior cesarean deliveries; 68% in women with 3 prior cesarean deliveries.

INFORMED CONSENT

Informed Consent Is a Process

Informed consent should be considered a process that includes sharing of information and discussion of the choices reflected in the informed consent document. ^[266] Ordinarily, effective informed consent requires active participation by both the physician and the patient. It is the physician's responsibility to make sure that the patient is well informed; has under ordinary circumstances reasonable time to contemplate the information provided; and is encouraged to ask questions when necessary. It is the patient's responsibility to provide accurate and complete information and, if matters are unclear, to pose questions. ^[267]

The patient and her partner should participate in the decision-making process leading to cesarean delivery. There is considerable variation in both the style and substance of obtaining informed consent for cesarean birth. Although there is certainly merit to nondirected counseling, it should be somewhat obvious that it is difficult to transmit a minimum of 8 years of training and a number of years of clinical experience into a 5- to 10-minute discussion for informed consent, particularly when stress and emotions are high. The provision of informed consent involves walking a fine line; it is part of the so-called art of medicine. Much of the information provided will depend on whether the procedure is scheduled or unplanned. A key feature in the process is physician-patient rapport and associated patient trust of the managing physician. Current practice patterns often dictate that the patient receive care from several members of a large group practice, in which case rapport is not always optimal. Some patients want a detailed explanation, whereas others desire whatever the doctor advises. Sadly, much of what is discussed is often not understood or is forgotten when stress is high. Provision of too much information may overwhelm the patient. On the other hand, provision of inadequate or unbalanced information may result in a decision that the patient later regrets.

Content Disclosure Guidelines

There may be variation from state to state regarding the degree of disclosure required for a valid surgical consent (i.e., what is adequate information?). Most states use the "professional" or "reasonable physician standard," whereas others use the "materiality" or "patient viewpoint standard."

"Professional" Approach

The "professional" approach to consent is determined by what is customary practice in the medical community. Less information is provided, that is, extremely remote risk even with serious consequences may not necessarily be disclosed. In the case of an anticipated cesarean delivery when time is not an issue, the patient would be informed about the commonly encountered risks of any operative procedure, namely, infection and hemorrhage, as well as major complications associated with anesthesia. Injury to nearby organs, including bladder and ureters, at the time of cesarean delivery is a rare complication that is not ordinarily discussed. Should vaginal delivery be an acceptable alternative, the patient may benefit from knowledge regarding the relative risks and benefits of that approach.

Should primary cesarean delivery be considered for conditions such as a frank breech presentation, much of the focus of the discussion commonly may relate to the potential and theoretical fetal advantages, if any, of cesarean birth. Some mention of the severalfold increase in maternal morbidity and mortality associated with a cesarean delivery and its complications is also appropriate.

The patient should *not* be asked, "Do you want to do everything possible for your baby?" There are as yet few data to suggest that a cesarean birth, except in the presence of selective indications, has a beneficial effect with regard to survival and long-term outcome. Should cesarean delivery be considered for a very low birth-weight fetus, it may be advantageous to review the anticipated weight and gestational age-specific rate of intact survival by either route. If the procedure would not follow labor, discussion of the potentially higher risk of respiratory distress with an elective cesarean birth may be appropriate.

Contingencies can also be important. Should the physician anticipate a repeat cesarean procedure in a patient with a current diagnosis of anterior placenta previa, informed consent may include some discussion regarding the potential need for hysterectomy for placenta accreta, as well as the potential need for transfusion and its associated risks (see Chapter 17). When an elective cesarean delivery likely to require blood replacement is anticipated, the option of autologous transfusion is a possible topic for discussion. ^[268]

Patient Viewpoint Approach

There may be an evolution to a new conceptual framework, the "materiality" or "patient viewpoint standard." Under the "materiality" or "patient viewpoint standard," even if the risk of a procedure is extremely remote, but has serious consequences, the risk would be disclosed, i.e., the amount of information provided should be based on what a "reasonable person in the patient's position" would "want to know in similar circumstances." This approach would then be based on what a patient would "need to know" to make a decision rather than on professional perception of what a patient "should know." The problem with such an approach is that the "needs" and "the reasonable patient" have not been objectively defined; clearly, there are many patients who, in foresight, are happy to rely on the physician's advice, but, in hindsight, would want to know virtually everything. Clearly, there are degrees of ability of the physician to communicate and of the patient to comprehend and remember. Such an approach would require physicians to discard their experience regarding what patients are capable of comprehending under similar circumstances or even what the experienced physician, who has an ongoing relation with the patient, believes the patient or most patients would like to know or understand.

Possible Components of Consent

Under either approach, the physician should not guarantee or even suggest a guarantee of outcome. To obtain fully informed consent, the physician should explain the following:

1. The diagnosis and nature of the condition calling for the intervention
2. The nature and the purpose of the treatment/procedure recommended
3. The material risks and potential complications associated with the recommended treatment/procedure
4. Feasible alternative treatments/procedures, including the option of taking no action
5. Description of material risks and potential complications associated with the alternatives
6. A relative probability of success for the treatment/procedure in understandable terms

Patient Refusal of Treatment/Procedure

On occasion, a patient may refuse a cesarean delivery that is perceived by the physician to be necessary to save either her life or that of the fetus; in most cases there are either religious or ethical considerations. Although there is no "correct" way to manage such a circumstance, the record should reflect the fact that the patient was informed of the benefits anticipated and that the patient refused the procedure. The ACOG Committee on Ethics has released a Committee Opinion that addresses such a situation: "Every reasonable effort should be made to protect the fetus, but the pregnant woman's autonomy should be respected. . . . The role of the obstetrician should be one of an informed educator and counselor, weighing

587

the risks and benefits to both patients, as well as realizing that tests, judgments, and decisions are fallible. Consultation with others, including an institutional ethics committee, should be sought when appropriate, to aid the patient and obstetrician in making decisions. The use of the courts to resolve these conflicts is warranted only in extraordinary circumstances."^[265]

Is Informed Consent a Prerequisite for VBAC-TOL?

The need for specific consent from a patient attempting VBAC seems somewhat superfluous if one acknowledges that the inherent risks of a VBAC are less than or equal to those of an attempted vaginal delivery in other patients. Because likelihood of a successful VBAC is only minimally dependent on the indication for the prior cesarean delivery, the physician should present the chances of success in a positive manner. An increasing number of clinicians now obtain written consent. However, an equally reasonable approach would be to indicate in the patient's prenatal record that the patient has been informed that labor following a prior cesarean delivery is an acceptable alternative to routine repeat cesarean delivery with only minor attendant risks that are not significantly greater than those of a repeat cesarean procedure.^[3]

Patient Refusal of VBAC-TOL

Despite increasingly widespread acknowledgement that VBAC-TOL is safe and has a high success rate, only 40 to 50 percent of eligible candidates are reported to request an elective repeat procedure.^[215], ^[216] A desire to avoid labor-related pain and the convenience of a scheduled elective repeat cesarean are the most common reasons.^[270] A woman should not be coerced to undergo a VBAC-TOL. Certain social, geographic, and past obstetric complications may justify the patient's electing to have a repeat cesarean birth. ACOG has recently stated that "the ultimate decision to attempt this procedure (VBAC) or undergo a repeat cesarean delivery should be made by the patient and her physician. . . . Global mandates for a trial of labor after a previous cesarean delivery are inappropriate because individual risk factors are not considered. . . ."^[3]

PERIPARTUM HYSTERECTOMY

Peripartum or obstetric hysterectomy is the surgical removal of the uterus at the time of a planned or unplanned cesarean delivery or in the immediate postpartum period. Peripartum hysterectomies can be classified as total, subtotal or, occasionally, as radical (with or without node dissection and/or adnexectomy) or alternatively as "unplanned" (emergency), "planned" (scheduled), or "elective" (sterilization being the only indication). Such distinctions are critical when comparing the relative benefits and operative risks of hysterectomy with alternative management options.

Historically, the first cesarean hysterectomy was performed by H.R. Storer, in Boston, in a patient who expired on the third postpartum day.^[271] Eduardo Porro (1876) performed the first procedure on a surviving patient.^[9] In that case, subtotal hysterectomy (amputation of the uterine fundus following hysterotomy with subsequent marsupialization of the stump to the anterior abdominal wall) was performed to increase the likelihood of survival.^[272] Twenty-five percent of cesarean deliveries were performed as Porro cesarean hysterectomies as late as 1922.^[273]

Incidence

Two reports from the same institution over a 10-year span summarize a possible trend of increasing incidence of hysterectomy following cesarean delivery. The rate following cesarean delivery increased from 7.0 (1989) to 8.3 (1993) per 1,000 and continues to be dramatically higher than the rate following vaginal delivery (0.2 per 1,000 births in 1984 and 0.09 per 1,000 in 1993).^[125], ^[274] The increased rate following cesarean births may reflect the change in prevalence of prior cesarean deliveries. In the early series, only 44 percent of patients requiring hysterectomy had a prior cesarean delivery, whereas 67 percent had a prior cesarean in the more recent cases from 1985 to 1990.

Unplanned Emergency Indications

Most peripartum hysterectomies are unplanned (Table 18-22) and follow cesarean delivery.^[125] Most are performed after more conservative efforts to control bleeding have been unsuccessful. Although hysterectomy may be the ultimate remedy for control of obstetric hemorrhage, conservative measures remain the primary approach; hysterectomy is reserved for circumstances in which these efforts either fail or are not applicable as would often be the case with abnormal placentation.^[274]

Risk Factors for Emergency Hysterectomy

Sixty percent of emergency hysterectomies performed at Harvard were done in women with a history of a prior cesarean delivery.^[275] Prior cesarean delivery heightens the risk for subsequent placenta previa, placenta accreta, and symptomatic uterine rupture, each of which increases the likelihood for an emergency hysterectomy.^[272], ^[275] The adverse impact of placenta previa as a

82 (67%) had at least one prior cesarean.

risk factor for unplanned hysterectomy in patients with a prior cesarean is established.^[91], ^[276]

The importance of both previa and prior cesarean delivery as risk factors is supported by several studies from the same institution. In the first of three reports from southern California, a strong association (25 to 30 percent) between placenta accreta and a preexisting cervical uterine scar was reported.^[89] The linkage was even greater in the subset who required hysterectomy. In the second of the series, 52 percent of hysterectomies performed for placenta accreta were associated with a previous cesarean scar.^[125] In the third report, 69 percent of 58 patients with placenta previa had one or more prior cesarean births. In that series, peripartum hysterectomy followed cesarean delivery in 94 percent of cases; 67 percent had a prior cesarean delivery, 47 percent had a placenta previa, and 50 percent had an accreta or percreta.^[274] In another series from Massachusetts, the risk of peripartum hysterectomy in association with placenta previa increased from 7 per 1,000 deliveries in nulliparous women to 1 in 4 deliveries in women with a history of 4 or more prior births ($p < 0.001$).^[275]

Placenta Accreta/Percreta

Placenta accreta/percreta with or without previa is now the most common indication for peripartum hysterectomy.^[242], ^[274], ^[275]

In the past, the most common indication for peripartum hysterectomy had been uterine atony. The introduction of prostaglandin F₂ as a therapeutic intervention has reduced the relative impact of uterine atony as an indication for hysterectomy. Furthermore, hysterectomy is seldom performed solely for a Couvelaire uterus in the absence of other more pressing complications or for asymptomatic cesarean scar dehiscence. The shift to abnormal placentation as the most common indication for hysterectomy also reflects the dramatic increase in cesarean deliveries, including repeat cesarean procedures.^[85] The shift in relative importance is illustrated (Table 18-22) by two reports from southern California.^[129],^[274] In the first report, uterine atony was the most common indication; however, in the more recent series from the same institution, Stanco et al.^[274] found that abnormal implantation of the placenta had assumed greater relative importance as the most common indication. In a recent series from Harvard, 64 percent of 117 cases were performed for this indication, whereas only 21 percent were done for uterine atony.^[275]

Uterine Dehiscence and Rupture

Uterine rupture requiring hysterectomy is reported to occur in 0.2 percent (1 in 555) to 0.8 percent (1 in 122) of VBAC-TOL.^[242],^[274]

In one series, 14 (11 percent) of 123 peripartum hysterectomies (Table 18-22) were performed for uterine rupture in patients undergoing a VBAC-TOL, the institutional incidence in such patients being 0.18 percent.^[274] These data complement a report from the same institution in which uterine rupture occurred in 0.8 percent of 7,598 patients with a prior cesarean delivery undergoing a TOL.^[207]

In early years, hysterectomy for asymptomatic uterine dehiscence was accepted practice. However, this is no longer the case. Should symptomatic rupture occur, hysterectomy is not always necessary, particularly if the patient has a desire for future fertility and the rupture site is in a favorable location where repair is feasible. The clinician may simply repair the defect or, should dehiscence be discovered at routine exploration following vaginal delivery, it may be followed by expectant observation as detailed above.

Extension of Uterine Incision

Extension of a uterine incision into the uterine vessels is an uncommon indication for hysterectomy. However, such extensions can pose a therapeutic dilemma. Should hemorrhage be significant, consideration should be given to the alternative of hypogastric or uterine artery ligation (as opposed to hysterectomy), depending on the patient's parity and desire for future pregnancy. Ligation of the anterior division of one or both hypogastric or internal iliac arteries may decrease the arterial pulse pressure up to 85 percent distal to the point of the ligation, thus allowing clot formation.^[277] Alternatively, it is possible to ligate the uterine arteries.^[279] In some cases it may be advisable to attempt to identify the ureter, which may be in close proximity, by either palpation or direct visualization before ligating the uterine vessels.^[118]

Elective Procedures

Permanent sterilization combined with elimination of potential long-term risks for later uterine pathology were acceptable indications for cesarean hysterectomy in the 1950s and 1960s. Elective procedures were commonly performed for sterilization.^[129],^[121] Justification for hysterectomy was based on an observed need for hysterectomy in 20 percent of patients within a mean interval of 6.3 years from the most recent cesarean delivery.^[279] Several reports supported the safety of the planned/elective hysterectomy subset based on a low morbidity rate (Table 18-23).^[280],^[281] Despite the relative safety of this subset, the incidence of elective cesarean hysterectomy has fallen dramatically in recent years. As other contraceptive options became available, authors such as Brenner et al.^[282] suggested that if hysterectomy is performed primarily for sterilization, the morbidity of a scheduled procedure will outweigh its benefits.

Nonemergency Cesarean Hysterectomy

Some have included "elective" procedures in this category; however, it is not appropriate to consider planned procedures as "elective" a term that would imply that there is no indication. In most cases, a planned hysterectomy is performed when a woman requiring cesarean delivery also has a gynecologic problem that is appropriately managed by hysterectomy. Large or symptomatic uterine leiomyomas and cervical intraepithelial neoplasia are the most common indications as well as benign gynecologic conditions, occasional pelvic malignancy, and prior uterine scars.^[283] Several investigators have reported their experience with a scheduled procedure for women referred for cervical cancer and early cervical neoplasia complicating pregnancy.^[284],^[285] Because invasive disease can be excluded by colposcopy during pregnancy, some prefer vaginal delivery after carcinoma in situ of the cervix is confirmed as the most serious lesion. However, in some cases the patient may desire a single procedure or be noncompliant, in which case cesarean hysterectomy is a reasonable option. An occasional cesarean hysterectomy may be performed for microinvasive disease. Rarely, invasive cancer of the cervix may be treated with a primary cesarean delivery followed by radical hysterectomy with pelvic lymphadenectomy.^[286],^[287]

Total Versus Subtotal Hysterectomy

The relative merits of subtotal versus total peripartum hysterectomy will vary according to whether the procedure is a planned or unplanned one. Should the procedure

be planned, total hysterectomy is most commonly performed; contrarily, if the procedure is unplanned, a larger fraction will be subtotal. Some have viewed subtotal hysterectomy as a faster procedure, one to be used particularly when the patient is unstable, based on the belief that subtotal hysterectomy has less blood loss and requires less operative time. A recent publication does not support this hypothesis; the authors were unable to detect a significant difference between total and

subtotal procedures with respect to blood loss, operating time, or length of hospital stay. ^[128] Clark et al. ^[128] did suggest that this observation was attributable to a selection bias, reflecting the indication and its management prior to the decision to proceed to hysterectomy. This possible bias is most evident should the indication be uterine atony or placenta accreta.

Uterine Atony

In one series, a subtotal procedure was performed in 77 percent of 30 cases associated with uterine atony. ^[128] Uterine atony requiring hysterectomy is commonly associated with amnionitis, oxytocin augmentation, preoperative magnesium sulfate infusion, increased fetal weight, and cesarean delivery for an arrest of labor; however, 23 percent of patients undergoing a hysterectomy for atony have no identifiable risk factors. Not surprisingly, both blood loss and operating time may be increased in patients undergoing hysterectomy for uterine atony. ^[129] The surgeon, when faced with uterine atony, commonly follows a predetermined series of pharmacologic interventions (oxytocin, methergine, and prostaglandin F₂ [Hemabate, Upjohn Co., Kalamazoo, MI]), as well as other maneuvers including curettage and hypogastric artery ligation in an effort to control bleeding and maintain fertility. Such procedures may be effective in controlling hemorrhage; however, if control is not achieved, blood loss experienced prior to the time the procedure is initiated would tend to be greater and the time spent on conservative measures is reflected in a longer operative time, both commonly attributed to the unplanned hysterectomy.

Placenta Accreta/Percreta

In contrast to atony as an indicator, only 23 percent of 21 hysterectomies performed for placenta accreta were of the subtotal variety. ^[128] Since placenta accreta is less often amenable to conservative management, the transition to a decision for hysterectomy may be somewhat more rapid. Only rarely can accreta be managed by curetting or oversewing the placental bed (see Chapter 17). Implantation site involvement is usually too extensive to respond to treatment other than hysterectomy, particularly when it is associated with placenta previa. Subtotal hysterectomy is also less likely to be effective should placentation be in the lower uterine segment, presumably because blood flow via the cervical branch of the uterine artery remains uncontrolled.

Maternal Morbidity and Mortality

It is important to distinguish those procedures performed primarily for gynecologic indications plus or minus sterilization from those performed for obstetric problems requiring emergency intervention, most commonly hemorrhage. Maternal morbidity (Table 18-23) and mortality (Table 18-24) associated with peripartum hysterectomy is not simply the product of the procedure itself. Maternal morbidity and mortality will in large part depend on whether (1) the procedure is a planned/scheduled or an unplanned/emergency procedure, (2) the patient was previously in labor and had significant risk factors for infection, or (3) the patient had coincidental pregnancy-related complications. Unplanned hysterectomies have a greater risk for maternal mortality than planned procedures, since they are commonly performed in response to life-threatening hemorrhage with independent morbidity and mortality consequences. Nonetheless, the risk is very low for both types, and as a result, single-institution reports seldom report mortality. Only one death (Table 18-23) was noted in three studies (series of 123 and 70 emergency cases from California ^[129], ^[274] and 117 emergency procedures from Massachusetts ^[275]). The combined mortality rate for the three series is 3.2 per 100,000 (1 in 310).

Unfortunately, population-based mortality data specific for indication/procedure type are not available. However, Wingo et al. ^[288] assessed data collected by the Commission on Professional and Hospital Activities (1979 and 1980) to determine risk factors for 477 deaths among more than 317,000 women having abdominal hysterectomies. Not surprisingly, mortality rates for hysterectomy, when standardized for age and race, were higher when the procedure was associated with pregnancy or cancer than if not associated with these conditions. Although only 8 percent of all hysterectomies performed are associated with pregnancy or cancer, they account for approximately 61 percent of all deaths. The authors estimated the minimum and maximum standardized mortality rates for pregnancy-related abdominal hysterectomy to be 22.8 and 32.0 per 10,000 procedures, respectively. ^[288] Although not strictly applicable, the minimum and maximum rate estimates should provide some insight into rates to be associated with planned and unplanned procedures, respectively.

Operative Technique

Should the procedure be an emergency one in which there has been preexisting and ongoing rapid blood

§ Cardiac arrest secondary to amniotic fluid embolus.

loss, it may be necessary to compress the aorta manually until the operative field can be suctioned sufficiently to allow identification and clamping of bleeding points. In some cases, bilateral internal iliac, anterior hypogastric, or uterine artery ligation may be required to reduce arterial bleeding from the uterine, vesicle, and pudendal arteries. The operative technique for peripartum hysterectomy uses the general principles applicable to abdominal hysterectomy in the nongravid state. In initiating the surgical procedure, the surgeon should direct attention to (1) early adequate displacement of the bladder from the lower uterine segment and cervix, (2) use of overlapping sutures for successive vascular pedicles, (3) selective as opposed to mass placement of clamps and sutures to control bleeders, (4) periodic inspection of the bladder for an inadvertent cystotomy, (5) possible localization of the ureter should a lateral extension/laceration of the incision be the indication for the procedure, and (6) avoidance of excessive removal of vaginal length, particularly when the cervix is completely effaced.

There is considerable variation in operative technique. Variation involves the use of two versus three clamps for pedicles above the cardinal ligament, use of single versus double ligation of vascular pedicles, the relative desirability for skeletonization of vessels in the broad ligament, and the relative need for an additional step to separate and individually ligate the uterosacral ligaments.

Although the uterine vessels are considerably larger in the pregnant than in the nonpregnant state, tissue planes are more easily developed. Blood loss from a peripartum procedure is greater than (500 to 1,000 ml) that associated with hysterectomy in the nongravid patient, particularly if it is an unplanned one. The altered hemodynamics of normal pregnancy as well as associated obstetric problems are largely responsible. The uterus is enlarged and highly vascular. The associated collateral circulation results in prominence of vessels that would be of little concern in the nonpregnant state. It is for this reason that some surgeons use a three-clamp rather than a two-clamp technique for pedicle development above the cardinal ligaments. In the case of the three-clamp technique the incision is made between a single medial clamp (to reduce the likelihood of retrograde blood loss from the medial pedicle) and two lateral clamps (to prevent clamp slippage from the lateral pedicle).

Planned Hysterectomy Considerations

Should the hysterectomy be a planned one, the cesarean procedure is performed in the usual manner except that the initial peritoneal/vesicle uterine fold incision may be extended more laterally to the round ligaments. There is also advantage to early mobilization and separation of the bladder from the underlying lower segment in the midline with gentle blunt dissection to a point approximately 1 to 2 cm below the cervical vaginal junction and to some extent laterally. On occasion, the bladder may be adherent, requiring sharp dissection with down-turned scissors. This will result in displacement of the bladder and ureters caudad or inferiorly. There is also some advantage in use of a low vertical

592

incision, particularly if the lower segment is not completely developed, to reduce the possibility of extension into the broad ligament and provide a site for placement of the surgeon's finger in the apex of the incision to facilitate later traction and manipulation of the uterus.

Procedure

Upon completion of the cesarean delivery, the placenta may be delivered and the lower uterine incision quickly reapproximated, or alternatively the surgeon may simply proceed rapidly to gain control of the vascular supply of the uterus while the placenta spontaneously separates. Polyglycolic acid or chromic catgut suture (0 or 1 gauge) may be used throughout the procedure.

Placement of an O'Conner-O'Sullivan retractor or perhaps a large Balfour retractor in the abdominal wall may be helpful, particularly should the patient be obese or exposure difficult. The uterine fundus is then delivered through the incision, and constant traction is maintained on the uterus to maximize pedicle exposure, facilitate development of tissue planes, and stretch the uterine veins, thereby narrowing their lumen and reducing venous blood loss. If a vertical uterine incision has been made, it is often convenient for the assistant to hook an index finger in the upper extreme of the uterine incision to manipulate the fundus and to expose the operative site. If the placenta is still in place, it can be removed. If bleeding of the uterine incision is excessive, further bleeding can be controlled by a variety of techniques, including use of oxytocin, ligation of individual bleeders, or even closure of the uterine incision. In many instances, however, it is possible to complete the isolation of the uterine pedicles in a time period that approximates that required to close the uterine incision.

If the bladder has not been previously mobilized, this can be done with blunt and sharp dissection. Once the bladder separation is completed, the round ligaments ([Fig. 18-12](#)) are then clamped with Heaney or Kocher clamps, cut, and ligated with transfixing sutures. If not done earlier, the previously made vesicouterine peritoneum incision is extended laterally and cephalad across the anterior leaf of the broad ligament through the point of the previously incised round ligaments.

The ovaries should be inspected; it is seldom necessary to remove them. If the ovaries are normal, placement of the utero-ovarian clamps and a free tie at the intended site is facilitated by perforation of the avascular portion of the posterior leaf of the broad ligament adjacent to the uterus just inferior to the fallopian tube, utero-ovarian ligaments, and ovarian vessels with a curved Kelly clamp. The intent is to provide enough room to insert two or three clamps, either atraumatic (e.g., Masterston) or crushing (e.g., Heaney), across the utero-ovarian ligament and fallopian tube between the previously placed utero-ovarian free tie and the uterus. The utero-ovarian ligament and tube may then be ligated with clamps or free tie. An attempt should be made to avoid placement of the clamps or ligature across ovarian tissue, which may result in immediate or delayed bleeding. If the intent is to place three Kocher/Ochsner or Heaney/Masterson clamps on the utero-ovarian ligament and fallopian tube, sequential placement of clamps should move in the direction of the dorsum of the surgeon's dominant hand so as to avoid placement of the surgeon's hand between clamps. If the three-clamp technique is used, the pedicle is incised between the single medial clamp and the two lateral clamps.

If a lateral free tie is used, the utero-ovarian/adnexal pedicle is then doubly clamped medial to the free tie. The pedicle is incised between the clamps and the lateral pedicle and ligated with a transfixing suture ([Fig. 18-12B](#)). Some surgeons also ligate the opposing medial pedicle so as to remove the most medial clamp from the operative field, while avoiding back-bleeding.

Some surgeons then incise the avascular portion of the broad ligaments and skeletonize the large uterine veins. This is more difficult in a cesarean hysterectomy than in a simple abdominal hysterectomy. The ascending uterine vessels adjacent to the uterus near their origin are then identified near the junction of the cervix and uterus and doubly or triply clamped with Heaney or Masterson clamps, incised, and ligated, either singularly or doubly. The surgeon should attempt to place the clamp tip snugly against the uterine margin at a right angle to the ascending uterine vessels to reduce the likelihood of back-bleeding. Placement of the clamp tip on this vascular pedicle against the lower segment is easy should the cervix be long and uneffaced. However, if the lower segment is well developed, soft, and without distinct margins, palpation of the lateral margin of the lower uterine segment (between thumb and forefinger straddling the intended broad ligament pedicle) may be required to facilitate closer approximation of the clamp tip to the uterine margin. Prior to placement of the clamps on the uterine vessel, it is often useful to confirm that the bladder is displaced inferiorly and, should ureteral location be an issue, the ureter can occasionally be palpated between the forefinger and thumb.

The incision of the uterine vessel pedicle should occur in such a manner as to leave a small portion of tissue medial to the clamp to diminish the likelihood of clamp or later suture slippage. Before incising the uterine pedicle there may be advantage to placement of a medial Heaney or Ochsner/Kocher clamp on the uterine vessels above the intended site of incision of the vascular pedicle. Others prefer isolation of the uterine vessels

593

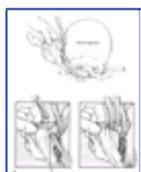

Figure 18-12 Cesarean hysterectomy. *A*, After extending the bladder flap, each round ligament is cut and ligated. The posterior leaf of the broad ligament can be opened for a short distance, taking care to incise only the surface layer. The avascular space beneath the utero-ovarian ligament may be opened by blunt finger dissection to isolate the adnexal pedicle. *B*, (left) A free tie is passed through the avascular space and firmly tied. The advantage of this tie is to secure the vessels within the pedicle before it is cut. (right) The adnexal pedicle is doubly clamped and cut. In addition, a transfixing suture will then be placed around the pedicle.

bilaterally prior to incising either pedicle as a technique to avoid back-bleeding. A variation of the two-clamp technique is presented [in Figure 18-13](#).

Subtotal Hysterectomy

Supracervical/subtotal hysterectomy may be a consideration at this point either as a transitional step to remove the fundus and provide better visualization of the lower pelvis or as a permanent strategy (i.e., should the patient be unstable or dissection unusually difficult). The obstetrician should usually plan to perform a total

hysterectomy. However, should the patient be unstable or the procedure unusually difficult, a subtotal hysterectomy may occasionally be desirable because it is simpler, particularly should the pathology be confined to the upper uterine segment and the surgeon judge that prolongation of the procedure associated with removal of the cervix will adversely affect the patient.

Once the ascending uterine artery and vein are doubly clamped and the pedicles cut and ligated as in a total hysterectomy, the cervix is amputated at the level of the pedicles. In amputating the cervix it may be useful to cone the amputation downward toward the canal (Fig. 18-14A). The resultant cervical stump can be closed with several interrupted figure-of-eight sutures. Some surgeons doubly suture ligate the ascending uterine vessels by the angles of the cervix (Fig. 18-14B) to minimize the risk of angle bleeding. Additional bleeding points are ligated and reperitonealization performed

594

Figure 18-13 A, The ascending branches of the uterine artery are clamped, cut, and a suture is placed just below the tip of the clamp and immediately next to the uterine wall. B, After removing the clamp, the suture is tied, thus securing the vessels before they are cut. C, The pedicle is regrasped just above the tie and then doubly ligated.

Figure 18-14 Subtotal hysterectomy. A, The cervix is incised just below the level of the ligated pedicles of the uterine arteries, amputating the uterine corpus from its cervical stump. B, The cervical stump may be closed with several interrupted figure-of-eight sutures; reperitonealization is then accomplished as in a total hysterectomy.

595

Figure 18-15 The cardinal ligaments are clamped at their point of insertion, cut, and singly ligated. Because these structures are hypertrophied, several bites may be necessary. Some physicians clamp, cut, and ligate the uterosacral ligaments separately.

in a fashion similar to that required for total hysterectomy.

Total Hysterectomy

Should the patient be stable after removal of the fundus, two or more Ochsner/Kocher clamps may be placed on the remaining cervical stump to control bleeding and provide traction for later manipulation while completing the hysterectomy. After the ascending uterine vessels have been ligated, the cervix is separated from the supporting cardinal and uterosacral ligaments and vagina. Pedicles containing descending branches of the uterine vessels and the cardinal and uterosacral ligaments are clamped (doubly or singularly) with either Heaney-type curved clamps or Ochsner/Kocher-type straight clamps, attempting to place the clamps as close to the cervix as possible. Approximately 1.0 to 1.5 cm of cardinal pedicle tissue should be encompassed within the instrument with each "bite." Placement of the Heaney or Kocher straight clamps should be done in such a manner that the progressively closing jaws of the clamp slide off the firm body of the cervix to decrease the likelihood of inclusion of the adjacent ureters. Should the lower segment be well developed and thinned out, delineation of the margin can be accomplished by palpating the tissues between forefinger and thumb. The resultant wedge-shaped pedicle is then incised and sutured. Inclusion of a portion of the adjacent more superior uterine pedicle in the tie may reduce bleeding between the two pedicles.

Should the lower uterine segment be well developed, it is often necessary to develop more than one pedicle for each cardinal ligament. Successive clamps are placed medial to the preceding clamp, with care to avoid the possibility of unsecured tissue between successive bites. After reconfirming that the bladder reflection is retracted away from the site of intended clamp placement, successive more inferior pedicles are clamped, incised, and suture ligated until the surgeon is confident that the supporting cardinal and uterosacral ligaments have been separated and the level of the lateral vaginal fornix is reached (Fig. 18-15). Although some surgeons attempt to identify and ligate the uterosacral ligaments individually, the uterosacral ligaments are generally not as distinct at this time as would be the case in the nonpregnant state. In most cases they are included in the cardinal ligament pedicles.

The vagina may be entered anteriorly (or posteriorly) in the midline with the scalpel or alternatively following placement of a curved Heaney clamp just below the inferior margin of the cervix at the lateral angle. Separation of the cervix from its vaginal attachments can be quite difficult should the lower uterine segment be thinned out and long as a result of effacement. One should avoid both incomplete removal of the cervix and excessive removal of the upper vagina. In some instances it is possible to palpate and milk superiorly the lower margin of the cervix by palpating the approximate site with thumb and forefinger placed anteriorly and posteriorly about the cervicovaginal junction. Should identification of the cervicovaginal junction not be possible by external palpation, there are several alternatives. The surgeon may insert an index finger through a vertical incision in the anterior lower uterine segment/cervical canal into the upper vagina to locate the cervical vaginal margin (Fig. 18-16). Should the index-finger method to locate the lower margin of the cervix be used, the circulating nurse may reglove the surgeon. After the vagina is entered, the vagina and cervix are circumferentially separated under direct visualization with large curved Mayo scissors, attempting to maintain the full length of the vagina. Once the cervix is freed from the vagina, the specimen is then inspected to ensure that the cervix has been completely excised. The two angles of the resultant vaginal cuff are identified and clamped with Kocher/Heaney clamps (Fig. 18-17). The vaginal angle containing the vaginal artery can then be secured by a variety of techniques.

The apex of the vaginal cuff is then supported by approximating the vaginal angles to the cardinal ligament pedicle and the uterosacral ligament if previously incised separately. Some incorporate the vaginal angle

596

Figure 18-16 Because the cervix is elongated, it may be useful to insert an index finger through the cervical canal to demarcate the vaginal incision and to ensure complete removal of the cervix and avoid unnecessary removal of vaginal length.

to the cardinal and uterosacral ligaments via a lock loop suture (Fig. 18-18). The vaginal cuff may be left open or closed. The decision to leave the vaginal cuff open in most instances will depend on the presence of adequate hemostasis and absence of obvious infection. The open cuff will allow excess blood or serous material to drain from the lower pelvis. The vaginal cuff may be closed in either one or two layers, particularly if the pelvis is dry and there are no major additional risks for cuff infection, using either interrupted figure-of-eight sutures or a continuous closure (Fig. 18-19). Alternatively,

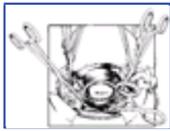

Figure 18-17 The vagina is circumferentially incised at its cervical attachment and grasped with four clamps.

the cuff can be left open by running a locking circumferential suture about the cuff margins to minimize vaginal cuff bleeding and facilitate drainage; some prefer figure-of-eight sutures.

The cul-de-sac and peritoneal gutters are suctioned of blood and accumulated debris and all previous pedicles examined for bleeding points. Bleeding sites should be individually controlled by picking up as little tissue as possible to avoid ligation or kinking of the ureters. Once the surgeon is assured that hemostasis is adequate and that there have been no lacerations of the bladder, the pelvis may be irrigated.

Should the surgeon decide to reoperitonealize the pelvic floor ([Fig. 18-20](#)), this can be accomplished in several ways using a continuous suture. The end result is inversion of the pedicle of the ligated fallopian tube and ovarian ligament and round ligament retroperitoneally,

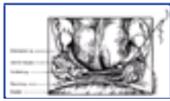

Figure 18-18 The angles of the vaginal cuff are closed with sutures to include the cardinal and uterosacral ligaments, thus providing fascial support to the vaginal vault. A simple loop suture is commonly used at this location to reduce the likelihood of breakage during the stage of postoperative edema.

597

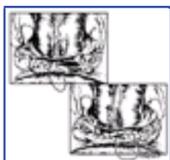

Figure 18-19 There are a number of methods of closing the vaginal cuff. Illustrated is a two-layer closure. The first layer closes the vagina, and the second layer closes the endopelvic fascia. Many operators prefer to leave the cuff "open" by using one continuous suture that circles the cuff, approximating the cut edge to its surrounding fascia.

avoiding fixation of the ovary to the cuff in the cul-de-sac. A continuous suture reapproximates the medial and lateral leaves of the broad ligament, burying the round ligament stump and approximating the anterior vesicouterine peritoneum over the vaginal vault to the cul-de-sac peritoneum on the posterior margin of the vagina. The procedure is then conducted in reverse order on the opposing side. Some accomplish the dual goals of reoperitonealization and support of the apex of the vaginal vault by successive placement of the suture on the anterior vaginal wall to the cardinal ligament to the round ligament pedicle and back to the uterosacral ligaments/posterior vaginal wall, which is then drawn down to the cuff. Many surgeons have discontinued the process of reoperitonealizing the pelvic floor and simply allow the sigmoid and bladder to fall into place over the vaginal cuff, an approach that may also minimize the admittedly small chance of suturing the ureter during reoperitonealization. The surgeon may avoid attachment of the ovarian pedicles to the angle of the vagina by suturing the ovarian pedicle to the ipsilateral round ligament.

Intraoperative Complications

Intraoperative complications associated with peripartum hysterectomy, although similar to those following non-obstetric total abdominal hysterectomy, occur with greater frequency, especially in unplanned procedures. Total hysterectomy may add 30 to 60 minutes to the operating and anesthesia times ([Table 18-23](#) and [Table 18-24](#)), depending on (1) the surgeon's experience, (2) whether the procedure is emergent or elective, (3) the degree of development of the lower uterine segment, (4) coincidental pelvic pathology such as leiomyomata or obesity, and (5) the presence of ureteral or bladder laceration.

Increased blood loss and occasional injury to either bladder or ureters are the two most commonly encountered intraoperative complications. ^[289] There is an associated

598

Figure 18-20 The bladder flap is closed with a continuous suture that inverts the pedicles of the round ligaments and adnexae. Note that these structures have not been attached to the vaginal cuff.

additional blood loss of 500 to 1,000 ml, depending on preexisting blood loss and whether the procedure is planned or unplanned. In emergency procedures, a major portion of the blood loss can be attributed to the indication for the procedure. This is particularly true for uterine atony that has been unresponsive to more conservational obstetric interventions, including prostaglandin F₂. Intraoperative blood loss may be secondary to slippage of a clamp off a pedicle or bleeding between pedicles and may be a function of the type of clamp and/or suture placement. It may involve the utero-ovarian or the uterine pedicles, or there may be bleeding at the angle of the vagina and cardinal ligament. On occasion, the adnexal bleeding is the result of suture placement through an ovarian vessel. This can often be avoided by the placement of a free-tie suture at the site of the most lateral of two or three clamps and subsequent placement of a transfixing suture at the site of the more medial (middle) clamp of the lateral pedicle. On occasion it may be necessary to perform a salpingo-oophorectomy to control hematoma formation. In a recent series from Harvard, 17 percent of 117 women who underwent emergency hysterectomy required removal of their adnexa. ^[279]

Injuries to the bladder and ureter are most common during unplanned/emergency procedures. Most bladder injuries are easily recognized and repaired, since they most often occur when dissecting the bladder from the lower uterine segment, particularly in patients with multiple prior cesarean births. The bladder is infrequently included in the lateral margin of the vaginal cuff at the time of the separation of the cardinal ligaments. Rarely, spontaneous laceration of the bladder may occur coincident with uterine rupture.

Cystotomy as a complication of cesarean hysterectomy occurred in approximately 4 to 5 percent of procedures in early series. ^[120], ^[121] Bladder injury can be minimized at two points first, by separation and downward displacement of the bladder from the anterior vaginal wall prior to the cesarean delivery while the anterior vaginal wall is still taut; and second, by rolling the Oschner/Kocher clamps off the cervix when developing the cardinal pedicles.

The incidence of ureteral injury during cesarean delivery is reported to be approximately 1 in 1,000 cesarean deliveries. ^[119] The risk of ureteral injury is increased even further with cesarean hysterectomy, with rates of 0.2 to 0.5 percent being observed in early series including planned procedures. ^[120], ^[121] In more recent series typically involving emergency unplanned hysterectomies ([Table 18-23](#)), most urinary tract injuries involve the bladder, although on occasion the ureter may be incised or incorporated within a pedicle. Stanco et al., ^[274] in a 5-year review of 123 (1.3 per 1,000 births) emergency peripartum hysterectomies, found a 3.2 percent incidence of urinary tract injury; in addition, they performed 12 (10 percent) intentional cystotomies to facilitate passage of a ureteral stent. Zelop et al., ^[275] in an 8-year review of 117 (1.55 per 1,000 births) emergency peripartum hysterectomies, found that 10 (8.5 percent) patients sustained urologic injuries. Of these, there were nine (7.7

percent) cystotomies and three (2.5 percent) ureteral injuries that required stenting.

Injury to the ureter is more common in cases where there is a necessity to control a broad ligament bleeding or hematoma formation or to dissect a pelvic tumor. In the case of pelvic tumors, careful dissection of the mass, palpation of the lateral cervical margins, and careful placement of the clamps as close to the cervical margin as possible with successive bites more medial to the preceding pedicle will make inclusion of the ureter highly unlikely. Should the surgeon be concerned about the possibility of a ureteral injury, intentional cystotomy in the bladder dome and placement of retrograde ureteral catheters may be used to assess the patency and integrity of the ureter.

Postoperative Complications

As is the case in any hysterectomy, infection and bleeding are the most common major postoperative complications. The incidence of infectious complications is closely linked to the presence of preexisting risk factors for infection and whether the procedure is planned or unplanned. The incidence of urinary tract infection in the absence of preexisting amnionitis is strongly linked to the duration of indwelling catheter placement. Scheduled procedures performed before labor have an

associated incidence of febrile morbidity less than 10 percent; most cases involve the urinary tract, with an occasional wound or vaginal cuff infection. In contrast, febrile morbidity rates approach 30 percent for unplanned procedures. ^[274], ^[275], ^[290] Postoperative infectious morbidity may be reduced by prophylactic antibiotics to women who have been either in labor or at risk for infection and early removal of indwelling catheters. Prophylactic antibiotics are generally administered intraoperatively, immediately following delivery of the fetus.

The pelvic tissues, if there has been hemorrhage or infection, are frequently quite friable and may tear easily. There may be later ligature slippage as tissue edema resolves. Vaginal bleeding is commonly associated with a bleeder at the lateral angle/junction of the vagina and cardinal ligament; it also may involve the uterine vessels. In some instances, bleeding will involve the formation of a broad ligament hematoma arising from the uterine or ovarian vessels. Should the hematoma be small, stable, and asymptomatic, such patients may require no further treatment. The surgeon may evaluate the patient serially using sonography; on occasion, it may be necessary to use CT scan or magnetic resonance imaging.

Reexploration for bleeding following a peripartum hysterectomy has been reported to be necessary in as many as 2.6 to 4 percent of cases. ^[274], ^[275] Reexploration may be indicated should the hematoma progressively enlarge. Alternatively, it may be necessary if the patient remains unstable or demonstrates a progressive unanticipated fall in serial hematocrit determinations, after taking into account preoperative and intraoperative blood loss and replacement. Evacuation of the pelvic hematoma and identification and ligation of bleeders are the surgical goals; in some cases it may not be possible to isolate a definite bleeder. On occasion, it may be necessary to place cervical drains postoperatively.

ELECTIVE MYOMECTOMY AND APPENDECTOMY

The propriety of performing an elective myomectomy or appendectomy during a cesarean delivery is a matter of dispute. The majority opinion is that, with the possible exception of a subserosal myoma on a thin pedicle, myomectomy is contraindicated because achieving hemostasis may be difficult. Others assert that hemostasis will be excellent because of the action of the contracting uterus. A better argument for abstention is the knowledge that most myomas will involute to an insignificant size during the puerperium. Although the risk of elective appendectomy is quite low, there are no statistics to prove that the benefits to be gained are greater than the possible surgical complications.

COINCIDENTAL OVARIAN NEOPLASMS AT CESAREAN DELIVERY

Should an ovarian neoplasm be discovered at the time of cesarean delivery, the surgeon should first rule out the possibility of a theca-lutein cyst or the rare luteoma of pregnancy. Other ovarian neoplasms should be excised, sparing the ovary whenever possible.

Key Points

Even when morbidity and mortality arising from the indications leading to cesarean delivery are excluded, maternal morbidity and mortality remain many times higher for cesarean delivery than for vaginal delivery.

As the percentage of laboring patients presenting with prior cesarean births has increased, there have been associated increases in more difficult repeat cesarean deliveries and complications, including a higher incidence of placenta previa, placenta accreta, symptomatic uterine rupture, hemorrhage, requirement for transfusion, and need for unplanned hysterectomy.

The reported incidence of maternal mortality following cesarean delivery is estimated to range from 6.1 to 22 per 100,000 live births. Approximately one third to one half of maternal deaths can be attributed directly to the cesarean procedure itself.

There are no well-documented prospective trials demonstrating benefit to the fetus or to the mother that would justify the extent of the increase in the primary cesarean delivery rate over the past two decades. Although perinatal mortality rates have decreased as cesarean birth rates have increased, the improvement is largely attributable to major advances in prenatal and intrapartum care, as well as dramatic improvements in neonatal intensive care implemented in the same time frame.

If the patient is massively obese, it may be better to use an incision directly over the lower

uterine segment that does not involve the underside of the panniculus, an area that is more heavily colonized with bacteria and that is difficult to prepare surgically, to keep dry, and to inspect in the postoperative period.

The physician contemplating a cesarean delivery for placenta previa, particularly a repeat procedure, should consider the possibility of hysterectomy. The reported incidence of placenta accreta (1 in 2,500 deliveries) increases to approximately 4 percent in patients with a placenta previa and may approach 25 percent in patients with a prior cesarean birth.

Although cesarean delivery is often elected to minimize trauma to the preterm breech fetus, the actual delivery mechanism via the cesarean incision is essentially identical to that of the vaginal route. Should head entrapment be encountered, the first action should be to extend the abdominal incision and to enlarge the uterine incision.

Elective repeat cesarean delivery is estimated to be responsible for a significant proportion of the increase in the cesarean birth rate during the past two decades. VBAC-TOL lowers the self-perpetuating contribution of the indication of previous cesarean birth.

Most patients with a prior cesarean birth are candidates for VBAC. The only established contraindication is a prior classical incision. VBAC reduces the incidence of postpartum infection, the need for postpartum transfusion, maternal length of stay and, as a result, offers the potential to generate significant cost savings. VBAC trial candidates are no more likely to require a cesarean delivery than a population of women with no prior cesarean deliveries. VBAC trial of labor is successful in 60 to 80 percent of acceptable candidates.

Chapter 19 - Surgical Procedures in Pregnancy

Jack Ludmir
Phillip G. Stubblefield

Approximately 0.2 to 2.2 percent of pregnant women require surgery in pregnancy.^[1]^[2]^[3] Changes in the maternal cardiovascular system and increased uterine perfusion and size during gestation require special adaptation of anesthesia and surgical technique to the pregnant patient (see the box "[Maternal Physiologic Changes Relevant to Surgery](#)").^[4]^[5]^[6]^[7]^[8]^[9]^[10] During advanced pregnancy, abdominal pain and symptoms of gastrointestinal disease are difficult to assess secondary to a large uterus. Advances in diagnostic modalities, including computed tomographic (CT) imaging, magnetic resonance imaging (MRI), high-resolution ultrasound, and Doppler studies have improved our ability to make the diagnosis of surgical conditions during gestation.^[11]^[12]^[13]^[14] Furthermore, new surgical therapeutic modalities, including laparoscopy, well established in the gynecologic and surgical arena, are now being evaluated in the management of the pregnant patient with a surgical condition.^[15]^[16]^[17]^[18]^[19]^[20]^[21]^[22] The patient and physician facing the possibility of surgery during pregnancy are concerned about the possible ill effects of anesthesia and surgery on the developing fetus versus the consequences of delaying such surgery. In the largest study to date of surgical procedures in pregnancy, Mazze and Kallen in Sweden^[23] studied the effects of 5,405 nonobstetric procedures performed in 720,000 pregnant Swedish women during the 1970s and 1980s. These authors found that surgery was performed in the first trimester in 41 percent, compared with 35 percent in the middle, and 24 percent in the third trimester. Abdominal surgery constituted one fourth of all operations, and almost 20 percent were gynecologic and urologic procedures. Although laparoscopy was the most commonly performed first-trimester operation to rule out ectopic gestation, appendectomy was the most common procedure in the second trimester. One half of the surgeries were performed using general anesthesia, and in 90 percent of the cases, nitrous oxide was given. To determine the effects of the surgery and anesthesia on the 5,405 pregnancies, the authors compared the outcomes to the total database of 720,000 pregnancies for the study period. The rate of congenital malformation and stillbirth were not significantly increased. However, the rate of low-birth-weight infants, as well as neonatal deaths during the first 7 days of life in patients undergoing surgery, was significantly increased. These authors concluded that surgery, in particular nonobstetric, during pregnancy could increase the rate of poor obstetric outcomes. This increase in perinatal morbidity was thought to be secondary to the surgical disease process affecting the pregnancy rather than to the adverse effects of anesthesia or surgery. In approaching the pregnant patient requiring surgery, reassurance can be given regarding the rate of birth defects and stillbirths, but prematurity and growth restriction may be significantly increased, secondary to the ill-effects of the underlying condition requiring surgery.

This chapter will describe the most common obstetric and nonobstetric surgical procedures performed during gestation.

CERVICAL CERCLAGE

Few subjects in obstetrics are as controversial as the ubiquitous term cervical incompetence. The term was initially used by Lash and Lash^[24] while describing repetitive abortion presenting with painless extrusion of the products of conception. The work by Iams et al.^[25] and others^[26]^[27]^[28]^[29] using sonography to evaluate the cervix in pregnancy, have challenged the historical notion that the cervix is either competent or incompetent, to one of

608

variable cervical competence. Cervical function in gestation is described by a bell-shaped curve that correlates to length.^[25] Cervical function could change secondary to interaction with different variables, such as physical activity, infection, uterine distention, and uterine contractility.^[30] This new concept of a continuum in cervical competence could be helpful to explain why a cervix that appears and feels long and closed could result in an early pregnancy loss, whereas a cervix that feels short and soft could carry a pregnancy to term. The traditional criteria used for performing a cervical cerclage are a classic history of painless dilatation with delivery of a premature infant, history of rapid labors, history of recurrent premature rupture of membranes (particularly in patients with prior history of cervical surgeries or trauma), or a history of diethylstilbestrol (DES)-exposure. These criteria are currently being challenged as the only criteria (see the box "Diagnostic Criteria for Cervical Incompetence").^[31]^[32]^[33]^[34]^[35]^[36]^[37] The use of vaginal sonography in gestation to evaluate the cervix longitudinally may be a more objective way of screening patients at risk for cervical incompetence and of helping the clinician to decide which women would benefit from a cerclage. Sonographic parameters such as cervical shortening and/or funneling (Fig. 19-1) and (Fig. 19-2)^[38]^[39]^[40]^[41]^[42]^[43] may be particularly helpful in the patient in whom a classic history of painless dilatation cannot be elucidated and the benefit of placing a prophylactic cerclage remains unclear. We have used this technology to follow patients with historical risk factors such as prior surgical conization, uterine anomalies, and DES exposure in utero.^[42] Recent studies by Guzman et al.^[43] suggest that following patients at risk for cervical incompetence with vaginal ultrasound, and placing a cerclage only in those patients demonstrating sonographic changes, results in the same obstetric outcomes as in a group of women who have a prophylactic cerclage placed between 12 and 16 weeks. Contrary to this study, Berghella et al.^[44] in an observational study of 168 singleton pregnancies at risk for preterm labor did not show benefit in placing cerclage in patients with sonographic changes compared with those without intervention. The ideal cervical length at which to place a cerclage has not been determined. Studies have recommended cerclage for cervical lengths varying from as low as 1.5 to 2.5 cm in length.^[43]^[44]^[45] Currently, randomized studies to determine the value of therapeutic cerclage based on sonographic cervical changes are being performed both in patients at risk for cervical incompetence and in low-risk patients in whom a short cervix is found during routine ultrasound obstetric evaluation.^[46]^[47] It remains to be seen if cerclage, pessary, or bed rest are justifiable therapeutic interventions in patients demonstrating sonographic cervical change.

Maternal Physiologic Changes Relevant to Surgery

Cardiovascular changes

- Increased cardiac output
- Increased blood volume
- Decreased systematic vascular resistance
- Decreased venous return from the lower extremities

Respiratory changes

- Increased minute ventilation
- Decreased functional residual capacity

Gastrointestinal changes

- Decreased gastric motility
- Delayed gastric emptying

Coagulation changes

- Increased clotting factors II, V, VII, VIII, IX, X, and XII
- Increased fibrinogen
- Increased risk for thromboembolic disease

Renal changes

- Increased renal plasma flow and glomerular filtration rate
- Ureteral dilatation
- Increased bladder capacity

Cerclage Technique

Prophylactic Cerclage

In 1950, Lash and Lash described repair of the cervix in the nonpregnant state involving partial excision of the cervix to remove the area of presumed weakness. [24] Unfortunately, this technique had a high incidence of subsequent infertility. In 1955, Shirodkar reported successful management of cervical incompetence with the

609

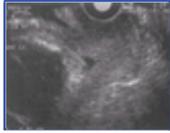

Figure 19-1 Transvaginal sonogram of the cervix at 22 weeks' gestation. Patient is at risk for cervical incompetence. Note minimal evidence of cervical funneling.

Figure 19-2 Transvaginal sonogram of the same patient as (Figure 19-1) after standing up for 15 minutes. Note cervical funneling and decreased cervical length.

610

Figure 19-3 Placement of sutures for McDonald cervical cerclage. *A*, We use a double-headed Mersilene band with four "bites" in the cervix, avoiding the vessels. *B*, The suture is placed high upon the cervix close to the cervical-vaginal junction, approximately the level of the internal os.

use of a submucosal band. [48] Initially, he used catgut as suture material, and later he used Mersilene placed at the level of the internal cervical os. The procedure required anterior displacement of the bladder in an attempt to place the suture as high as possible at the level of cervical internal os. This type of procedure resulted in a greater number of patients being delivered via cesarean section because of the difficulty in removing the suture buried under the cervical surface and may require leaving the suture in place postpartum. Several years later, McDonald described a suture technique in the form of a purse string, not requiring cervical dissection, easily placed during pregnancy. [49] This technique involves taking four or five bites as high as possible in the cervix, trying to avoid injury to the bladder or the rectum, with placement of a knot anteriorly to facilitate removal (Fig. 19-3). Several types of suture material have been used. [50] We have been successful in using a Mersilene tape. However, the use of thinner suture material, such as Prolene or other synthetic nonabsorbable sutures like Ethibond is advocated by others, with the argument that the width of the Mersilene tape places the patient at greater risk for infection. [50], [51] Currently, there is no evidence that placing two sutures results in better outcomes than placing one. [52], [53], [54] Preoperative patient preparations, including the use of prophylactic antibiotics or tocolytics, have not been proven to be of benefit. We perform a culture for group B streptococcus and give preoperative penicillin to the patient with a positive culture. Prophylactic cerclage placement is performed after the first trimester, to avoid the risk of spontaneous loss most likely attributable to chromosomal abnormalities. [52], [53] The choice of anesthesia for cerclage varies. [55] Chen et al. [56] did not show difference in outcome between general versus regional anesthesia. In our experience, a short-acting regional anesthetic is sufficient. We advise patients to remain on bed rest for the first 48 hours after cerclage and to avoid intercourse until follow-up postoperative visit. Decisions regarding physical activity and intercourse are individualized and based on the status of the cervix as determined by outpatient digital evaluation or sonographic findings (Fig. 19-4). [39], [40], [57], [58], [59] The suture is usually removed at 37 weeks electively. [52], [53]

Diagnostic Criteria for Cervical Incompetence

Historical factors

- History of painless cervical dilatation with preterm delivery
- History of forceful cervical dilatation and evacuation
- History of obstetric trauma: cervical lacerations, prolonged second stage followed by cesarean
- Prior cervical surgery: cone, loop
- DES exposure in utero

Cervical sonography

- Short cervical length
- Cervical funneling

In patients with a hypoplastic cervix, such as those exposed to DES in utero, history of large cervical conization, or prior history of failed vaginal cerclage, an abdominal cerclage has been recommended. [60] This procedure is usually done at 11 weeks and requires a laparotomy. A bladder flap is created and a Mersilene tape is placed at the level of the junction between the lower uterine segment and the cervix. Novy et al. have reported extensive experience with this procedure, with low morbidity and favorable outcome. [61] Greater morbidity including injury to the uterine vessels requires expertise with this procedure. Delivery by cesarean section is necessary. We have described the placement of a transvaginal cerclage when there is a hypoplastic cervix, or the cervix is flush against the vaginal wall. [62] Under ultrasound guidance, the supravaginal portion of the cervix is dissected away from the bladder and a suture is placed either in a purse-string fashion, or in cross fashion from 12 to 6 o'clock and 3 to 9 o'clock (Fig. 19-5). We have performed this procedure in 18 patients, avoiding an abdominal procedure with successful pregnancy outcome. Fifty percent of patients delivered by cesarean section and the rest delivered vaginally after the suture was cut through a small posterior colpotomy

611

Figure 19-4 Transvaginal sonogram picture of the cervix after cerclage placement. Internal os closed and no funneling. Echogenic spots in the cervix correspond to cerclage.

incision. Recently, a laparoscopic abdominal approach to the cervix has been described using the same principles as an abdominal cerclage.^[63] A need for randomized trials evaluating this new technique compared with a vaginal approach is necessary to determine the best approach to patients with a history of failed cerclage.

Therapeutic and Emergent Cerclage

Patients demonstrating cervical change either by digital evaluation or transvaginal sonography may benefit from a therapeutic cerclage.^{[32], [34], [35], [37], [39], [43]} The gestational age limit for cerclage placement is ill defined. Although some clinicians will offer this therapeutic modality up to 28 weeks,^[64] we do not advocate the use of therapeutic cerclage beyond 24 weeks' gestation, because of fetal viability concerns and potentially causing a preterm delivery while placing the cerclage. Some of these patients have been managed successfully with strict bed rest.^[44] If the decision is made to place a cerclage, we treat preoperatively with antibiotics and nonsteroidal anti-inflammatory agents, such as indomethacin. The patient is placed on strict bed rest for the first 72 hours and is advised to refrain from intercourse and strenuous physical activity for the remainder of the pregnancy. We follow these patients with frequent sonographic assessment of the cervix and recommend strict bed rest if the membranes are prolapsing to the level of the suture.^[59] Prophylactic tocolytics are not used after the procedure.

In situations in which the cervix has dilated enough to allow visualization of the membranes or the membranes have prolapsed into the vagina, placing an emergent cerclage constitutes a heroic maneuver.^{[64], [65], [66], [67], [68]} These patients are at high risk of having a subclinical infection and subsequent poor outcome.^{[65], [69]} To rule out infection, some clinicians advocate amniocentesis prior to cerclage placement.^[70] Several techniques have been described to reduce the prolapsing membranes, including the following: placing the patient in Trendelenburg position; the use of a pediatric Foley catheter to tease the membranes into the endocervical canal, and instilling 1 L of saline into the bladder with upper displacement of the lower uterine segment.^{[67], [68], [70], [71]} Although the efficacy of antibiotics or tocolytics has not been properly studied, some case series advocate their use. Although clinicians have been reluctant to offer cerclage in patients with protruding membranes, some reports have suggested salvage rate in excess of 70 percent despite advanced cervical dilatation.^{[72], [73], [74]}

Risks of Cerclage

Cervical lacerations at time of delivery are one of the most common complications from a cerclage, occurring in 1 to 13 percent of patients.^[52] Three percent of patients require cesarean birth because of the inability of

Figure 19-5 Transvaginal cerclage under ultrasound guidance. (Modified from Ludmir J, Jackson GM, Samuels P: *Transvaginal cerclage under ultrasound guidance in cases of severe cervical hypoplasia*. *Obstet Gynecol* 78:1067, 1991.)

the cervix to dilate secondary to cervical scarring and dystocia.^[52] Although the risk of infection is minimal with a prophylactic cerclage, the risk increases significantly in cases of advanced dilatation with exposure of membranes to the birth canal.^[69] Cervical cerclage displacement occurs in a small number of patients. We have not performed revision of the cerclage during the index pregnancy, although small series have reported successful surgical treatment of failed cerclage.^[54] When the clinician is faced with premature rupture of membranes distant from term in a patient with cerclage, the decision to remove or leave the suture is controversial. Our own data suggests that with suture retention, there is an increased period of latency, at the expense of increased risk for neonatal sepsis and mortality.^[75] These data have been recently challenged by reports suggesting increased latency period without increase in neonatal morbidity.^{[76], [77]} Decisions to remove the suture at time of ruptured membranes should be individualized until more information becomes available. Finally, even though cerclage placement is considered a benign procedure, a maternal death secondary to sepsis in a patient with retained cerclage has been reported.^[78] The liberal use of this surgical procedure should be carefully balanced against potential harm, in particular for patients in whom the indications for cerclage are not clear.

Efficacy of Cervical Cerclage

Most reports demonstrating improvement in pregnancy outcome with cerclage placement have done so by using each patient as her own historical control. Four prospective, randomized, controlled trials of cerclage, including one for multiple gestations, failed to demonstrate significant improvement in pregnancy outcome in patients receiving prophylactic cerclage.^{[79], [80], [81], [82]} Unfortunately, these trials did not involve patients with classic indications for cerclage, but used as criteria for randomization increased risk for preterm birth, or cases in which obstetricians were unsure as to whether a cerclage should be placed. The introduction of sonography in assessing the cervix during gestation will provide additional diagnostic criteria to help the clinician decide if therapeutic intervention with cerclage is indicated.^{[43], [44]}^[45] Initial information from ongoing randomized trials in

patients at high risk for cervical incompetence do not demonstrate differences in preterm delivery between prophylactic cerclage versus sonographically indicated therapeutic cerclage.^[43] Based on this new information, it seems prudent to incorporate cervical sonography in the management of patients at risk for cervical incompetence. Further recommendations regarding patient selection and treatment require continuing research in this evolving area.

Gabbe: Obstetrics - Normal and Problem Pregnancies, 4th ed. , Copyright © 2002 Churchill Livingstone, Inc.

MYOMECTOMY

Uterine myomas (fibroids) are the most common pelvic masses found in gestation. Myomas can increase in size during gestation, and place the patient at risk for preterm birth, abruption, dystocia, and bleeding.^[83] When myomas outgrow their blood supply, they can develop cystic areas of red degeneration resulting in severe pain requiring nonsteroidal agents or narcotic medication.^[83] Follow-up of myoma size by ultrasound has been studied extensively.^[84] Lev-Toaff and colleagues^[85] found that small fibroids increased in size during the second trimester, but during the third trimester, most fibroids decrease in size, regardless of their initial size. Most of the complications in pregnant patients with myomas are secondary to myoma location in the uterus.^[86]^[87]^[88] The removal of a fibroid in pregnancy is contraindicated unless there is the presence of a pedunculated myoma twisting its stalk and giving the patient severe discomfort. Laparoscopic removal of this type of fibroid could be considered, but lack of experience with this situation precludes its routine use. The finding of myomas at time of cesarean section constitutes a challenge to the obstetrician.^[88]^[89] If the myomas are encountered on the uterine incision line, careful myomectomy may be performed,^[89] but may cause profuse bleeding and even may require hysterectomy to control hemorrhage. To avoid massive hemorrhage, routine myomectomy at time of cesarean section should be avoided; most myomas will involute in size in the nonpregnant state.

OOPHORECTOMY

The frequent use of ultrasound in early gestation has resulted in a significant number of asymptomatic adnexal masses diagnosed early in pregnancy. This knowledge creates a dilemma for the clinician: the appropriate management of an asymptomatic adnexal mass on the pregnant patient.^[90] Ovarian masses in pregnancy could undergo torsion, rupture, and cause obstruction of labor (Fig. 19-6).^[91] They also carry a small risk of malignancy.^[92] If the clinical presentation is consistent with torsion, rupture, or hemorrhage, immediate surgical intervention is indicated. Hess and associates^[93] found that if surgery for an adnexal mass was delayed until onset of severe symptoms, pregnancy outcome was worse compared with those patients that had elective surgery. If an adnexal mass is identified coincidentally at the time of cesarean section, Koonings and colleagues^[93] advocate its removal including those smaller than 5 cm. In their study, only 2 of 41 masses smaller than 5 cm were functional cysts. Some authors have advocated aspiration and cytologic evaluation of cysts in selected cases. Rodin et al.^[94] caution against this approach, in particular if the cyst is greater than 5 cm,

Figure 19-6 Laparotomy for 12-cm ovarian serous cystadenoma at 16 weeks' gestation.

TABLE 19-1 -- RISK OF OVARIAN MALIGNANCY BASED ON SONOGRAPHIC FINDINGS

Low risk of malignancy	Simple smooth wall cyst
	Size <5 cm
Increased risk of malignancy	Solid mass
	Nodules
	Thick septations
	Size >5 cm

because malignancy could be missed even with simple smooth-walled cysts. The patient with a simple sonographic cyst, smaller than 5 cm, has a very small risk for malignant change.^[95] This patient can be followed during gestation without surgical intervention.^[96],^[97] For those patients demonstrating masses greater than 5 cm, and with presence of solid elements, surgical intervention should be considered during the early second trimester, to minimize fetal risk. Surgery in the second trimester is felt to be the safest time to perform an oophorectomy or ovarian cystectomy via laparotomy. However, the risk of surgical intervention may favor a conservative approach on the basis of sonographic findings (Table 19-1). Laparoscopy offers a newer approach to the pregnant patient with an adnexal mass. A recent report by Soriano et al.^[17] described 88 pregnant women who underwent 93 operations for suspected adnexal pathology. Laparoscopy was performed during the first trimester in 39 patients. The remaining 54 patients underwent laparotomy, 25 during the first trimester and 29 during the second trimester. The authors concluded that laparoscopic surgery during pregnancy appears to be safe in the management of adnexal masses, but cautioned against its liberal use until prospective controlled studies to determine the safety of this procedure in pregnancy are performed. We recently performed operative laparoscopy in a patient at 20 weeks' gestation presenting with symptoms of adnexal torsion (Fig. 19-7). On the basis of recent studies that seem to indicate that adnexal torsion can be safely managed by untwisting the ovarian pedicle,^[98] we untwisted the adnexal mass laparoscopically and the patient continued with an uneventful pregnancy to term. With increased knowledge of the role of laparoscopy in pregnancy, the management of the adnexal mass in pregnancy may change in the future, favoring a laparoscopic approach instead of the traditional open laparotomy.

TUBAL STERILIZATION

Surgical approach to tubal sterilization is influenced by whether the procedure is being performed on a postpartum or on an interval basis. Advantages to the postpartum approach include the use of one anesthesia for labor, delivery, and sterilization, and only one hospitalization. ^[99] Tubal

Figure 19-7 Laparoscopic appearance of adnexal torsion at 20 weeks' gestation.

615

Figure 19-8 Pomeroy sterilization. A knuckle of tube is ligated with absorbable suture, and a small segment is being excised. Note that the ligation is performed at a site that will favor reanastomosis, should that become desirable. Some surgeons place an extra tie of nonabsorbable suture around the proximal stump as added protection against recanalization.

ligations after vaginal delivery are performed through a minilaparotomy incision at the level of the uterine fundus, usually subumbilically. The same surgical techniques are applied if tubal ligation is performed at time of cesarean section. Interval sterilizations are performed by laparoscopy or minilaparotomy.

The choice of surgical approach influences the choice of methods of tubal occlusion. For example, most procedures performed via minilaparotomy use some type of partial salpingectomy technique as the method of tubal occlusion. Most laparoscopic sterilizations use either coagulation, application of silicone rubber bands, or application of clips as the method of tubal occlusion. ^[100] The long-term failure rate is approximately 1 percent overall.

Modified Pomeroy

The method of tubal occlusion used by Pomeroy was described in 1930, ^[101] and is the most popular means of postpartum tubal ligation because of its simplicity. The Pomeroy technique as originally described included grasping the fallopian tube at its midportion, creating a small knuckle, and then ligating the loop of tube with a double strand of No. 1 chromic catgut suture. It is critical that the fallopian tube be conclusively identified. Visualizing the fimbriated portion of the tube and identifying the round ligament as a separate structure can accomplish this. Absorbable sutures are used so that the tubal ends will separate quickly after surgery, leaving a gap between the proximal and distal ends. The most popular modification of the Pomeroy technique involves the use of No. 1 catgut suture instead of chromic catgut suture. Other modifications include placing nonabsorbable suture in the proximal ends of each resected tube. In performing the procedure, care should be taken to make the loop of fallopian tube sufficient in size to ensure that complete transection of the tubal lumen will occur. After the loop of fallopian tube is ligated, the mesosalpinx of the ligated loop should be perforated using scissors, and the knuckle of the tube is transected ([Fig. 19-8](#)). It is important not to resect the fallopian tube so close to the suture that the remaining portion of the fallopian tube slips out of the ligature and causes delayed bleeding.

The Irving Procedure

Irving first reported his sterilization technique in 1924, with a modification in 1950. ^[102] In the modified procedure, a window is created in the mesosalpinx and the fallopian tube is doubly ligated with No. 1 chromic catgut. The fallopian tube is then transected approximately 4 cm from the uterotubal portion; the two free ends of the ligation stitch on the proximal tubal segment are held long. The proximal portion of the fallopian tube is dissected free from the mesosalpinx and then buried into the incision into the myometrium of the posterior uterine wall, near the uterotubal junction. This is accomplished by first creating a tunnel approximately 2 cm in length with a mosquito clamp in the uterine wall. The two free ends of the ligation stitch on the proximal tubal segment are then brought deep into the myometrial tunnel, and brought out through the uterine serosa. Traction is then placed on the sutures to

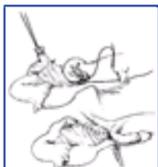

Figure 19-9 Irving sterilization. The tube is transected 3 to 4 cm from its insertion, and a short tunnel is created by means of a sharp-nosed hemostat in either the anterior or posterior uterine wall. The cut end of the tube can then be buried in the tunnel and, if necessary, further secured by an interrupted suture at the opening of the tunnel. The distal cut end is buried between the leaves of the broad ligament.

616

draw the proximal tubal stump into the myometrial tunnel; tying the free sutures fixes the tube in that location. No treatment of the distal tubal stump is necessary, but some choose to bury the segment in the mesosalpinx ([Fig. 19-9](#)). Although this technique is slightly more complicated than the others, it has the lowest failure rate. ^[103]

The Uchida Procedure

In this sterilization procedure, ^[104] the fallopian tube muscular portion is separated from its serosal cover and grasped approximately 6 to 7 cm from the uterotubal junction, saline solution is injected subserosally, and the serosa is then incised. The muscular portion of the fallopian tube is grasped with a clamp and divided. The serosa over the proximal tubal segment is bluntly dissected toward the uterus, exposing approximately 5 cm of the proximal tubal segment. The tube is then ligated with chromic suture near the uterotubal junction, and approximately 5 cm of the tube is resected. The shortened proximal tubal stump is allowed to retract into the

mesosalpinx. The serosa around the opening in the mesosalpinx is sutured in a purse-string with a fine absorbable stitch; when the suture is tied the mesosalpinx is gathered around the distal tubal segment ([Fig. 19-10](#)). Some surgeons choose to excise only 1 cm of fallopian tube rather than the recommended 5 cm in case the patient wishes tubal reanastomosis in the future.

Kroener Fimbriectomy

This technique consists of excising the distal tube and fimbriae and ligating the cut ends of the tube with silk sutures. In one series, the failure rate was 3 percent.

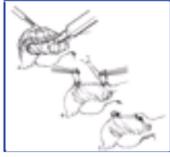

Figure 19-10 Uchida sterilization. The leaves of the broad ligament and peritubal peritoneum are infiltrated with saline so that the tube can be easily isolated from these structures, divided, and ligated. The broad ligament is then closed, burying the proximal stump between the leaves and including the distal stump in the line of closure.

SPECIFIC SURGICAL PROBLEMS IN PREGNANCY

617

Appendicitis

Appendicitis is one of the most common surgical complications of pregnancy, with an incidence of 1 to 2 per 1,000 gestations.^[105] This incidence is roughly similar to that in the nonpregnant population. There is no evidence that pregnancy appears to increase the risk for appendicitis.^[106] Baer in 1932^[107] described the change in appendiceal location as pregnancy progresses with upper displacement of the appendix with advancing gestation (Fig. 19-11). The change in appendiceal location with advancing gestation would change the location of perceived pain toward the patient's right upper quadrant or right flank. Mourad et al.,^[108] in a retrospective review of 66,993 deliveries, found 68 pregnancies complicated by appendicitis, and challenged this concept. Pain in the right lower quadrant of the abdomen was

Figure 19-11 Locations of the appendix in pregnancy. As modified from Bauer et al., the approximate location of the appendix during succeeding months of pregnancy is diagrammed. In planning an operation, it is better to make the abdominal incision over the point of maximum tenderness unless there is a great disparity between that point and the theoretical location of the appendix. (Modified from Baer JL, Reis RA, Arens RA: *Appendicitis in pregnancy with changes in position and axis of the normal appendix in pregnancy*. JAMA 98:1359, 1932.)

the most common symptom of appendicitis regardless of gestational age. The diagnosis of appendicitis in pregnancy is difficult secondary to a clinical picture mimicking common symptoms in gestation including nausea, vomiting, and abdominal discomfort.^[109]

Early in the course of appendicitis, temperature and pulse rate may be normal; later, a low-grade temperature elevation or even a normal temperature may be present. Only 20 percent of patients exhibit rectal or vaginal tenderness. The normal leukocytosis of pregnancy ($14,000/\text{mm}^3$) might mask appendicitis. Radiographic studies are rarely helpful, but most recently ultrasound and CT scan of the abdomen have been advocated as another objective way of making the diagnosis.^[110] Even though the diagnosis is only found in 50 percent of patients undergoing surgery, it is better to operate unnecessarily rather than postpone surgery until generalized peritonitis has developed. Surgery can minimize maternal-fetal morbidity by preventing progression to appendiceal rupture and peritonitis.^[105] Fetal mortality is low when acute appendicitis is diagnosed and treated, but could rise significantly in the presence of peritonitis. Maternal death may occur in the presence of peritonitis and overwhelming intra-abdominal sepsis. Mazze and Kallen, using the Swedish registry of surgery during pregnancy, performed a review of 778 cases of appendectomy during gestation.^[105] The diagnosis was confirmed in 64 percent of cases. These findings showed an increase in the risk for delivery the week after appendectomy when the operation was performed after 23 weeks' gestation. Cesarean section is rarely indicated at the time of appendectomy. A recent abdominal incision presents no problem during labor and vaginal delivery. Recently, several small case series of laparoscopic appendectomies in pregnancy have been reported demonstrating success during all trimesters, without complications (Fig. 19-12).^[115] Some investigators note that laparoscopy expands the ability to explore the abdomen with less uterine manipulation. Further studies evaluating laparoscopic appendectomy in pregnancy are necessary prior to determining the safety of this procedure.

Acute Cholecystitis

After appendicitis, biliary tract disease is the second most common general surgical condition encountered in pregnant women. Its incidence varies from 1 in 2,000 to 1 in 4,000 pregnancies.^[112] Pregnancy increases the risk of gallstones, probably secondary to high progesterone levels that inhibit smooth muscle contractility. This results in greater gallbladder volume with retention of cholesterol crystals prerequisite for gallstone formation.^[113]

Cholecystitis during pregnancy usually develops when

618

Figure 19-12 Laparoscopic appearance of appendix at 18 weeks' gestation.

there is obstruction of the cystic duct. This clinical entity ranges from intermediate attacks of biliary colic to persistent pain radiating into the subcapsular area in cases where the common duct is obstructed by a stone. There is usually right subcostal tenderness along with a low-grade fever. Ultrasound is helpful in detecting the presence of stones as small as 2 mm, and confirms the diagnosis of gallstones in about 90 percent of patients.^[114] The differential diagnoses for cholecystitis include conditions unique to pregnancy such as acute fatty liver of pregnancy and severe preeclampsia. Initial attacks of cholecystitis should be treated conservatively, with intravenous fluids, nasogastric suction, antibiotics, and antispasmodics. Without prompt resolution of symptoms, surgery should be considered. Eighty percent of patients with an initial attack will get relief with conservative medical treatment. In the presence of common duct obstruction or pancreatitis, cholecystectomy is necessary and should not be delayed.^[114]

Laparoscopic cholecystectomies have revolutionized the management of the pregnant patient with cholecystitis.^[115] Small case series demonstrate the same good outcomes compared with open laparotomies. Our own experience demonstrates that delaying surgery for cholecystitis results in increased perinatal morbidity, with lower morbidity found in those patients managed surgically, particularly in cases of bile duct obstruction.^[117] Larger studies are needed to recommend the laparoscopic approach to cholecystectomy in pregnancy, once the diagnosis of cholecystitis is made.^[115]

Intestinal Obstruction

The incidence of bowel obstruction in pregnancy is similar to that of the general population, approximately 1 in 3,000 deliveries. ^[119] Intestinal obstruction usually involves the small bowel, and is commonly caused by an adhesive band or hernia (Table 19-2). ^[120] Prior abdominal and pelvic surgery are the most frequent causes for intestinal obstruction. Ludmir et al. ^[121] reported a case of spontaneous bowel obstruction in a patient carrying triplets, without risk factors for bowel obstruction. Intestinal obstruction is a grave complication of pregnancy and results from pressure of the growing uterus on intestinal adhesions. Patients with bowel obstruction

TABLE 19-2 -- CAUSES OF INTESTINAL OBSTRUCTION IN PREGNANCY

619

present with colicky midabdominal pain associated with hyperactive peristalsis. Nausea and vomiting is found in 80 percent of cases as reported by Perdue et al. ^[122] As time passes, the intestinal peristalsis decreases and the abdomen finally becomes silent. Bowel distention may be marked, and difficult to access in pregnancy. Limited radiography are clearly indicated. In cases of small bowel obstruction, radiologic findings include dilatation of small bowel loops with air-fluid levels. Initial treatment of intestinal distention includes decompression with nasogastric tube or long tube, adequate fluid resuscitation, and correction of electrolyte imbalance. Perdue and colleagues reported a maternal mortality rate of 6 percent primarily caused by sepsis and shock, with a 26 percent incidence of fetal demise. If after 6 to 8 hours of treatment there is no satisfactory patient response, laparotomy should be performed before bowel necrosis and perforation occur. The uterus rarely interferes with the surgery, and if preterm labor follows the procedure, tocolytics can be used.

Ogilvie's syndrome, or pseudo-obstruction of the colon, is caused by an adynamic colonic ileus; about 10 percent of cases follow delivery. The syndrome is characterized by massive abdominal distention with cecal dilation. Laparotomy may be indicated, ^[117] and colonoscopy for decompression has been described in a postpartum patient. ^[123]

Trauma

Trauma from accidental injuries complicates 6 to 7 percent of all pregnancies. ^[124] The majority of these patients suffer only minor injuries and would not require hospital admission in the absence of pregnancy. ^[125] Unfortunately, trauma is the leading nonobstetric cause of maternal mortality, accounting for 20 percent of maternal deaths. ^[126] Fort and Harlen report that the risk of fetal demise from major blunt trauma increases from 8.7 percent in the first trimester, to 40 to 50 percent during the second and third trimesters. ^[127] Poole and associates, ^[128] in a recent study of trauma in pregnancy, determined that 31.5 percent of patients were victims of domestic violence, in most cases from the husband or boyfriend. The authors concluded that interpersonal violence during pregnancy is an increasingly common cause of maternal injury.

Automobile restraint systems with a shoulder harness prevent forward flexion of the maternal torso, and when used correctly reduce fetal death rates by preventing ejection of the mother from the vehicle. A waist-type seat belt can produce distortion of the uterus produced by the sudden compression of the belt resulting in placental abruption (Fig. 19-13). ^[129], ^[130] Blunt trauma may result in rupture of the membranes and preterm labor. Placental abruption is the most common cause of fetal demise when the maternal injuries are not lethal. ^[131] The placenta separation may manifest at the time of injury or later, with the great majority of them in the first 24 hours. For this reason, even moderate blunt trauma should be an indication for fetal heart rate monitoring and close observation. ^[132] ^[133] ^[134]

Uterine rupture resulting from trauma is an infrequent event reported in about 0.6 percent of trauma cases in pregnancy. ^[124] In early pregnancy, the uterus is resistant to injury, but after the first trimester the uterus becomes an abdominal organ and is susceptible to injury. Prompt diagnosis of rupture is imperative to reduce the risk of maternal and fetal mortality. It is important to emphasize that normal vital signs in the mother do not preclude the possibility of uterine rupture, and fetal heart rate abnormalities could be the first sign of a rupture.

Figure 19-13 Seat belt injury. The mechanisms by which placental separation might be produced by a waist-type seat belt are illustrated. A, The force of a collision propels the body forward. B, Acute flexion of the trunk results in elongation of the uterus, including elongation of the site of placental attachment. C, As the trunk recoils, the placental site is shortened and the posterior wall of the uterus collides with the vertebral column. (Redrawn from Lees DH, Singer A: *Gynecologic Survey*. Vol 6. London, Wolfe Medical, 1983, with permission.)

620

Penetrating injuries to the maternal upper abdomen may cause damage to intra-abdominal organs. Franger et al. recommended conservative management of the these injuries if (1) the mother is hemodynamically stable, (2) the entrance wound is below the uterine fundus, (3) there is no evidence of blood in the gastrointestinal and urinary tracts, and (4) the bullet can be demonstrated within the uterus. ^[135]

Management of the pregnant trauma patient requires a team effort and complete understanding of the physiologic changes unique to gestation. Initially, the "ABCs" (airway, breathing, and circulation) should be assessed. If possible, the injured pregnant woman who is more than 20 weeks' gestation should be kept in the lateral decubitus position. Once the maternal vital signs have been stabilized, appropriate diagnostic studies to rule out internal injury, including CT scan and MRI are performed, if necessary. Fetal assessment with continuous electronic monitoring is advocated, as well as uterine contraction monitoring. ^[136], ^[134] Possible placental abruption is predicted by using continuous electronic monitoring and findings of frequent uterine contractions. ^[124]

The American College of Obstetricians and Gynecologists (ACOG) recommends that any pregnant woman sustaining trauma beyond 22 to 24 weeks' gestation should undergo fetal monitoring for a minimum of 24 hours. In the presence of ruptured membranes, bleeding, fetal arrhythmia, fetal heart rate deceleration, or more than four contractions per hour, the patient should be admitted with continuous fetal monitoring for at least 24 hours. ^[136] Ultrasound is useful to determine gestational age, to determine fetal well-being if monitoring is equivocal, and to confirm fetal death.

A recent study attempted to elucidate risk factors that would predict adverse outcome in pregnant trauma patients, and would require monitoring greater than 4 to 6 hours. Curet and colleagues ^[137] studied 271 pregnant patients admitted after blunt trauma. The following risk factors were predictive of fetal death: ejections, motorcycle and pedestrian collisions, maternal death, maternal tachycardia, abnormal fetal heart rate, and lack of restraints. Risk factors significantly predictive for contractions or preterm labor included assaults and pedestrian collisions.

Several studies have established that fetal maternal hemorrhage is increased in women who have suffered trauma in pregnancy. ^[124] The use of the Kleihauer-Betke test is advocated in particular in RhD-negative women, so adequate anti-D immune globulin can be administered. The role of a routine Kleihauer-Betke test after trauma in predicting adverse outcome is not clear. A recent study by Pak et al. found negative results in all 85 pregnant patients with blunt abdominal trauma that had a Kleihauer-Betke test. ^[134]

Burns

Thermal burns occur with the same frequency as in the nonpregnant state. Most authors feel that pregnancy does not alter the chances for survival. ^[138], ^[139] Amy et

al.^[139] reported that mothers with second- and third-degree burns involving less than 20 percent body surface area, as well as their fetuses, survived the burn period. Of the mothers with 20 to 50 percent body surface area burns, all survived but the fetal survival rate was only 70 percent because of frequent preterm delivery. Burns greater than 50 percent body surface area were associated with high mortality rate, with subsequent high fetal death rate. Complications such as inhalation injury with hypoxemia, sepsis, and hypovolemic shock require aggressive management of maternal airway and fluid status with concurrent assessment of fetal condition. These patients are at high risk for preterm delivery, and the severely burned patient may not tolerate the use of tocolytic agents.^[140]

LAPAROSCOPY IN PREGNANCY

Laparoscopic surgery has revolutionized the management of many surgical disorders.^{[15] [16] [17] [18] [19] [20] [21] [22]} However, during the 1980s and early 1990s, pregnancy remained a relative contraindication to laparoscopy, with most surgeons performing open laparotomy. As more case reports and small series of laparoscopic surgery in pregnancy appeared in the literature, the initial reluctance by surgeons for this approach changed to one of cautious optimism.^{[15] [116] [141]} Laparoscopy offers several advantages over traditional laparotomy,^{[15] [18] [20]} including better visualization, especially with small incisions. Total operative time for laparoscopic procedures is less, and postoperative pain is reduced ([see the box "Advantages of Laparoscopic Surgery"](#)). Unfortunately, access

issues in late and second or third trimester in pregnancy are still considered a relative contraindication to this approach ([see the box "Relative Contraindications to Laparoscopy in Pregnancy"](#)). Limited published physiologic data exist concerning maternal-fetal interactions during laparoscopic surgery.^{[142] [143]} The normally decreased maternal PaCO₂ during pregnancy may be important in ensuring adequate transplacental CO₂ diffusion from the fetus to the mother. CO₂ pneumoperitoneum may cause maternal and fetal hypercarbia because of decreased maternal ventilation and increased transplacental CO₂ absorption by the mother. Hunter and associates, studying pregnant ewes,^[143] demonstrated that carbon dioxide pneumoperitoneum induced maternal hypercarbia, which led to fetal hypercarbia, acidosis, and tachycardia when pneumoperitoneum pressure exceeded 15 mm Hg. These effects were minimized by using a low pneumoperitoneum pressure or by using nitrous oxide as the distending gaseous agent. The significance of these findings for humans is debatable, but on the basis of these findings, in 1998, the Society of American Gastrointestinal Endoscopic Surgeons (SAGES) published a list of guidelines for laparoscopic surgery during pregnancy ([see the box "Laparoscopy During Pregnancy Guidelines \[SAGES\]"](#)).^[144] Affleck et al.^[15] have recently modified these criteria, recommending a maternal end-tidal CO₂ within physiologic range (30 to 40 mm Hg) instead of performing serial arterial blood gases, and raising the pneumoperitoneum pressure from a minimal of 8 to 12 mm Hg to a pressure of 10 to 15 mm Hg. These authors also recommend the use of tocolytic agents only for uterine irritability and not prophylactically.^[15]

Advantages of Laparoscopic Surgery

- Better visualization
- Small incision
- Less pain
- Less operative time
- Postoperative convalescence reduced
- Less use of postoperative analgesics
- Earlier ambulation
- Decreased risk of thromboembolic disease
- Shorter hospital stay

Relative Contraindications to Laparoscopy in Pregnancy

- Access issues
 - Late second or third trimester
 - Multiple gestations
 - Advanced disease process (e.g., walled-off abscess)
 - Retrocecal location of appendix
- Medical complications
 - Intra-abdominal sepsis
 - Bleeding disorders
 - Ileus

Laparoscopy During Pregnancy Guidelines (SAGES)

- Pneumatic compression devices
- Lead shield with selective fluoroscopy
- Dependent position
- Obstetric consultation
- Intraoperative fetal monitoring
- Minimal pneumoperitoneum (812 mm Hg)
- Serial arterial blood gas analysis
- Second-trimester deferment
- Open technique

Modified from Guidelines for laparoscopic surgery during Pregnancy. Surg Endosc 4:100, 1998.

Laparoscopic appendectomy during pregnancy continues to be controversial. Case reports and small series have reported success during all trimesters, when compared with an open approach.^{[18], [141], [145]} In the largest series to date of laparoscopic appendectomies in pregnancy, Affleck et al. reported 19 patients.^[19] Six underwent surgery in the first trimester, nine in the second, and four in the third. Three patients delivered preterm, one prior to 35 weeks. There were no uterine injuries, spontaneous abortions, or fetal losses (Table 19-3).

Several small series of laparoscopic cholecystectomies in pregnancy suggest that the procedure may be performed safely, without major complications.^{[18], [19], [146], [147]} In an attempt to analyze a large number of patients undergoing cholecystectomy in pregnancy, Barone et al.^[119] obtained data from the Connecticut Laparoscopic

Modified from Barone JE, Bears S, Chen S, et al: Outcome study of cholecystectomy during pregnancy. Am J Surg 177:232, 1999.

Cholecystectomy Registry and data from the Connecticut Hospital Association for the years 1992 through 1996. Complete data were available for 46 patients, 20 laparoscopic and 26 open cases (Table 19-4). The groups were comparable, except for the timing of cholecystectomy, which was performed earlier for the laparoscopic group, 18.4 ± 6.7 weeks, compared with 24.0 ± 4.7 weeks for the open cases. The authors concluded that laparoscopic cholecystectomy does not lead to increased numbers of fetal complications; furthermore, preterm labor was more common in the open cholecystectomy group (eight vs. one, p = 0.057) compared with the laparoscopy group. Unfortunately, this large study found a maternal fatality 2 weeks after laparoscopic cholecystectomy at 20 weeks. The death was secondary to intra-abdominal hemorrhage, but the source of bleeding could not be identified. Complications from laparoscopic surgery are well recognized and should always be considered (Table 19-5). On the basis of this experience, it seems prudent that when a laparoscopic approach to appendectomy or cholecystectomy is considered during pregnancy, specific guidelines for monitoring maternal and fetal condition should be established in individual institutions.^{[19], [119]} Large studies with long-term follow-up of infants exposed to laparoscopy in utero are needed before establishing the true safety of this surgical procedure.

FERTILITY CONTROL AND HEALTH

Pregnancy can result in illness and death. The U.S. maternal mortality rate is about 9 per 100,000 live births. Risk of death from legal abortion in the United States is less than 1 death per 100,000 induced abortions.^[148] Pregnancy risk for women with preexisting illnesses can be much greater. Women in their 40s are seven times more likely to die in pregnancy than are women in their early 20s, the safest time to have a baby.^[149] Fertility control, or lack of it, also impacts on child health. When pregnancies are too close together, the risk of prematurity and perinatal mortality increase.^[150] Higher order births to young mothers are at very great risk. Second births to mothers under 20 are more likely to be premature and to die than are first-born children, and the risk is still higher for a third-born infant to a woman under 20.^[151], ^[152]

Legal Abortion and Voluntary Control of Fertility

Modern methods of contraception can be highly effective but fail more often than we usually appreciate. Only about half of U.S. pregnancies are intended.^[153] Young people are much more likely to experience contraceptive failure^[154] because they are more fertile, and because they are more likely to have unexpected intercourse. Contraception is preventive medicine, and as such requires advance motivation. Abortion, on the other hand, is sought after the fact, when pregnancy has occurred. For all of these reasons, induced abortion is essential for a high level of voluntary control of fertility.

History of Abortion

Some means for attempting abortion can be found in all cultural groups and are evident in the artifacts of ancient civilizations.^[155], ^[156] Folk methods in use today include ingested wild plants, insertion of sticks through the cervix into the uterus, and forceful massage of the

uterus.^[157] Abortion was common in the 19th century United States. The complications of these procedures, and the competition from lay abortionists, so concerned the "regular" physicians that medical societies carried out intensive campaigns that resulted in the passage of laws making abortion illegal in most states by the end of the century.^[158] These laws remained on the books until 1973, when the Supreme Court legalized abortion throughout the land.^[159]

Duty of Health Professionals

As health professionals, we have a duty "to put health first, to do so by respecting the best available scientific evidence, and to be frank when we put aside such evidence for other considerations, be they moral, or religious, or economic, or simply expedient."^[159] We are not required to perform abortions if this is against our ethical principles, but we have a duty to our patients to help them assess pregnancy risks and make appropriate referrals.

LEGAL ABORTION IN THE UNITED STATES

Overview

Approximately 1,200,000 abortions are reported to the Centers for Disease Control each year in the United States, a number that has been declining since 1990. In 1996, the national abortion ratio was 314 abortions for every 1,000 live births, and the national abortion rate was 20 per 1,000 women aged 15 to 44. ^[148] The majority of women who obtain abortions are unmarried (78.7 percent in 1996), and the ratio of abortions

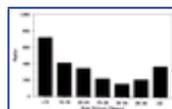

Figure 19-14 Abortion ratio (per 1,000 live births) by age group United States 1996. (From Koonin LM, Strauss LT, Chrisman CE, et al: *Abortion surveillance. United States, 1996. MMWR Morb Mortal Wkly Rep* 48:1, 1999.)

to live births is eight times higher for unmarried women than for married women. Utilization of abortion varies markedly with age. Twenty percent of women obtaining abortions were 19 or younger and 52 percent were 24 or younger in 1996. In 1996, the abortion ratio for women under 15 was 723 per 1,000 live births, almost as many abortions as births (Fig. 19-14). Abortion ratios for black women are almost three times those for whites, although 59 percent of abortions nationally are performed for white women. ^[148]

Risk of death from legal abortion in the United States is 0.7 per 100,000 induced abortions. The risk of death from legal abortion prior to 16 weeks is 5- to 10-fold less than that from continuing the pregnancy. As shown in Table 19-6, the risk of death increases with gestational age. ^[160] For individual women with high-risk conditions, for example, cyanotic heart disease, even late abortion is undoubtedly a safer alternative. Because of the availability of low-cost, out-of-hospital first-trimester abortion, 88 percent of legal abortions are performed in the first trimester, when abortion is the safest. ^[148] Type of procedure also determines risk. First-trimester abortions are virtually all performed by vacuum curettage; however, early medical abortion induced with methotrexate/misoprostol is practiced in some centers, and may increase when mifepristone, the antiprogesterone, becomes available in the United States. Currently, 93 percent of abortions after 12 weeks are performed by variations of "dilatation and evacuation" (D&E), the surgical evacuation of the uterus through the vagina. ^[148] Risk of death from abortion by the various techniques at different gestational ages is given in Table 19-7. The data clearly show the greater safety of D&E over other procedures, especially in the early midtrimester. Anesthesia is another determinant of risk. General anesthesia increases the risk for perforation of the uterus, visceral injury, hemorrhage,

TABLE 19-6 -- DEATH TO CASE RATES FOR LEGAL ABORTION MORTALITY BY WEEKS OF GESTATION, UNITED STATES, 1972-1987

hysterectomy, and death. ^[161] ^[162] ^[163] Paracervical block augmented with conscious sedation is preferred.

Benefits of Legal Abortion

In the 1940s, more than 1,000 women died each year from abortion complications. ^[164] In 1996, the last year for which complete data are available, there were 17 deaths from spontaneous abortion, 10 deaths from abortion legally induced, and no deaths from illegal abortion (abortion induced by a nonprofessional) in the entire United States. ^[148] The American Medical Association attributes the decline in deaths to the introduction of antibiotics; the widespread use of effective contraception beginning in the 1960s, which reduced the number of unwanted pregnancies; and more recently, the shift from illegal to legal abortion. ^[165]

Indications for Abortion

Since 1973, the only legal condition necessary for abortion in the first trimester is that the woman consult with her physician. The critical question has become: when should abortion of a desired pregnancy be recommended on medical grounds? In some situations, for example, congenital heart disease with pulmonary hypertension, the risk of death in late pregnancy is so great that any prudent physician would recommend abortion. Similarly, if major fetal malformation leaves no hope for meaningful life, most would recommend abortion. However, in the majority of cases of maternal illness or fetal malformation, the patient and her family can determine how much risk they are willing to take and make their own informed choice with medical advice. Table 19-8 (Table Not Available) and Table 19-9 (Table Not Available) list some fetal and maternal indications for abortion of a desired pregnancy. ^[166] This list is meant only as a guide, and is by no means all inclusive.

First-Trimester Abortion

Dilatation and curettage is an ancient procedure. ^[155] Vacuum curettage was described for the first time by two Chinese physicians in 1954. ^[167] The vacuum technique was introduced in England in the 1960s and then brought to the United States by Burdick. After 1973, it quickly became the procedure of choice. Subsequent

comparative trials have demonstrated that vacuum curettage is quicker, less traumatic, and safer than sharp curettage. ^[169]

Manual Vacuum Procedures

In 1972, Karman and Potts described a small-bore, flexible vacuum cannula used with a 50-ml syringe to evacuate the uterus through 7 menstrual weeks with only minimal cervical dilatation.^[169] The procedure is readily accomplished in the physician's office. The only instruments required in addition to speculum and tenaculum are the Karman cannula and modified 50-ml syringe (Fig. 19-15).

Technique for Manual Vacuum Procedure (see Fig. 19-16) (see Fig. 19-16) (see Fig. 19-16) (see Fig. 19-16)

After examination to determine uterine position and to be sure that pregnancy is 7 weeks or less, the cervix is exposed with a speculum, infiltrated with local anesthetic, and grasped with a tenaculum placed vertically at 12 o'clock. Four- and 5-mm-diameter cannulas are passed through the cervical canal as dilators, and then a 6-mm cannula is inserted and attached to the evacuated 50-ml syringe to establish suction. The 4- and 5-mm cannulas are not large enough to dependably evacuate the uterus in pregnancy, but are useful as atraumatic dilators and for endometrial biopsies in the nonpregnant state. The 6-mm cannula is rotated and pushed in and out with gentle strokes, taking care to rotate the cannula only on the outstroke so as to avoid twisting off the flexible tip by rotating it when it is pressed against the uterine fundus. When no more tissue comes through, the cannula is withdrawn, its tip cleared in a sterile fashion, and it is reinserted and vacuum reestablished for a final, check curettage to

prove the uterus empty. The operator must then carefully examine the aspirated tissue to identify the gestational sac, to prevent failed abortion, to diagnose molar pregnancy, and to detect ectopic pregnancy.^[170] The fresh exam is best accomplished by floating the aspirated tissue in a clear plastic dish over a light source. Figure 19-17 demonstrates the appearance of an early pregnancy.

This same procedure allows treatment of incomplete spontaneous abortion in an office or emergency department without need for an operating room and general anesthesia. A double-valve version of the instrument accommodates vacuum cannulas as large as 10 mm and makes possible manual vacuum evacuation of the uterus through 12 weeks of pregnancy.

Edwards and Carson have modified the manual vacuum technique and applied it to pregnancies as early as 3 weeks from last menstrual period.^[171] The cervix is dilated to 7 mm with Pratt dilators and then a 7-mm rigid curved vacurette is used with a hand-held 60-ml syringe as vacuum source (Mylex, Chicago). An intracervical block of 20 ml 0.5 percent lidocaine with 2 units of vasopressin and conscious sedation with midazolam and nalbuphine intravenously are used for analgesia. A series of 1,530 patients were treated prior to 6 weeks from last menstrual period after preoperative ultrasound and with careful examination of the aborted tissue and follow-up with serial -human chorionic gonadotropin (-hCG) titers to ensure diagnosis of ectopic pregnancy. No serious complications occurred and nine unsuspected ectopic pregnancies were diagnosed and treated.

Technique for Standard Vacuum Curettage

Standard vacuum curettage applies essentially the same technique as manual vacuum, but uses larger cannulas, from 7 to 12 mm, with an electric vacuum pump. After establishing a paracervical block as above, the operator dilates the cervical canal, using serial insertion of tapered rods that increase progressively in size. We favor the Denniston dilators pictured in Figure 19-18 for their blunt tips, gentle taper, and semirigid "fee." Dilatation is continued to a diameter 1 mm less than the estimated length of gestation in menstrual weeks and then a vacuum cannula of that same outside diameter is inserted. After aspiration is complete, we gently insert a sharp curette and use it as a finger to gently explore the cavity and prove it empty. Finally, the suction cannula is reintroduced for a final few seconds to remove any additional tissue remaining. Finally, the operator must perform a careful fresh examination of the aspirated tissue. An instrument kit sufficient for all first-trimester procedures is pictured in Figure 19-19.

Pain Control for First-Trimester Abortion

Most first-trimester abortions are performed out of hospital, without a major anesthetic. This practice has contributed to the remarkable safety record of U.S. abortion services. Local anesthetic is injected around or into the cervix to produce paracervical block. There is residual pain in spite of this. Pain is increased for women who exhibit preprocedure anxiety, for the youngest women, and for procedures done prior to 8 weeks or at the end of the first trimester. ^[172] Premedication with naproxen ^[173] or ibuprofen ^[174] is helpful. Lidocaine, chlorprocaine, and bupivacaine are equally effective for paracervical anesthesia. Lidocaine is most widely used and

627

Figure 19-16a Early vacuum curettage abortion. *A*, Examining the patient. *B*, Administering paracervical block and superficial injection into the cervix at 12 o'clock to anesthetize tenaculum site. *C*, Completing paracervical block and injecting local anesthetic superficially, just under the vaginal mucosa, at the lateral margins of the cervix, 4 and 8 o'clock.

is least expensive. Buffering the lidocaine solution by adding 2 ml of 8.4 percent sodium bicarbonate to 18 ml of 1 percent lidocaine reduces the pain of injection. ^[174] Where the local anesthetic is injected is more important than what is injected. Glick described a combination superficial and deep injection technique at multiple sites around the cervix. ^[175] Wiebe demonstrated the superior pain relief of injections deep into the cervical stroma as compared with superficial submucosal injection. ^[176] We use a modification of Glick's technique. The cervix is infiltrated superficially at 12 o'clock with 2 to 3 ml of the anesthetic solution. The needle is then advanced through the anesthetized area for 3 cm to reach the junction of cervix and lower uterine segment, where an additional 3 ml are injected. The tenaculum is placed in the anesthetized area and used to steady the cervix for placement of an additional anesthetic at 4 and 8 o'clock, again injecting first superficially, and then advancing the needle 3 cm into the cervical stroma for the deep injection ^[177] (Fig. 19-20). Aspiration is performed prior to each injection to prevent intravascular injection. To avoid systemic toxicity, the initial dose of lidocaine should not exceed 200 mg for the average weight patient (20 ml of 1 percent solution). Vasopressin, 2 units, is added to each 10 ml of lidocaine to reduce blood loss during the procedure.

Conscious Sedation

Conscious sedation is the use of drugs to reduce pain while maintaining consciousness, protective airway reflexes, and the ability to respond to commands. We use midazolam 2 mg intravenously, then 0.050 mg of fentanyl, a short-acting narcotic, given intravenously and repeated in a few minutes as needed. Respiratory depression occurs with both drugs at higher doses, ^[178] and we routinely use a pulse oximeter for monitoring. If oxygen saturation falls, it is usually only necessary to

628

Figure 19-16b *D*, Dilatation, using a 4-mm Karman cannula. This will be followed by the 5-mm Karman and then the 6-mm cannula. Alternatively, the Denniston dilators 4, 5, and 6 can be used (*inset*). *E*, Insertion of the 6-mm Karman cannula, as far as the top of the cavity (*inset*). *F*, Preparing the syringe by closing the pinch valve.

tell the patient to take a deep breath. Occasionally, supplemental oxygen is briefly required. Patients who receive intravenous sedation must be under constant observation until fully recovered.

Cervical Dilatation

Forcible dilatation with tapered rods is the standard. We place a single tooth tenaculum vertically with one branch inside the cervical canal to provide traction near the internal os, the region of greatest resistance. Traction straightens the angle between cervix and uterus, helping to avoid perforation (Fig. 19-21). Then dilators are inserted slowly and carefully. The dilator tip must negotiate a curve where cervix and uterus join, and to guide the dilator properly with an anteфлекed uterus, the operator's hand must follow a downward curve (Fig. 19-22). The direction is reversed if the uterus is retroverted. If the cervical os is very small, use the small, semirigid plastic os finder instrument (Cheshire Medical Specialties, Inc., Branford, CT) or misoprostol treatment as described below.

Osmotic Dilators

Osmotic dilators reduce the risk of perforation, although they do not completely prevent it. A fivefold reduction in cervical lacerations ^[179] and in uterine perforations was seen when laminaria were used instead of forcible dilatation in a large national study. ^[180] Use of laminaria has not been associated with increased risk for infection. ^[181]

Laminaria is a genus of seaweed. The stems are inserted into the cervical canal as small dry sticks. They take up water and swell, exerting gentle pressure (Fig. 19-23). Over several hours, this produces softening of the cervix and considerable dilatation. If the laminaria are left in place overnight, additional forcible dilatation will not be needed. Medical laminaria are either of two species: *L. japonicum* and *L. digitatum*. *L. japonicum* tents are preferred, as they retain their integrity when wet. The main drawbacks of laminaria are the need for insertion by a skilled practitioner and the requirement of several hours for dilatation to be accomplished. Hypan, ^[182] a plastic dilator, achieved greater cervical dilatation than laminaria among primigravid women.

629

Figure 19-16c *G*, Evacuating the syringe, with side arms on the plunger assembly locking it in the withdrawn position, maintaining vacuum. *H*, Uterine evacuation through the Karman cannula into the syringe. *I*, The cannula is rotated and is slid in and out of the cavity in a pistonlike fashion. Care must be taken to rotate only on the out stroke, when the cannula tip is withdrawn away from the top of the uterus. Rotation when the cannula is pressed against the top of the fundus may cause the tip of the cannula to break off inside the uterine cavity.

Prostaglandin for Dilatation

Until recently, vomiting, diarrhea, and pain limited the usefulness of prostaglandins for preoperative cervical dilation. ^[183] Misoprostol, the 15-methyl analogue of prostaglandin E₁ (PGE₁), produces effective dilatation with few side effects and low cost. Vaginal misoprostol, 400 g given 3 hours prior to surgery, produces adequate dilation for first-trimester procedures, with few side effects. ^[183] Misoprostol (Cytotec) is sold in the United States for the indication of prevention of ulcers of the stomach and duodenum. It is stable at room temperature, unlike the other prostaglandins which must be refrigerated.

Rh Prophylaxis

Risk of Rh sensitization is said to be 2 percent after spontaneous abortion and 4 to 5 percent after induced abortion. ^[184] All Rh-negative women are given 50 g of

630

Figure 19-16d *J*, When no further tissue comes through the cannula, it is withdrawn; using a sterile glove, the tip is cleared. *K*, Repeat aspiration. After clearing the tip, the cannula is reinserted, the

syringe emptied (*inset*) and reevacuated, and vacuum established for a final check to ensure that the uterus is empty. Omission of this step results in incomplete abortion. *L*, Preparing the tissue for examination. The tissue is emptied into a tea strainer and washed with saline. *M*, Fresh examination. The tissue is floated in saline in a clear plastic dish over a light source. The gestational sac must be identified.

Rh immune globulin within 72 hours of induced or spontaneous first-trimester abortion. Whether this is necessary for the earliest procedures has not been determined. Patients in the midtrimester, 13 weeks or more, are routinely given a full dose, 300 g. If administration of Rh immune globulin is accidentally omitted, it should still be given, even as late as 2 weeks after the procedure, because partial protection will still be provided.

Medical Means for First-Trimester Abortion

Historically, women have eaten a variety of plant substances in attempts to produce abortion.^[155] The prostaglandins were the first modern means for pharmacologic induction of abortion.^[189] Misoprostol, the analog of PGE₁, has many fewer side effects than other prostaglandins, and as described below, is an effective abortifacient when combined with mifepristone or methotrexate.

Mifepristone (RU-486)

Mifepristone, an analog of the progestin norethindrone, has strong affinity for the progesterone receptor, but acts as an antagonist, blocking the effect of natural progesterone.^[186] Addition of a low dose of prostaglandin improves efficacy.^[187] The standard protocol is as follows: women with amenorrhea of less than 50 days and pregnancy confirmed by serum -hCG or ultrasonography receive an oral dose of 600 mg of mifepristone on day 1. On day 3, the patient returns for the prostaglandin: sulprostone (a PGE₂ analog), gemeprost (a PGE₁ analog), or misoprostol. Rh-negative patients receive Rh immune globulin. Patients remain in the clinic for 4 hours, during which expulsion of the pregnancy often occurs. They return 8 to 15 days later for measurement of -hCG or ultrasonography.^[188] ^[189] ^[190] If treatment fails or if the patient bleeds excessively, vacuum curettage is performed. In a series of almost 17,000 cases, 600 mg of mifepristone orally followed in 36 to 48 hours by either sulprostone or gemeprost produced complete abortion in 95 percent of cases.^[188] ^[189] About 2 percent abort incompletely and will require curettage; 1 percent require urgent curettage for bleeding, and about 1 percent do not respond at all and will require vacuum curettage. Three myocardial infarctions and one death have occurred with mifepristone/prostaglandin of a total of 60,000 women treated.^[190] The myocardial infarctions were attributed to coronary artery spasm from sulprostone in women over age 35

Figure 19-21 Effect of proper tenaculum placement in straightening the angle between the cervix and uterus by traction.

who were smokers. Age greater than 35 and smoking or history of cardiovascular disease are now considered contraindications to mifepristone/sulprostone for abortion. No myocardial infarctions have occurred with the PGE₁ analogues gemeprost and misoprostol. The mifepristone/misoprostol

combination is highly effective.^[191],^[192] Mifepristone has been used by more than 3 million women in Europe and China. For additional details of management, see Creinin and Aubeny's summary.^[193] Mifepristone can also be used to trigger cervical softening and dilatation before surgical abortion.^[194]

Methotrexate and Misoprostol

The antifolate methotrexate provides another medical approach to pregnancy termination. Widely used to treat ectopic pregnancies without surgery,^[195] it can also be used with intrauterine gestations. Creinin and Darney proved that methotrexate, 50 mg/m² intramuscularly followed by vaginal misoprostol 800 g, effectively terminated early intrauterine pregnancies.^[196] In a subsequent study, 300 women received methotrexate at or before 56 days of gestation, followed 7 days later with vaginal misoprostol.^[197] Misoprostol was repeated at 24 hours if the patient had not aborted. Fifty-three percent aborted after the first dose of misoprostol, an additional 15 percent after the second dose, and a total of 92 percent aborted by 35 days. The methotrexate/misoprostol regimen takes longer than mifepristone/misoprostol, but the regimen is inexpensive and already available in the United States.

Selective Termination of Anomalous Twins and Reduction of Multifetal Pregnancies

Multifetal pregnancies are likely to lead to extreme prematurity with resultant perinatal loss or serious neonatal handicap. Reduction of multifetal pregnancies in the first trimester and selective termination of second-trimester anomalous twins have become standard practices in many centers.^[198]^[199]^[200]^[201]^[202] The most effective technique is transabdominal intracardiac instillation of potassium chloride (see Chapter 24). A 22-gauge spinal needle is advanced through the maternal abdominal and uterine walls toward the fetal cardiac echo under guidance with high-resolution ultrasound. In the first trimester, 0.2 to 0.4 ml of a 2-mmol solution of potassium chloride (KCl) is injected at a time until cardiac asystole is seen. The amount required is 0.2 to 1.8 ml.^[199] Observation is continued for 2 minutes, and the needle is then redirected into another gestational sac. In the second trimester, 0.5 ml is injected at a time, and 0.5 to 3 ml will be needed. Cardiac activity resumed 30 minutes later in 2 of 42 first-trimester cases and one of four second-trimester cases in Wapner's series and were successfully reinjected the same day.^[199] Evans and colleagues described 463 pregnancies with multifetal gestation treated at nine centers in four countries.^[200] There were no failed procedures. The rate of pregnancy loss was 3.9 percent at 2 weeks or less after procedure, and 4.6 percent at 4 weeks or less. A total of 16.2 percent were lost before 24 weeks of gestation. Eighty-three percent of the pregnancies delivered at 33 weeks or later, and there was no evident damage to any surviving fetus. Gestational age at delivery was principally determined by the number of fetuses remaining. Multifetal pregnancies are usually reduced to two gestations, since the morbidity of diamniotic twins is acceptable. Selective reduction improves outcome for triplet pregnancies as well. In a comparative study, Lipitz and colleagues found that reduction of triplets to twins decreased rates of prematurity, low birth weight, very low birth weight, neonatal morbidity, neonatal mortality, and pregnancy complications.^[201]

Selective termination is also performed for one anomalous fetus of a multifetal gestation. The procedure was first reported in 1978.^[202] Evans' group described 183 completed cases of selective termination for fetal anomalies.^[203] One hundred sixty-nine were twins, 11 were triplets, and 3 were quadruplets. Termination of the

affected fetus was successful in all cases. Injection of KCl was a safer means for termination than air embolization, producing an 8.3 percent rate of loss as compared with a 41.7 percent rate of loss. Twelve percent of the pregnancies subsequently miscarried before 24 weeks, and 83 percent of viable pregnancies delivered after 33 weeks. The most recent report from this group describes a total of 402 patients treated with intracardiac or intrafunic KCl. Three hundred forty-five were twin gestations, 39 were triplets, and 18 were quadruplets or greater. All were believed to be dizygotic. There were no procedural failures. Rates of pregnancy loss after procedure by gestational age at the time of procedure were 5.4 percent at 9 to 12 weeks, 8.7 percent at 13 to 18 weeks, 6.8 percent from 19 to 24 weeks, and 9.1 percent for procedures performed at 25 weeks or more. No maternal coagulopathy occurred and no ischemic damage or coagulopathies were seen in the surviving neonates. In one case at the beginning of the series, the wrong fetus was terminated in a trisomy 21 pregnancy. When there is no distinct morphologic abnormality detectable by ultrasound at the time of procedure, a direct determination of karyotype is advised.^[204]

Selective reduction should not be tried with monoamniotic twins, or for twintwin transfusion syndrome, as embolization or exsanguination through the shared circulation to the remaining twin is likely. Maternal serum -fetoprotein remains elevated into the second trimester after first-trimester procedures.^[53]

First-Trimester Abortion Complications and their Prevention

For a more detailed description of the management of postabortal complications, the reader is referred to Pearlman and Tintinalli's text.^[205]

Complications of Local Anesthesia

Intravascular injection or an overdose of the medication can produce a severe systemic response: convulsions, cardiorespiratory arrest, and death.^[205] Management requires endotracheal intubation and support of respiration plus anticonvulsive therapy. Care must be taken to aspirate before injecting each dose of the local anesthetic to guard against intravascular injection. Epinephrine-containing solutions should not be used for paracervical block. Fatal anaphylaxis from allergy to the metabisulfite preservative in epinephrine solutions can occur in asthmatic patients.^[206]

Cervical Shock

Vasovagal syncope produced by stimulation of the cervical canal can be seen even after paracervical block. Although brief tonic-clonic activity is observed, this is distinguished from a true seizure by the presence of a very slow pulse, the patient's rapid recovery, and the absence of any postictal state. Routine use of low-dose vasopressin mixed with the paracervical anesthetic prevents "cervical shock."

Cervical Lacerations

Minor lacerations are common during forcible dilatation when the cervical tenaculum pulls off, but more serious injury can also be inflicted with actual full-thickness tearing of the cervical wall. A superficial laceration that is bleeding minimally may not need to be sutured if bleeding stops with pressure. If bleeding persists in spite of pressure or the tear is full thickness, then it should be sutured. A long laceration extending through the internal os may well be a partial or complete perforation, and if lateral, may involve the descending branch of the uterine artery. Cervical lacerations are prevented by use of gently tapered dilators and by use of osmotic dilators.

Perforation

Perforation may cause injury to major blood vessels, bowel, or bladder and endanger the patient's life. In a study of U.S. national data from 67,175 abortions, the rate of perforation was 0.9 per 1,000.^[207] Laminaria use reduced the risk of perforation to less than one in five, and performance by a resident as opposed to an attending physician was associated with a fivefold increase in risk.^[69] Each 2-week increase in gestational age was associated with a 1.4-fold increase in risk of perforation. A much lower rate of perforation (1 in 10,625) in a series of 170,000 abortions was accomplished without laminaria, by a small group of very experienced clinicians with predominantly first-trimester procedures.^[208]

Management of Perforation

Suspected perforation can often be confirmed by inserting a sterile blunt instrument through the cervix into the suspect area with ultrasound guidance. The best management of perforation is immediate laparoscopy to determine the extent of the injury and complete the abortion under laparoscopic guidance.^[209] Perforations of

the cervix, either at the junction of the cervix and lower uterine segment, or lower down the canal, produce two different clinical syndromes, depending on the precise anatomic location of the perforation (Fig. 19-24).^[210] Perforations at the junction of the cervix and lower uterine segment can lacerate the ascending branch of the uterine artery within the broad ligament, giving rise to severe pain, a broad ligament hematoma, and intra-abdominal bleeding. These perforations are

635

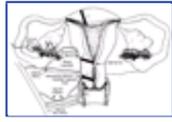

Figure 19-24 Possible sites of uterine perforation at abortion. 1, Low cervical perforation with laceration of descending branches of uterine artery; 2, perforation at junction of cervix and lower uterine segment with laceration of ascending branch of uterine artery; 3, fundal perforation. (Redrawn from Berek JS, Stubblefield PG: *Anatomical and clinical correlations of uterine perforations. Am J Obstet Gynecol* 135:181, 1979.)

usually recognized at the time. They are managed by laparoscopy to confirm the injury, and then by laparotomy to ligate the severed vessels and repair the uterine injury. Hysterectomy should not be required for injury in this location. Low cervical perforations, on the other hand, may injure the descending branch of the uterine artery within the dense collagenous substance of the cardinal ligaments. In this case, there is no intra-abdominal bleeding; the bleeding is only outwards, through the cervical canal, and may subside temporarily as the artery goes into spasm. Deaths have occurred when a low cervical perforation was not appreciated and the patient bled again later. If low cervical perforation is suspected, bleeding can be controlled by inflating the balloon of a Foley catheter in the cervical canal while the patient is transferred for x-ray arteriography with selective embolization of the injured vessel. Otherwise, hysterectomy may be needed.

Bowel Injury

If perforation is not recognized, the bowel may be grasped with the vacuum cannula or forceps and lacerated or stripped off its mesentery. A suspected bowel injury must be completely visualized. An experienced operator may accomplish this at laparoscopy, but laparotomy is indicated if the site of injury cannot be completely visualized. Small areas of injury can be managed by oversewing the lesion, irrigating thoroughly, and leaving a large intra-abdominal drain. Full-thickness injury or stripping of the mesentery will require segmental resection and anastomosis. High-dose antibiotics are given prophylactically. Larger injuries to the colon will require diverting colostomy after anastomosis.

Bladder Injury

The evaluation of a major perforation includes catheterization of the bladder to look for gross hematuria, a sign of bladder laceration. The injury is confirmed at laparoscopy, but laparotomy is required for management. Injuries to the dome are closed in two layers with catheter drainage for 7 days. Injuries to the trigone must not be repaired directly, but require an ample cystotomy incision in the dome for good visualization

636

of the injury, catheterization of the ureters, and then closure in two layers. The best possible operative consultation with an experienced surgical specialist is advised for management of these more extensive injuries. Inadequate initial management of major injury adds markedly to the patient's problems and may jeopardize survival.

Hemorrhage

Excessive bleeding during vacuum curettage may indicate uterine atony, uterine trauma, cervical pregnancy, or a pregnancy of more advanced gestational age than anticipated. Bleeding from atony is common with general anesthesia using halothane or enflurane. Management requires a rapid reassessment of gestational age by examination of the fetal parts already extracted, and gentle exploration of the uterine cavity with curette or forceps to confirm that there is no perforation. Intravenous oxytocin is administered and the abortion completed. The uterus is then massaged between two hands to ensure contraction. Intracervical administration of 10 units of vasopressin diluted to 10 ml helps to reduce bleeding and produce a strong uterine contraction. Misoprostol, 800 g given rectally, is an important adjunct. When these measures fail, adequate fluid resuscitation is begun and the patient is transferred immediately to the hospital. Insertion of a Foley urinary catheter into the uterine cavity and inflating the 30-ml balloon may be an effective temporizing measure. Persistent postabortal bleeding suggests retained tissue or clot (hematometra), cervical or uterine laceration or perforation, uterine atony, or (rarely in the first trimester) disseminated intravascular coagulopathy (DIC). If bleeding persists, tests are drawn to rule out DIC and the patient is prepared for laparoscopy. Cervical pregnancy and low cervical perforation described above are best managed with arteriography and selective embolization of the bleeding vessels.^[211]

Postabortal Syndrome (Hematometra)

This syndrome is a type of uterine atony.^[212] In the classic presentation, the patient begins to complain of increasing lower abdominal pain a half hour or so after abortion and may develop tachycardia and diaphoresis. On exam, the uterus is large, globular, and tense, and could be mistaken for a broad ligament hematoma except that the mass is midline and arises from the cervix. The treatment is immediate reevacuation. The uterus will then contract to its normal postabortal size. Sands, Burnhill, and colleagues reported that pretreatment with ergot, 0.1 mg intramuscularly, reduces the incidence of this phenomenon.^[212]

Failed Abortion, Continued Pregnancy, and Ectopic Pregnancy

Failure to interrupt the pregnancy is more often a problem with very early abortions. Pregnancy may continue in spite of the aspiration of histologically proven chorionic villi. The problem is prevented by insistence on identification of the gestational sac in the fresh exam of the aborted tissue.^[213] When no chorionic villi are found in the fresh exam, ectopic pregnancy is a risk. Death from ectopic pregnancy is five times more likely when it is associated with attempted abortion than when it is not, presumably because the history of apparent induced abortion delays diagnosis.^[214] Various plans of management to reduce risk from ectopic pregnancy have been proposed.^[17] Evaluation with quantitative -hCG levels and vaginal probe ultrasound are essentials. Women with unruptured ectopics 3.5 cm or less in diameter can be treated with methotrexate, 50 mg/m² intramuscularly.^[195] Patients with larger ectopics or peritoneal signs indicating rupture are offered immediate laparoscopy.

Postabortal Triad

The most common postabortal problem is the triad of pain, bleeding, and low-grade fever. Although these symptoms may be managed successfully by oral antibiotics and ergot preparations, the great majority of cases will exhibit some retained gestational tissue or clot in the uterine cavity. The best management is repeat uterine evacuation, performed under local anesthesia in the ambulatory setting. Results obtained in 54 consecutive reaspirations performed for these symptoms are displayed in Table 19-10.

Incomplete Abortion

Retained tissue will produce increased postabortal bleeding and places the patient at risk for infection. Management

is by repeat curettage. If the uterus is larger than 12 weeks, it is wise to obtain a preoperative ultrasound to determine the amount of tissue remaining. Where fever is present, a cervical Gram's stain and appropriate cultures are taken; then, high-dose intravenous antibiotic therapy is initiated and the curettage is performed shortly thereafter. There should be no delay in evacuating the uterus. Women have gone into septic shock in spite of antibiotic therapy while awaiting curettage. [215]

Endometritis, myometritis, and pelvic peritonitis can be seen without any retained tissue. This is probably most likely in patients with preexisting cervical colonization with gonorrhea, chlamydia, or mycoplasma. A small, firm uterus on pelvic exam suggests that the uterus is empty and the curettage will not be needed. Where there is a question as to retained tissue, ultrasound is useful in making the decision whether to perform curettage or to treat with antibiotics alone.

Management of Septic Abortion

Delay in initiating adequate therapy may result in preventable death. We review management in the box, "Management of Septic Abortion." [215] Clostridial sepsis, not uncommon as a complication of illegal abortion, is occasionally seen as a complication of legal abortion. This should be suspected from the presence of large gram-positive rods on Gram's stain of the cervical secretions or curetted tissue, when tachycardia seems out of proportion to the fever, and especially when hematuria and shock develop rapidly. These patients can rapidly develop a severe adult respiratory distress syndrome. Initial treatment requires high-dose penicillin, vacuum aspiration of the uterus, and fluid management. A superficial clostridial infection will respond to these measures, but if hemolysis is present, indicating systemic release of clostridial toxins, prompt hysterectomy will be probably necessary if the patient is to survive. [215] [216] [217] Hyperbaric oxygenation may play a role in addition to effective surgical and medical management of clostridial sepsis. [218]

Choice of Antibiotics for Postabortal Infection

A number of different species of bacteria, chlamydia, and mycoplasma have been implicated in postabortal sepsis. No one agent or even pair of agents is effective against all possible organisms. When the patient is seriously ill, we have used three drugs: ampicillin (2 to 3 g intravenously every 6 hours), clindamycin (900 mg intravenously every 8 hours), and gentamicin (loading dose of 2 mg/kg of body weight, followed by 1.5 mg/kg every 8 hours, depending on the blood level and renal status). [215] Once-a-day dosing is recommended currently for gentamicin, as it increases efficacy and decreases toxicity and cost.

Prophylactic Antibiotics

The use of perioperative doxycycline with induced abortion is advisable. [219] [220] [221] [222] [223] The major determinant of postabortal infection is previous chlamydia colonization of the cervix. Both chlamydia-positive and chlamydia-negative

patients have almost 10-fold reduction in risk of postabortal pelvic inflammation if they receive perioperative oral doxycycline (Table 19-11). [223]

Management of Septic Abortion

1. Be suspicious when a woman of childbearing age presents with unexplained fever, vaginal bleeding, and a history of amenorrhea
2. Make the diagnosis with a sensitive pregnancy test and pelvic examination
3. Eradicate the infection

Obtain cultures by endometrial biopsy or uterine evacuation

Start high-dose, broad-spectrum antibiotics

4. Empty the uterus

First trimester: vacuum curettage under local anesthesia with conscious sedation

Midtrimester: D&E, with ultrasound guidance or prostaglandin induction (carboprost 250 g IM q2h or misoprostol 200 g vaginally q12h) or high dose oxytocin regimen

5. Laparotomy if no response to uterine evacuation and adequate medical therapy, or perforation with suspected bowel injury, pelvic abscess, or clostridial myometritis. Hysterectomy, bilateral salpingoophorectomy for severe myometritis. Copious irrigation of abdominal cavity, drainage, closure with Smead-Jones or similar stay sutures, delayed primary closure
6. Supportive care

Severe sepsis and septic shock require intensive care unit management

Provide cardiovascular support to restore close to normal blood pressure. Monitor with arterial line, balloon-flotation right heart catheter. Fluid resuscitation plus dopamine and dobutamine as needed if pulmonary wedge pressure becomes elevated before target mean arterial pressure is reached.

Manage adult respiratory distress syndrome. Monitor tissue oxygenation and begin ventilation if oxygen saturation falls below 90 percent or if pulmonary compliance begins to decrease

Second-Trimester Abortion

D&E is the most commonly used method through 20 menstrual weeks in the United States, with labor induction methods favored only for those procedures performed after 20 weeks.^[148] The abandonment of older labor induction methods in favor of D&E was strongly stimulated by Centers for Disease Control publications documenting the greater safety of early midtrimester D&E over other methods of the time.^[223]

Dilatation and Evacuation in the Midtrimester

The variety of techniques that have been used for D&E are summarized elsewhere.^[224]^[225]^[226] These differ primarily in the preparatory steps that precede the evacuation, whether one stage, with forcible dilation and followed by forceps evacuation of the fetus; two stage, with initial dilation of the cervix using laminaria tents, followed by instrumental evacuation; or multistage, with several sets of laminaria over 40 to 48 hours.

Choice of technique becomes more important as gestational age advances. Preoperative ultrasound is routine prior to midtrimester abortion. Pregnancies at 13 to 14 menstrual weeks are readily evacuated using the 12-mm vacuum cannula.^[227] Dilatation of this amount is usually readily accomplished with Pratt's or Deniston's dilators. We advise the routine use of laminaria tents after 13 weeks. The actual evacuation of the uterine content is usually accomplished with long, heavy forceps, whereas the vacuum curette is used as an adjunct, to rupture the fetal membranes and drain amniotic fluid, and then to ensure evacuation is complete at the end of the procedure. The 16-mm vacuum system (Rocket of London, Branford, CT) allows standard vacuum curettage to be performed through 16 menstrual weeks.

Anesthesia for D&E

With good psychological support from trained counselors, midtrimester D&E can be performed under paracervical block with conscious sedation. The necessary psychological support may be difficult to provide in the operating rooms of a busy general hospital, oriented toward major anesthetics. In a multicenter study, general anesthesia increased the risk for cervical laceration and hemorrhage with D&E.^[228] On the other hand, large series have been reported with very low rates of uterine injury with general anesthesia.^[229]^[230] When general anesthesia is used, it is all the more critical to have adequate preparation of the cervix with osmotic dilators. When general anesthesia is used, full compliance with current standards for monitoring tissue oxygen levels, end-expiratory CO₂, and frequent vital signs is mandatory.^[231] When these procedures will take place out of hospital, more stringent patient selection is required. Combinations of short-acting intravenous barbiturates and inhaled nitrous oxide/oxygen mixtures or intravenous propofol combined with small doses of short-acting intravenous narcotic agents with inhaled air/oxygen mixtures are preferred regimens. Potent inhalant agents are avoided altogether, or used in very low concentrations to avoid uterine relaxation. Close observation during recovery is essential. Use of intravenous sedation or general anesthesia requires personnel trained in cardiorespiratory support.

An Approach to D&E

Most patients perceive the procedure as relatively minor, especially as compared with the alternatives of labor or major surgery.^[229] When all goes well, as it usually does, the procedure takes only 10 to 20 minutes, the patient recovers for an hour or two, and goes home. Yet, the potential for sudden, life-threatening complications is always there: perforation and intestinal or bladder injury, amniotic fluid embolism, and DIC. The D&E procedure must be approached with caution and gentleness in the handling of instruments, and the patient must know that serious injury is possible, although not likely.

We describe our own technique in hopes this will help others to prevent complications. For a more detailed description, the reader is referred to Hern's excellent monograph,^[226] and to Haskell, Easterling, and Lichtenberg.^[232] After adequate counseling, complete menstrual and medical history, and physical examination with attention to uterine size and ultrasound dating

history, osmotic dilators are inserted into the cervical canal and held in place with two 4 X 4-inch gauze sponges tucked into the fornices. At menstrual ages 13 to 15 weeks, two laminaria tents will suffice; at 16 to 20 weeks we insert four or more tents, and use 8 to 10 tents after 20 weeks. Paracervical anesthesia is produced with 10 ml of 1 percent lidocaine for the insertion. The patient is kept lying down for a few minutes after insertion to avoid syncope and then goes home. For gestations of 13 to 20 menstrual weeks, the abortion procedure will be performed the following day. At menstrual ages 20 weeks and beyond, the laminaria may be left in place for 48 hours. The additional dilatation greatly facilitates the procedure (P. D. Darney, MD, personal communication). A narcotic analgesic is prescribed, as approximately half of patients will experience significant cramping during laminaria dilatation. Doxycycline is given routinely, 100 mg after the insertion, an additional 100 mg with food before sleep and then 100 mg twice a day after the procedure for 2 days. Occasionally, the fetal membranes rupture a few hours after laminaria insertion. The laminaria are left in place and the abortion performed as scheduled the following day. Ultrasound guidance during the surgery is helpful for the more advanced cases and has been found to reduce the risk of perforation for new operators. ^[233]

Uterine evacuation is performed as follows. An intravenous line is established and the anesthetic of choice is begun. The patient is placed in lithotomy position, avoiding the Trendelenburg or head-down position, which might increase negative pressure in the uterine veins and increase risk for embolic phenomena. The previously placed vaginal sponges and laminaria are removed. Occasionally, especially in the young, primigravid patient at 13 to 15 weeks, the cervix is quite resistant to dilatation and the laminaria tents may be entrapped. This is more often a problem when a single large laminaria or Dilapan has been used, and is obviated by using two or more tents. If the laminaria cannot be removed with gentle traction, it is best to stop and wait 6 hours for additional cervical softening to occur. Next, the vagina and cervix are cleansed with povidone-iodide and paracervical block established with 20 ml of lidocaine 1 percent with 10 units of vasopressin injected deeply into the cervix at the 12-, 4-, and 8-o'clock positions. ^[234] If general anesthesia is used, the Xylocaine is omitted, and the vasopressin is diluted in 10 ml of saline and injected into the cervix as above. Two single-toothed tenaculi are placed vertically, each with one branch inside the cervical canal. Intravenous infusion of oxytocin, 40 units/1,000 ml, is begun at 150 to 200 ml/h. A large dilator is gently inserted to confirm dilatation. The vacuum cannula is then inserted and vacuum established briefly to rupture membranes

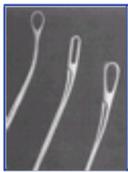

Figure 19-25 Instruments for D&E. Kelly placental forceps, Sopher forceps, and Bierer forceps (left to right).

and drain amniotic fluid. The cannula is then removed and replaced with an ovum forceps of appropriate size: Forester forceps for 13 to 15-week procedures; and Bierer, Sopher, or Kelly placental forceps for more advanced procedures ([Fig. 19-25](#)). The forceps are manipulated within the lower uterine segment to remove the pregnancy tissue. The vacuum cannula is reinserted as needed to pull tissue downward, where it can be grasped with the forceps. When the procedure feels complete, a large sharp curette is inserted and used to explore the cavity. If any additional tissue is encountered, the forceps or cannula is reinserted to remove it. After the procedure, the operator carefully examines the fetal parts to be sure all have been evacuated. On occasion, the fetal calvarium is retained in the uterus. If gentle attempts at extraction fail, operative ultrasound is used. If ultrasound is not available, it is best to stop, administer an oxytocin infusion for 2 hours, and then try again. By then, the remaining fetal parts will have been pushed down to the internal os, where they can be easily extracted.

Attempting evacuation of a pregnancy of gestational age beyond the operator's skill and experience poses serious risk. The chance that this will occur is reduced by routine use of preoperative ultrasound. However, if the procedure has begun, the operator can tell gestational age by the size of the fetal parts ([Table 19-12](#)). Where multiple laminaria tents have been used and the

cervix is widely dilated, a surgeon familiar with D&E can satisfactorily extract a pregnancy up to 20 or 21 weeks. Beyond this, we feel the procedure should be abandoned unless the surgeon routinely performs these more advanced procedures. The patient can be treated instead with high-dose intravenous oxytocin or systemic prostaglandins (see below). Perforation with midtrimester D&E is more likely to result in major visceral injury than is perforation in first-trimester procedures and will usually require a laparotomy.

Facilitating D&E

Modifications of technique are often used to facilitate D&E in the late midtrimester. Wright inserts multiple laminaria tents into the cervix, and injects 1.5 mg digoxin into the fetal heart to produce fetal death. The D&E is carried out under brief general anesthesia the following day. Oxytocin is administered as 50 to 100 units/1,000 ml during the procedure. In his series of 2,400 cases at 19 to 23 weeks, there were no perforations. ^[230] Hern described a personal series of gestations with anomalies at 15 to 34 weeks managed as outpatients with a similar technique. ^[235] After multistage laminaria treatment and ultrasound-guided intrafetal injection of 1.5 to 2.0 mg digoxin, membranes are ruptured on day 3, intravenous oxytocin (167 mU/min) is started, and assisted delivery is performed after a few hours.

Intact D&E

This variation of D&E is typically used at 20 to 24 weeks. Paracervical block is placed, the cervix is dilated to 9 to 11 mm with Pratt dilators and then several laminaria or Dilapan dilators are inserted. The next day, the original osmotic dilators are removed, and 15 to 25 Dilapan dilators are inserted into the cervical canal. On the third day, uterine evacuation is performed. Ultrasound is used to determine fetal position and presentation. In the variation described by Haskell, the membranes are ruptured and a large grasping forceps such as a Hern or Bierer forceps are inserted through the dilated cervix and a fetal foot is grasped and pulled downward,

converting the presentation to breech.^[232] The surgeon manually delivers the second lower extremity into the vagina, then the torso, and then the upper extremities, rotating the fetus so the dorsum remains up. The calvarium remains at the internal cervical os. Next, traction is applied to the shoulders of the fetus with the surgeon's fingers while elevating the cervical lip with one finger, and a scissors is advanced into the base of the fetal skull. A suction catheter is introduced and the central nervous system aspirated. With the calvarium thus decompressed, the fetus is delivered intact. McMahon described a similar procedure, with dilatation followed by laminaria placement twice a day for 2 days or more, followed by rupture of the membranes, administration of 250 mg of carboprost, and then 20 minutes later, fetal evacuation, as described above if the fetus is breech or transverse. If the fetus is in vertex presentation, the calvarium is allowed to descend into the cervical canal by uterine contractions and then decompressed by insertion of a trocar and aspiration of the cerebrospinal fluid and central nervous system followed by forceps extraction of the collapsed calvarium and intact fetus.^[236]

Labor Induction Methods

Hypertonic Saline

Amnioinfusion of hypertonic saline is historically important as one of the oldest of the labor induction methods for abortion. There are serious hazards unique to hypertonic saline: cardiovascular collapse, pulmonary and cerebral edema, and renal failure occur if the solution is injected intravenously, and all patients are at risk for DIC. Hypertonic saline produces mean times from instillation to abortion of 33 to 35 hours.^[237],^[238] Augmentation with high doses of intravenous oxytocin reduces instillation to abortion time, and results in fewer failed abortions, fewer retained placentas, less blood loss, and less risk of infection. Unfortunately, the addition of oxytocin increases the rate of occurrence of DIC and adds risk for water intoxication, uterine rupture, and annular detachment of the cervix.^[237] When saline is used as a primary method, 200 ml of a 20 percent solution is administered. In current practice, much lower doses are used to augment prostaglandin

641

abortion, and the amnioinfusion is performed under ultrasound guidance.

Hypertonic Urea

Hypertonic urea is attractive as an alternative to saline because of its greater safety, but the interval from injection to abortion is prolonged. In a series of papers, a group from Johns Hopkins explored this method, augmenting it at first with intravenous oxytocin, and subsequently with low doses of prostaglandin F₂. The combination of 5 mg of PGF₂ and 80 g of urea instilled into the amniotic sac produces abortion in a mean time of 17.5 hours, with 80 percent of the patients aborting within 24 hours.^[239] Fetal survival appears to be very rare with abortion by this method. In a comparative study, urea-prostaglandin produced shorter times from instillation to abortion and fewer serious complications than hypertonic saline.^[240]

Prostaglandins

Prostaglandins, oxygenated metabolites of C₂₀ carboxylic acid, are found naturally in most biologic tissues, where they act as modulators of cell function. They act via specific receptors of the G-protein family, which are coupled to a variety of intracellular signaling mechanisms that may stimulate or inhibit adenylyl cyclase or phosphatidylinositol.^[241] Prostaglandins of the E and F series can cause uterine contraction at any stage of gestation. Pioneering work by Karim demonstrated that intravenous infusion of prostaglandins produced abortion,^[189] but this route proved impractical because of associated vomiting and diarrhea. Side effects were much reduced when PGF₂ was given by the intra-amniotic route, and a clinically useful means for midtrimester abortion developed.

Intra-amniotic Prostaglandins

Though initially hailed as a better alternative than intra-amniotic saline, acceptance of intra-amniotic PGF₂ was limited because of problems with incomplete abortion, the need for a second injection in many cases, the risk for cervical rupture in the primigravida, and the lack of a direct toxic effect on the fetus. Results with intra-amniotic PGF₂ are much improved if overnight treatment with laminaria is used prior to infusion: mean times to abortion are reduced from 29 hours to 14 hours, many fewer require a second dose, and cervical rupture becomes rare.^[242] PGF₂ was withdrawn by the manufacturer after intense picketing by "anti-choice" extremists, but can be replaced with the analogue 15(s)-15-methyl prostaglandin F₂ (carboprost tromethamine [Hemabate]). An extensive experience with midtrimester abortion induced by intra-amniotic carboprost has been reported by Osathanondh from Brigham and Womens' Hospital in Boston.^[243] Patients are pretreated overnight with multiple intracervical laminaria tents. The following morning, the tents are removed and an intra-amniotic injection of 2 mg of carboprost combined with 64 mg of 23.4 percent sodium chloride is given. Four hours later, the membranes are artificially ruptured and, unless the cervix is found to be well effaced and dilated, a prostaglandin E₂ suppository is placed into the cervical canal on the end of an osmotic dilator. Subsequently, vaginal suppositories of the PGE₂ are given at 3-hour intervals. All patients have a brief exploration of the uterine cavity and curettage under low-dose intravenous sedation after expulsion of the placenta. If the patient has not aborted by 14 hours, a D&E procedure is performed. The Boston group reports a mean time from instillation to abortion of 8 hours and no cervical lacerations or uterine rupture in over 4,000 consecutive cases treated with this protocol. Ferguson and colleagues report a similar procedure, with laminaria placed in the cervical canal and then immediate administration of 80 g of urea and 2.0 mg of carboprost by the intra-amniotic route.^[244] The mean time to abortion was 13 hours for a group of 62 patients. One patient sustained a transverse cervical laceration.

Systemic Prostaglandins

Dinoprostone (prostaglandin E₂) by vaginal suppository and intramuscular carboprost are approved by the U.S. Food and Drug Administration for induction of abortion. Both are easy to administer, and are highly effective. With vaginal dinoprostone, 20 mg every 3 hours, the mean time to abortion is 13.4 hours, with 90 percent of patients aborting by 24 hours.^[245] When carboprost is given as 250 g intramuscularly every 2 hours, the mean times to abortion are 15 to 17 hours, with about 80 percent aborting by 24 hours.^[246] Gastrointestinal side effects are common, with 39 percent of dinoprostone-treated patients experiencing vomiting and 25 percent experiencing diarrhea in one large trial.^[245] These side effects are more common with carboprost: 83 percent had vomiting and 71 percent had diarrhea in the trial cited above.^[246] Fever is more common with dinoprostone than with carboprost. About one third of patients treated with dinoprostone 20 mg every 3 hours will have a temperature elevation of 1°C or more. In abortions induced by prostaglandins of the F series, pretreatment with overnight placement of osmotic dilators shortens the length of prostaglandin treatment, reduces the dose of the drug required, and hence reduces the prostaglandin-related side effects.^[247] Whether there is benefit from laminaria for abortion induced by E prostaglandins appears not to have been demonstrated,

642

although laminaria is commonly used prior to dinoprostone treatment.

Misoprostol for Midtrimester Abortion

A randomized comparison of vaginal dinoprost suppositories (20 mg every 3 hours) and vaginally administered misoprostol (200 g every 12 hours) in patients 12 to 22 weeks pregnant showed equal efficacy. The patients receiving misoprostol had fewer side effects of fever, uterine pain, vomiting, and diarrhea. The misoprostol cost much less and was easier to administer.^[248] Fifty-seven percent of patients treated with misoprostol aborted after a single 200-g vaginal dose. Both patient groups included women with fetal death and intact gestations. The mean time intervals from start of treatment to fetal expulsion for fetal death and intact pregnancies were 9.1 and 13.2 hours, respectively, for those receiving dinoprost, and 10.4 and 15.4 hours, respectively, for those receiving misoprostol. More than half of patients in both groups needed manual or instrumental extraction for retained placentae, as is usual with prostaglandin abortions. In a subsequent study, these authors found laminaria inserted at the same time as the misoprostol did not shorten the treatment-to-abortion interval.^[249] Whether overnight pretreatment with laminaria would improve efficacy of the misoprostol method seems not to have been investigated.

High-Dose Oxytocin

Winkler and colleagues compared dinoprost suppositories to a high-dose oxytocin protocol at 17 to 24 weeks and found equal efficacy with fewer side effects from the oxytocin.^[250] Patients initially received an infusion of 50 units oxytocin in 500 ml of 5 percent dextrose and normal saline over 3 hours, 1 hour of no oxytocin, followed by a 100-units/500 ml solution over 3 hours, another hour of rest, then a 150-units/500 ml solution over 3 hours, etc., alternating 3 hours of oxytocin with 1 hour of rest, increasing the oxytocin by 50 units in each successive time period until a final concentration of 300 units/500 ml was reached. Fifty-nine percent of the oxytocin patients had either fetal death or ruptured membranes, which could be expected to make the uterus more responsive to induction.

Complications of Labor Induction Abortions and Their Management

The labor induction methods share common hazards: failure of the primary procedure to produce abortion within a reasonable time, incomplete abortion, retained placenta, hemorrhage, infection, and embolic phenomena. Failed abortion can lead to serious infection and continued blood loss. Intramuscular injections of carboprost or vaginal suppositories of PGE₂ are important second-line therapies when the primary method has not produced abortion within a reasonable time period. If dinoprost vaginal suppositories have been used initially and the patient does not abort by 14 to 16 hours, it is reasonable to change to intramuscular carboprost. Also, blood or amniotic fluid may dilute vaginally administered prostaglandin and limit efficacy; hence, early change to intramuscular carboprost is advised. Formerly, hysterotomy was used to manage these cases, but experienced physicians can safely use D&E techniques, sparing the patient major surgery.^[251] Failed saline or prostaglandin abortions are technically easier to manage by D&E than is a primary procedure at the same gestational age, because the cervix is usually widely dilated, the uterus is well contracted, and the fetus and placenta are compacted into the lower uterine segment. All labor induction methods can lead to fetal expulsion through a rent in the cervix above the external os, a cervicovaginal fistula, or even annular detachment of the lower cervix. Use of laminaria tents helps protect the cervix. The protection is greatest with 12 or more hours of exposure to laminaria prior to uterine stimulation. Uterine rupture may occur when saline, urea, or prostaglandins are augmented with high-dose oxytocin infusion.^[252] Easy availability of a treatment room outfitted with a uterine aspirator to allow for early instrumental removal of retained placenta using conscious sedation improves care and avoids the need for an operating room and a major anesthetic. Prostaglandin abortions are frequently incomplete and hence associated with late bleeding. If the placenta has not delivered within 1 hour after fetal expulsion, further waiting is not advised. Either routine exploration of the uterus with ring forceps and vacuum curettage after all abortions, or routine ultrasound to confirm the uterus is empty, appear to reduce rates of postabortal hemorrhage and infection to low levels. Oxytocin should be used with caution in prostaglandin-treated patients in order to avoid uterine rupture.

DIC is rare after first-trimester vacuum curettage, where the incidence is 8 per 100,000 procedures.^[253] The incidence is higher after midtrimester D&E, 191 per 100,000, and highest for saline instillation procedures, 658 per 100,000. DIC must be considered whenever postabortal hemorrhage is seen and, if present, must be managed aggressively with infusions of fresh frozen plasma and packed red cells. Heparin therapy is not helpful in these cases.

With increasing use of D&E for the early midtrimester, labor induction methods primarily are reserved for late procedures, when concerns about fetal viability and transient fetal survival are the greatest. In our experience with prostaglandins, 7 to 10 percent of fetuses exhibit some transient survival. For this reason, and to improve efficacy, reduced doses of intra-amniotic hypertonic

tonic saline or urea may be used to augment prostaglandin abortion. If the fetus is near viability, intracardiac injection of digoxin or KCl should be performed under ultrasound guidance, prior to the prostaglandin.^[235]

Choice of Midtrimester Procedure

Many different procedures are available in the United States for midtrimester abortion. Resident physicians on our service have been able to terminate 16- to 20-week pregnancies consistently and safely by D&E under the following conditions: overnight placement of multiple laminaria tents, use of the 16-mm vacuum cannula system, good nursing support, and direct hands-on supervision by a small group of experienced faculty.^[254] Robbins and Surrage^[255] have found D&E to be safer and more effective than a prostaglandin method. Therefore, we see little indication for any procedure other than D&E prior to 17 menstrual weeks.

When the entire midtrimester is considered, D&E appears safer than the alternatives but, as noted by Kafrissen et al.^[256] in their comparison of D&E to urea-PGF₂, the advantage of D&E is for procedures performed at 13 to 16 weeks. Thereafter, the risks for major complications and death are comparable. Urea, prostaglandins, and saline infusion all involve overnight hospitalization, which greatly increases expense. As documented by Kaltreider et al.,^[229] the psychological impact on the patient is much greater with labor induction abortion than with D&E. Several skilled surgeons offer D&E techniques to 24 weeks and beyond. Indeed, the lowest reported rate of complications for any late abortion technique is that of Hern^[235] serial multiple laminaria over several days to achieve wide cervical dilatation, amniotomy, intravenous oxytocin, and then D&E. For the operator faced with the need to perform an occasional abortion in the midtrimester, we would suggest ultrasound-guided intracardiac injection of 1.5 mg of digoxin and then vaginal misoprostol, 200 g every 12 hours.

Induced Abortion and Subsequent Reproduction

Hogue et al.^[257] reviewed current literature on this topic and concluded that legal abortion as currently practiced in the United States has no measurable adverse effect on later reproduction. A single induced abortion appears safe as far as later reproduction is concerned. Studies of reproductive outcome are difficult because of the need to control for multiple confounding factors that are frequently present among women who report multiple abortions. Our group found that women with two or more induced abortions appeared at greater risk for later first- or second-trimester spontaneous loss, even after appropriate control for other factors.^[258] In a separate study, we found that women who reported two or more induced abortions prior to their present pregnancy appeared initially to have more pregnancy complications. However, statistical control by multiple logistic regression analysis found multiple abortions to be associated only with first-trimester bleeding, abnormal presentations, and premature rupture of the membranes prior to labor, but not with low birth weight, prematurity, or increased perinatal loss.^[259] A large Hawaiian study found even two or more induced abortions to have no detectable adverse effect.^[260] Concerns about infertility as a result of induced abortion seem largely unfounded, except for the rare severe complication managed by hysterectomy. A prospective follow-up study found no reduction in subsequent pregnancy rates when an abortion group was compared with two control groups.^[261] The lack of adverse effects on later pregnancy probably reflects the safety of current abortion technology in the United States: most abortions are performed by vacuum curettage under local anesthesia in the first trimester. The safety of midtrimester methods for subsequent pregnancy remains to be demonstrated and unquestionably varies with the method. Forcible dilation of the cervix to large diameters for D&E in the late midtrimester may well increase the risk of midtrimester loss or prematurity later.^[262] We have shown that by 2 weeks after laminaria dilation, the cervical canal has recovered to an internal diameter smaller than that found prior to abortion.^[263] We feel strongly that laminaria tents, their synthetic alternative, or low-dose prostaglandins should be used to prepare the cervix prior to late abortion and that forcible dilation to large diameters should be avoided.

Pregnancy Termination After Fetal Death In Utero

Whereas fetal death in utero can be managed exactly as induced abortion in the first and second trimesters, there are some differences. After fetal death, laminaria treatment may result in onset of labor. This is not a problem if the patient knows this may happen and has been instructed to return to the hospital. DIC is more common after D&E or induction of labor after a fetal death than with a living fetus. The amniotic sac may be more permeable after fetal death, and intra-amniotic injection becomes technically more difficult. Systemic reactions from hypertonic saline or intra-amniotic prostaglandin are more common in these cases. Indeed, it was this experience that spurred the development of vaginal PGE₂ suppositories to treat fetal death. In cases of fetal death, the response to prostaglandins is faster than with intact gestations, and treatment-to-expulsion

times are shorter. Special caution is required for managing fetal death after 28 weeks with prostaglandins. A full dose of 20 mg of PGE₂ has produced fatal uterine rupture. Our protocol, used successfully for many years, is to cut the suppository into fourths and treat the patient with one fourth of the suppository (approximately 5 mg of PGE₂) at 2-hour intervals. The same protocol allows safe, effective treatment for women with severe asthma.

The Limit to Midtrimester Abortion

Women must have access to legal abortion. Efforts to ban abortion by making it illegal do not reduce the number of abortions performed but rather results in expensive and dangerous procedures with many complications and high rates of maternal mortality.^[264] However, our society will not countenance infanticide. Inevitably, there must be a gestational age limit for abortion. The U.S. Supreme Court used viability as the limit for abortion based on the decision of the women and allowed states to limit abortion thereafter.^[265] With the use of surfactant treatment and current U.S. neonatal intensive care practice, 23-week infants that survive to reach the nursery have at most a 35 percent probability of survival to leave the hospital, and 24-week infants have approximately a 60 percent probability of survival, but infants born prior to 23 weeks almost never survive.^[266] In our opinion, 23 weeks should be considered the threshold of viability. We would avoid performing abortion after 22 weeks unless the mother's life were endangered or unless the fetus had major malformations so severe as to preclude prolonged survival. Current ultrasound techniques combine measurements of several fetal dimensions to give more reliable estimates of gestational age than previous techniques that relied on the biparietal diameter alone.^[267] When abortion is performed just prior to viability, a method that ensures fetal demise should be selected to avoid the anguished decisions occasioned by the live birth of a fetus of borderline viability. When termination of pregnancy will be undertaken at or after 23 weeks because of serious risk to maternal health, the fetus must be considered as well. Each case must be managed individually, based on the mother's status, and intervention delayed until survival of the fetus is probable, if maternal condition permits.

The ethics of abortion after viability have been explored by Chervanek and colleagues.^[268] They conclude that abortion should be considered ethical in cases of fetal conditions with no prospect for prolonged survival after birth and when there is a completely accurate means for diagnosing the conditions. Fetal anencephaly was cited as such a condition.

Key Points

Surgery in pregnancy requires knowledge and understanding of the physiologic alterations in gestation.

Symptoms of gastrointestinal disease during gestation can mimic pregnancy-related symptomatology. Careful evaluation of the patient with abdominal pain in pregnancy is mandatory.

Delay in surgical intervention for patients with intra-abdominal surgical pathology results in increased maternal and fetal morbidity and mortality.

Elective surgery early during the second trimester is associated with the most favorable outcome for both mother and fetus.

Decisions regarding cervical cerclage placement require careful evaluation of the patient's history and cervical status.

Evaluation of the cervix by ultrasound is helpful in the management of patients at risk for cervical incompetence.

Surgery for asymptomatic adnexal masses in pregnancy should include sonographic evaluation of the mass.

High index of suspicion for appendicitis is required for the pregnant patient presenting with right lower quadrant abdominal pain.

Recent series of laparoscopic appendectomies and cholecystectomies during gestation demonstrate similar outcomes to an open approach.

The performance of laparoscopic surgery in gestation should be subject to specific guidelines to ensure maternal and fetal well-being. Further studies are necessary before making absolute recommendations regarding the safety of this technique.

The risk of death from legal abortion in the United States performed prior to 16 weeks is 5- to 10-fold less than that of continuing the pregnancy.

Mifepristone (RU-486) and low-dose prostaglandin provide a medical means for terminating early pregnancy, producing complete abortion in 95 percent of cases.

Selective termination of multifetal pregnancies is practical and improves perinatal outcome.

In the United States, midtrimester abortion is most often accomplished with D&E as opposed to labor induction abortion. Safety with D&E requires close attention to procedural details.

Induced abortion as currently practiced in the United States does not increase risk of loss in later pregnancies.

Chapter 20 - The Neonate

Adam A. Rosenberg

The first 4 weeks of an infant's life, the neonatal period, are marked by the highest mortality rate in all of childhood. The greatest risk occurs during the first several days after birth. Critical to survival during this period is the infant's ability to adapt successfully to extrauterine life. During the early hours after birth, the newborn must assume responsibility for thermoregulation, metabolic homeostasis, and respiratory gas exchange, as well as undergo the conversion from fetal to postnatal circulatory pathways. This chapter reviews the physiology of a successful transition as well as the implications of circumstances that disrupt this process. Implicit in these considerations is the understanding that the newborn reflects the sum total of its genetic and environmental past as well as any minor or major insults to which it was subjected during gestation and parturition. The period of neonatal adaptation is then most meaningfully viewed as continuous with fetal life.

CARDIOPULMONARY TRANSITION

Pulmonary Development

Lung development and maturation require a carefully regulated interaction of anatomic, physiologic, and biochemical processes. The outcome of these events provides an organ with adequate surface area, sufficient vascularization, and the metabolic capability to sustain oxygenation and ventilation during the neonatal period. Five stages of morphologic lung development have been identified in the human fetus ^[1]

1. Embryonic period conception to 7 weeks
2. Pseudoglandular period 8th to 16th weeks
3. Canalicular period 17th to 27th weeks
4. Saccular period 28th to 35th weeks
5. Alveolar period at or after 36 weeks

The lung arises as a ventral diverticulum from the foregut during the fourth week of gestation. During the ensuing weeks, branching of the diverticulum occurs, leading to a tree of narrow tubes with thick epithelial walls composed of columnar-type cells. By 16 weeks, the conducting portion of the tracheobronchial tree up to and including terminal bronchioles has been established. The vasculature derived from the pulmonary circulation develops concurrently with the conducting airways, and by 16 weeks preacinar blood vessels are formed. The canalicular stage is characterized by differentiation of the airways, with widening of the airways and thinning of epithelium. In addition, primitive respiratory bronchioles begin to form, marking the start of the gas-exchanging portion of the lung. Vascular proliferation continues, along with a relative decrease in mesenchyme, bringing the vessels closer to the airway epithelium. The saccular stage is marked by the development of the gas-exchanging portion of the tracheobronchial tree (acinus) composed of respiratory bronchioles, alveolar ducts, terminal saccules, and finally alveoli. During this stage, the pulmonary vessels continue to proliferate with the airways and surround the developing air sacs. The final phase of prenatal lung development (alveolar) is marked by the formation of thin secondary alveolar septae and the remodeling of the capillary bed. Several million alveoli will form before birth, which emphasizes the importance of this last few weeks of pregnancy to pulmonary adaptation. Postnatal lung growth is characterized by generation of alveoli. At birth, there are approximately 50 million airspaces and by 8 years of age, 300 million. ^[2]

In early gestation, respiratory epithelial cells are simple and columnar in type. A slow transition from columnar

Figure 20-1 (Figure Not Available) Metabolism of surfactant. Surfactant phospholipids are synthesized in the endoplasmic reticulum, transported through Golgi apparatus to multivesicular bodies, and finally packaged in lamellar bodies. After lamellar body exocytosis, phospholipids are organized into tubular myelin before aligning in a monolayer at the air-fluid interface in the alveolus. Surfactant phospholipids and proteins are taken up by type II cells and either catabolized or reutilized. Surfactant proteins are synthesized in polyribosomes, modified in endoplasmic reticulum, Golgi apparatus, and multivesicular bodies. (Adapted from Whitsett JA, Pryhuber GS, Rice WR, et al: *Acute respiratory disorders*. In Avery GB, Fletcher MA, MacDonald MG (eds): *Neonatology: Pathophysiology and Management of the Newborn*, 5th ed. Philadelphia, Lippincott Williams & Wilkins, 1999, p 485, with permission.)

epithelium to the lining of a fully developed alveolus starts during the fifth month. ^[3] By the time of birth, the epithelial lining of the gas-exchanging surface is thin and continuous with two alveolar cell types (types I and II). Type I cells contain few subcellular organelles, while type II cells contain abundant mitochondria, endoplasmic reticulum, Golgi apparatus, and osmiophilic lamellar bodies known to contain surfactant. A scheme for the synthesis of surfactant is presented in Figure 20-1 (Figure Not Available). The kinetics of movement of surfactant from synthesis to lamellar body storage and secretion is slow. Surfactant is secreted as lamellar bodies that unravel into tubular myelin. Tubular myelin is a loose lattice of phospholipids and surfactant-specific proteins. The surface active component of surfactant then adsorbs at the alveolar interface between air and water in a monolayer. ^[4] With repetitive expansion and compression of the surface monolayer, material is extruded that is either cleared by alveolar macrophages via endocytic pathways or taken up by the type II cell for recycling back into lamellar bodies. ^[5]

Because of the development of high surface forces along the respiratory epithelium when breathing begins, the availability of surfactants in terminal airspaces is critical to postnatal lung function. Just as surface tension acts to reduce the size of a bubble in water, so too it acts to reduce lung inflation, promoting atelectasis. This is described by the LaPlace relationship, which states that the pressure, P, within a sphere is directly proportional to surface tension, T and inversely proportional to the radius of curvature, r (Fig. 20-2) (Figure Not Available). Surfactant has the physical property of variable surface tension

655

Figure 20-2 (Figure Not Available) LaPlace's law. The pressure, P, within a sphere is directly proportional to surface tension, T, and inversely proportional to the radius of curvature, r. In the normal lung, as alveolar size decreases, surface tension is reduced because of the presence of surfactant. This serves to decrease the collapsing pressure that needs to be opposed and maintains equal pressures in the small and large interconnected alveoli. (Adapted from Netter FH: *The Ciba Collection of Medical Illustrations. The Respiratory System, Vol 7*. Summit, NJ, Ciba-Geigy, 1979.)

dependent on the degree of surface area compression. In other words, as the radius of the alveolus decreases, surfactant serves to reduce surface tension, preventing collapse of the alveolus. If this property is extrapolated to the lung, smaller alveoli will remain stable because of lower surface tension than other larger alveoli. This feature is emphasized in Figure 20-3, which compares pressure-volume curves from surfactant-deficient and surfactant-treated preterm rabbits. Surfactant deficiency is characterized by high opening pressure, low maximal lung volume, and lack of deflation stability at low pressures. ^[6]

Saturated phosphatidylcholine (the surface tension-reducing component of surfactant) is found in lung tissue of the human fetus earlier in gestation than in other species (Fig. 20-4). ^[7] Tissue stores of surfactant are considerable at term. Surfactant is released from storage

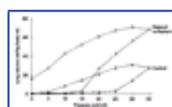

Figure 20-3 Pressure-volume relationships for the inflation and deflation of surfactant-deficient and surfactant-treated preterm rabbit lungs. (Adapted from Jobe AH: *Lung development*. pools into fetal lung fluid at a basal rate during late gestation. Secretion is stimulated by labor and the initiation of air breathing. ^[8]

Natural surfactant contains 80 percent phospholipids, 10 percent neutral lipids, and 10 percent protein (Fig. 20-5).^[6],^[9] Approximately half of the protein is specific for surfactant. The principal classes of phospholipids are saturated phosphatidylcholine compounds, 45 percent (more than 80 percent of which are dipalmitoyl-phosphatidylcholine [DPPC]); 25 percent unsaturated phosphatidylcholine compounds; and 10 percent phosphatidylglycerol, phosphatidylinositol, and phosphatidylethanolamine. Four unique surfactant-associated proteins have been identified.^[10] All are synthesized and secreted by type II alveolar cells. DPPC is the molecule critical to the surface tension-lowering property of surfactant at the air-liquid interface in the alveolus. Surfactant protein (SP)-A functions cooperatively with the other surfactant proteins and lipids to improve surface properties and regulate secretory and reuptake pathways.^[10],^[11] SP-B and SP-C are lipophilic proteins that facilitate the adsorption and spreading of lipid to form the surfactant monolayer.^[10],^[11] SP-D is the least well-described surfactant-associated protein, but appears to function in pulmonary host defense mechanisms.^[12]

Several hormones and growth factors contribute to the regulation of pulmonary phospholipid metabolism and lung maturation: glucocorticoids, thyroid hormone, thyrotropin-releasing hormone, prolactin, cyclic adenosine monophosphate (cAMP), epidermal growth factor, and others. Glucocorticoids are the most important of the stimulating factors. They augment the synthesis of all surfactant components and accelerate morphologic development.^[9],^[13]

Pregnant women with anticipated preterm delivery have received corticosteroid treatment since 1972.^[14] Numerous

656

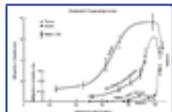

Figure 20-4 Accumulation of saturated phosphatidylcholine during gestation. Gestational age is plotted as percentage of term. (Adapted from Clements JA, Tooley WH: *Kinetics of surface-active material in the fetal lung*. In Hodson WA [ed]: *Development of the Lung*. New York, Marcel Dekker, 1977.)

controlled trials have since been done and have been cumulatively evaluated using meta-analysis.^[15] Meta-analysis uses quantitative methods to summarize results from a systematic review of randomized controlled trials. Based on such analysis, a significant reduction of about 50 percent in the incidence of respiratory distress syndrome (RDS) is seen in infants born to mothers who received antenatal corticosteroids. In secondary analysis, a 70 percent reduction in RDS was seen among babies born between 24 hours and 7 days after corticosteroid administration. In addition, evidence suggests a reduction in mortality and RDS even with treatment started less than 24 hours before delivery. Although most babies in the trials were between 30 and 34 weeks' gestation, clear reduction in RDS was evident when the population of babies less than 31 weeks was examined. Gender and race do not influence the protective effect of corticosteroids. In the population of patients with preterm premature rupture of the membranes, antenatal corticosteroids also reduce the frequency of RDS.

Corticosteroids also accelerate maturation of other organs in the developing fetus, including cardiovascular, gastrointestinal, and central nervous system. Corticosteroid therapy reduces the chances of both periventricular-intraventricular hemorrhage and necrotizing enterocolitis.^[15],^[16] The significant reductions in serious neonatal morbidity are also reflected in a reduction in the risk of early neonatal mortality. The short-term beneficial effects of antenatal corticosteroids are enhanced by reassuring reports about long-term outcome. The children of mothers treated with antenatal corticosteroids

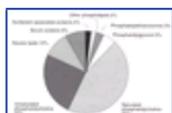

Figure 20-5 Composition of pulmonary surfactant. (Adapted from Ballard PL: *Hormonal regulation of pulmonary surfactant*. *Endocr Rev* 10:165, 1989.)

657

show no lag in intellectual or motor development, no increase in learning disabilities or behavioral disturbances, and no effect on growth compared with untreated infants.^[17],^[18]

Since the advent of antenatal steroids for the prevention of RDS, other maternal and neonatal therapies have been introduced that decrease mortality and morbidity. Surfactant replacement therapy to treat specifically the surfactant deficiency that is the cause of RDS has been shown to decrease mortality and the severity of RDS.^[19]^[20]^[21]^[22] The effects of antenatal corticosteroids and postnatal surfactant appear to be additive in terms of decreasing the severity of and mortality caused by RDS.^[23] Finally, in recent years thyroid-releasing hormone (TRH) has been introduced as an agent to accelerate lung maturation. TRH efficiently crosses the placenta and elicits a striking fetal TSH response.^[24] Animal studies have demonstrated improvement in fetal pulmonary maturation after maternal administration of TRH.^[25] In addition, thyroid hormone has an additive effect with glucocorticoid on choline incorporation into phosphatidylcholine^[26] and is synergistic with cortisol and prolactin in increasing lung compliance and surfactant production.^[27] However, the only large doubleblind, placebo-controlled trial performed during the era of routine surfactant replacement in newborns showed that TRH and glucocorticoid is no more beneficial than glucocorticoid alone in altering the frequency of RDS death at 28 days and chronic lung disease.^[28] In addition, initial follow-up data from a previous Australian trial suggest that antenatal TRH may be associated with delays in early developmental milestones.^[29] Currently, routine use of TRH in women at risk for preterm delivery cannot be recommended.

The First Breaths

A critical step in the transition from intrauterine to extrauterine life is the conversion of the lung from a dormant fluid-filled organ to one capable of gas exchange. This requires aeration of the lungs, establishment of an adequate pulmonary circulation, ventilation of the aerated parenchyma, and diffusion of oxygen and carbon dioxide through the alveolar-capillary membranes. This process has its roots in utero as fetal breathing.

Fetal Breathing

Fetal breathing has been demonstrated in a large number of mammalian species.^[30] Fetal breathing has been most extensively studied in fetal sheep and to a lesser degree in humans. Fetal breathing in third-trimester fetal sheep occurs primarily during periods of low-voltage electrocortical activity (rapid-eye-movement [REM] sleep).^[31],^[32] The predominant respiratory pattern is one of rapid, irregular movements varying in amplitude at a rate of 60 to 120 per minute. Isolated deep inspiratory efforts can occur at one to three times per minute unassociated with any particular stage of sleep. During high-voltage electrocortical activity (quiet sleep), only occasional breaths occur after tonic muscular discharges associated with body movements. During non-REM sleep, the breathing movements are inhibited by a mechanism situated in the midbrain and pons.^[33],^[34] Developmental studies on the ontogeny of fetal breathing have been conducted primarily in the fetal lamb and to a lesser extent the human fetus. The onset of breathing in the fetal sheep has been noted as early as 40 days of gestation. By days 90 through 115, breathing is almost continuous, with rare apneic pauses of less than 2 minutes' duration. From day 115 to term, breathing is episodic as described above. Human fetal breathing is quite similar to that observed in fetal sheep.^[35] Respiratory activity is initially detectable at 11 weeks. The most prevalent pattern is rapid, small-amplitude movements (60 to 90 per minute) present 60 to 80 percent of the time. Less commonly, irregular low-amplitude movements interspersed with slower larger amplitude movements are seen.

Initially, fetal breathing was thought to depend on behavioral influences. However, subsequent work has shown responses to chemical stimuli and other agents. Acute hypercapnea stimulates breathing in both human and sheep fetuses.^[36],^[37] Hypoxia abolishes fetal breathing,^[37] while an increase in oxygen tension to levels above 200 mm Hg induces continuous fetal breathing.^[38] Hyperglycemia after bolus injections of glucose to the mother or after ingestion of a meal increases fetal breathing in humans.^[39],^[40] Of the pulmonary reflexes, the inflation reflex (decreasing frequency of breathing) is active in fetal life.^[41] Peripheral and central chemoreflexes as well as vagal afferent reflexes can be demonstrated in the fetus, but their role in spontaneous fetal breathing appears minimal.^[42]

Breathing is intermittent in the fetus and becomes continuous after birth. The mechanism responsible for this transition is unknown. In the fetal lamb, the REM sleep dependence of breathing can be overcome in a number of ways. The most profound continuous intrauterine breathing is caused by prolonged infusion of large doses

of prostaglandin synthesis inhibitors,^[43] suggesting that prostaglandins may be involved in the transition to continuous postnatal respiration. Other factors surrounding birth, including blood gas changes and various sensory stimuli, are also postulated to be involved.^{[42], [44]} Another factor possibly involved is the "release" from a placental inhibitory factor that is removed after cord occlusion.^[45]

The role of fetal breathing in the continuum from fetal to neonatal life is still not completely understood. Fetal respiratory activity is probably essential to the

658

development of chest wall muscles (including diaphragm) and serves as a regulator of lung fluid volume and thus lung growth.^[42]

Mechanics of the First Breath

With its first breaths, the neonate must overcome several forces resisting lung expansion: (1) viscosity of fetal lung fluid, (2) resistance provided by lung tissue itself, and (3) the forces of surface tension at the air-liquid interface.^[46] Viscosity of fetal lung fluid is a major factor as the neonate attempts to displace fluid present in the large airways. As the passage of air moves toward small airways and alveoli, surface tension becomes more important. Resistance to expansion by the lung tissue itself is less significant. The process begins as the infant passes through the birth canal. The intrathoracic pressure caused by vaginal squeeze is up to 200 cm H₂O.^{[47], [48]} With delivery of the head, approximately 5 to 28 ml of tracheal fluid is expressed. Subsequent delivery of the thorax causes an elastic recoil of the chest. With this recoil, a small passive inspiration (no more than 2 ml) occurs.^[47] This is accompanied by glossopharyngeal forcing of some air into the proximal airways (frog breathing)^[49] and the introduction of some blood into pulmonary capillaries.^{[50], [51]} This pulmonary vascular pressure may have a role in producing initial continuous surfaces throughout the small airways of the lung into which surfactant can deploy.^[51]

The initial breath is characteristically a short inspiration followed by a more prolonged expiration (Fig. 20-6).^{[47], [52], [53]} The initial breath begins with no air volume and no transpulmonary pressure gradient. Considerable negative intrathoracic pressure during inspiration

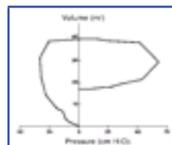

Figure 20-6 Pressure-volume loop of the first breath. Air enters the lung as soon as intrathoracic pressure falls and expiratory pressure greatly exceeds inspiratory pressure. (Modified from Milner AD, Vyas H: Lung expansion at birth. *J Pediatr* 101:879, 1982.)

is provided by diaphragmatic contraction and chest wall expansion. An opening pressure of about 25 cm H₂O usually is necessary to overcome surface tension in the smaller airways and alveoli before air begins to enter. The volume of this first breath varies between 30 and 67 ml and correlates with intrathoracic pressure. The expiratory phase is quite prolonged, as the infant's expiration is opposed by intermittent closure at the pharyngolaryngeal level^[49] with the generation of large positive intrathoracic pressure. This pressure serves to aid both in maintenance of a functional residual capacity (FRC) and with fluid removal from the air sacs. The residual volume after this first breath ranges between 4 and 30 ml, averaging 16 to 20 ml. There are really no major systematic differences among the first three breaths, demonstrating similar pressure patterns of decreasing magnitude. The FRC rapidly increases with the first several breaths and then more gradually. By 30 minutes of age, most infants attain a normal FRC with uniform lung expansion.^[54] The presence of functional surfactant is instrumental in the accumulation of an FRC.^{[7], [8]}

In utero, alveoli are open and stable at nearly neonatal lung volume because they are filled with fetal lung liquid, probably produced by ultrafiltration of pulmonary capillary blood as well as by secretion by alveolar cells.^[55] Transepithelial chloride secretion appears to be a major factor responsible for the production of luminal liquid in the fetal lung.^{[56], [57]} Normal expansion and aeration of the neonatal lung is dependent on removal of fetal lung liquid. This process begins before a normal term birth because of decreased fluid secretion and increased absorption.^[58] Factors involved in this process postnatally are (1) the thoracic squeeze during delivery, (2) a marked increase in pulmonary lymph flow, and (3) removal via the pulmonary circulation.^{[59], [59]} The role of the thoracic squeeze in fluid removal is thought to be minimal during a normal birth.^[58] With the onset of breathing, residual liquid from the lung lumen moves into the interstitium. Puddling of fluid in connective tissue spaces away from sites of gas exchange allows time for the pulmonary microcirculation and lymphatics to remove the fluid.^{[60], [61]} In normal circumstances, the process is complete within 6 hours of birth. Cesarean-delivered infants without benefit of labor and premature infants have delayed lung fluid clearance. In both groups, the prenatal decrease in lung water does not occur.^{[59], [62]} In addition, in the premature, fluid clearance is diminished by increased alveolar surface tension, increased left atrial pressure, and hypoproteinemia.^{[58], [63]} Overall, lymphatic pathways remove about 10 percent of lung liquid, with most fluid taken up by the pulmonary circulation.^[61] The stimulus for absorption of lung liquid with birth appears to be active sodium transport across the pulmonary

659

epithelium driving fluid into the pulmonary interstitium.^{[58], [64]}

Circulatory Transition

The circulation in the fetus (Fig. 20-7) has been studied in a variety of species using several techniques (see Chapter 2). These studies have been the subject of a number of excellent reviews.^{[65], [66], [67], [68]}

Umbilical venous blood, returning from the placenta, has a P_{O₂} about 30 to 35 mm Hg. Because of the left shift of the oxyhemoglobin disassociation curve caused by fetal hemoglobin, this corresponds to a saturation of 80 to 90 percent. About 50 percent of this blood passes through the liver (mainly to the middle and left lobes). This blood will ultimately enter the inferior vena cava (IVC) through the hepatic veins. The remainder bypasses the hepatic circulation via the ductus venosus, which empties directly into the IVC. Because of streaming in the IVC, the more oxygenated blood from the ductus venosus and left hepatic vein, as it enters the heart, is deflected by the crista dividens through the foramen ovale to the left atrium. The remainder of left atrial blood is the small amount of venous return from the pulmonary circulation. The remainder of return from the IVC, less oxygenated blood from the lower body, renal, mesenteric, and right hepatic veins, streams across the tricuspid valve to the right ventricle. Almost all the return from the superior vena cava (SVC) and the coronary sinus passes through the tricuspid valve to the right ventricle, with only 2 to 3 percent crossing the foramen ovale. In the near-term fetus, the combined ventricular output is about 450 ml/kg/min. Two thirds of the cardiac output is from the right ventricle, and one third is from the left ventricle. The blood in the left ventricle has a P_{O₂} of

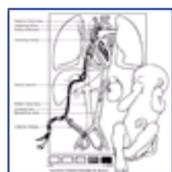

Figure 20-7 The fetal circulation.

660

25 to 28 mm Hg (saturation of 60 percent) and is distributed to the coronary circulation, brain, head, and upper extremities, with the remainder (10 percent of combined output) passing into the descending aorta. The major portion of the right ventricular output (60 percent of combined output) is carried by the ductus arteriosus to the descending aorta, with only 7 percent of combined output going to the lungs. Thus, 70 percent of combined output passes through the descending aorta, with a P_{O₂} of 20 to 23 mm Hg (saturation of 55 percent) to supply the abdominal viscera and lower extremities. Forty-five percent of combined output will go through the umbilical arteries to the placenta. This arrangement provides blood of a higher P_{O₂} to the critical coronary and cerebral circulations and serves to divert

venous blood to where oxygenation occurs.

The diversion of right ventricular output away from the lungs through the ductus arteriosus is caused by the very high pulmonary vascular resistance (PVR) in the fetus. This high pulmonary pressure results from chronic exposure to a low P_{O_2} causing vasoconstriction and an increase in the medial muscle layer in pulmonary arteries.^[66], ^[69] In addition, compression of capillaries by fetal lung liquid may contribute to pulmonary vascular resistance.^[70] With advancing gestational age, an increase in the number of small pulmonary vessels occurs that increases the cross-sectional area of the pulmonary vasculature. This contributes to the gradual decline in PVR that begins during later gestation (Fig. 20-8). With delivery, a variety of factors interact to

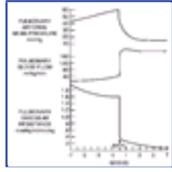

Figure 20-8 Representative changes in pulmonary hemodynamics during transition from the late-term fetal circulation to the neonatal circulation. (Adapted from Rudolph AM: *Fetal circulation and cardiovascular adjustments after birth*. In Rudolph AM, Hoffman JIE, Rudolph CD [eds]: *Rudolph's Pediatrics*, 20th ed. Stamford, CT, Appleton & Lange, 1996, p 1409.)

TABLE 20-1 -- PRESSURES IN THE PERINATAL CIRCULATION

	Fetal (mm Hg)	Neonatal (mm Hg)
Right atrium	4	5
Right ventricle	65/10	40/5
Pulmonary artery	65/40	40/25
Left atrium	3	7
Left ventricle	60/7	70/10
Aorta	60/40	70/45

Modified from Nelson NM: *Respiration and circulation after birth*. In Smith CA, Nelson NM (eds): *The Physiology of the Newborn Infant*, 4th ed. Springfield, IL, Charles C Thomas, 1976, p 117.

decrease PVR acutely. Mechanical expansion of the lungs with a hypoxic gas mixture causes a decrease in PVR and a fourfold increase in pulmonary blood flow.^[71] When oxygen was used to ventilate in this study, a further increase in pulmonary blood flow was seen, caused by an increase in oxygen tension of the blood. Finally, various hormones and vascular mediators may be involved in the decrease in PVR after birth. Increased production of endothelium-derived relaxing factor or nitric oxide appears to play an important role in this regard.^[72], ^[73]

With the increase in pulmonary flow, left atrial return increases with a rise in left atrial pressure (Table 20-1). In addition, with the removal of the placenta, inferior vena cava return to the right atrium is diminished. The foramen ovale is a flap valve, and, when left atrial pressure increases over that on the right side, the opening is functionally closed. It is still possible to demonstrate patency with insignificant right-to-left shunts in the first 12 hours of life in a human neonate, but in a 7- to 12-day newborn such a shunt is rarely seen, although anatomic closure is not complete for a longer time.

With occlusion of the umbilical cord, the large runoff of blood to the placenta is interrupted, causing an increase in systemic pressure. This, coupled with the decrease in right-sided pressures, serves to reverse the shunt through the ductus arteriosus to a predominantly left-to-right shunt. By 15 hours of age, shunting in either direction is physiologically insignificant.^[74] Although functionally closed by 4 days of age,^[75] the ductus is not irreversibly and anatomically occluded for 1 month. The role of an increased oxygen environment in ductal closure is well established.^[76] Prostaglandin metabolism has also been shown to play an important role in ductal patency in utero and in closure after birth.^[77] Ductal closure appears to occur in two phases: constriction and destruction. Initially, the muscular wall constricts followed by permanent closure achieved by endothelial destruction, subintimal proliferation, and connective tissue formation.^[78] The ductus venosus is

functionally occluded shortly after the umbilical circulation is interrupted.^[65]

Shortly after birth in the neonatal lamb, resting cardiac output is about 350 ml/kg/min.^[66] This represents an increase in left ventricular output from about 150 (fetal) to 350 (postnatal) ml/kg/min, while right ventricular output increases from 300 (fetal) to 350 (postnatal) ml/kg/min. The most dramatic increase in individual organ blood flow is that to the lungs (30 to 350 ml/kg/min). Myocardial, renal, and gastrointestinal blood flows also increase, while adrenal, cerebral, and carcass flows decrease.^[79]

ABNORMALITIES OF CARDIOPULMONARY TRANSITION

Birth Asphyxia

Even normal infants may experience some asphyxia during the birth process. A variety of circumstances can exaggerate the degree of asphyxia, resulting in a depressed infant, including (1) acute interruption of umbilical blood flow, as occurs during cord compression; (2) premature placental separation; (3) maternal hypotension or hypoxia; (4) any of the above superimposed on chronic uteroplacental insufficiency; and (5) failure to execute a proper resuscitation. ^[80] Other contributing factors include anesthetics and analgesics used in the mother, mode and difficulty of delivery, maternal health, and prematurity.

Fortunately, some characteristics of the newborn provide protection from these insults. The fetus and neonate are more resistant to asphyxia than are adults. ^[81] In response to asphyxia, the mature fetus redistributes blood flow to the critical cardiac, cerebral, and adrenal circulations. ^[82] Unlike adults, who develop tachycardia in response to hypoxia, the fetus responds initially with a reflex bradycardia. ^[83] As the fetus becomes more hypoxic, it becomes dependent on anaerobic glycolysis to meet energy requirements. During asphyxia, glucose can be released from glycogen stores into the circulation to increase substrate availability. ^[84], ^[85] In addition, in response to hypoxia, there is a reduction in body movements, a cessation of fetal breathing, and diminished energy utilization by the brain. ^[86], ^[87] Cumulatively, these features may serve to protect vital organ function.

The neonatal response to asphyxia follows a predictable pattern demonstrable in a number of species. Dawes ^[88] investigated the responses of the newborn rhesus monkey (Fig. 20-9). After delivery, the umbilical cord was tied and the monkey's head was placed in a plastic bag. Within about 30 seconds, a short series of respiratory efforts began. These were interrupted by a convulsion or a series of clonic movements accompanied

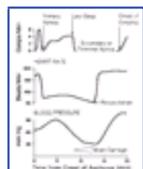

Figure 20-9 Schematic depiction of changes in rhesus monkeys during asphyxia and on resuscitation by positive-pressure ventilation. (Adapted from Dawes GS: *Foetal and Neonatal Physiology*. Chicago, Year Book, 1968.)

by an abrupt fall in heart rate. The animal then lay inert with no muscle tone. Skin color became progressively cyanotic and then blotchy because of vasoconstriction in an effort to maintain systemic blood pressure. This initial period of apnea lasted about 30 to 60 seconds. The monkey then began to gasp at a rate of three to six per minute. The gasping lasted for about 8 minutes, becoming weaker terminally. The time from onset of asphyxia to last gasp could be related to postnatal age and maturity at birth; the more immature the animal, the longer the time. Secondary or terminal apnea followed and, if resuscitation was not quickly initiated, death ensued. As the animal progressed through the phase of gasping and then on to terminal apnea, heart rate and blood pressure continued to fall, indicating hypoxic depression of myocardial function. As the heart failed, blood flow to critical organs decreased, resulting in organ injury.

The response to resuscitation has also been described in great detail and is qualitatively similar in all species, including humans. ^[89], ^[90] During the first period of apnea, almost any physical or chemical stimulus will cause the animal to breathe. If gasping has already ceased, the first sign of recovery with initiation of positive-pressure ventilation is an increase in heart rate. The blood pressure then rises, rapidly if the last gasp has only just passed, but more slowly if the duration of asphyxia has been longer. The skin then becomes pink, and gasping ensues. Rhythmic spontaneous respiratory efforts become established after a further interval. For each 1

minute past the last gasp, 2 minutes of positive-pressure breathing is required before gasping begins and 4 minutes to reach rhythmic breathing. Not until some time later do the spinal and corneal reflexes return. Muscle tone gradually improves over the course of several hours.

Delivery Room Management of the Newborn

A number of situations during pregnancy, labor, and delivery place the infant at increased risk for asphyxia: (1) maternal diseases, such as diabetes and hypertension, third-trimester bleeding, and prolonged rupture of membranes; (2) fetal conditions, such as prematurity, multiple births, growth retardation, fetal anomalies, and rhesus isoimmunization; and (3) conditions related to labor and delivery, including fetal distress, meconium staining, breech presentation, and administration of anesthetics and analgesics.

When an asphyxiated infant is expected, a resuscitation team should be in the delivery room. The team should have at least two persons, one to manage the airway and one to monitor heart rate and provide whatever assistance is needed. The necessary equipment for an adequate resuscitation is listed in [Table 20-2](#). The equipment should be checked regularly and should be in a continuous state of readiness.

Steps in the resuscitation process ^[91], ^[92] are as follows (Fig. 20-10):

1. Dry the infant well and place under the radiant heat source on the back or side with the neck slightly extended.
2. Gently suction the oropharynx and nose.
3. Assess the infant's condition ([Table 20-3](#)). The best criteria to assess are the infant's respiratory effort (apneic, gasping, regular) and heart rate (more or less than 100). A depressed heart rate indicative of hypoxic myocardial depression is the single most reliable indicator of the need for resuscitation. ^[90], ^[93]
4. Generally, infants who are breathing with heart rates over 100 bpm will require no further intervention. If the infant is breathing with an adequate heart rate, but is cyanotic, provide supplemental oxygen. Infants with heart rates less than 100 bpm with apnea or irregular respiratory efforts should be vigorously stimulated by rubbing the baby's back with a towel while blowing oxygen over the face.
5. If the baby fails to respond rapidly to tactile stimulation, proceed to bag and face mask ventilation, using a soft mask that seals well around the mouth and nose. Choice of ventilation bags includes a flow-inflating bag (500 to 750 ml) with a pressure gauge and flow control valve or a self-inflating bag (240 to 750 ml) with an oxygen reservoir and pressure release valve (Fig. 20-11) (Figure Not Available). For the initial inflations, pressures of 30 to 40 cm H₂O may be necessary to overcome surface active forces in the lungs. Adequacy of ventilation is assessed by observing expansion of the infant's chest with bagging and a gradual improvement in color, perfusion, and heart rate. After the first few breaths, attempts should be made to lower the peak pressure to 15 to 20 cm H₂O. Rate of

bagging should not exceed 40 to 60 bpm.

6. Most neonates can be effectively resuscitated with a bag and face mask. If the infant does not initially respond to bag and mask ventilation, try to reposition the head (slight extension), reapply the mask to achieve a good seal, consider suctioning the mouth and oropharynx, and try ventilating with the mouth open. It may be necessary to increase the pressure used. However, if there is not favorable response in 30 to 40 seconds, one must proceed to intubation:

663

- a. The head should be stable, with the nose in the sniffing position (pointing straight upward).
- b. Insert the laryngoscope blade, and sweep the tongue to the left.
- c. Advance the blade to the base of the tongue, and identify the epiglottis.
- d. Pick up the proper size endotracheal tube (2.5 mm OD for infants <1,000 g, 3.0 mm for infants 1,000 to 2,000 g, and 3.5 mm for larger infants) with the right hand.
- e. Slide the laryngoscope anterior to the epiglottis, and gently lift along the angle of the handle of the laryngoscope (Fig. 20-12) (Figure Not Available) .
- f. Identify the vocal cords.
- g. Insert the tube in the right side of the mouth, and visualize the tube passing through the vocal cords. The tube should be located 7 cm at the lip for a 1,000-g infant, 8 cm for a 2,000-g infant, and 9 cm for a 3,000-g infant.
- h. Ventilate as described above.
- i. Failure to respond to intubation and ventilation

664

- can result from (i) mechanical difficulties (Table 20-4) , (ii) profound asphyxia with myocardial depression, and (iii) inadequate circulating blood volume.
- j. The mechanical causes listed in Table 20-4 should be quickly ruled out. Check to be sure the endotracheal tube passes through the vocal cords. Occlusion of the tube should be suspected when there is resistance to bagging and no chest wall movement. If the endotracheal tube is in place and not occluded, and the equipment is functioning, a trial of bagging with higher pressures is indicated. The other causes listed in Table 20-4 are rare compared with equipment failure or tube problems. A pneumothorax is characterized by asymmetric breath sounds not corrected by repositioning the tube above the carina. Pleural effusions usually occur with fetal hydrops, while a diaphragmatic hernia should be ruled out in the setting of asymmetric breath sounds and a scaphoid abdomen. Pulmonary hypoplasia should be considered if the pregnancy has been complicated by oligohydramnios. It is very unusual for a neonatal resuscitation to require either cardiac massage or drugs. Almost all newborns respond to ventilation with 100 percent oxygen.
 7. If mechanical causes are ruled out, external cardiac massage should be performed for persistent heart rate at less than 60 bpm. Compression of the anterior-posterior diameter of the chest should be performed, interposed with ventilation at a 3:1 ratio (90 compressions, 30 breaths per minute).
 8. If drugs are needed for a persistent heart rate less than 60 bpm after ventilation and chest compressions (Table 20-5) , the drug of choice is 0.1 to 0.3 ml/kg of 1:10,000 epinephrine through the endotracheal tube or preferably an umbilical venous line. Sodium bicarbonate 1 to 2 mEq/kg of the neonatal dilution (0.5 mEq/ml) can be used in prolonged resuscitation efforts in which response to other measures is poor or with a documented metabolic acidosis. If volume loss is suspected (e.g., documented blood loss with clinical evidence of hypovolemia), 10 ml/kg of a volume expander (normal saline) should be administered through an umbilical venous line. The appropriateness of continued resuscitative efforts should always be reevaluated in an infant who fails to respond to all of the above efforts. Today, resuscitative efforts are made even in "apparent stillbirths," that is, infants whose 1-minute Apgar scores are 0 to 1. However, efforts should not be sustained in the face of little or no improvement over a reasonable period of time (i.e., 10 to 15 minutes).^[94]

TABLE 20-2 -- EQUIPMENT FOR NEONATAL RESUSCITATION

Clinical Needs	Equipment
Thermoregulation	Radiant heat source with platform, mattress covered with warm sterile blankets, servo control heating, temperature probe
Airway management	<i>Suction:</i> bulb suction, meconium aspirator, wall vacuum suction with sterile catheters <i>Ventilation:</i> manual infant resuscitation bag connected to pressure manometer capable of delivering 100% oxygen, appropriate masks for term and preterm infants, oral airways, stethoscope, gloves <i>Intubation:</i> neonatal laryngoscope with #0 and #1 blades; extra bulbs and batteries; endotracheal tubes 2.5, 3.0, and 3.5 mm OD with stylet; scissors, adhesive tape
Gastric decompression	Nasogastric tube, 8.0 Fr
Administration of drugs/volume	Sterile umbilical catheterization tray, umbilical catheters (3.5 and 5.0 Fr), volume expanders (lactated Ringer's, normal saline), drug box with appropriate neonatal vials and dilutions (see Table 20-5) , sterile syringes, and needles
Transport	Warmed transport isolette with oxygen source

Figure 20-10 Delivery room management of the newborn. PPV, positive-pressure ventilation.

TABLE 20-3 -- THE APGAR SCORING SYSTEM

Sign	0	1	2
Heart rate	Absent	<100 bpm	>100 bpm
Respiratory effort	Apneic	Weak, irregular, gasping	Regular
Reflex irritability*	No response	Some response	Facial grimace, sneeze, cough
Muscle tone	Flaccid	Some flexion	Good flexion of arms and legs

* For correction of metabolic acidosis only after adequate ventilation has been achieved; give slowly over several minutes.

Infuse slowly over several minutes.

After proceeding with proper airway management and other resuscitative techniques.

A few special circumstances merit discussion at this point. Infants in whom respiratory depression secondary to narcotic administration is suspected may be given naloxone (Narcan). However, this should not be done until the airway has been managed and the infant resuscitated in the usual fashion. In addition, naloxone should not be given to the infant of an addicted mother, as it will precipitate withdrawal. A second special group are preterm infants. Minimizing heat loss improves survival, so prewarmed towels should be available, and the environmental temperature of the delivery suite should be raised. In the extremely-low-birth-weight infant (<1,000 g), proceed quickly to intubation. Volume expanders and sodium bicarbonate should be infused slowly to avoid rapid swings in blood pressure.

Finally, there is the issue of meconium-stained amniotic fluid. Meconium aspiration syndrome (MAS) is a form of aspiration pneumonia that occurs most often in term or postterm infants who have passed meconium in utero (10 to 15 percent of all deliveries^[95]). Overall, 4 to 6 percent of children born through meconium-stained fluid will be diagnosed with meconium aspiration syndrome, and an additional 4 to 9 percent will be diagnosed with other respiratory disorders.^[95] Delivery room management of meconium in the amniotic fluid has been based on the notion that aspiration takes place with the initiation of extrauterine respiration and that the pathologic condition is related to the aspirated contents. This resulted in the practice of oropharyngeal suction on the perineum after delivery of the head followed by airway visualization and suction by the resuscitator after delivery.^[96] Both of these assumptions are now being questioned. Meconium is found below the vocal cords in 35 percent of births from meconium-stained fluid.^[97] In utero aspiration has been induced in animal models^[97],^[98] and confirmed in autopsies of human stillbirths.^[97],^[99] In addition, the combined suction approach to prevention of MAS has not been uniformly successful in decreasing the incidence of MAS.^[97],^[100],^[101] Further concern has been raised by the experience that routine suctioning of the neonatal airway has been associated itself with respiratory morbidity.^[102],^[103] Of note as well is the finding that infants with meconium-stained fluid in whom only pharyngeal suctioning is performed suffer no increase in the incidence of MAS.^[102],^[103] Recently, a large multicenter, prospective, randomized controlled trial assessing selective intubation of apparently vigorous meconium-stained infants was completed.^[95],^[104] Compared with expectant management, intubation and tracheal suction did not result in a decreased incidence of MAS or other respiratory disorders.

In terms of the role of meconium in the genesis of MAS, 35 percent of infants born with meconium in the amniotic fluid will have meconium in the lungs. Up to 55 percent will have abnormal chest radiographs, yet respiratory distress develops in only 5 to 10 percent of these infants.^[97] Severe MAS is associated with persistent pulmonary hypertension of the newborn and is likely the result of a long-standing intrauterine process with meconium only a marker of intrauterine hypoxia.^[105],^[106]

Current clinical and experimental data support that MAS is the result of intrauterine asphyxia. The best

666

method of prevention is to identify the fetus at risk (postterm, oligohydramnios). Intrapartum management should emphasize treatments that enhance uteroplacental perfusion. Aminoinfusion in cases with oligohydramnios may reduce cord compression, gassing, and intrapartum aspiration.^[107] The management of the infant's airway remains controversial, although postnatal prevention of MAS will often not be possible. A reasonable approach is as follows:

1. The obstetrician carefully suctions the oro- and nasopharynx after delivery of the head with a suction apparatus, hooked to wall suction.
2. The delivery is then completed and the baby given to the resuscitator.
3. If the baby is active and breathing and requires no resuscitation, the airway need not be inspected, thus avoiding the risk of inducing vagal bradycardia.
4. Any infant in need of resuscitation should have the airway inspected and suctioned before instituting positive-pressure ventilation.
5. Suction the stomach when airway management is complete and vital signs are stable.

Sequelae of Birth Asphyxia

The incidence of birth asphyxia varies between 1 and 5 percent, depending on criteria utilized in making the diagnosis.^[108],^[109] As would be expected, the incidence increases in infants of lower gestational age. In a study involving more than 38,000 deliveries, MacDonald et al.^[108] reported an incidence of 0.4 percent in infants more than 38 weeks and 62.3 percent in those less than 27 weeks. The acute sequelae that need to be managed in the neonatal period are listed in [Table 20-6](#). It is evident that widespread organ injury occurs.^[110] Management focuses on supportive care and treatment of

TABLE 20-6 -- THE ACUTE SEQUELAE OF ASPHYXIA

System	Manifestations
Central nervous system	Cerebral edema, seizures, and hemorrhage
Cardiac	Papillary muscle necrosis-transient tricuspid insufficiency, cardiogenic shock
Pulmonary	Aspiration syndromes (meconium, clear fluid), acquired surfactant deficiency, persistent pulmonary hypertension, pulmonary hemorrhage
Renal	Acute tubular necrosis
Adrenal	Hemorrhage with adrenal insufficiency

Hepatic	Enzyme elevations, liver failure
Gastrointestinal	Necrotizing enterocolitis
Metabolic	Hypoglycemia, hypocalcemia
Hematologic	Coagulation disturbances, thrombocytopenia

specific abnormalities. This includes careful fluid management, blood pressure support, intravenous glucose, and treatment of seizures. Phenobarbital (40 mg/kg) 1 to 6 hours after the event given as neuroprotective therapy is associated with an improved neurologic outcome.^[111] The roles of hypothermia (in particular selective head cooling), oxygen free radical scavengers, excitatory amino acid antagonists, and calcium channel blockers in minimizing cerebral injury after asphyxia are still investigational.^[112]^[113]^[114] If the infant survives, the major long-term concern is permanent central nervous system (CNS) damage. The challenge is identifying criteria that can provide information about the risk of future problems for a given infant. A variety of markers have been examined to identify birth asphyxia and risk for adverse neurologic outcome.^[97],^[115]^[116]^[117]^[118]^[119]^[120]^[121] Meconium in the amniotic fluid considered in isolation does not increase the risk of unfavorable outcome.^[97] Marked fetal bradycardia is associated with some increase in risk, but use of electronic fetal monitoring and cesarean delivery have not altered the incidence of cerebral palsy over the last several decades.^[115]^[116]^[117]^[118] Low Apgar scores at 1 and 5 minutes are not very predictive of outcome, but infants with low scores that persist at 15 and 20 minutes after birth have a 50 percent chance of manifesting cerebral palsy if they survive.^[119] Cord pH is predictive of adverse outcome only after the pH is less than 7.00.^[120] The best predictor of outcome is the severity of the neonatal neurologic syndrome.^[121] Infants with mild encephalopathy all survive and are normal on follow-up examination. Moderate encephalopathy carries a 5 percent mortality risk and a 15 percent chance of late disability, while the severe syndrome carries a 100 percent risk of death or disability. Diagnostic aids including electroencephalograms, evoked potentials, computed tomography (CT) and magnetic resonance imaging (MRI) scans, and Doppler flow studies can also aid in predicting outcome.^[122] It is also important to keep in mind that the circulatory response to hypoxia is to redistribute blood flow to provide adequate oxygen delivery to critical organs (e.g., brain, heart) at the expense of other organs. Thus, it is hard to imagine an insult severe enough to damage the brain without evidence of other organ dysfunction. In particular, renal dysfunction correlates with neurologic outcome.^[123]

The long-term neurologic sequelae of intrapartum asphyxia are cerebral palsy with or without associated cognitive deficits and epilepsy.^[115],^[124],^[125] Although cerebral palsy can be related to intrapartum events, the large majority of cases are of unknown cause.^[125],^[126] Furthermore, cognitive deficits and epilepsy, unless associated with cerebral palsy, cannot be related to asphyxia or to other intrapartum events.^[124],^[125] To attribute cerebral palsy to peripartum asphyxia, there must be an absence of other demonstrable causes, substantial

or prolonged intrapartum asphyxia (fetal heart rate abnormalities, fetal acidosis), and clinical evidence during the first days of life of neurologic dysfunction in the infant.^[127],^[128]

BIRTH INJURIES

Birth injuries are defined as those sustained during labor and delivery. Although significant birth injury accounts for fewer than 2 percent of neonatal deaths and stillborns, the frequency is 6 to 8 injuries per 1,000 live births (excluding cephalohematomas).^[127] Factors predisposing to birth injury include macrosomia, cephalopelvic disproportion, shoulder dystocia, prolonged or difficult labor, precipitous delivery, abnormal presentations (including breech), and use of forceps (especially mid-forceps). Injuries range from minor (requiring no therapy) to life threatening (Table 20-7).

Soft tissue injuries are most common. Most are related to dystocia and to the use of forceps. Accidental lacerations of the scalp, buttocks, and thighs may be inflicted with the scalpel during cesarean delivery. Cumulatively, these injuries are of a minor nature and respond well to therapy. Hyperbilirubinemia, particularly in the premature, is the major neonatal complication related to soft tissue damage.

A cephalhematoma occurs in 0.2 to 2.5 percent of live births.^[128] Caused by rupture of blood vessels that traverse from the skull to the periosteum, the bleeding is subperiosteal and therefore limited by suture lines,

TABLE 20-7 -- BIRTH INJURIES

Classification	Example

Scalp abscess*	Fetal scalp electrode, pH

* More common occurrences.

† Secondary to hemorrhage into the sternocleidomastoid muscle.

with the most common site of bleeding being over the parietal bones. Associations include prolonged or difficult labor and mechanical trauma from forceps. Linear skull fractures beneath the hematoma have been reported in 5.4 percent of cases,^[128] but are of no major consequence except in the unlikely event that a leptomeningeal cyst develops. Most cephalhematomas are reabsorbed in 2 weeks to 3 months. Subgaleal bleeds, which are not limited by suture lines, can occur in association with vacuum extraction and difficult forceps deliveries, and can result in life-threatening anemia, hypotension, or consumptive coagulopathy. Depressed skull fractures are also seen in neonates, but most do not require surgical elevations.

Intracranial hemorrhages related to trauma include subdural and subarachnoid bleeds.^[129] With improvements in obstetric care, subdural hemorrhages fortunately are now rare. Three major varieties of subdural bleeds have been described: (1) tentorial laceration with rupture of the straight sinus, vein of Galen, or lateral sinus; (2) falx laceration, with rupture of the inferior sagittal sinus; and (3) rupture of the superficial cerebral veins. The clinical symptomatology is related to the location of bleeding. With tentorial laceration, bleeding is infratentorial, causing brain stem signs and a rapid progression to death. Falx tears will cause bilateral cerebral signs until blood extends infratentorially to the brain stem. Subdural hemorrhage over the cerebral convexities can cause several clinical states, ranging from an asymptomatic newborn to one with seizures and focal neurologic findings. Infants with lacerations of the tentorium and falx have a poor outlook. In contrast, the prognosis for rupture of the superficial cerebral veins is much better, with more than one half the survivors being normal. Primary subarachnoid hemorrhage is the most common variety of neonatal intracranial hemorrhage.^[129] Clinically, these infants are often asymptomatic, although they may present with a characteristic seizure pattern. The seizures begin on day 2 of life, and the infants are "well" between convulsions. In general, the prognosis for subarachnoid bleeds is good.

Trauma to peripheral nerves produces another major group of birth injuries. Brachial plexus injuries are caused by stretching of the cervical roots during delivery, usually when shoulder dystocia is present. Upper arm palsy (Erb-Duchenne), the most common brachial plexus injury, is caused by injury to the fifth and sixth cervical nerves; lower arm paralysis (Klumpke) results from damage to the eighth cervical and first thoracic nerves. Damage to all four nerve roots produces paralysis of the entire arm. Outcome for these injuries is variable, with some infants left with significant residual.^[130],^[131] Horner's syndrome may accompany Klumpke's palsy, and approximately 5 percent of patients with Erb's palsy have an associated phrenic nerve

paresis.^[127] Facial palsy is another fairly common injury caused either by pressure from the sacral promontory as the infant passes through the birth canal or by forceps. Most of these palsies resolve, although in some infants paralysis is persistent.

The majority of bone fractures resulting from birth trauma involve the clavicle and result from shoulder dystocia or breech extractions that require vigorous manipulations. Clinically, many of these fractures are asymptomatic, and symptoms when present are mild. Prognosis for clavicular as well as limb fractures is uniformly good. The most commonly fractured long bone is the humerus.

Spinal cord injuries are a relatively infrequent but often severe form of birth injury. Accurate incidence is difficult to assess, because symptomatology mimics other neonatal diseases and autopsies often do not include a careful examination of the spine. Depressed tone and hyporeflexia are clues to this diagnosis. Excessive

longitudinal traction and head rotation during forceps delivery predispose to spinal injury, and hyperextension of the head in a footling breech is particularly dangerous. Outcomes include death or stillbirth caused by high cervical or brain stem lesions, long-term survival of infants with paralysis from birth, and minimal neurologic symptoms or spasticity.^[132]

NEONATAL THERMAL REGULATION

Physiology

The human newborn is a homeotherm possessing the ability to maintain a stable core body temperature over a range of environmental temperatures.^[133] The range of environmental temperatures over which the neonate can operate is narrower than that of an adult as a result of the infant's inability to dissipate heat effectively in warm environments and, more critically, to maintain temperature in response to cold.

Heat Production

The heat production within the body is a by-product of metabolic processes and must equal heat losses through the skin and lungs. In the adult, heat production in response to cold can come from voluntary muscle activity, involuntary muscle activity (shivering), and nonshivering chemical thermogenesis. While some increases in activity and shivering have been observed, nonshivering thermogenesis is the most important means of increased heat production in the cold-stressed newborn.^[134] Nonshivering thermogenesis can be defined as an increase in total heat production without detectable (visible or electrical) muscle activity. From both animal^[135] and human^[137] observations, it has been inferred that the site of this increased heat production is brown fat. More abundant in newborns than adults, brown fat accounts for 2 to 6 percent of total body weight.^[136] This fat is located between the scapulae; around the muscles and blood vessels of the neck, axillae, and mediastinum; between the esophagus and trachea; and around the kidneys and adrenal glands. Brown fat differs both morphologically and metabolically from white fat. Brown fat cells contain more mitochondria and fat vacuoles and have a richer blood and sympathetic nerve supply. Brown fat metabolism is stimulated by norepinephrine released through sympathetic innervation causing triglyceride hydrolysis.^[136] The initiation of nonshivering thermogenesis at birth depends on cooling, separation from the placenta, and a euthyroid state. Sympathetic nervous system stimulation by cold increases local catecholamine turnover within brown fat, resulting in a marked increase in oxygen consumption.^[139]

Heat Loss

Heat loss to the environment is dependent on both an internal temperature gradient (from within the body to the surface) and an external gradient (from the surface to the environment). The infant can change the internal gradient by altering vasomotor tone and, to a lesser extent, by postural changes that decrease the amount of exposed surface area. The external gradient is dependent on purely physical variables. Heat transfer from the surface to the environment involves four routes: radiation, convection, conduction, and evaporation. Radiant heat loss, heat transfer from a warmer to a cooler object that is not in contact, depends on the temperature gradient between the objects. Heat loss by convection to the surrounding gaseous environment depends on air speed and temperature. Conduction or heat loss to a contacting cooler object is minimal in most circumstances. Heat loss by evaporation is cooling secondary to water loss at the rate of 0.6 cal/g water evaporated and is affected by relative humidity, air speed, exposed surface area, and skin permeability. In infants in excessively warm environments, under overhead radiant heat sources, or in very immature infants with thin, permeable skin, evaporative losses increase considerably.

Compared with an adult, the newborn is compromised in the ability to conserve as well as dissipate heat. Conservation of heat is impaired because of a large surface area/body weight ratio and less tissue insulation because of less subcutaneous fat.^[140] With a cold stress, heat is conserved chiefly by vasoconstriction in both mature and immature neonates. When the environment is too warm, heat loss is augmented by vasodilation

TABLE 20-8 -- NEONATAL RESPONSE TO THERMAL STRESS

Stressor	Response	Term	Preterm
Cold	Vasoconstriction	++	++
	Exposed surface area (posture change)	+/-	+/-
	Oxygen consumption	++	+
	Motor activity; shivering	+	-
Heat	Vasodilation	++	++
	Sweating	+	-

++, Maximum response; +, intermediate; +/-, may have a role; -, no response.

of skin vessels and an increase in evaporative heat loss by sweating. Sweating is present in term infants when rectal temperatures rise above 37.2°C.^[141] With sweating, evaporative heat losses can increase two- to fourfold in term babies, but this is not enough to prevent a rise in core temperature. [Table 20-8](#) summarizes the neonate's efforts to maintain a stable core temperature in the face of cold or heat stress.

Neutral Thermal Environment

Although most available information confirms that the human neonate is a homeotherm, the range of temperatures over which core body temperature remains stable is narrower than in an adult and decreases with decreasing gestational age. It is therefore advantageous to maintain an infant in a neutral thermal environment ([Fig. 20-13](#)). A neutral thermal environment makes minimal demands on the neonate's energy reserves, core body temperature being regulated by changes in skin blood flow and posture. Body temperature remains normal, while oxygen consumption and heat production are minimal and match heat loss.^[142] With a drop in environmental temperature out of the thermoneutral range, the infant will increase oxygen consumption and thus heat production to keep up with heat losses and maintain a stable core temperature. Core temperature will be maintained until heat loss exceeds the infant's ability to increase heat production further. When the infant is placed in an environment warmer than neutral thermal zone, hyperthermia rapidly occurs because of the neonate's inability to dissipate heat and an increase in oxygen consumption that ensues as the infant's body temperature rises. The neutral thermal environment for a given infant depends on size, gestational age, and

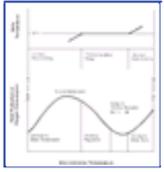

Figure 20-13 Effect of environmental temperature on oxygen consumption and body temperature. (Adapted from Klaus MH, Martin RJ, Fanaroff AA: *The physical environment*. In Klaus MH, Fanaroff AA [eds]: *Care of the High-Risk Neonate*, 4th ed. Philadelphia, WB Saunders Company, 1993, p 114.)

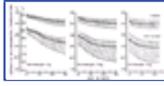

Figure 20-14 Range of environmental temperatures to maintain naked or cot-nursed 1-kg, 2-kg, and 3-kg infants in a neutral thermal environment. (From Hey EN, Katz G: *The optimum thermal environment for naked babies*. *Arch Dis Child* 45:328, 1970.)

postnatal age.^[143] The optimal thermal environment for naked babies and cot-nursed (dressed and bundled) babies has been defined (Fig. 20-14).^[142],^[144] It is important to note that the environmental temperatures shown in Figure 20-14 are operative temperatures for an infant in an incubator. The operative temperature can differ from the measured environmental temperature because of changes in relative humidity and temperature of the incubator walls. Incubator wall temperature will vary as a function of room temperature. In general, maintaining the abdominal skin temperature at 36.5°C minimizes oxygen consumption.^[145]

CLINICAL APPLICATIONS

Delivery Room

In utero, fetal thermoregulation is the responsibility of the placenta and is dependent on maternal core temperature, with fetal temperature 0.5°C higher than maternal temperature.^[146] At birth, the infant's core temperature drops rapidly from 37.8°C because of evaporation from its wet body and radiant and convective losses to the cold air and walls of the room. Heat loss can occur at a rate of 0.2 cal/kg/min in the term infant and at a greater rate in premature and sick or unstable infants.^[146], ^[147] Even with an increase in oxygen consumption to the maximum capability of the newborn (15 ml/kg/min), the infant can produce only 0.075 cal/kg/min and will rapidly lose heat. Measures taken to reduce heat loss after birth depend on the clinical situation. For the well term infant, drying the skin and wrapping the baby with warm blankets is sufficient. When it is necessary to leave an infant exposed for close observation or resuscitation, the infant should be dried and placed under a radiant heat source. Room temperature can be elevated as an added precaution for the low-birth-weight infant.

Nursery

Babies are cared for in the newborn nursery wrapped in blankets in bassinets (cot nursed), in isolettes, or under a radiant heat source. Healthy full-term infants (weighing >2.5 kg) need only be clothed and placed in a bassinet under a blanket. A nursery temperature of 25°C should be adequate (Fig. 20-14). Infants weighing 2 to 2.5 kg who are either slightly premature or growth retarded should be allowed 12 to 24 hours to stabilize in an isolette and then advanced to a bassinet. Lower birth weight babies (<2 kg) will require care in either isolettes or under radiant heat sources. Adequate thermal protection of the low-birth-weight infant is essential. Several groups have demonstrated decreased mortality in low-birth-weight infants kept in warmer environments.^[148] ^[149] ^[150] This is especially important for the very-low-birth-weight infant (<1.5 kg), who often does not behave like a mature homeotherm. These neonates can react to a small change in environmental temperature with a change in body temperature rather than a change in oxygen consumption. In addition, warmer environments have also been shown to hasten growth of the premature.^[151]

The isolette, which heats by convection, is the most commonly used heating device for the low-birth-weight nude infant. The major source of heat loss while in a neutral thermal environment is radiant to the walls of the isolette. The magnitude of this loss is predictable if

room temperature is known. These losses can be minimized using double-walled isolettes in which the inner wall temperature is very close to the air temperature within the isolette. An isolette permits adequate observation of the infant and is suitable for caring for the most sick low-birth-weight or full-sized infants. Once clinical status has been stabilized the child can be dressed, which will afford increased thermal stability.

Radiant warmers can also be used to ensure thermal stability of both low-birth-weight and full-sized infants. Radiant warmers are used most effectively for short-term warming during initial resuscitation and stabilization as well as for performing procedures. They provide easy access to the infant while ensuring thermal stability. The main heat losses are convection, which can be quite significant because of variable air speed in a room, and evaporation. Evaporative heat loss resulting in significant fluid losses is a major concern for the very-low-birth-weight premature cared for under a radiant warmer. Placing a plastic shield over the infant or covering the skin with a semipermeable membrane can minimize these fluid losses.^[152], ^[153]

The most economical means of thermal support for the low-birth-weight infant is skin-to-skin contact with a parent. This "kangaroo" care has been shown to reduce serious illness and enhance lactation while providing adequate thermal support.^[154] ^[155] ^[156] ^[157]

Hypothermia and Neonatal Cold Injury

Hypothermia is seen in low-birth-weight infants, particularly following delivery room resuscitation. Hypothermia may also be a sign of infection or intracranial pathology. Neonatal cold injury is a consequence of excessive cold exposure most commonly seen in both term and preterm infants born unexpectedly outside the hospital. Clinical features include poor feeding, lethargy, coolness of skin, bright red color, edema, and occasionally sclerema (hardening of the skin associated with reddening and edema), slow and shallow respiratory effort, and bradycardia.^[158] Metabolic derangements include metabolic acidosis, hypoglycemia, hyperkalemia, and elevated blood urea nitrogen. The infant should be warmed slowly in an isolette set at an operative temperature of 2°C higher than the infant's core body temperature.

Gabbe: *Obstetrics - Normal and Problem Pregnancies, 4th ed.* , Copyright © 2002 Churchill Livingstone, Inc.

NEONATAL NUTRITION AND GASTROENTEROLOGY

At birth, the newborn infant must assume various functions performed during fetal life by the placenta. Cardiopulmonary transition and thermoregulation have already been discussed. The final critical task for the newborn is the assimilation of calories, water, and electrolytes.

Nutritional Requirements

The required caloric, water, and electrolyte intake of the newborn depends on body stores and normal rate of energy expenditure. Body composition varies considerably with gestational age (Fig. 20-15).^[159],^[160] The average 1-kg neonate consists of 85 percent water, 10 percent protein, and 3 percent fat as compared with 74 percent water, 12 percent protein, and 11 percent fat at term. Carbohydrate stores in the term infant are eight times higher. Rates of energy expenditure differ as well. Although basal metabolic rate is lower in premature than in term infants, the premature infant frequently has increased metabolic demand secondary to cold stress and work of breathing. The small-for-gestational-age (SGA) infant provides another special consideration, possessing a higher basal metabolic rate per kilogram than a normally grown infant.^[161]

Water and Electrolyte

Maintenance water requirements are dependent on metabolic rate (evaporative losses to dissipate the heat of oxidation) and the necessary water to excrete the renal solute load. Other pertinent factors, especially for the premature infant, include environmental variation in insensible water losses and diminished ability to concentrate urine.^[162],^[163] An individual infant's water requirement can be determined by measuring urine and stool losses and estimating insensible losses through skin and mucosa. It is normal during the first 3 to 4 postnatal days for an infant to experience a weight loss

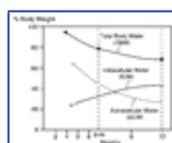

Figure 20-15 Changes in body water during gestation and infancy. (Adapted from Friis-Hansen B: *Water distribution in the foetus and newborn infant. Acta Paediatr Scand Suppl* 305:7, 1983.)

of up to 10 percent as the physiologic contraction of extracellular body fluid takes place. Maintenance electrolyte requirements are 2 to 3 mEq/kg/day for sodium, chloride, and bicarbonate and 1 to 2 mEq/kg/day for potassium. During periods of rapid growth, requirements will be higher.

Calories

Caloric needs are primarily dependent on oxygen consumption. The character of the feeding also affects caloric needs by altering specific dynamic action and fecal losses. The average caloric requirement for a normal full-term infant is estimated to be about 100 to 110 kcal/kg/day. The needs of the low-birth-weight infant are more variable, but usually 105 to 130 kcal/kg/day is adequate.^[164] Standard infant formulas and breast milk provide approximately 20 kcal/oz. Therefore, volumes of 150 to 180 ml/kg/day will provide the necessary caloric intake of 100 to 120 kcal/kg/day for the average term or preterm infant beyond 32 to 34 weeks' gestation. However, infants less than 1,500 g should be fed with either formulas designed specifically for the premature (20 to 24 kcal/oz) or fortified breast milk.

Protein

Both the quantity and quality of protein intake are important for adequate growth, particularly for the premature infant.^[165] Suggested intakes range from 2.25 to 4.0 g/kg/day (3.5 g/kg/day for the premature).^[164] The "gold standard" for amino acid content is that which provides a plasma amniogram as close as possible to that seen with human milk.^[166]

Fat and Carbohydrate

Fat intake plays several important roles in infant nutrition. It is a major energy source, a component of cellular membranes, a carrier of fat-soluble vitamins, and a source of essential fatty acids.^[164] Long-chain polyunsaturated fatty acids such as arachidonic acid and docosahexaenoic acid play an important role in infant retinal and brain development. Because mammalian cells lack the enzymes to insert a double bond at the -6 or -3 position, a dietary source of these fatty acids is required. The precursors are linoleic and linolenic acids, but the newborn is not able to effectively lengthen the fatty acid chain and produce these long-chain molecules. Breast milk contains the -6 and -3 long-chain fats, and ongoing work is assessing the need for supplementation in formulas.^[167] Fat is also not completely absorbed; more so in the premature than in the term infant.^[164],^[168] For that reason, preterm formulas provide a portion of the fat energy as medium-chain triglycerides. Fat represents 40 to 50 percent of the caloric intake in the newborn, with 3 percent of total calories in the form of linoleic acid.^[164]

Intestinal disaccharidases develop early in fetal life, with lactase reaching mature levels at term.^[169] Both term and preterm infants can digest lactose, the major sugar in human milk and standard infant formulas, although there is some evidence that digestion may not be fully efficient the first several days of life.^[164] Carbohydrate represents 40 to 50 percent of total calories in most formulas as well as human milk. These levels are more than adequate to maintain normal blood glucose levels and prevent ketosis.

Vitamins and Minerals

Published requirements are available for all major minerals and vitamins for term and preterm infants.^[164],^[170],^[171] Information on trace minerals^[164],^[170],^[171] is available as well.

Infant Feeding

For the well term or slightly preterm infant, institution of oral feeds within the first 2 to 4 hours of life is reasonable practice. For infants who are SGA or large for gestational age (LGA), feeds within the first hour or two of life may be indicated to avoid hypoglycemia. Premature infants (<34 weeks' gestation) who are unable to

nipple feed present a more complex set of circumstances. In addition to an inability to suck and swallow efficiently, such infants face a number of problems: (1) relatively high caloric demand; (2) small stomach capacity; (3) incompetent esophageal-cardiac sphincter, leading to gastroesophageal reflux; (4) poor gag reflex, creating a tendency for aspiration; (5) decreased digestive capability (especially for fat); and (6) slow gastric emptying and intestinal motility. These infants can initially be supported adequately with parenteral nutrition followed by institution of nasogastric tube feedings when their cardiopulmonary status is stable.

Although a wide range of infant formulas satisfy the nutritional needs of most neonates, breast milk remains the standard on which formulas are based. The distribution of calories in human milk is 7 percent protein, 55 percent fat, and 38 percent carbohydrate. The whey/casein ratio is 60:40, allowing ease of protein digestion, while fat digestion is augmented by the presence of a breast milk lipase. In addition to easy digestibility, the amino acid make-up is well suited for the newborn. Despite the low levels of several vitamins and minerals, bioavailability is high. Besides the nutritional features, breast milk's immunochemical and cellular components provide protection against infection.^{[164], [172]}

The major area of controversy regarding breast milk has been its use for the small premature infant. The

growth demands of the low-birth-weight infant exceed the contents of human milk for protein, calcium, phosphorus, sodium, zinc, copper, and possibly other nutrients.^[173] These shortcomings can be addressed through the addition of human milk fortifiers to mother's preterm breast milk.^[173] Advantages of breast milk for the premature include its anti-infective properties, possible protection against necrotizing enterocolitis, and its role in enhancing neurodevelopmental outcome.^{[174] [175] [176] [177]}

Under certain circumstances, breast-feeding might be deleterious. For example, phenylketonuria (PKU), a condition requiring special nutritional products, precludes breast-feeding. The presence of environmental pollutants has been documented in breast milk, but to date no serious side effects have been reported. Most drugs do not contraindicate breast-feeding, but there are a few exceptions (see Chapter 9). Transmission of some viral infections via breast milk is a concern as well. Mothers who are hepatitis B surface antigen (HB_s Ag) or human immunodeficiency virus (HIV) positive should not breast-feed. Finally, there is the insufficient milk syndrome and breast-feeding failure. Monographs that deal with this as well as other minor breast-feeding problems are available for mother and physician.^[178] The obstetrician and pediatrician should serve as a source of knowledge and, most importantly, support. Table 20-9 illustrates what a mother can expect as she breast-feeds her infant.

Neonatal Hypoglycemia

Glucose is a major fetal fuel transported by facilitated diffusion across the placenta. After birth, before an appropriate supply of exogenous calories is provided, the newborn must maintain blood glucose through endogenous sources. This homeostasis depends on an adequate supply of gluconeogenic substrates (amino acids, lactate, glycerol), functionally intact hepatic glycogenolytic and gluconeogenic enzyme systems, and a normal endocrine counterregulatory hormone system (glucagon, catecholamines, growth hormone, cortisol) integrating and modulating these processes. Hepatic glycogen stores are almost entirely depleted within the first several hours before birth. Fat and protein stores are then used for energy, while glucose levels are maintained by hepatic gluconeogenesis.

In utero, fetal blood glucose concentration is 15 mg/dl lower than maternal levels. In the healthy unstressed neonate, glucose falls over the first 1 to 2 hours after birth, stabilizes at a minimum of about 40 mg/dl, and then rises to 50 to 80 mg/dl by 3 hours of life.^[179] Hypoglycemia can be defined as blood glucose levels less than 40 mg/dl.^[180] Infants at risk for hypoglycemia and in whom glucose should be monitored include preterm infants, SGA infants, hyperinsulinemic (LGA) infants, and infants with perinatal asphyxia. As in term babies, blood sugar drops after birth in preterm babies, but the latter are less able to mount a counterregulatory response.^[181] In addition, the presence of respiratory distress, hypothermia, and other factors can increase glucose demand, exacerbating hypoglycemia. SGA infants are at risk for hypoglycemia resulting from decreased glycogen stores as well as impaired gluconeogenesis and ketogenesis.^[182] Onset of hypoglycemia in SGA and preterm infants usually occurs at 2 to 6 hours of life. Hyperinsulinemia occurs in the infant of a diabetic mother as well as other rare conditions, including Beckwith-Weidemann syndrome and islet cell dysregulation syndrome (nesidioblastosis).^[179] Onset of hypoglycemia in these infants can be in the first 30 to 60 minutes after birth. In the case of perinatal asphyxia, hypoglycemia is the result of excessive glucose demand.^[180]

Symptoms of hypoglycemia include jitteriness, seizures, cyanosis, respiratory distress, apathy, hypotonia, and eye rolling.^[179] However, many infants, particularly prematures, are asymptomatic. Because of the risk of subsequent brain injury,^{[183], [184]} hypoglycemia, when present, should be aggressively treated. However, the single best treatment is prevention by identifying infants at risk, including prematures, SGA, LGA, and any stressed infant. These newborns should have blood glucose screened with a bedside glucose meter. All values less than or equal to 40 mg/dl should be confirmed with a laboratory or rapid glucose analyzer measurement of whole blood glucose.^[185] Treatment is provided by early institution of feeds or an intravenous glucose bolus (2 ml/kg of D₁₀W solution) followed by a glucose infusion at a rate of 6 mg/kg/min.

Congenital Gastrointestinal Surgical Conditions

Several congenital surgical conditions of the gastrointestinal tract interfere with a normal transition. Many of these conditions can be diagnosed with antenatal ultrasound, allowing transfer of the mother to a perinatal center for delivery.

Gastrointestinal Tract Obstruction

Tracheoesophageal fistula and esophageal atresia are characterized by a blind esophageal pouch and a fistulous connection between either the proximal or distal esophagus and the airway.^[186] Eighty-five percent of infants with these conditions have the fistula between the distal esophagus and the airway. Polyhydramnios is common because of the high level of gastrointestinal obstruction. Infants present in the first hours of life with copious secretions, choking, cyanosis, and respiratory distress. Diagnosis can be confirmed with chest radiography after careful placement of a nasogastric

TABLE 20-9 -- GUIDELINES FOR SUCCESSFUL BREAST FEEDING

	First 8 Hours	824 Hours	Day 2	Day 3	Day 4	Day 5	Day 6 Onward
Milk Supply	You may be able to express a few drops of milk.		Milk <u>should</u> come in between the 2nd & 4th day.			Milk should be in. Breasts may be firm and/or leak milk.	Breasts should feel softer after nursing.
Baby's Activity	Baby is usually wide awake in the first hour of life. Put baby to breast within ½ to 1 hour of birth.	Wake up your baby. Babies may not wake up on their own to feed.	Baby should be more cooperative and less sleepy.	Look for early feeding cues such as rooting, lip smacking, and hands to face.		You should be able to hear your baby swallow your milk.	Baby should appear satisfied after feedings.
Feeding Routine	Baby may go into a deep sleep 24 hours after birth.		Use chart on back side of page to write <u>down</u> time and length of each feeding.			May go <u>one</u> longer interval (up to 5 hours) between feeds in a 24-hour period.	
		Feed your baby every 1 to 4 hours, as often as wanted, a minimum of 812 times each day.					

Breast-Feeding	Baby will wake up and be alert and responsive for several more hours after initial deep sleep.	As long as Mom is comfortable, nurse at both breasts as long as baby is actively sucking.	Try to nurse both sides each feeding, aiming for 10 minutes each side. Expect some nipple tenderness.	Consider hand expressing or pumping a few drops of milk to soften the nipple if the breast is too firm for the baby to latch on.	Nurse a minimum of 1020 minutes each side every feeding for the first few weeks of life.	Once your milk supply is well established, allow your baby to finish the first breast before offering the second.	Mom's nipple tenderness is improving or is gone.
Baby's Urine Output		Baby must have a minimum of 1 wet diaper in first 24 hours.	Baby must have at least one wet diaper every 8-12 hours.	You should see an increase in wet diapers to 4-6 times in 24 hours.	Baby's urine should be light yellow or clear.	Baby should have 6-8 wet diapers each day.	
Baby's Stools		Baby should have a black-green stool (meconium stool).	Baby may have a second very dark (meconium) stool.	Baby's stools should be changing color from black-green to yellow.		Baby should have 3-4 yellow, soft stools a day.	The number of stools may decrease gradually after 4-6 weeks of life.

tube to the point where resistance is met. The tube will be seen in the blind pouch. If a tracheoesophageal fistula is present to the distal esophagus, gas will be present in the abdomen.

Infants with high intestinal obstruction present early in life with either bilious or nonbilious vomiting. ^[187] A history of polyhydramnios is common and the amniotic fluid, if bile stained, can easily be confused with thin meconium staining. In duodenal atresia, vomitus may or may not contain bile, whereas malrotation with midgut volvulus and high jejunal atresia are characterized by bilious vomiting. Malrotation and midgut volvulus involve torsion of the intestine around the superior mesenteric artery, causing occlusion of the vascular supply to most of the small intestine. If not treated promptly, the infant can lose most of the small bowel because of ischemic injury. Therefore, bilious vomiting in the neonate demands immediate attention and evaluation. Diagnosis of high intestinal obstruction can be confirmed with radiographs. Duodenal atresia is characterized by a "double-bubble sign" (stomach and dilated duodenum). Diagnosis of midgut volvulus can be confirmed with an upper gastrointestinal tract series, looking for contrast not to pass the ligament of Treitz. Approximately 30 percent of cases of duodenal atresia are associated with Down syndrome. ^[187]

Low intestinal obstruction presents with increasing intolerance of feeds (spitting progressing to vomiting), abdominal distention, and decreased or absent stool. ^[187] Differential diagnosis of lower intestinal obstruction includes imperforate anus, Hirschsprung's disease, meconium plug syndrome, small left colon, colonic and ileal atresia, and meconium ileus. Plain x-ray film of the abdomen will show gaseous distention, with air through a considerable portion of the bowel and air-fluid levels. Diagnosis of meconium ileus, meconium plug, and small left colon syndrome can be made by appearance on contrast enema. Rectal biopsy searching for absence of ganglion cells will confirm the diagnosis of Hirschsprung's disease. Infants with meconium ileus and meconium plug should be screened for cystic fibrosis.

Abdominal Wall Defects

Omphaloceles ^[188] are formed by incomplete closure of the anterior abdominal wall after return of the midgut to the abdominal cavity. The size of the defect is variable, but usually the omphalocele sac contains some intestine, stomach, liver, and spleen. The abdominal cavity is small and underdeveloped. The umbilical cord can be seen to insert onto the center of the omphalocele sac. There is a high incidence of associated anomalies, including cardiac, other gastrointestinal anomalies, and chromosomal syndromes (trisomy 13). Delivery room treatment involves covering the defect with sterile warm saline to prevent fluid loss and nasogastric tube decompression. ^[189]

Gastroschisis ^[188] a defect in the anterior abdominal wall lateral to the umbilicus with no covering sac, with the herniated viscera usually limited to intestine. Furthermore, the intestine has been exposed to amniotic fluid and has a thickened, beefy red appearance. The herniation is thought to occur as a rupture through an ischemic portion of the abdominal wall. Other than intestinal atresia, associated anomalies are uncommon. Delivery room management is as described for omphalocele.

Diaphragmatic Hernia

In diaphragmatic hernia, ^[190] herniation of abdominal organs into the hemithorax (usually left) occurs because of a posterolateral defect in the diaphragm. Infants usually present in the delivery room with respiratory distress, cyanosis, decreased breath sounds on the side of the hernia, and shift of the mediastinum to the side opposite the hernia. The rapidity and severity of presentation with respiratory distress is dependent on the degree of associated pulmonary hypoplasia. The ipsilateral and to some extent contralateral lung are compressed in utero because of the hernia. Delivery room treatment is to intubate, to ventilate, and to decompress the gastrointestinal tract with a nasogastric tube. A chest radiograph will confirm the diagnosis. See [Chapter 11](#) for a discussion of fetal surgical approaches to diaphragmatic hernia aimed at minimizing lung hypoplasia. ^[191], ^[192]

Necrotizing Enterocolitis

Necrotizing enterocolitis (NEC) is the most common acquired gastrointestinal emergency in the neonatal intensive care unit. This disorder predominantly affects premature infants, with higher incidences present with decreasing gestational age, although it is seen in term infants with polycythemia, congenital heart disease, and birth asphyxia. ^[193], ^[194] The pathogenesis is multifactorial with intestinal ischemia, infection, provision of enteral feedings, and gut maturity playing roles to varying degrees in individual patients. ^[193], ^[195] Tocolysis with indomethacin presumably related to changes in intestinal circulation has been associated with an increased incidence of NEC and isolated intestinal perforation, while antenatal betamethasone may decrease the incidence. ^[15], ^[196], ^[197]

Clinically, there is a varied spectrum of disease, from a mild gastrointestinal disturbance to a rapid fulminant course characterized by intestinal gangrene, perforation, sepsis, and shock. The hallmark symptoms are abdominal distention, ileus, delayed gastric emptying, and bloody stools. The radiographic findings are bowel wall

edema, pneumatosis intestinalis, biliary free air, and free peritoneal air. Associated symptoms include apnea, bradycardia, hypotension, and temperature instability.

NEONATAL JAUNDICE

The most common "problem" encountered in a term nursery population is jaundice. Neonatal hyperbilirubinemia occurs when the normal pathways of bilirubin metabolism and excretion are altered. Figure 20-16 (Figure Not Available) demonstrates the metabolism of bilirubin. ^[196] The normal destruction of circulating red cells accounts for about 75 percent of the newborn's daily bilirubin production. The remaining sources include ineffective erythropoiesis and tissue heme proteins. Heme is converted to bilirubin in the reticuloendothelial system. Unconjugated bilirubin is lipid soluble and transported in the plasma reversibly bound to albumin. Bilirubin enters the liver cells by dissociation from albumin in the hepatic sinusoids. Once in the hepatocyte, bilirubin is conjugated with glucuronic acid in a reaction catalyzed by uridine diphosphoglucuronosyl transferase (UDPGT). The water-soluble conjugated bilirubin is sufficiently polar to be excreted into bile or filtered through the kidney. After conjugation, bilirubin is excreted rapidly into the bile canaliculi and into the small intestine. The enzyme -glucuronidase is present in small bowel and hydrolyzes some of the conjugated bilirubin. This unconjugated bilirubin can be reabsorbed into the circulation, adding to the total unconjugated bilirubin load (enterohepatic circulation). Major predisposing factors of neonatal jaundice are (1) increased bilirubin load because of increased red cell volume

Figure 20-16 (Figure Not Available) Neonatal bile pigment metabolism. (Adapted from Maisels MJ: *Jaundice*. Figure 20-17 Risk of developing significant hyperbilirubinemia in term and near-term infants based on hour-specific bilirubin determinations. (From Bhutani VK, Johnson L, Sivieri EM: Predictive ability of a pre-discharge hour-specific serum bilirubin for subsequent significant hyperbilirubinemia in healthy term and near-term newborns. *Pediatrics* 103:6, 1999. Copyright 1999 American Academy of Pediatrics, with permission.)

with decreased cell survival, increased ineffective erythropoiesis, and the enterohepatic circulation; and (2) decreased hepatic uptake, conjugation, and excretion of bilirubin. These factors result in the presence of clinically apparent jaundice in approximately two thirds of newborns during the first week of life. ^[196] This transient jaundice has been called physiologic jaundice. Infants whose bilirubin levels are above the 95th percentile for age in hours require close follow-up (Fig. 20-17). ^[196]

Pathologic jaundice during the early neonatal period is indirect hyperbilirubinemia usually caused by overproduction of bilirubin. The leading cause in this group of patients is hemolytic disease, of which fetomaternal blood group incompatibilities (Rh and ABO) are the most common (see Chapter 26). Other causes of hemolysis include genetic disorders such as hereditary spherocytosis and nonspherocytic hemolytic anemias, such as glucose-6-phosphate dehydrogenase (G6PD) deficiency. Other etiologies of bilirubin overproduction include extravasated blood (bruising, hemorrhage), polycythemia, and exaggerated enterohepatic circulation of bilirubin because of mechanical gastrointestinal obstruction or reduced peristalsis from inadequate oral intake. Disease states involving decreased bilirubin clearance must be considered in the patients in whom no cause of overproduction can be identified. Causes of indirect hyperbilirubinemia in this category include familial deficiency of UDPGT (Crigler-Najjar syndrome), Gilbert syndrome, breast milk jaundice, and hypothyroidism. Mixed or direct hyperbilirubinemia are rare during the first week of life.

A strong association exists between breast-feeding and neonatal hyperbilirubinemia. The syndrome of breast milk jaundice is characterized by full-term infants who have jaundice that persists into the second and third weeks of life with maximal bilirubin levels of 10 to 30 mg/dl. If breast-feeding is continued, the levels persist for 4 to 10 days and then decline to normal by 3 to 12 weeks. Interruption of breast-feeding is associated with a prompt decline in 48 hours. ^[200] In addition to this syndrome, breast-fed infants as a whole have higher bilirubin levels over the first 3 to 5 days of life than their formula-fed counterparts (Fig. 20-18). ^[201] Rather than interrupting breast-feeding, this early jaundice is responsive to increased frequency of breast-feeding. Suggested mechanisms for breast-feeding-associated jaundice include decreased early caloric intake,

678

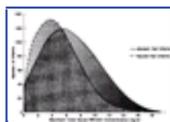

Figure 20-18 Distribution of maximum serum bilirubin concentrations in white infants who weigh more than 2,500 g. (Adapted from Maisels MJ, Gifford KL: *Normal serum bilirubin levels in the newborn and the effect of breast-feeding*. *Pediatrics* 78:837, 1986.)

inhibitors of bilirubin conjugation in breast milk, and increased intestinal reabsorption of bilirubin. ^[201], ^[202] In some patients, there is considerable overlap in these described syndromes.

The overriding concern with neonatal hyperbilirubinemia is the development of bilirubin toxicity causing the pathologic entity of kernicterus, the staining of certain areas of the brain (basal ganglia, hippocampus, geniculate bodies, various brain stem nuclei, and cerebellum) by bilirubin. Neuronal necrosis is the dominant histopathologic feature at 7 to 10 days of life. The clinical syndrome in term infants is marked by refusal to feed, high-pitched cry, hypertonicity, and opisthotonos. Survivors usually suffer sequelae, including athetoid cerebral palsy, high-frequency hearing loss, paralysis of upward gaze, and dental dysplasia. ^[203] The risk of kernicterus in a given infant is not well defined. The only group that one can speak of with any certainty is those infants with Rh isoimmunization in whom a level of 20 mg/dl has been associated with an increased risk of kernicterus. ^[204] This observation has been extended to the management of other neonates with hemolytic disease, although no definitive data exist regarding these infants. The risk is probably small for term infants without hemolytic disease even at levels higher than 20 mg/dl. ^[205] ^[206] ^[207] Recent descriptions of kernicterus in breast-fed infants with dehydration and hyperbilirubinemia in whom an adequate supply of breast milk has not been established mandates close follow-up of all breast-feeding mothers. ^[208], ^[209] The true risk for nonhemolytic hyperbilirubinemia to produce brain damage in the preterm in the current era of liberal use of phototherapy that prevents marked elevation of severe bilirubin in these infants is unknown. However, most currently available data would suggest this risk is low. ^[198], ^[210]

NEONATAL HEMATOLOGY

Anemia

Early hematopoietic cells originate in the yolk sac. By 8 weeks' gestation, erythropoiesis is taking place in the liver, which remains the primary site of erythroid production through the early fetal period. By 6 months of gestation, the bone marrow becomes the principal site of red cell development. ^[211] Normal hemoglobin levels at term range from 13.7 to 20.1 g/dl.^[212] In the very preterm infant, values as low as 12 g/dl are acceptable. ^[213] Anemia at birth or appearing in the first few weeks of life is the result of blood loss, hemolysis, or underproduction of erythrocytes. ^[214] Blood loss resulting in anemia can occur prenatally, at the time of delivery, or postnatally. In utero blood loss can be the result of fetomaternal bleeding, twin-to-twin transfusion, or blood loss resulting from trauma (maternal trauma, amniocentesis, external cephalic version). The diagnosis of fetomaternal hemorrhage large enough to cause anemia can be made using the Kleihauer-Betke technique of acid elution to identify fetal cells in the maternal circulation. Blood loss at delivery can be caused by umbilical cord rupture, incision of the placenta during cesarean delivery, placenta previa, or abruptio placentae. Internal hemorrhage can occur in the newborn, often related to a difficult delivery. Sites include intracranial,

cephalhematomas, subgaleal space, retroperitoneal, liver capsule, and ruptured spleen. When blood loss has been chronic (e.g., fetomaternal), infants will be pale at birth but well compensated and without signs of volume loss. The initial hematocrit will be low. Acute bleeding will present with signs of hypovolemia (tachycardia, poor perfusion, hypotension). The initial hematocrit can be normal or decreased, but after several hours of equilibration it will be decreased. Anemia caused by hemolysis from blood group incompatibilities is common in the newborn period. Less common causes of hemolysis include erythrocyte membrane abnormalities, enzyme deficiencies, and disorders of hemoglobin synthesis. Impaired erythrocyte production is an unusual cause of neonatal anemia.

Polycythemia

Elevated hematocrits occur in 1.5 to 4 percent of live births. ^[215] Although 50 percent of polycythemic infants are appropriate for gestational age (AGA), the proportion of polycythemic infants is greater in the SGA and LGA populations. ^[215] Causes of polycythemia include twin-to-twin transfusion, maternal-to-fetal transfusion, intrapartum transfusion from the placenta associated with fetal distress, chronic intrauterine hypoxia (SGA infants, LGA infants of diabetic mothers), delayed cord clamping, and chromosomal abnormalities. ^[216] The consequence of polycythemia is hyperviscosity, resulting in impaired perfusion of capillary beds. Therefore, clinical symptoms can be related to any organ system (see Box). As viscosity measurements are not routinely performed at most institutions, hyperviscosity is inferred from hematocrit because the major factor influencing viscosity in the newborn is red cell mass. Cord blood hematocrit greater than or equal to 57 percent ^[217] and capillary hematocrit of at least 70 percent are indicative of polycythemia. Confirmation of the diagnosis is a peripheral venous hematocrit of at least 64 percent. ^[217] Reduction of venous hematocrit to less than 60 percent may improve acute symptoms, but it has not been shown to improve long-term neurologic outcome. ^[218] ^[219] ^[220]

Organ-Related Symptoms of Hyperviscosity	
Central nervous system	Irritability, jitteriness, seizures, lethargy
Cardiopulmonary	Respiratory distress caused by congestive heart failure or persistent pulmonary hypertension
Gastrointestinal	Vomiting, heme-positive stools, abdominal distention, necrotizing enterocolitis
Renal	Decreased urine output, renal vein thrombosis
Metabolic	Hypoglycemia
Hematologic	Hyperbilirubinemia, thrombocytopenia

TABLE 20-10 -- DIFFERENTIAL DIAGNOSIS OF NEONATAL THROMBOCYTOPENIA

Diagnosis	Comments
Immune	Passively acquired antibody (e.g., idiopathic thrombocytopenic purpura, systemic lupus erythematosus, drug induced)
	Alloimmune sensitization to HPA-1a antigen
Infections	Bacterial; congenital viral infections (e.g., cytomegalovirus, rubella)
Syndromes	Absent radii; Fanconi's anemia
Giant hemangioma	
Thrombosis	
High-risk infant with respiratory distress syndrome, pulmonary hypertension, and so forth	Disseminated intravascular coagulation
	Isolated thrombocytopenia

Thrombocytopenia

Neonatal thrombocytopenia can be isolated or occur associated with deficiency of clotting factors. A differential diagnosis is presented in [Table 20-10](#). The immune thrombocytopenias have important implications for perinatal care. In idiopathic thrombocytopenic purpura (ITP), maternal antiplatelet antibodies that cross the placenta lead to destruction of fetal platelets. Correlation between the degree of thrombocytopenia in mother and fetus is not good ^[221], ^[222] thus, the severity of thrombocytopenia in an individual fetus cannot be predicted with certainty. The incidence of severe neonatal thrombocytopenia varies from 5 to 20 percent of cases. ^[223], ^[224] However, even in the presence of severe neonatal thrombocytopenia, there is a very low rate of significant bleeding complications in these infants including intracranial bleeds, irrespective of route of delivery. ^[223] ^[224] ^[225] In alloimmune thrombocytopenia, maternal antibody to paternal platelet antigen on fetal platelets crosses the placenta and causes destruction of fetal platelets. In the largest series of cases of suspected alloimmune thrombocytopenia, the majority were caused by HPA-1a alloantibodies. ^[226] As the maternal platelet count is normal, the diagnosis is suspected on the basis of a history of a previously affected pregnancy. Intracranial hemorrhage is more common with

680

this condition than in maternal ITP (10 to 20 percent) and can occur in the antenatal or intrapartum periods. ^[227], ^[228] Recurrence risk is 75 percent. Percutaneous umbilical blood sampling (PUBS) at 18 to 20 weeks can be done to measure platelet count. If severe thrombocytopenia is present, intravenous immunoglobulin can be given weekly to the mother. ^[227], ^[228] Other treatment options include serial in utero platelet transfusions and combination therapy with intravenous immune globulin (IVIG) and steroids. ^[227] Route of delivery is determined by fetal platelet count on a PUBS sample. Cesarean delivery is done for counts less than 50,000/l.

Vitamin K Deficiency

Vitamin K₁ oxide (1 mg) should be given intramuscularly to all newborns to prevent hemorrhagic disease caused by a deficiency in vitamin K-dependent clotting factors. ^[229] Babies born to mothers who are on anticonvulsant medication are particularly at risk of having vitamin K deficiency. Oral vitamin K has been shown to be effective in raising vitamin K levels, but is not as effective in preventing late hemorrhagic disease of the newborn (presenting at 4 to 6 weeks of age). Late hemorrhagic disease of the newborn most commonly occurs in breast-fed infants whose courses have been complicated by diarrhea.

RESPIRATORY DISTRESS

The establishment of respiratory function at birth is dependent on expansion and maintenance of air sacs, clearance of lung fluid, and provision of adequate pulmonary perfusion. In many premature and other high-risk infants, developmental deficiencies or unfavorable perinatal events hamper a smooth respiratory transition. Furthermore, a neonate has a limited number of ways to respond symptomatically to a variety of pathophysiologic insults. The presentation of respiratory distress is among the most common symptom complexes seen in the newborn and may be secondary to both noncardiopulmonary and cardiopulmonary etiologies (Table 20-11). The symptom complex includes an elevation of the respiratory rate to greater than 60 bpm with or without cyanosis, nasal flaring, intercostal and sternal retractions, and expiratory grunting. The retractions are the result of the neonate's efforts to expand a lung with poor compliance utilizing a very compliant chest wall. The expiratory grunt is caused by closure of the glottis during expiration in an effort to increase expiratory pressure to help maintain functional residual capacity. The evaluation of such an infant requires utilization of history, physical examination, and laboratory data to arrive at a diagnosis. It is important to consider causes other than those related to the heart and lungs, because one's natural tendency is to focus immediately on the more common cardiopulmonary etiologies.

Cardiovascular Causes

Cardiovascular causes of respiratory distress in the neonatal period can be divided into two major groups: those with structural heart disease and those with persistent right-to-left shunting through fetal pathways and a structurally normal heart. The two presentations of serious structural heart disease in the first week of life are cyanosis and congestive heart failure. Examples of cyanotic heart disease include transposition of the great vessels, tricuspid atresia, certain types of truncus arteriosus, total anomalous pulmonary venous return, and right-sided outflow obstruction including tetralogy of Fallot and pulmonary stenosis or atresia. Although cyanosis is the central feature in these disorders, tachypnea will develop in many infants because of increased pulmonary blood flow or secondary to metabolic acidosis from hypoxia. Infants with congestive heart failure generally have some form of left-sided outflow obstruction. Left-to-right shunt lesions such as ventricular septal defect do not present with increased pulmonary blood flow and congestive heart failure until pulmonary vascular resistance is low enough to permit a significant shunt (usually 3 to 4 weeks of age at sea level). Infants with left-sided outflow obstruction generally do well the first day or so until the source of systemic flow, the ductus arteriosus, closes. With ductal narrowing, dyspnea, tachypnea, and tachycardia develop, followed by rapid progression to congestive heart failure and metabolic acidosis. On examination, these infants all have pulse abnormalities. With hypoplastic left heart syndrome and critical aortic stenosis, pulses are profoundly diminished in all extremities, while infants with coarctation of the aorta and interrupted aortic arch will have differential pulses when the arms and legs are compared.

The syndrome of persistent pulmonary hypertension of the newborn (PPHN) occurs when the normal postnatal decrease in pulmonary vascular resistance does not occur, maintaining right-to-left shunting across the patent ductus arteriosus and foramen ovale. Most infants with PPHN are full term or postmature and have experienced perinatal asphyxia. Other clinical associations include hypothermia, MAS, hyaline membrane

TABLE 20-11 -- RESPIRATORY DISTRESS IN THE NEWBORN

Noncardiopulmonary	Cardiovascular	Pulmonary
Hypo- or hyperthermia	Left-sided outflow obstruction	Upper airway obstruction
Hypoglycemia	Hypoplastic left heart	Choanal atresia
Metabolic acidosis	Aortic stenosis	Vocal cord paralysis
Drug intoxications; withdrawal	Coarctation of the aorta	Meconium aspiration
Polycythemia	Cyanotic lesions	Clear fluid aspiration
Central nervous system insult	Transposition of the great vessels	Transient tachypnea
Asphyxia	Total anomalous pulmonary venous return	Pneumonia
Hemorrhage	Tricuspid atresia	Pulmonary hypoplasia
Neuromuscular disease	Right-sided outflow obstruction	Primary
Werdnig-Hoffman disease		Secondary
Myopathies		Hyaline membrane disease
Phrenic nerve injury		Pneumothorax
Skeletal abnormalities		Pleural effusions
Asphyxiating thoracic dystrophy		Mass lesions
		Lobar emphysema
		Cystic adenomatoid malformation

disease, polycythemia, neonatal sepsis, chronic intrauterine hypoxia, pulmonary hypoplasia, and premature closure of the ductus arteriosus in utero. ^[230] ^[231] ^[232]

On the basis of developmental considerations, these infants can be separated into three groups ^[231] (1) acute vasoconstriction caused by perinatal hypoxia, (2) prenatal increase in pulmonary vascular smooth muscle development, and (3) decreased cross-sectional area of the pulmonary vascular bed caused by inadequate vessel number. In the first group, an acute perinatal event leads to hypoxia and failure of pulmonary vascular resistance to drop. In the second, abnormal muscularization of the pulmonary resistance vessels results in PPHN after birth. The third circumstance includes infants with pulmonary hypoplasia (e.g., diaphragmatic hernia). Clinically, the syndrome is characterized by cyanosis, often unresponsive to increases in F_{IO_2} , respiratory distress, an onset at less than 24 hours, evidence of right ventricular overload, systemic hypotension, acidosis, and no evidence of structural heart disease.

Infants with PPHN make up the majority of patients who are treated in some centers with extracorporeal membrane oxygenation (ECMO). ^[233] When conventional medical therapy (ventilator, systemic pressors, respiratory alkalosis) fails, infants are placed on bypass, with blood exiting the baby from the right atrium and returning to the aortic arch after passing through a membrane oxygenator. Over several days, pulmonary hypertension resolves, and the infants are weaned from ECMO back

to conventional ventilator therapy. In recent years, new modes of treatment have been introduced that are decreasing the need for ECMO. [234] Specifically, use of high-frequency ventilators and inhaled nitric oxide have shown great promise. [235] [236] [237] Nitric oxide is identical or similar to endogenously produced endothelium-derived relaxing factor and is used as a selective pulmonary vasodilator in infants with PPHN. [236]

Pulmonary Causes

Of the causes of respiratory distress related to the airways and pulmonary parenchyma listed in [Table 20-11](#), the differential diagnosis in a term infant includes transient tachypnea, aspiration syndromes, congenital pneumonia, and spontaneous pneumothorax. The syndrome of transient tachypnea (wet lung or type II RDS) presents as respiratory distress in nonasphyxiated term infants or slightly preterm infants. The clinical features include various combinations of cyanosis, grunting, nasal flaring, retracting, and tachypnea during the first hours after birth. The chest radiograph is the key to the diagnosis, with prominent perihilar streaking and fluid in the interlobar fissures. The symptoms generally subside in 12 to 24 hours, although they can persist longer. The preferred explanation for the clinical features is delayed reabsorption of fetal lung fluid. [238] Transient tachypnea is seen more commonly in infants delivered by elective cesarean section or in the slightly preterm infant (see Mechanics of the First Breath, above).

At delivery, the neonate may aspirate clear amniotic fluid or fluid mixed with blood. Whether infants can aspirate a sufficient volume of clear fluid to cause symptoms is controversial. However, there are a group of infants whose clinical course is more prolonged (4 to 7 days) and severe than that of infants with transient tachypnea. These infants have a radiologic picture similar to transient tachypnea often associated with more marked hyperexpansion. Occasionally, the infiltrates are quite impressive, with evidence of far more fluid than is seen with transient tachypnea.

682

MAS occurs in full-term or postmature infants. The perinatal course is often marked by fetal distress and low Apgar scores. These infants exhibit tachypnea, retractions, cyanosis, overdistended and barrel-shaped chest, and coarse breath sounds. Chest radiography reveals coarse, irregular pulmonary densities with areas of diminished aeration or consolidation. There is a high incidence of air leaks, and many of the infants exhibit persistent pulmonary hypertension. [97], [105]

The lungs represent the most common primary site of infection in the neonate. Both bacterial and viral infections can be acquired before, during, or after birth. The most common route of infection, particularly for bacteria, is ascending from the genital tract before or during labor. Thus, prolonged rupture of the membranes in excess of 12 to 18 hours is a major predisposing factor. [239], [240] Major pathogens include group B -hemolytic *Streptococcus*, gram-negative enterics, and *Listeria monocytogenes*. [241], [242] Infants with congenital pneumonia present with symptomatology from very early in life, including tachypnea, retractions, grunting, nasal flaring, and cyanosis. The chest radiograph pattern is often indistinguishable from other causes of respiratory distress, particularly hyaline membrane disease (HMD). [243]

Spontaneous pneumothorax occurs in 1 percent of all deliveries, but a much lower percent result in symptoms. [244] The risk is increased by manipulations such as positive-pressure ventilation. Respiratory distress is usually present from shortly after birth, and breath sounds may be diminished on the affected side. The majority of these resolve spontaneously without specific therapy.

Despite improved understanding and recent advances, HMD remains the most common etiology for respiratory distress in the neonatal period. HMD affects approximately 20,000 infants per year in the United States, developing in 50 percent of infants at 26 to 28 weeks of gestation and in 30 percent of those at 30 to 31 weeks. It was the initial reports of Avery and Mead [245] demonstrating a high surface tension in extracts of lungs from infants dying of RDS that led to the present understanding of the role of surfactant in the pathogenesis of HMD. The deficiency of surfactant in the premature infant increases alveolar surface tension and, according to LaPlace's law (Fig. 20-2) (Figure Not Available) increases the pressure necessary to maintain patent alveoli. The end result is poor lung compliance, progressive atelectasis, loss of FRC, alterations in ventilation-perfusion mismatch, and uneven distribution of ventilation. [244] HMD is further complicated by the weak respiratory muscles and compliant chest wall of the premature. Hypoxemia and respiratory and metabolic acidemia contribute to increased pulmonary vascular resistance, right-to-left ductal shunting, and worsening ventilation-perfusion mismatch that exacerbate hypoxemia. Hypoxemia and hypoperfusion result in alveolar epithelial damage, with increased capillary permeability and leakage of plasma into alveolar spaces. Leakage of protein into airspaces serves to inhibit surfactant function, exacerbating the disease process. [246] The materials in plasma and cellular debris combine to form the characteristic hyaline membrane seen pathologically. The recovery phase is characterized by regeneration of alveolar cells, including type II cells, with an increase in surfactant activity.

Clinically, neonates with HMD demonstrate tachypnea, nasal flaring, subcostal and intercostal retractions, cyanosis, and expiratory grunting. As the infant begins to tire with progressive disease, apneic episodes occur. If some intervention is not undertaken at this point, death ensues. The radiologic appearance of the lungs is what would be expected in an extensive atelectatic process. The infiltrate is diffuse, with a ground-glass appearance. Major airways are air filled and contrast with the atelectatic alveoli, creating the appearance of air bronchograms, while the diaphragms are elevated because of profound hypoexpansion. Acute complications of HMD include infection, air leaks, and persistent patency of the ductus arteriosus.

Of more concern than acute complications are the long-term sequelae suffered by infants with HMD. The major long-term consequences are chronic lung disease requiring prolonged ventilator and oxygen therapy and significant neurologic impairment. In 1967, Northway et al. [247] first described the syndrome of bronchopulmonary dysplasia in infants surviving severe HMD requiring mechanical ventilation. Today, many infants who develop chronic lung disease are extremely-low-birth-weight infants who require prolonged ventilation for apnea and poor respiratory effort. The incidence is now estimated at about 20 percent in preterm infants weighing less than 1,000 g requiring mechanical ventilation. [248] The severity is variable, ranging from very mild pulmonary dysfunction to severe disease with prolonged mechanical ventilation, frequent readmissions for respiratory exacerbations after nursery discharge, and a higher incidence of neurodevelopmental sequelae compared with very-low-birth-weight controls. [249] Although pulmonary function improves over time and most children do quite well, long-term pulmonary sequelae are evident. [250], [251] Factors involved in the etiology of chronic lung disease are gestational age, elevated inspired oxygen concentration, positive-pressure ventilation, severity of underlying disease, inflammation, and infection. [252]

One of the exciting areas in neonatology is the development of surfactant replacement therapy for the management of hyaline membrane disease. Modified natural surfactant, which is extracted by alveolar lavage or from lung tissue (usually bovine) and then modified by selective addition and/or removal of components, and true artificial surfactant, which is a mixture of synthetic

683

TABLE 20-12 -- CUMULATIVE RESULTS OF PLACEBO-CONTROLLED SURFACTANT TRIALS*

	Modified Natural (%)		Synthetic (%)	
	Surfactant	Control	Surfactant	Control
Mortality	15	24	11	18
Patent ductus arteriosus	46	43	44	48
Severe ICH	19	19	7	8
Chronic lung disease	37	37	11	11

* Higher incidences of intracranial hemorrhage (ICH) and chronic lung disease in modified natural surfactant studies reflects the lower gestational age on average in both groups in these studies compared to the artificial surfactant studies.

Studies with Survanta, Curosurf, and Infasurf; 2,000 patients.

Studies with Exosurf; 4,400 patients.

compounds that may or may not be components of natural surfactant, have been extensively studied. [19] [20] [21] [22], [253] In most studies, these agents (administered

intratracheally) have shown efficacy in decreasing the severity of acute HMD and the frequency of air leak complications. Efficacy has been demonstrated when used in the delivery room to "prevent" or when used as a rescue treatment for established HMD. Although surfactant replacement therapy has decreased mortality and acute pulmonary morbidity, this therapy has not affected the frequency of other complications of prematurity ([Table 20-12](#)). Of note is that, despite resulting in lower ventilator settings and F_IO₂ concentration over the first several days of life, the incidence of chronic lung disease has not been changed. However, the severity of long-term pulmonary complications is less. Long-term neurodevelopment follow-ups show rates of handicap similar to placebo-treated infants. ^[254]

NEONATAL NEUROLOGY

Intraventricular Hemorrhage

Although related most closely to degree of prematurity, periventricular hemorrhage (PVH) and intraventricular hemorrhage (IVH) should also be considered within the context of sequelae of asphyxia. The incidence of this complication is 20 to 30 percent in infants weighing less than 1,500 g or at 31 weeks' gestation. The highest incidence is seen in babies of the lowest gestational age (26 weeks).^[255],^[256]

Bleeding originates in the subependymal germinal matrix located ventrolateral to the lateral ventricles in the caudothalamic groove. The germinal matrix is made up of a rete or meshwork of thin-walled vessels in the process of remodeling into a capillary network and a mass of undifferentiated cells that are destined to become cortical neurons, astrocytes, and oligodendroglia. Rupture of a germinal matrix hemorrhage into the ventricular system leads to intraventricular hemorrhage. A proposed pathogenesis derived from a review of available information is presented in [Figure 20-19](#). The critical predisposing event is likely an ischemia-reperfusion injury to the capillaries in the germinal matrix. Physiologic data from beagle puppies have shown that the germinal matrix is a low blood flow region prone to ischemia.^[257] Furthermore, IVH is most reliably produced in these puppies by a sequence of hemorrhagic hypotension followed by hypertension.^[258] The amount of bleeding is then influenced by a variety of factors that affect the pressure gradient across the injured capillary wall. This pathogenic scheme also applies to intraparenchymal bleeding (venous infarction in a region rendered ischemic) and periventricular leukomalacia (PVL; ischemia in a watershed region of arterial supply).^[259] Periventricular hemorrhagic infarction is most often an asymmetric lesion, with the more affected areas occurring on the same side as the larger amount of intraventricular blood, PVL can develop independent of IVH and is usually bilateral and symmetric. PVL has a peak incidence in babies born between 28 and 32 weeks' gestation and is associated with maternal chorioamnionitis.^[260],^[261] Up to 50 percent of bleeds occur at less than 24 hours of age, and virtually all occur by day 4 of life.^[262] Bleeds are graded according to severity as indicated in [Table 20-13](#).^[263] Diagnosis is confirmed with real-time ultrasound.

The neurodevelopmental outcome of infants with IVH is determined by the severity of the original bleed, development of posthemorrhagic hydrocephalus, and the degree of associated parenchymal injury. Infants with grade I or II IVH have neurodevelopmental outcomes similar to preterm infants without IVH, although recent reports of outcome in school-aged children do show that survivors of mild IVH display a variety of subtle neurologic and cognitive abnormalities, including motor incoordination, hyperactivity, attention and learning deficits, and visual motor difficulties.^[264],^[265] On

684

Figure 20-19 Pathogenesis of periventricular/intraventricular hemorrhage in the preterm infant.

the other hand, infants with progressive ventricular dilatation (grade III) or periventricular hemorrhagic infarction (grade IV) are at high risk for major neurodevelopmental handicap as well as less severe neurologic and cognitive disabilities.^[266],^[267] In addition, the presence of severe PVL carries an ominous prognosis.^[268],^[269]

Although incidence and severity of intracranial hemorrhage have progressively decreased as a result of advances in both obstetric and neonatal care, the therapeutic focus continues to be on strategies to prevent this complication of prematurity ([see Box](#)). Both antenatal and postnatal approaches have been developed. Postnatal pharmacologic strategies have for the most part not had a major effect in decreasing the incidence and severity of IVH. The prostaglandin synthesis inhibitor indomethacin has been most widely studied and has shown some promise when used in the first several hours after birth.^[270] Since IVH and PVL are likely perinatal

TABLE 20-13 -- CLASSIFICATION OF INTRAVENTRICULAR HEMORRHAGE

Grade	Definition
I	Subependymal hemorrhage
II	Intraventricular hemorrhage without ventricular dilatation
III	Intraventricular hemorrhage with ventricular dilatation
IV	Intraventricular hemorrhage with associated parenchymal hemorrhage

From Papile L-A, Burstein J, Burstein R, Koffler H: Incidence and evolution of subependymal and intraventricular hemorrhage: a study of infants with birth weights less than 1500 gm. *J Pediatr* 92:529, 1978, with permission.

events, antenatal prevention holds the most promise. Both vitamin K and phenobarbital have been administered in this way.^[271] Antenatal phenobarbital has resulted in a decrease in both frequency and severity of IVH. The proposed mechanism of action is thought to be scavenging of oxygen free radicals, although phenobarbital

685

TABLE 20-14 -- DIFFERENTIAL DIAGNOSIS OF NEONATAL SEIZURES

Diagnosis	Comments
Hypoxic-ischemic encephalopathy	Most common etiology (60%, onset first 24 hours)
Intracranial hemorrhage	15% of cases; PVH/IVH, subdural or subarachnoid bleeds, stroke
Infection	12% of cases
Hypoglycemia	SGA, IDM
Hypocalcemia, hypomagnesemia	Low-birth-weight infant, IDM

Hyponatremia	Rare, seen with syndrome of inappropriate secretion of antidiuretic hormone (SIADH)
Disorders of amino and organic acid metabolism, hyperammonemia	Associated acidosis, altered level of consciousness
Pyridoxine dependency	Seizures refractory to routine therapy; cessation of seizures after administration of pyridoxine
Developmental defects	Other anomalies, chromosomal syndromes
Drug withdrawal	
Benign familial neonatal seizures	
No cause found	10% of cases

PVH/IVH, periventricular/intraventricular hemorrhage; SGA, small for gestational age; IDM, infant of diabetic mother.

does decrease both brain blood flow and cerebral metabolic rate. However, two large randomized prospective studies failed to confirm the positive effects of phenobarbital shown in smaller studies.^[272], ^[273] One reason for the discrepancy may be the widespread use of antenatal corticosteroids in the more recent studies. Antenatal corticosteroids, although not used specifically to decrease the incidence of IVH and PVL, do appear to decrease the frequency of these complications and likely represent the most important antenatal strategy to prevent intracranial hemorrhage.^[15], ^[16] Phenobarbital may still have a role in the mother who has not been "prepared" and is delivering at under 28 weeks' gestation. The route of delivery may also play a role, with infants delivered by cesarean section showing a decreased rate of intracranial bleeds, but this issue is controversial.^[274]

Interventions for the Prevention of Periventricular/Intraventricular Hemorrhage
Antenatal interventions
Pharmacologic
Phenobarbital
Vitamin K
Corticosteroids
Obstetric
Prevention of prematurity
Optimal management of preterm labor and delivery
Postnatal interventions
Pharmacologic
Indomethacin
Optimal NICU care
Aggressive resuscitation
Careful ventilation to avoid airleaks
Blood pressure management avoiding hypotension and sudden changes
Correction of coagulation abnormalities

NICU, neonatal intensive care unit.

Seizures

Newborns rarely have well-organized tonic-clonic seizures because of incomplete cortical organization and a preponderance of inhibitory synapses. Newborn seizures can be classified into four subtypes.^[275] The first is the subtle seizure characterized by ocular phenomena, oral-buccal-lingual movements, peculiar limb movements (e.g., bicycling movements), autonomic alterations, and apnea. Clonic seizures are characterized by rhythmic (one to three jerks per second) movements that can be focal or multifocal. The third seizure type is focal or generalized tonic seizures marked by extensor posturing. The fourth seizure type is myoclonic activity that is distinguished from clonic seizures by the more rapid speed of the myoclonic jerk and the predilection for flexor muscle groups. The differential diagnosis of neonatal seizures is presented in [Table 20-14](#). The most frequent cause of neonatal seizures is hypoxic ischemic encephalopathy, with the second leading cause being intracranial hemorrhage. The prognosis for neonatal seizures depends on the cause. Difficult-to-control seizure activity caused by hypoxic ischemic encephalopathy and hypoglycemic seizures in particular have a high incidence of long-term sequelae.

CLASSIFICATION OF NEWBORNS BY GROWTH AND GESTATIONAL AGE

In assessing the risk for mortality or morbidity in a given neonate, evaluation of birth weight and gestational age together provide the clearest picture. This requires an accurate assessment of the infant's gestational age. When large populations are considered, maternal dates remain the single best determinant of gestational age. Early obstetric ultrasound is also a very useful adjunct in determining pregnancy dating. However, in the individual neonate, especially when dates are uncertain, a reliable postnatal assessment of gestational age is necessary. A scoring system appraising gestational age on the basis of physical and neurologic criteria was developed by Dubowitz et al.^[276] and later simplified and updated by Ballard et al.^[277],^[278] (Fig. 20-20). The Ballard exam is less accurate before 28 weeks' gestation,^[279] but additional features can be examined to aid in the determination of an accurate gestational age. The anterior vascular capsule of the lens reveals complete coverage of the lens by vessels at 27 to 28 weeks. Foot length (from the heel to the tip of the largest toe) is 4.5 cm at 25 weeks and increases by 0.25 cm/wk. Infants can then be classified, using growth parameters and gestational age, by means of intrauterine growth curves such as those developed by Lubchenco et al.^[280] (Fig. 20-21). Infants born between 38 and 42 weeks are classified as term; less than 38 weeks, preterm; and greater than 42 weeks, postterm. In each grouping, infants are then identified according to growth as AGA if birth weight falls between the 10th to 90th percentile, SGA if birth weight is below the 10th percentile, and LGA if birth weight is above the 90th percentile. On

686

Figure 20-20 Assessment of gestational age. (From Ballard JL, Khoury JC, Wedig K, et al: New Ballard Score, expanded to include extremely premature infants. *J Pediatr* 119:41, 1991, with permission.)

the basis of a given infant's classification, the risk of mortality^[281],^[282] (Fig. 20-22) can be assessed. Not only does mortality risk vary, but specific clinical problems can also be anticipated by an infant's birth weight/gestational age distribution.

There are numerous causes of growth restriction (see Chapter 25). Those operative early in pregnancy such as chromosomal aberrations, congenital viral infections, and some drug exposures induce symmetric restriction of weight, length, and head circumference. In most

687

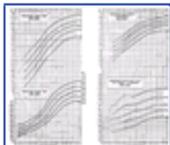

Figure 20-21 Intrauterine growth curves for weight, length, and head circumference for singleton births in Colorado. (From Lubchenco LO, Hansman C, Boyd E: Intrauterine growth in length and head circumference as estimated from live births at gestational ages from 26 to 42 weeks. *Pediatrics* 37:403, 1966, with permission.)

cases, the phenomenon occurs later in gestation and leads to more selective restriction of birth weight alone. Such factors include hypertension or other maternal vascular disease and multiple gestation.^[283] Neonatal problems besides chromosomal abnormalities and congenital viral infections common in SGA infants include birth asphyxia, hypoglycemia, polycythemia, and hypothermia. In addition, congenital malformations are seen more frequently among undergrown infants.^[284]

The most common identifiable conditions leading to excessive infant birth weight are maternal diabetes and maternal obesity. Other conditions associated with macrosomia are erythroblastosis fetalis, other causes of fetal hydrops, and Beckwith-Weidemann syndrome. LGA infants are at risk for hypoglycemia, polycythemia, congenital anomalies, cardiomyopathy, hyperbilirubinemia, and birth trauma.

NURSERY CARE

Nurseries are classified on the basis of level of care provided. Level I nurseries care for infants presumed healthy, with an emphasis on screening and surveillance. Level II nurseries can care for infants more than 30 weeks' gestation, who weigh at least 1,200 g, and who require special attention short of the need for circulatory or ventilator support and major surgical procedures. Level

688

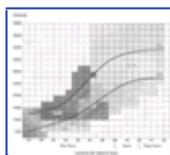

Figure 20-22 Neonatal mortality risk by birth weight and gestational age based on 14,413 live births at the University of Colorado Health Sciences Center, 1974-1980. (From Koops BL, Morgan LJ, Battaglia FC: Neonatal mortality risk in relation to birth weight and gestational age: update. *J Pediatr* 101:969, 1982, with permission.)

III nurseries care for all newborn infants who are critically ill regardless of the level of support required. A perinatal center encompasses both high-risk obstetric services and level III nursery services.

Care of the normal newborn involves observation of transition from intra- to extrauterine life, establishing breast- or bottle-feeds, noting normal patterns of stooling and urination, and surveillance for neonatal problems. Signs suggestive of illness include temperature instability, change in activity, refusal to feed, pallor, cyanosis, jaundice, tachypnea and respiratory distress, delayed (beyond 24 hours) passage of first stool or void, and bilious vomiting. In addition, the following laboratory screens should be performed: (1) blood type and direct and indirect Coombs' test on infants born to mothers with type O or Rh-negative blood; (2) glucose screen in infants at risk for hypoglycemia; (3) hematocrit in infants with signs and symptoms of anemia or polycythemia; (4) serologic test for syphilis; and (5) mandated screening for inborn errors of metabolism, such as PKU, maple syrup urine disease, homocystinuria, galactosemia, sickle cell disease, hypothyroidism, cystic fibrosis, and congenital adrenal hyperplasia. All newborns should also have an initial hearing screen performed prior to discharge.^[285] Finally, babies routinely receive 1 mg intramuscular of vitamin K to prevent vitamin K-deficient hemorrhagic disease of the newborn and either 1 percent silver nitrate or erythromycin ointment to prevent gonococcal ophthalmia neonatorum. Hepatitis B vaccine and hepatitis B immunoglobulin are administered to infants born to HB_s Ag-positive mothers.

Infants should be positioned supine or lying on the right side with the dependent arm forward for sleep to minimize the risk of sudden infant death syndrome.^[286]

It is now common on most services for mothers and babies to be discharged within 24 to 36 hours of delivery. Criteria for early discharge at the University of Colorado are presented in the Box.^[287] These criteria have been adapted from those of the American Academy of Pediatrics.^[288] Discharge at 24 to 36 hours appears safe and appropriate for most infants without contraindications, provided a follow-up at 48 to 72 hours after discharge is ensured.^[287]

689

Infant Criteria for Early Discharge

1. Delivery is vertex, single, sterile, and vaginal.
2. Apgar scores at 1 and 5 minutes are 7.
3. The infant is term (38 to 42 weeks) and weighs 2,700 to 4,000 g.
4. Minimum length of stay is 20 hours. A transition to normal thermoregulation in an open crib, completion of two successful feedings, evidence of stool and void, completion of neonatal screening for metabolic disease, and blood type and Coombs' test (Rh-negative and O mothers) prior to discharge.
5. Vital signs within normal ranges at discharge; axillary temperature, 36.1° to 37.2°C; heart rate, 110 to 150 bpm; respiratory rate, 40 to 60 breaths/min.
6. The infant has a normal neonatal hospital course and presents no signs or symptoms that require continuous observation:
Blood glucose maintained, >45 mg/dl ABO-incompatible infants usually held 48 hours and released only if not requiring therapy for jaundice. These infants may leave at 24 hours with good follow-up examination if no jaundice is present. Jaundice at <24 hours for any reason mandates a longer stay.
7. Infants born to group B *Streptococcus*-positive mothers with inadequate antenatal chemoprophylaxis or born to mothers with >12 hours ruptured membranes are observed for 48 hours.
8. Physical examination is completed by physician or trained physician's assistant.
9. Minimum 2 hours of observation after circumcision with no bleeding.
10. Mother demonstrates understanding and ability to provide adequate care for her newborn; infant care education is provided on a one-to-one or classroom basis by the nursing staff before discharge.
11. Signed documentation by the mother that states her obligation to participate in follow-up care within 48 hours of discharge.

Circumcision is an elective procedure to be performed only in healthy, stable infants. The procedure probably has medical benefits, including prevention of phimosis, paraphimosis, and balanoposthitis as well as a decreased incidence of cancer of the penis, cervical cancer (in partners of circumcised men), sexually transmitted diseases (including HIV), and urinary tract infection in male infants. ^[289] Most parents, however, make the decision regarding circumcision for nonmedical reasons. The risks of the procedure include local infection, bleeding, removal of too much skin, and urethral injury. The combined incidence of these complications is less than 1 percent. Local anesthesia (dorsal penile nerve block or circumferential ring block) with 1 percent lidocaine without epinephrine or topical application of an anesthetic cream are safe and effective and should always be used. ^[289] Techniques that allow visualization of the glans throughout the procedure (Plastibell and Gomco clamp) are preferred to a "blind" technique (Mogen clamp) because of occasional amputation of the glans with the latter. Circumcision is contraindicated in infants with genital abnormalities. Appropriate lab evaluation should be performed prior to the procedure in infants with a family history of bleeding disorders.

Care of the Parents

Klaus and Kennell^[290] outline these steps in maternal-infant attachment: (1) planning the pregnancy; (2) confirming the pregnancy; (3) accepting the pregnancy; (4) noting fetal movement; (5) accepting the fetus as an individual; (6) going through labor; (7) giving birth; (8) hearing and seeing the baby; (9) touching, smelling, and holding the baby; (10) caretaking; and (11) accepting the infant as a separate individual. Numerous influences can affect this process. A mother's and father's actions and responses are derived from their own genetic endowment, their own interfamily relationships, cultural practices, past experiences with this or previous pregnancies, and, most importantly, how they were raised by their parents. ^[290] Also critical is the in-hospital experience surrounding the birth: how doctors and nurses act, separation from the baby, and hospital practices.

The 60- to 90-minute period after delivery is a very important time. The infant is alert, active, and able to follow with his or her eyes, ^[291] allowing meaningful interaction to transpire between infant and parents. The infant's array of sensory and motor abilities evokes responses from the mother and initiates communication that may be helpful for attachment and induction of reciprocal actions. Whether a critical time period for these initial interactions exists is not clear, but improved mothering behavior does seem to occur with increased contact over the first 3 postpartum days. ^[292] The practical implications of this information are that labor and delivery should pose as little anxiety as possible for the mother, and parents and baby should have time together immediately after delivery if the baby's medical condition permits. Eye prophylaxis for gonococcal ophthalmitis should ideally be withheld until after

the initial bonding has taken place. It can be performed safely within 1 hour of birth.

Mothers with high-risk pregnancies are at increased risk for subsequent parenting problems. It is important for both obstetrician and pediatrician alike to be involved prenatally, allowing time to prepare the family for anticipated aspects of the baby's care as well as providing reassurance that the odds are heavily in favor of a live baby who will ultimately be healthy. If before birth one can anticipate a need for neonatal intensive care (known congenital anomaly, refractory premature labor), maternal transport to a center with a unit that can care for the baby should be planned. In this way, a mother can be with her baby during its most critical care. Before delivery it is also very helpful to allow the parents to tour the unit their baby will occupy. This practice greatly reduces anxiety after the baby is born.

The single basic principle in dealing with parents of a sick infant is to provide essential information clearly and accurately to both parents, preferably when they are together. With improved survival rates, especially in prematures, most babies, despite early problems, will do well. It is therefore reasonable in most circumstances to be positive about the outcome. There is also no reason to emphasize problems that might occur in the future or to deal with individual worries of the physician. Questions, if asked, need to be answered honestly, but the list of parents' worries does not need to be voluntarily increased.

Before the parents' initial visit to the unit, a physician or nurse should describe what the baby and the equipment look like. When they arrive in the nursery, this can again be reviewed in detail. If a baby must be moved to another hospital, the mother should be given time to see and to touch her infant prior to transfer. The father should be encouraged to meet the baby at the receiving hospital so he can become comfortable with the intensive care unit. He can serve as a link between baby and mother with information and photographs.

As a baby's course proceeds, the nursery staff can help the parents to become comfortable with their infant. This can include participation in caretaking as well as skin-to-skin contact with the infant (Kangaroo care). ^[293] Individualized developmentally based care has also shown some benefit for high-risk infants. ^[294] It is also important for the staff to discuss among themselves any problems that parents may be having as well as to keep a record of visits and phone calls. This approach will allow early intervention to deal with potential problems.

The birth of an infant with a congenital malformation provides another situation in which staff support is essential. Parents' reactions to the birth of a malformed infant follow a predictable course. For most, there is initial shock and denial, a period of sadness and anger, gradual adaptation, and finally an increased satisfaction with and the ability to care for the baby. The parents must be allowed to pass through these stages and, in effect, to mourn the loss of the anticipated normal child. ^[295]

The death of an infant or a stillborn is a highly stressful family event. This fact has been emphasized by Cullberg, ^[296] who found that psychiatric disorders developed in 19 of 56 mothers studied 1 to 2 years after the deaths of their neonates. One of the major predispositions was a breakdown of communication between parents. The health care staff need to encourage the parents to talk with each other, discuss their feelings, and display emotion. The staff should talk with the parents at the time of death and then several months later to review the findings of the autopsy, answer questions, and see how the family is doing.

OUTCOME OF NEONATAL INTENSIVE CARE

More sophisticated neonatal care has resulted in improved survival of very-low-birth-weight (1,500 g) infants, in particular those less than 1,000 g (Fig. 20-23). Current survival rates are 90 percent or greater for infants greater than 1,000 g and 28 weeks' gestation, 80 percent at 800 to 1,000 g and 26 to 27 weeks' gestation, and nearly 70 percent for infants 700 to 800 g and 25 weeks' gestation, with a considerable drop in survival below 700 g and 25 weeks.^[297] It is important to note that survival in terms of best obstetric estimate is greater at very low gestational ages than survival in terms of postnatal assessment of gestational age. The numbers in terms of best obstetric estimate should be referred to for antenatal counseling. This improved survival comes with a price, as a variety of morbidities are seen in these infants. However, concern that improved survival would be associated with an increased rate of neurologic sequelae has been largely unfounded. Major neurologic morbidities seen in very-low-birth-weight infants include cerebral palsy (spastic diplegia, quadriplegia, hemiplegia, or paresis), cognitive delay, and hydrocephalus. Lesser disabilities include learning and behavior difficulties that can cause problems when school age is attained. The rate of significant neurologic disability is fairly constant at 10 to 25 percent of all very-low-birth-weight (<1,500 g) survivors. The number trends toward the higher side in infants of extremely low birth weight (<1,000 g).^[298]^[299]^[300] In addition to a slight increase in severe disability, extremely-low-birth-weight infants have an increased rate of lesser

691

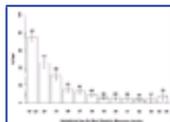

Figure 20-23 Survival by gestational age according to best obstetric measures among infants born in National Institute of Child Health and Human Development Neonatal Research Network centers between January 1993 and December 1994. Data are expressed as percentage who died with 95 percent confidence intervals. (From Stevenson DK, Wright LL, Lemons JA, et al: Very low birth weight outcomes of the National Institute of Child Health and Human Development Neonatal Research Network, January 1993 through December 1994. *Am J Obstet Gynecol* 179:1632, 1998, with permission.)

disabilities, including subnormal mental performance and the need for special education in school (Fig. 20-24).^[301]^[302] Risk factors for neurologic morbidity include seizures, major intracranial hemorrhage or periventricular leukomalacia, severe intrauterine growth retardation, need for mechanical ventilation, poor early head growth, and low socioeconomic class.^[302]^[303]^[304]^[305]^[306]^[307]^[308]

There are other morbidities that need to be considered as well. As the number of survivors weighing less than 1,000 g has increased, a reemergence of retinopathy of prematurity has been seen. This disorder, caused by retinal vascular proliferation leading to hemorrhage, scarring, retinal detachment, and blindness, originally was thought to be caused solely by inappropriate exposure to high concentrations of oxygen. It is now thought that the origin is multifactorial, with extreme prematurity a critical factor.^[309] Incidence of acute proliferative retinopathy by birth weight is less than 10 percent in infants weighing more than 1,250 g, 15 percent in those 1,000 to 1,250 g, 40 percent in those 750 to 1,000 g, and 50 percent in those less than 750 g.^[310] Severe retinopathy is evident in 5 percent of the infants 1,000 to 1,250 g, in 15 percent of infants 750 to 1,000 g, and 25 percent of infants less than 750 g. Of the infants with severe retinopathy, 10 percent (4 percent of the total population) will go on to have severe visual problems. The other major neurosensory morbidity is hearing loss, which occurs in 2 percent of neonatal

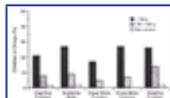

Figure 20-24 Percentage of children at different birth weights with subnormal functioning. (From Hack M, Taylor G, Klein N, et al: School-age outcomes in children with birth weights under 750 g. *N Engl J Med* 331:753, 1994, with permission.)

692

intensive care unit survivors.^[311] Other sequelae of neonatal intensive care include chronic lung disease, growth failure, short gut, and need for postdischarge rehospitalization.

Key Points

Surfactant maintains lung expansion on expiration by lowering surface tension at the air-liquid interface in the alveolus.

Respiratory distress syndrome in premature infants is in part caused by a deficiency of surfactant and can be treated with surfactant replacement therapy.

Antenatal corticosteroids accelerate fetal lung maturation and decrease neonatal mortality and respiratory distress syndrome in preterm infants. In addition, corticosteroids are associated with a decrease in intracranial hemorrhage and necrotizing enterocolitis.

Transition from intra- to extrauterine life requires removal of fluid from the lungs, switching from a fetal to neonatal circulation, and establishment of a normal neonatal lung volume.

The most important step in neonatal resuscitation is to achieve adequate expansion of the lungs.

Meconium aspiration syndrome likely is the result of intrauterine asphyxia with mortality related to associated persistent pulmonary hypertension.

The best predictor of neurologic sequelae of birth asphyxia is the presence of hypoxic ischemic encephalopathy in the neonatal period. The neurologic sequelae of birth asphyxia is cerebral palsy. Moreover, the large majority of cerebral palsy is of unknown origin.

The major neurologic complications seen in premature infants are periventricular/intraventricular hemorrhage and periventricular leukomalacia.

Hypoglycemia is a predictable and preventable complication in the newborn.

Survival, in particular for infants less than 1,000 g, has increased with improved methods of neonatal intensive care, including provision of exogenous surfactant.

Chapter 21 - Postpartum Care

Watson A. Bowes, JR.
Vern L. Katz

The postpartum time period, also called the puerperium, lasts from delivery of the placenta until 6 to 12 weeks after delivery. Most of the physiologic changes in pregnancy will have returned to prepregnancy physiology by 6 weeks. However, many of the cardiovascular changes and psychological changes may persist for many more months.

Much information is known about the changes and problems that can occur in the weeks after delivery. However, because the care of a new infant is so important to the survival of any family, clan, or tribe, the postpartum period is associated with as much tradition and superstition as any other time in life. In order to support the successful recovery of the mother, and the healthy transition through the neonatal period, customs, taboos, and rituals have developed in most cultures. Indeed, most of the current medical recommendations about puerperium have developed from adaptations of socially acceptable traditions, rather than science. This chapter examines the physiologic adjustments of the postpartum period, the return of the female genital tract to its prepregnancy state (involution), the major puerperal disease states, and the natural course of lactation.

Most of the postpartum traditions from non-Western cultures involve special activities and different foods for the newly delivered mother, as well as particular and unique taboos. In the rural Philippines, the mother, who works up until she goes into labor, is prohibited from working after delivery, and she is given a new name. The maternal grandmother visits daily unless she has died, in which case the visits are made by the grandmother-in-law. The grandmother does all the house work and cooking for 8 weeks. The mother is bathed by the grandmother daily. When the umbilical cord falls off the infant, a feast is prepared. The cord is blessed at the feast. The new father is prohibited from building stone walls and from driving nails for 6 months. For 2 months, the relatives tend the fields.

In parts of rural India, the new mother returns to her mother's house for 16 weeks. She is given a hot bath every day. Cold baths are taboo, as cold water is associated with disease.

Many cultures have rituals regarding treatment of the placenta. It may be dried and turned to powder for its "medical" powers. The umbilical cord was hung in a nearby tree by some eastern American Indian tribes. In European tradition, it was buried under certain corners of the house, to ensure prosperity. For many cultures, the period of rest for the mother and abstention from sexual activity was 40 days. The 40-day time period corresponds to the 6 weeks of restricted activity in American culture. Many European countries have adopted different time periods before the mother returns to her predelivery status.

POSTPARTUM INVOLUTION

The Uterus

The crude weight of the pregnant uterus at term (excluding the fetus, placenta, membranes, and amniotic fluid) is approximately 1,000 g.^[1] The weight of the nonpregnant uterus is between 50 and 100 g. It is not known how rapidly this 10-fold involution in organ weight occurs, but within 2 weeks after birth the uterus has usually returned to the pelvis, and by 6 weeks it is usually normal size, as estimated by palpation. The involution of the uterus after childbirth has been studied for more than 100 years. The gross anatomic and histologic characteristics of the involutorial process are

702

based on the study of autopsy, hysterectomy, and endometrial biopsy specimens.^[2]^[3]^[4] The decrease in the size of the uterus and cervix during the puerperium has been demonstrated with serial magnetic resonance imaging (MRI) as illustrated in [Figure 21-1](#).^[5] The findings are consistent with those of serial sonography and computed tomography (CT).^[6]^[7]^[8]

Immediately after delivery, the decrease in endometrial surface contributes to the shearing off of the placenta at the decidual layer. The average diameter of the placenta is 18 cm; in the immediate postpartum uterus the average diameter of the site of placental attachment measures 9 cm. The placental site in the first 3 days after delivery is infiltrated with granulocytes and mononuclear cells, a reaction that extends into the endometrium and superficial myometrium. By the seventh day, there is evidence of the regeneration of endometrial glands, often appearing atypical, with irregular chromatin patterns, misshapen and enlarged nuclei, pleomorphism, and increased cytoplasm. By the end of the first week, there is also evidence of the regeneration of endometrial stroma, with mitotic figures noted in gland epithelium; by postpartum day 16, the endometrium is fully restored.

Decidual necrosis begins on the first day, and by the seventh day, a well-demarcated zone can be seen between necrotic and viable tissue. An area of viable decidua remains between the necrotic slough and the deeper endomyometrium. Sharman^[9] described the non-necrotic decidual cells as participating in the reconstruction of the endometrium, a likely role, since they were originally endometrial connective tissue cells to which they ultimately revert in the involutorial process. By the sixth week, it is rare to find decidual cells.

The immediate inflammatory cell infiltrate of polymorphonuclear leukocytes and lymphocytes persists for

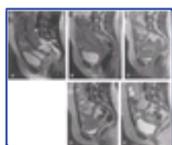

Figure 21-1 Sagittal T2-weighted fast spin echo magnetic resonance images (3/500/100) obtained serially after uncomplicated vaginal delivery. *A*, Initial image obtained less than 30 hours after delivery. Uterus and cervix are large and thick-walled. The uterine cervix is clearly distinguished from the uterine corpus by the high-signal-intensity outer cervical stroma (OCS) (*white arrow*). The low-signal-intensity inner cervical stroma (ICS) is apparent (*black arrows*). The myometrium has heterogeneous signal intensity, and prominent myometrial vessels are seen (*arrowhead*). The myometrial vessels remained prominent on images obtained 1 week (*B*) and 2 weeks (*C*) after delivery. At 1 week, the uterus and cervix have diminished substantially in size, the OCS has diminished in signal intensity, and the ICS is more clearly defined. The low signal intensity in the endometrial canal in *A* and *B* likely represents blood products. At 2 weeks (*C*), 6 weeks (*D*), and 6 months (*E*), the uterus has progressively decreased in size. At 2 weeks, the endometrium has returned to a normal high signal intensity. By 6 months, the junctional zone has been restored (*arrow in E*); however, it is broadened, measuring approximately 7 mm. (From Willms AB, Brown ED, Ketritz UI, et al: *Anatomic changes in the pelvis after uncomplicated vaginal delivery: evaluation with serial MR imaging. Radiology 195:91, 1995, with permission.*)

703

about 10 days, presumably serving as an antibacterial barrier. The leukocyte response diminishes rapidly after the 10th day, and plasma cells are seen for the first time. The plasma cell and lymphocyte response may last as long as several months. In fact, endometrial stromal infiltrates of plasma cells and lymphocytes are the sign (and may be the only sign) of a recent pregnancy.

Hemostasis immediately after birth is accomplished by arterial smooth muscle contraction and compression of vessels by the involuting uterine muscle. Vessels in the placental site are characterized during the first 8 days by thrombosis, hyalinization, and endophlebitis in the veins and by hyalinization and obliterative fibrinoid endarteritis in the arteries. The mechanism for hyalinization of arterial walls, which is not completely understood, may be related to the previous trophoblastic infiltration of arterial walls that occurs early in pregnancy. Many of the thrombosed and hyalinized veins are extruded with the slough of the necrotic placental site, but hyalinized arteries remain for extended periods as stigmata of the placental site.

Restoration of the endometrium in areas other than the placental site occurs rapidly, with the process being completed by day 16 after delivery. The gland epithelium does not undergo the reactivity or the pseudoneoplastic appearance noted in placental site glands.^[4]

The postpartum uterine discharge or lochia begins as a flow of blood lasting several hours, rapidly diminishing to a reddish brown discharge through the third or fourth day postpartum. This is followed by a transition to a mucopurulent, somewhat malodorous discharge, lochia serosa, requiring the change of several perineal pads per day. The median duration of lochia serosa is 22 to 27 days.^[9]^[10] However, 10 to 15 percent of women will have lochia serosa at the time of the 6-week postpartum examination. In the majority of patients, the lochia serosa is followed by a yellow-white discharge, lochia alba. Breast-feeding or the use of oral contraceptive agents does not affect the duration of lochia. Not infrequently there is a sudden but transient increase in uterine bleeding between 7 and 14 days postpartum. This corresponds to the slough of the eschar over the site of placental attachment. Myometrial vessels of greater than 5 mm in diameter are present for up to 2 weeks postpartum, which accounts for the dramatic bleeding that can occur with this phenomenon.^[5] Although it can be profuse, this bleeding episode is usually self-limited, requiring nothing more than reassurance of the patient. If it does not subside within 1 or 2 hours, the patient should be evaluated for possible retained placental tissue.

Ultrasound is useful in the management of abnormal postpartum bleeding. The empty uterus with a clear midline echo is quite easy to distinguish from the uterine cavity expanded by clot (sonolucent) or retained tissue (echo dense). Serial ultrasound examinations of postpartum patients showed that in 20 to 30 percent there was some retained blood or tissue within 24 hours after delivery. By the fourth postpartum day, only about 8 percent of patients showed endometrial cavity separation, a portion of which eventually had abnormal postpartum bleeding because of retained placental tissue.^[11] In cases of abnormal postpartum bleeding, ultrasound

examination efficiently detects patients who have retained tissue and who will therefore benefit from uterine evacuation and curettage. Those who have an empty uterine cavity will respond to therapy with oxytocin or methylergonovine. ^[12]

The Cervix

During pregnancy, the cervical epithelium increases in thickness, and the cervical glands show both hyperplasia and hypertrophy. Within the stroma, a distinct decidual reaction occurs. These changes are accompanied by a substantial increase in the vascularity of the cervix. ^[13] Colposcopic examination performed after delivery has demonstrated ulceration, laceration, and ecchymosis of the cervix. ^[14] Regression of the cervical epithelium begins within the first 4 days after delivery, and by the end of the first week edema and hemorrhage within the cervix are minimal. Vascular hypertrophy and hyperplasia persist throughout the first week postpartum. By 6 weeks' postpartum, most of the antepartum changes have resolved, although round cell infiltration and some edema may persist for several months. ^[15]

The Fallopian Tube

The epithelium of the fallopian tube during pregnancy is characterized by a predominance of nonciliated cells, a phenomenon that is maintained by the balance between the high levels of progesterone and estrogen. ^[16] After delivery, in the absence of progesterone and estrogen, there is further extrusion of nuclei from nonciliated cells and diminution in height of both ciliated and nonciliated cells. Andrews ^[16] demonstrated that the number and height of ciliated cells can be increased in the puerperium by treatment with estrogen.

Fallopian tubes removed between postpartum days 5 and 15 demonstrate inflammatory changes of acute salpingitis in 38 percent of cases, but no bacteria are found. The specific cause of the inflammatory change is unknown. ^[16] Furthermore, there is no correlation between the presence of histologic inflammation in the fallopian tubes and puerperal fever or other clinical signs of salpingitis.

Ovarian Function

It has long been recognized that women who breast-feed their infants will be amenorrheic for long periods of time, often until the infant is weaned. Several studies,

704

using a variety of methods to indicate ovulation, have demonstrated that ovulation occurs as early as 27 days after delivery, with the mean time being approximately 70 to 75 days in nonlactating women. ^[17], ^[18] Among those women who are breast-feeding their infants, the mean time to ovulation is about 6 months.

Menstruation resumes by 12 weeks' postpartum in 70 percent of women who are not lactating, and the mean time to the first menstruation is 7 to 9 weeks. In one study of lactating women, it was 36 months before 70 percent began to menstruate. The duration of anovulation depends on the frequency of breast-feeding, the duration of each feed, and the proportion of supplementary feeds. ^[19] The risk of ovulation within the first 6 months' postpartum in a woman exclusively breast-feeding is 1 to 5 percent.

The hormonal basis for puerperal ovulation suppression in lactating women appears to be the persistence of elevated serum prolactin levels. ^[20] Prolactin levels fall to the normal range by the third week postpartum in nonlactating women, but remain elevated into the sixth week postpartum in lactating patients. Estrogen levels fall immediately after delivery in both lactating and nonlactating women and remain depressed in lactating patients. In those who are not lactating, estrogen levels begin to rise 2 weeks after delivery and are significantly higher than in lactating women by postpartum day 17. Follicle-stimulating hormone (FSH) levels are identical in breast-feeding and non-breast-feeding women. It is therefore assumed that the ovary does not respond to FSH stimulation in the presence of increased prolactin levels.

Weight Loss

One of the most welcomed changes for the majority of women who have recently given birth is the loss of the weight that was accumulated during pregnancy. The immediate loss of 10 to 13 lb is attributed to the delivery of the infant, placenta, and amniotic fluid and to blood loss. ^[21] By six weeks postpartum, 28 percent of women will have returned to their prepregnant weight. The remainder of the weight loss occurs from 6 weeks postpartum until 6 months after delivery. Women with excess weight gain in pregnancy (>35 lb) are likely to have a net gain of 11 lb. ^[22] Breast-feeding has relatively little effect on postpartum weight loss. ^[23] In a program of diet and exercise, weight loss of approximately 0.5 kg/wk between 4 and 14 weeks postpartum in overweight women did not affect the growth weight of their infants. ^[24] Aerobic exercise had no adverse effect on lactation. ^[25]

Thyroid Function

Thyroid size and function throughout pregnancy and the puerperium have been quantitated with ultrasonography and thyroid hormone levels. ^[26] Thyroid volume increases approximately 30 percent during pregnancy and regresses to normal size gradually over a 12-week period. Thyroxine and triiodothyronine, which are both elevated throughout pregnancy, return to normal within 4 weeks postpartum. It is now recognized that the postpartum period is associated with an increased risk for the development of a transient autoimmune thyroiditis that may in some cases lead to permanent hypothyroidism. ^[27] Asymptomatic postpartum thyroid dysfunction may occur in as many as 10 percent of parturients. ^[28] Pedersen et al. found a relationship between subclinical thyroid dysfunction and postpartum depression, ^[29] although this was not confirmed by Kent et al. ^[28], ^[30]

Cardiovascular System and Coagulation

Blood volume increases throughout pregnancy to levels in the third trimester about 35 percent above nonpregnant values. ^[31] The greatest proportion of this increase consists of an expansion in plasma volume that begins in the first trimester and amounts to an additional 1,200 ml of plasma, representing a 50 percent increase by the third trimester. Red blood cell volume increases by about 250 ml.

Immediately after delivery, plasma volume is diminished by approximately 1,000 ml because of blood loss. By the third postpartum day, plasma volume has increased by 900 to 1,200 ml because of a shift of extracellular fluid into the vascular space. ^[32] The total blood volume by the third postpartum day, however, declines by 16 percent of the predelivery value. ^[33] Ueland found that blood volume changes in the puerperium were the same regardless of the method of delivery, but patients who delivered vaginally had a 5 percent increase in hematocrit, whereas those who had a cesarean delivery had a 6 percent decrease in hematocrit. ^[33] The rate at which red blood cell volume returns to prepregnancy levels is unknown, but when measured at 8 weeks postpartum it is found to be within the normal range. ^[34] As blood volume decreases, venous tone returns to normal. Macklon and Greer examined 42 women, longitudinally, at 4 and 42 days postpartum. The investigators demonstrated significant reduction in deep vein vessel size and a concomitant increase in venous flow velocity in the lower extremities. ^[35]

Pulse rate increases throughout pregnancy, as does stroke volume and cardiac output. Immediately after delivery, these remain elevated or rise even higher for 30 to 60 minutes. Following delivery, there is a transient rise of approximately 5 percent in both diastolic and systolic blood pressures throughout the first 4 days postpartum. ^[36] In 12 percent of otherwise normotensive patients, the diastolic blood pressure will exceed 100 mm Hg. Data are scant regarding the rate at which cardiac hemodynamics return to prepregnancy levels. Early studies suggested cardiac output had returned to

705

normal when measurements were made 8 to 10 weeks postpartum. ^[37] Clapp and Capeless performed longitudinal evaluations of cardiac function at bimonthly intervals in 30 healthy women using M-mode ultrasound, prior to pregnancy; during gestation; and at 12, 24, and 52 weeks postpartum. Cardiac output and left ventricular volume peaked at 24 weeks' gestation. There was a slow return to prepregnancy values over the year of study. However, even 1 year after delivery, there was a significantly higher cardiac output in both nulliparous and multiparous women than prepregnancy values. The authors suggested that this "cardiac remodeling" from pregnancy may last for an extended time in healthy women. ^[38] Elite athletes have tried to take advantage of this physiologic boost to cardiac function, by

planning pregnancies a year prior to major sporting events.

Ygge^[39] studied blood coagulation and fibrinolysis in 10 normal pregnant women during the 4 weeks before delivery, during labor and delivery, and 2 weeks postpartum. Compared with antepartum values, there was a rapid decrease in platelets in some patients and no change or an increase in others. However, 2 weeks after delivery, all patients demonstrated an increase in platelet count. Fibrinolytic activity increased in the first 1 to 4 days after delivery and returned to normal in 1 week. The greatest level of coagulability was observed immediately postpartum through 48 hours. Fibrinogen concentration gradually diminished over the 2-week postpartum period studied. The changes in the coagulation system together with vessel trauma and immobility account for the increased risk of thromboembolism noted in the puerperium, especially when operative delivery has occurred.

The Urinary Tract and Renal Function

It is generally accepted that the urinary tract becomes dilated during pregnancy, especially the renal pelvis and the ureters above the pelvic brim. These findings, demonstrated 50 years ago by Baird,^[40] affect the collecting system of the right kidney more than that of the left. These changes are caused by compression of the ureters by adjacent vasculature and by compression from the enlarged uterus, and by the effect of progesterone. Ureteral tone above the pelvic brim, which in pregnancy is higher than normal, diminishes in the lateral recumbent position and returns to nonpregnant levels immediately after cesarean delivery.^[41]

The intravenous urography studies performed by Dure-Smith^[42] suggest that subtle anatomic changes take place in the ureters that persist long after the pregnancy has ended. Ultrasound studies of the urinary tract also document the enlargement of the collecting system throughout pregnancy.^[43] A study of serial ultrasound examinations of the urinary tract in 20 women throughout pregnancy included a single postpartum examination 6 weeks after delivery.^[44] The overall trend was that of dilatation of the collecting system throughout pregnancy, estimated by measurements of the separation of the pelvis-calyceal echo complex, from a mean of 5.0 mm (first trimester) to 10 mm (third trimester) in the right kidney and from 3.0 to 4.0 mm in the left collecting system. Measurements in all but two patients had returned to prepregnancy status at the time of the 6-week postpartum examination. Cietak and Newton^[45] performed serial nephrosonography on 24 patients throughout pregnancy and the puerperium. At 12 weeks postpartum, more than half of the patients demonstrated persistence of urinary stasis, described as a slight separation of the renal pelvis. This finding is evidence of hyperdistensibility and suggests that pregnancy has a permanent effect on the size of the upper renal tract.

Studies in which water cystometry and uroflowmetry were performed within 48 hours of delivery and again 4 weeks postpartum demonstrated a slight but significant decrease in bladder capacity (from 395.5 to 331 ml) and volume at first void (from 277 to 224 ml) in the study interval. Nevertheless, all the urodynamic values studied were within normal limits on both occasions. The results were not affected by the weight of the infant or by an episiotomy. However, prolonged labor and the use of epidural anesthesia appeared to diminish postpartum bladder function transiently.^[46]

The most detailed study of renal function in normal pregnancy is that of Sims and Krantz,^[47] who studied 12 patients with serial renal function tests throughout pregnancy and for up to 1 year after delivery. Glomerular filtration, which increased by 50 percent early in pregnancy and remained elevated until delivery, returned to normal nonpregnant levels by postpartum week 8. Endogenous creatinine clearance, similarly elevated throughout pregnancy, also returned to normal by the eighth postpartum week. Renal plasma flow increased by 25 percent early in pregnancy, gradually diminished in the third trimester (even when measured in the lateral recumbent position), and continued to decrease to below-normal values in the postpartum period for up to 24 weeks.^[48] Normal values were finally established by 50 to 60 weeks after delivery. The reason for the prolonged postpartum depression of renal plasma flow is not clear.

Other Changes

Hair growth slows in the puerperium. Often, women will experience hair loss, as temporarily more hair is lost than is regrown. This is a transient phenomenon, and the patient may be reassured that hair patterns return to normal within a few months.

Several investigators have reported on bone mineral changes with lactation and the associated amenorrhea. After delivery, there is a generalized decrease in bone mineralization that is most always temporary and resolves

by 18 months postpartum in most women.^[49] Bone loss appears to be greatest in the femoral neck than in other areas of the skeleton.^[50], ^[51] Calcium supplementation does not seem to ameliorate the bone loss, since it is not a problem of inadequate calcium stores. Exercise does not prevent this bone loss.^[52]

Management of the Puerperium

For most parturients, the immediate puerperium is spent in the hospital or birthing center. The ideal duration of hospitalization for patients with uncomplicated vaginal births has been controversial, with most authorities recommending a 2-day stay for first-time mothers. For patients with an uncomplicated postoperative course following cesarean delivery, the postpartum stay is 3 or 4 days. Approximately 3 percent of women who have vaginal deliveries and 9 percent of women who have cesareans have at least one childbirth-related complication requiring prolonged hospitalization after delivery or readmission to the hospital.^[53]

In a recent study, 1,249 randomly selected patients were questioned 8 weeks following delivery about health problems that occurred during the puerperium.^[54] Eighty-five percent reported at least one problem during their hospitalization, and 76 percent noted at least one problem that persisted for 8 weeks. A wide range of problems were reported by the patients, including a painful perineum, difficulties with breast-feeding, urinary infections, urinary and fecal incontinence, and headache. Three percent of the patients had been rehospitalized, most commonly for abnormal bleeding or infection. This study draws attention to a substantial amount of symptomatic morbidity that occurs during the puerperium.

If a patient has adequate support at home (i.e., help with housekeeping and meal preparation), there is little value in an extended hospital stay, provided the mother is adequately educated about infant care and feeding, family planning, and identification of danger signs in either the infant or herself. Except for an increased incidence of rehospitalization of some neonates for hyperbilirubinemia, there are few disadvantages to postpartum hospitalization of less than 48 hours for many patients.^[55] ^[56] ^[57] ^[58] For mothers who do not have adequate support at home and who are insecure about infant care and feeding, extending the hospital stay will provide time for mothers to gain adequate education and some measure of self-confidence.^[59] Video presentations are an efficient means of patient education. Also, home nursing visits can be helpful in providing support, education, and advice to mothers.

In addition to the video presentation, patients should be given ample opportunity to discuss specific questions or concerns with a nurse or physician. It is also important to provide a new mother time and a sympathetic listener so that she can express her feelings and ask questions about her labor and delivery experience.

The time from delivery until complete physiologic involution and psychological adjustment has been called "the fourth trimester."^[60] Patients should understand that lochia will persist for 3 to 8 weeks and that on days 7 to 14 there is likely to be an episode of heavy vaginal bleeding, which occurs when the placental eschar sloughs. Tampons are permissible if they are comfortable upon insertion and are changed frequently and if there are no perineal, vaginal, or cervical lacerations, which preclude insertion of a tampon until healing has occurred.

Physical activity, including walking up and down stairs, lifting heavy objects, riding in or driving a car, and performing muscle-toning exercises, can be resumed without delay if the delivery has been uncomplicated. Instructions regarding exercise are patient specific. Recent studies have found that exercise postpartum does not affect lactation, and may decrease anxiety levels.^[61], ^[62] As such, exercise may have benefits beyond the mother's desire to "get back into shape." The most troublesome complaint is lethargy and fatigue. Consequently, every task or activity should be a brief one in the first few days of the puerperium. Mothers whose lethargy persists beyond several weeks must be evaluated, especially as regards thyroid dysfunction. Transient postpartum thyrotoxicosis may occur followed by hypothyroidism. These episodes are characterized by goiter formation, the presence of antithyroid antibodies, and eventual resolution.^[63], ^[64]

Sexual activity may be resumed when the perineum is comfortable and when bleeding has diminished. The desire and willingness to resume sexual activity in the puerperium varies greatly among women, depending on the site and state of healing of perineal or vaginal incisions and lacerations, the amount of vaginal atrophy secondary to breast-feeding, and the return of libido.^[65] Although the median time to resuming intercourse after delivery is 6 weeks, approximately one half of women who do so have dyspareunia, and in a substantial number it lasts for a year or more.^[66], ^[67] Postpartum dyspareunia is not predominantly related to vulvar repair and

occurs in some women who have a cesarean delivery. It is also observed in women who use oral contraceptives and do not breast-feed, suggesting that lack of estrogen effect on the vagina is not the major cause of postpartum dyspareunia. In a study of 50 parturients, Ryding^[68] found that 20 percent had little desire for sexual activity 3 months after delivery, and an additional 21 percent had complete loss of desire or aversion to sexual activity. This variation in attitude, desire, and willingness must be acknowledged when counseling women about the resumption of sexual activity.

Many patients will be returning to work situations outside the home after their pregnancies. Frequently,

707

the physician must complete insurance or employer forms to establish maternity leave for patients. Six weeks is regarded as the normal period of "disability" following delivery,^[69] although some mothers return to work sooner.

A follow-up examination is frequently scheduled for 6 weeks after delivery. Several studies have shown that a routine postpartum visit to the physician at 1 or 2 weeks after delivery or a home visit by a nurse midwife does not reduce maternal or infant morbidity.^[70],^[71] Nevertheless, for some patients, an appointment approximately 2 weeks postpartum or a home visit by a visiting nurse or nurse midwife will be more productive in detecting problems and providing support for a mother. Late puerperal infections, postpartum depression, and problems with infant care and feeding often occur before the 6-week postpartum visit.

Some women with chronic medical diseases, such as collagen vascular disease, autoimmune disorders, and neurologic conditions, should be seen at close intervals. Many patients with these disorders may experience "flares" of their symptoms after delivery. This has been theorized as a rebound of the immune system after a period of relative immune suppression during pregnancy. Prophylactic therapy is not recommended for women with systemic lupus or multiple sclerosis. However, warning patients to be attuned to signs and symptoms that reflect a flare of their illness allows for early and more effective interventions.

Perineal Care

Many women who give birth have an episiotomy or spontaneous lacerations of the perineum or vagina. In the United States, episiotomies are more often performed as midline than as mediolateral incisions. Provided that the incision or the laceration does not extend beyond the transverse perineal muscle, that there is no hematoma or extensive ecchymosis, and that a satisfactory repair has been accomplished, there is little need for perineal care beyond routine cleansing with a bath or shower. Analgesia can be accomplished in most patients with nonsteroidal anti-inflammatory drugs such as ibuprofen. These drugs have been shown to be superior to acetaminophen or propoxyphene for episiotomy pain and uterine cramping.^[72] Furthermore, because of a low milk/maternal plasma drug concentration ratio, a short half-life, and transformation into glucuronide metabolites, ibuprofen is safe for nursing mothers.

A patient who has had a mediolateral episiotomy or who has a third- or fourth-degree extension of a midline episiotomy and extensive spontaneous second-degree laceration or extensive perineal bruising may experience considerable perineal pain. Occasionally, the pain and periurethral swelling will prevent the patient from voiding, making urethral catheterization necessary. When a patient complains of inordinate perineal pain, the first and most important step is to reexamine the perineum, vagina, and rectum to detect and drain a hematoma or to identify a perineal infection. Perineal pain may be the first symptom of the rare but potentially fatal complications of angioedema, necrotizing fasciitis, or perineal cellulitis.^[73]^[74]^[75]

In cases of moderate perineal pain, sitz baths will provide additional pain relief. Although hot sitz baths have long been customary therapy for perineal pain, Droegemueller^[76] outlined the rationale for using cold or "iced" sitz baths. This therapy is similar to that for the treatment of athletic injuries, for which considerable success has been achieved with cold therapy. Cold provides immediate pain relief as a result of decreased excitability of free nerve endings and decreased nerve conduction. Further pain relief comes from local vasoconstriction, which reduces edema, inhibits hematoma formation, and decreases muscle irritability and spasm. Patients who have alternated using hot and cold sitz baths usually prefer the cold.

The technique for administering a cold sitz bath is first to have the patient sit in a tub of water at room temperature to which ice cubes are then added. This avoids the sensation of sudden immersion in ice water. The patient remains in the ice water for 20 to 30 minutes.

Frequently, what appears to be severe perineal pain is, in fact, the pain of prolapsed hemorrhoids. Witch hazel compresses, suppositories containing corticosteroids, or local anesthetic sprays or emollients may be helpful. Occasionally, a thrombus will occur in a prolapsed hemorrhoid. It is a simple task to remove the thrombus through a small scalpel incision using local anesthesia. Dramatic relief of pain usually follows this procedure.

Patients with perineal incisions or lacerations should be advised to postpone sexual intercourse for 3 weeks or until there is no perineal discomfort. Tampons may be inserted whenever the patient is comfortable doing so. However, to avoid any risk of toxic shock syndrome, the use of tampons should be confined to the daytime to prevent leaving a tampon in the vagina for prolonged periods. Urinary and anal incontinence occur in some women following delivery.^[77] Approximately 15 percent of women have urinary incontinence and 5 percent have anal incontinence 3 months after giving birth.^[78] Operative vaginal delivery and anal sphincter lacerations are associated with an increased risk of postpartum anal incontinence, while cesarean delivery, especially if performed prior to the second stage of labor, is associated with a decreased risk for this problem. Often, women do not complain of symptoms of incontinence because they are embarrassed or they regard the symptoms as the normal consequence of delivery. Postpartum urinary and fecal incontinence are often

708

transient and resolve within 6 months. If the symptoms persist for more than 6 months, studies should be undertaken to define the specific neuromuscular or anatomic abnormality so that the appropriate pharmacologic, biophysical, or surgical treatment can begin.

Delayed Postpartum Hemorrhage

The causes and management of immediate postpartum hemorrhage are discussed [in Chapter 17](#). Delayed postpartum uterine bleeding of sufficient quantity to require medical attention occurs in 1 to 2 percent of patients. One of the most common causes of postpartum hemorrhage that occurs 2 to 5 days after delivery is von Willebrand's disease. Women presenting in this time frame should be screened for this condition. Von Willebrand's factor increases in pregnancy, and thus bleeding usually does not occur in the first 48 hours after birth. Uterine atony and postpartum hemorrhage are responsible for approximately eight maternal deaths each year in the United States.^[79] The bleeding occurs most frequently between days 8 and 14 of the puerperium.^[80] The bleeding is usually self-limited and of short duration. The cause of most of these cases is presumed to be sloughing of the placental eschar. It is helpful to warn patients about these symptoms. However, when the bleeding is of greater amount, requiring curettage, retained gestational products will be found in about 40 percent of cases. Whether small placental remnants are the cause is not known. In the management of patients with heavy delayed bleeding, ultrasound examination will usually determine if there is a significant amount of retained material, although it is sometimes difficult to distinguish between blood clot and retained placental fragments. Suction evacuation of the uterus is successful in arresting the bleeding in almost all cases whether or not there is histologic confirmation of retained gestational products. If curettage is required at this time, especially if a sharp curette is used, a course of antibiotics begun prior to surgery is advisable for its possible benefit in reducing the formation of uterine synechiae. The curettage should be performed with care, as the postpartum uterine wall is soft and easier to perforate. In those rare instances in which delayed postpartum hemorrhage does not respond to the use of oxytocic agents and curettage, selective arterial embolization is effective in controlling the bleeding.^[81]

Postpartum Infection

The standard definition of postpartum febrile morbidity is a temperature of 38.0°C (100.4°F) or higher on any 2 of the first 10 days after delivery, exclusive of the first 24 hours. However, most clinicians do not wait 2 full days to begin evaluation and treatment of patients who develop a fever in the puerperium.^[82] The most common cause of postpartum fever is endometritis, which occurs after vaginal delivery in approximately 2 percent of patients and after cesarean delivery in about 10 to 15 percent. The differential diagnosis includes urinary tract infection, lower genital tract infection, wound infections, pulmonary infections, thrombophlebitis, and mastitis. The diagnosis and management of postpartum infection are discussed in detail [in Chapter 40](#).

Maternal/Infant Attachment

Klaus et al.^[83] were among the first investigators to study maternal/infant attachment and to bring attention to the importance of the first few hours of maternal/infant association. Their studies as well as those of others have contributed substantially to major changes in hospital policies dealing with patients in labor and delivery and during the postpartum confinement. It is now recognized that there should be opportunities for parents to be with their newborns even from the first few moments after birth and as frequently as possible during the first days thereafter. These associations are usually characterized by fondling, kissing, cuddling, and gazing at the infant, which are manifestations of maternal commitment and protectiveness toward her infant. Separation of mother and infant in the first hours after birth has been shown to diminish or delay the development of these characteristic mothering behaviors,^[84] a problem that is intensified when medical, obstetric, or newborn complications require intensive care for either the mother or her newborn infant.

Robson and Powell^[85] summarized the literature on early maternal attachment and emphasized how difficult it is to accomplish good research studies about this phenomenon. While it is generally agreed that early association of the mother and infant is beneficial and should not be interfered with unnecessarily, there are still doubts about the long-term implications, if any, of a lack of early maternal/infant association. In their monograph summarizing their investigations about parent/infant attachment, Klaus and Kennel^[86] warn against drawing far-reaching conclusions. Although favoring the theory of a "sensitive period" soon after birth, during which close parent/infant interaction facilitates subsequent attachment and beneficial parenting behavior, these investigators concur that humans are highly adaptable and state that "there are many fail-safe routes to attachment." This appears to be the prevailing view among experts at this time.

The modern hospital maternity ward should enhance and encourage parent/infant attachment by such policies as flexible visiting hours for the father, encouragement of the infant rooming with the mother, and supportive attitudes about breast-feeding. These policies also allow the nursing staff to observe parenting behavior and to identify inept, inexperienced, or even malicious

behavior toward the infant. Some situations may call for more intensive follow-up by visiting nurses, home health visitors, or social workers to provide further support for the family during the posthospital convalescence.

The role of postpartum home visits in enhancing parenting behavior is controversial. Gray et al.^[87] found this approach quite beneficial. Siegel et al.^[88] studied the effect of early and prolonged mother/infant contact in the hospital and a postpartum visitation program on attachment and parenting behavior. They found that early and prolonged maternal/infant contact in the hospital had a significant effect on enhancing subsequent parenting behavior, but the postpartum home visitations had no impact.

The development of the qualities associated with good parenting depends on many factors. Certainly it does not depend solely on what transpires in the few hours surrounding the birth experience. There is evidence that specific identification of an infant with its mother's voice begins in utero during the third trimester.^[89] Furthermore, the parents' own experiences as children, as well as their intellectual and emotional attitudes about children, must play a large role in their own parenting behavior. Areskog et al.^[90] showed that women who expressed fear of childbirth during the antenatal period had more complications and more pain in labor and also had more difficulties in attachment to their infants. Consequently, the peripartum period provides opportunities to enhance parenting behavior and to identify families for which follow-up after birth may be necessary to ensure the most favorable child development.

In summary, the postpartum ward should be an environment that provides parents ample opportunity to interact with their newborn infants. Personnel, including nurses, nurses' aides, and physicians, caring for mothers and infants should be alert to signs of abnormal parenting (e.g., refusal of the mother to care for the infant, the use of negative or abusive names in describing or referring to the infant, inordinate delay in naming the infant, or obsessive and unrealistic concerns about the infant's health). These or other signs that maternal/infant attachment is delayed or endangered are as deserving of frequent follow-up during the postpartum period as are any of the traditional medical or obstetric complications.

LACTATION AND BREAST-FEEDING

One of the important objectives of the puerperium is to enhance the maternal-infant interaction as regards nutrition of the infant. After several decades during which interest in breast-feeding languished in Western cultures, there has been renewed interest and enthusiasm for what is clearly the most reasonable means of feeding most newborn infants. In the United States, the proportion of mothers who breast-fed their infants in the early postpartum period increased from 52 percent in 1990 to 62 percent in 1997. The proportion of infants who were breast-fed for 6 months increased from 18 percent in 1990 to 26 percent in 1997.^[91] Although the increase in breast-feeding is seen in all demographic groups, it is greatest in upper income and more highly educated groups. The increase in the popularity of breast-feeding is due in part to an increasing awareness of the advantages. The benefits include improved infant nutrition, increased resistance to infection, decreased expense, and increased convenience.^[92] Furthermore, women who use lactation amenorrhea as a contraceptive alternative have higher rates of using other contraceptive methods and more effective delay of subsequent pregnancies than comparable women who do not breast feed.^[93] Successful breast-feeding depends to a great extent on the motivation of the mother and on the support she receives from family, friends, and health care providers. Undoubtedly, the mother's experiences as a child contribute to her attitudes about childbearing and infant feeding. Nevertheless, additional knowledge about breast-feeding may be gained during prenatal care from well-informed, enthusiastic, and supportive physicians and nurses, by reading from one of several lay books on breast-feeding, and by participating in classes on prepared childbirth. A variety of hospital practices, including the use of audiovisual aids, telephone hotlines, and in-service training for personnel, have been shown to increase the incidence of successful breast-feeding.^[94]

The prenatal physical examination may identify problems that will affect breast-feeding. These include inverted nipples, which can be corrected in part by wearing breast shields, or *Candida* vaginal infections, which should be treated to avoid thrush in the infant, and painful *Candida* infection of the nipples.

The Term Infant

Hospital routines should not interfere with reasonable breast-feeding practices. Allowing the infant to nurse in its wakeful period immediately after birth when the mouthing movements and rooting reflex are active will give the mother confidence and promote milk production and let-down. Furthermore, early suckling not only provides the infant with the important immunologic and anti-infective properties of colostrum, but also has been shown to enhance successful breast-feeding.

Rooming-in allows the parents to become accustomed to demand feeding and provides the mother with

opportunities to seek help from the nursing staff while she enhances her breast-feeding skills. Although the rooting and suckling reflexes are intact in a healthy newborn, successful breast-feeding is a learned talent for mother and infant. Neifert and Seacat^[95] recommend that the infant be allowed to suckle for 5 minutes per breast per feeding the first day, 10 minutes the second day, and 15 minutes or more per breast per feeding thereafter. If suckling is interrupted before initiation of the let-down reflex, the likelihood of breast engorgement and nipple soreness is increased.

The initial breast engorgement that occurs on the second to fourth postpartum days is caused by lymphatic and vascular congestion, interstitial edema, and increased tension in the milk ducts. It is best managed with 24-hour demand feedings and, in stubborn cases, the use of oxytocin nasal spray to promote milk let-down. Hot compresses before nursing will facilitate let-down, and cold compresses between feedings may provide additional relief.

A common problem is nipple confusion, in which an infant accepts an artificial nipple but refuses the mother's nipple. This can be avoided by not offering supplemental fluids and by informing the mother of methods to make her nipple more protractile. Breast engorgement enhances this problem, but with patience it usually resolves within 24 to 48 hours.

Nipple soreness, another common complaint during the immediate puerperium, can be relieved by rotating breasts and the infant's position every 5 minutes while nursing; using frequent, shorter feedings rather than prolonged feeding times; avoiding irritating soaps, wet nursing pads, or other applications; and exposing the nipples for air-drying followed by the application of hydrous lanolin. In cases of persistent nipple soreness or of sudden appearance of nipple soreness after lactation has been established, *Candida* infection of the nipple must be considered.^[96] The infection, which often occurs in association with thrush or *Candida* diaper rash, can be documented by culture; it responds promptly to applications of nystatin cream.

An empathetic and knowledgeable nursing staff is essential to successful breast-feeding by the mother who is attempting it for the first time. In the hospital, education and patient confidence can be facilitated with a brief videotape presentation about breast-feeding, which describes some of the problems that might be encountered and offers helpful solutions. Professional lactation counselors are often available to provide education and support in prenatal classes, during the immediate puerperium, and in the home following discharge from the hospital or birthing center. In many areas, the local chapter of the La Leche League will offer valuable advice to women who encounter problems with breast-feeding. Also, there are helpful Web sites on the Internet, such as www.breastfeeding.com.

Maternal Nutrition During Lactation

The impact of lactation on the nutritional status of the mother is well reviewed by Casey and Hambidge^[96] and in the publication by the Institute of Medicine entitled *Nutrition During Lactation*.^[97] A healthy mother breast-feeding a healthy infant will produce approximately 600 to 900 ml breast milk per day and will provide her infant with approximately 520 kcal/day. This requires about 600 kcal/day (including the energy required to produce the milk), which must be made up from the mother's diet or her body stores. For this purpose, the well-nourished woman stores about 5 kg of fat throughout pregnancy, which can be called on during lactation to make up any nutritional deficit.

The daily allowances of nutrients recommended for the mother during the first 6 months of lactation by the U.S. National Research Council^[98] are listed in [Table 21-1](#).

With the exception of iron and calcium, almost all of the other nutrients are provided in a well-balanced American diet. Even in situations in which there is obvious nutritional deprivation, the quantity and quality of breast milk seem to suffer very little. The composition of breast milk, however, can be influenced to some extent by the mother's diet. The protein content of breast milk is not influenced by the mother's diet, but the fat content is quite susceptible to dietary manipulation. Women who have diets in which the fat is largely of animal origin produce milk with high stearic acid content and low linoleic acid levels, whereas women

TABLE 21-1 -- DAILY ALLOWANCES OF NUTRIENTS RECOMMENDED FOR THE MOTHER DURING THE FIRST 6 MONTHS OF LACTATION*

Nutrients	Recommended Amount
-----------	--------------------

Calories	2,500
Protein	65 g
Vitamin A	1,300 g (retinol equiv.)
Vitamin D	10 g (400 IU)
Vitamin E	12 mg (-tocopherol equiv.)
Thiamine	1.6 mg
Riboflavin	1.8 mg
Niacin	20 mg (niacin equiv.)
Folacin	280 g
Vitamin B ₆	2.1 mg
Vitamin B ₁₂	2.6 g
Ascorbic acid	95 mg
Calcium	1,200 mg
Phosphorus	1,200 mg
Magnesium	355 mg
Iron	15 mg
Zinc	19 mg
Iodine	200 g

* U.S. National Research Council recommendations.

with diets high in polyunsaturated fatty acids produce milk with high levels of linoleate. The importance of these differences on the subsequent health of breast-fed infants is unknown.

Levels of some but not all vitamins in breast milk can be influenced by maternal intake, but there is little evidence that breast milk in the otherwise well-nourished mother is vitamin deficient. Consequently, the need for vitamin supplementation for the lactating woman on a normal diet is not well established. Some vegetarians may have diets deficient in vitamin B₁₂, and vitamin B₁₂ deficiency has been documented in a breast-fed infant of a vegetarian mother.^[99] Also, infants of dark-skinned mothers who have had inadequate exposure to sunlight may become vitamin D deficient. This can be avoided by brief daily exposure to sunlight.^[100]

Frequently, women inquire about the advisability of dieting and weight loss during lactation. Because of the increased metabolic rate and the increased energy requirements of lactating women, the appetite increases, leading to an increase in caloric intake. However, a persistent weight loss can be achieved through modest dietary restrictions without an untoward effect on the health of either the mother or the infant. Whiceloh^[101] found that lactating mothers who were losing weight had an average daily intake of 2,509 kcal, whereas women who were not losing weight consumed 2,946 kcal.

Bone mineral density decreases, especially in the spine, in women who breast-feed compared to those who do not. This is not affected by calcium supplementation; and bone mineral density returns to normal 12 months after lactation is discontinued.^{[49], [102]}

Contraindications to Breast-Feeding

There are very few contraindications to breast-feeding. Reduction mammoplasty with autotransplantation of the nipple simply makes breast-feeding impossible.

Puerperal infections, including acute mastitis, can be managed quite successfully while the mother continues to breast-feed. There is the possibility of transmitting certain viral infections in the breast milk, including cytomegalovirus, herpes simplex, hepatitis B virus (HBV), and human immunodeficiency virus (HIV). The morbidity of cytomegalovirus infection contracted by a healthy term neonate is sufficiently low that potentially infected mothers should not be discouraged from breast-feeding. Although one possible case of viral transmission in the breast milk occurred,^[103] the source of neonatal herpes infection is surface contact with the virus; consequently, instruction of the mother in proper handwashing and care of possibly contaminated articles of clothing is sufficient to protect the infant and to permit continued breast-feeding. As regards HBV infection, McGregor and Neifert^[104] recommend that breast-feeding not be encouraged in women with acute hepatitis, hepatitis B/e antigenemia (HB_e Ag), or other markers of heightened infectivity such as titers of HB_e Ag over 1:1,000. However, breast-feeding is permissible in women without active HBV disease and certainly in the uncommon circumstance of an HB_e Ag-positive newborn. Thus, most mothers with HBV infection before or during pregnancy can be supported in their decision to breast-feed. Women with chronic hepatitis C virus (HCV) infection may breast-feed their infants. A number of studies have found no evidence of transmission of HCV in breast milk.^[105] HIV is present in breast milk, and the risk of vertical transmission is doubled if an infant breast-feeds.^[106] In a randomized clinical trial conducted in Nairobi, Kenya, formula feeding significantly reduced HIV transmission to infants of infected mothers.^[107] Consequently, in developed countries where there is not a high risk of newborn infectious disease associated with bottle feeding, breast-feeding is contraindicated for mothers with HIV infection.

Most medications taken by the mother will enter the breast milk to a small degree (see Chapter 9). Because of the short duration for which most medications are prescribed, however, and the minimal amounts of drug that reach the breast milk (usually in concentrations similar to or less than in maternal plasma), it is usually safe to recommend that the infant continue nursing. The pharmacokinetics of most drugs ingested by breast-feeding women are such that administration of the drug at the time of or immediately after the infant nurses will result in the lowest amount of drug in the milk at the subsequent feeding. If there is any doubt about the effect of a specific drug taken by a mother and whether she should continue breast-feeding, one should consult a recent reference about the effects of drugs in the nursing infant (see Chapter 9).^{[108], [109]}

Breast Milk for the Premature Infant

There are substantial data confirming the psychological, nutritional, and immunologic advantages to using a mother's breast milk to feed her premature infant. Preterm infants fed their mothers' milk will gain weight at the same rate as when they are fed formula.^[110] Metabolic disturbances (azotemia, hyperaminoacidemia, and metabolic acidosis) are more frequent in infants receiving higher intakes of protein from formulas compared with human milk. Furthermore, the immunologically active constituents of breast milk (lactoferrin, lysozyme, lactoperoxidase, complement, leukocytes, and specific immunoglobulins) undoubtedly account for the lower incidence of infectious complications found in premature infants fed breast milk.^[109] (see Chapter 5).

In addition to the nutritional and immunologic^[111] advantages of breast milk for the premature infant, there are the important psychological benefits for the mother. Women

who give birth to preterm infants often have a sense of guilt and failure. By providing breast milk, the mother takes an active part in the infant's daily care, which gives

her a renewed sense of worth and importance.

In situations in which breast milk will be used for a premature infant, the mother must be instructed in the various methods of milk expression, collection, preservation, and transport. Most intensive care nurseries and many postpartum wards provide written instructions about milk expression and collection techniques. ^[112] A pump is more efficient and less time consuming than hand expression. Electric pumps, which simulate the physiologic suckling action of the infant, are available in many nurseries and can be leased from surgical supply companies or rental outlets. Often, the local chapter of the La Leche League will provide information on the availability of electric pumps. Hand pumps can also be used.

Occasionally, it is difficult to maintain an adequate milk supply using artificial expression. Hopkins et al. ^[113] have demonstrated that in mothers who have delivered prematurely, milk volume is inversely related to the delay in initiation of milk expression. Optimal milk production is associated with five or more milk expressions per day and pumping durations that exceed 100 min/day. Breast milk can be refrigerated for 24 hours at 1° to 5°C or frozen at -18° to -23°C for up to 3 months.

Complications of Breast-Feeding

The most common complication of breast-feeding is puerperal mastitis. This condition, which is characterized by fever, myalgias, and an area of pain and redness in either breast, usually has its onset before the end of the second postpartum week, but there is also an increase in its incidence in the fifth and sixth weeks postpartum. Niebyl et al. ^[114] reported 20 women in whom sporadic (nonepidemic) puerperal mastitis developed. The women were treated with penicillin V, ampicillin, or dicloxacillin and allowed to continue breast-feeding their infants. No abscess developed. This experience is similar to that of others, ^[115] who have found that in sporadic puerperal mastitis breast-feeding need not be discontinued. In fact, the combination of a penicillinase-resistant penicillin and continued breast-feeding will promptly result in resolution of the infection in 96 percent of cases.

From time to time, a patient will report problems with inadequate milk production, sometimes called *lactation failure*. This problem is usually caused by infrequent suckling, which can be corrected by shortening the interval between feedings. If the milk supply is inadequate in spite of these measures, endogenous suppression of prolactin may be the problem, as in the unusual situation of retained placental fragments inhibiting lactogenesis as described by Neifert et al. ^[116] Removal of the retained placental tissue by curettage will result in prompt resumption of milk production. In the absence of any obvious source of prolactin inhibition (e.g., ergot preparation, pyridoxine, or diuretics), pharmacologic enhancement of lactation should be considered. Metoclopramide (Reglan) ^[117] and sulpiride ^[118] have both been shown to enhance milk production, presumably by blocking dopamine receptors and stimulating prolactin secretion. Given in doses of 10 mg three or four times a day, metoclopramide may be helpful in stubborn cases of lactation failure.

Lactation Suppression

For those patients who for personal or medical reasons will not breast-feed, breast support, ice packs, and analgesic medications are helpful in ameliorating the symptoms of breast engorgement. The new mother should avoid suckling or other means of milk expression, and the natural inhibition of prolactin secretion will result in breast involution. In 30 to 50 percent of patients, this will be associated with breast engorgement and pain that may last for most of the first postpartum week. ^[119]

Bromocriptine is no longer approved by the Food and Drug Administration (FDA) for lactation suppression. This ergot derivative is a dopamine receptor agonist with prolonged action that inhibits the release of prolactin. Twenty-three percent of patients have side effects, including symptomatic hypotension, nausea, and vomiting, and 18 to 40 percent have rebound breast secretion, congestion, or engorgement following the termination of therapy. ^[120] Furthermore, there have been reports of puerperal stroke, seizures, and myocardial infarctions in association with the use of bromocriptine prescribed for lactation suppression. ^{[121] [122] [123] [124]} While these events are rare and a causal relationship with bromocriptine has not been established, the manufacturers' prescription recommendations include instructions to avoid the use of this medication in patients with hypertensive complications of pregnancy and to monitor blood pressure periodically during the time the patient is using the drug. Consequently, it can be questioned whether it is prudent to use a medication for 2 weeks that has this incidence of side effects, possibly life-threatening complications, and the requirement for blood pressure monitoring during therapy. Puerperal breast engorgement, although painful, is never fatal and in most instances resolves within the first postpartum week.

PREGNANCY PREVENTION AND BIRTH CONTROL

The immediate postpartum period is a convenient time for a discussion of family planning with patients. Ideally, these conversations begin during prenatal care. The period of anovulation infertility lasts from 5 weeks in nonlactating women to 8 weeks or more in women who breast-feed their infants without supplementation.^[119] The pregnancy rate during lactational amenorrhea is 1 percent at 1 year postpartum.^[125] Robson et al.^[126] found that most women have resumed intercourse by 3 months, and for some resumption of an active sexual life begins much earlier. Consequently, it is important that a decision be made about pregnancy prevention before the patient leaves the hospital.

A patient should be made aware of the various options of pregnancy prevention and birth control in terms that she and her partner can understand. This may be done by individual instruction from nurses, physicians, or physician assistants or by a variety of films or videotapes. The decision about family planning methods will depend on the patient's motivation, number of children, state of health, whether she is breast-feeding, and on the religious background of the couple. It cannot be assumed because a woman has used a method of contraception effectively before the current pregnancy that she will need no counseling thereafter. Debrovner and Winikoff^[127] found that more than one half of patients change contraceptive techniques between pregnancies.

Natural Methods

The natural family planning methods, which depend on predicting the time of ovulation by use of basal body temperature or assessment of cervical mucus, cannot be used until regular menstrual cycles have resumed.^[128] In the first weeks or months following birth, provided there is little or no supplemental feeding for the infant, breast-feeding will provide 98 percent contraceptive protection for up to 6 months. At 6 months, or if menses return, or if breast-feeding ceases to be full or nearly full before the sixth month, the risk of pregnancy increases.^[129] Once regular menses have resumed, natural family planning methods, which depend on detection of the periovulation period using changes in cervical mucus or basal body temperature or both, can be employed. These techniques are associated with pregnancy rates very close to those for barrier methods of contraception, yet they are often overlooked, poorly understood, or misrepresented by health care workers who are not well educated in their use.^[130]

Barrier Methods

Barrier methods of contraception and vaginal spermicides were long used in Europe and England before they were manufactured in this country beginning in the 1920s.^[131] The failure rate for the diaphragm varies from 2.4 to 19.6 per 100 woman-years. Because this method of contraception requires substantial motivation, instruction, and experience, it is more effective in older women who are familiar with the technique. Vessey and Wiggins^[132] found a failure rate of 2.4 per 100 woman-years among diaphragm users who were over 25 years old and who had a minimum of 5 months' experience using it. This pregnancy rate is comparable to that reported for intrauterine device users.

The proper size of the diaphragm should be determined at the 6-week postpartum visit, even in patients who previously used this form of contraception. In women who are breast-feeding, anovulation leads to vaginal dryness and tightness, which may make the proper fitting of a diaphragm more difficult than in women who are not lactating. The diaphragm should be used with one of the spermicidal lubricants, all of which contain nonoxynol-9.

The use of condoms alone or in combination with spermicides is often advised for women who wish to postpone a decision about sterilization or oral contraceptive therapy until the postpartum visit. Pregnancy rates for the condom are reported to be from 1.6 to 21 per 100 woman-years, depending on the age and motivation of the population studied.^[133]

Steroid Contraceptive Medications

The combined estrogen-progestin preparations have proved to be the most effective method of contraception, with pregnancy rates reported as less than 0.5 per 100 woman-years. Most compounds include 35 g or less of estrogen and varying amounts of progestins. Compounds containing the progestational components desogestrel, gestodene, or norgestimate appear to be less androgenic and have less impact on carbohydrate and lipid metabolism than compounds containing levonorgestrel or norethindrone.^[134] Cardiovascular complications, including hypertension, venous thrombosis, stroke, and myocardial infarction, have been substantially reduced with the reduction in estrogen content. The cardiovascular complications are found predominantly in women who smoke.^[135] In nonsmoking women, the risk benefit ratio is clearly in favor of using oral contraceptive agents. This is particularly true when the additional benefits of these agents are considered, which include lowered risks of benign breast disease, ovarian and endometrial cancer, iron deficiency anemia,

toxic shock syndrome, pelvic inflammatory disease, and ectopic pregnancy.^[136]

In patients who are not breast-feeding, oral contraceptive agents can be taken as early as 2 to 3 weeks after delivery. The effect of oral contraceptive agents on lactation is controversial. Controlled studies of the combined-type oral contraceptive agents with doses of ethinyl estradiol or mestranol of 50 g or more demonstrated a suppressive effect on lactation. Progestin-only medications (e.g., norethindrone 0.35 mg every day) do not diminish lactation performance and may, in fact, increase the quality and duration of lactation.^[137] While there is no direct evidence that has related lactation failure to the administration of progestin-only contraceptive agents taken before the onset of lactation, it is recommended that the use of these medications be delayed until lactation has been established.^[138] Also, progestin-only oral contraceptives should be avoided in Hispanic women with gestational diabetes who are breast-feeding, because of an increased risk for the subsequent development of type II diabetes.^[139]

Diaz et al.^[140] studied the effect of a low-dose combination oral contraceptive containing 0.03 mg ethinyl estradiol and 0.15 mg levonorgestrel. The medication was begun after all women had been nursing for 1 month. Among those women taking the oral contraceptive medications, there was a small but significant decrease in lactation performance and in the weight gain of their infants compared with controls. In women whose motivation to breast-feed is marginal, the slight inhibition of lactation induced by oral contraceptive agents may be sufficient to discourage them from continuing to nurse their infants, and so progestin-only preparations should be offered to these women. Depot medroxyprogesterone acetate (DMPA) 150 mg intramuscularly every 3 months, which has a contraceptive efficiency exceeding 99 percent, is used by many women following delivery.^[141] The most annoying side effect is unpredictable spotting and bleeding. Long-term DMPA use has been associated with reversible reduction in bone density and unfavorable changes in lipid metabolism. The major advantages of this form of contraception are the ease of

administration and patient convenience.

Levonorgestrel subdermal implants were approved by the FDA for contraceptive use in the United States in 1990. Each implant consists of six Silastic capsules that contain 36 mg of crystalline levonorgestrel. Although not as yet commercially available in the United States, a delivery system involving two levonorgestrel-containing rods has been tested and found to be equally effective for contraception but easier to insert and remove than the six-capsule system.^[142] Pregnancy rates in women using the implants are lower than with any other reversible contraception.^[143] Implants inserted 4 weeks after delivery have no effect on lactation or growth of an infant who is nursing even though small amounts of levonorgestrel are excreted in the milk. Although the usual time of insertion is 4 to 6 weeks following delivery, the implants can be inserted in the immediate puerperium or, in women who are breast-feeding, as soon as lactation is established. Irregular uterine bleeding, expense, and the occasional difficulty in removing the implants are the major drawbacks to the use of this form of contraception. Despite the proven contraceptive effectiveness of levonorgestrel implants, there has been a decline in the perceived desirability of this method of birth control in recent years.^[144]

Intrauterine Devices

The copper-containing TCu 380 Ag IUD (copper-T IUD, ParaGard T380A) and the progesterone-releasing device (Progestasert) are highly effective in preventing pregnancy (2 to 3 pregnancies per 100 woman-years).^[145], ^[146] The advantage of the copper-containing IUD is that it is effective for 10 years; its disadvantage is an increase in irregular uterine bleeding. The device that releases progesterone reduces uterine bleeding, but it must be replaced annually.

The biologic action of IUDs is a matter of concern to those who might object to this method if its principal action is prevention of implantation of the blastocyst. The investigations of Alvarez et al.^[147] convincingly support the concept that the principal mode of action of IUDs is by a method other than destruction of live embryos. Both the World Health Organization (WHO) and the American College of Obstetricians and Gynecologists (ACOG) have reviewed the evidence and concluded that the IUD is not an abortifacient.^[148]

The pregnancy rate with an IUD is reported to be between 1 and 6 per 100 woman-years, with expulsion rates being 4 to 18 and removal for medical reasons being 12 to 16 per 100 women during the first year of use.^[149] Addition of bioactive materials such as copper or progesterone to the IUD has not significantly reduced pregnancy rates but has reduced the risk of expulsion or abnormal bleeding.

The major side effects and complications are syncope and uterine perforation during insertion, abnormal uterine bleeding, uterine and pelvic infection, and ectopic pregnancy.^[119] Syncope is a result of the vagal response that occurs in some women at the time of IUD insertion. Patients with a history of syncope or severe menstrual pain may be at greater risk from a complication, and the use of sedatives, analgesics, or atropine should be considered. These reactions are less common when the IUD is inserted in the puerperium, because functionally the cervix is slightly dilated.

Uterine perforation occurs in 0 to 8 per 1,000 insertions and is highest when the insertion is performed from 1 to 8 weeks after delivery. This is an important consideration when the insertion of the device is

planned for the 6-week postpartum visit. If there is any doubt about adequate involution of the uterus, IUD insertion should be postponed for 2 to 3 additional weeks. However, Mishell and Roy^[150] demonstrated no increase in perforation with the use of the copper-T inserted 4 to 8 weeks after delivery using a withdrawal method for insertion which appears to reduce the risk of this complication.

Bleeding and uterine cramping occur in 8 to 10 percent of women using an IUD and account for 4 to 15 removals of the device per 100 women in the first year of use. The causes of these symptoms are unknown, although they may be caused by the local production of proteolytic enzymes and prostaglandins within the endometrium adjacent to the IUD. A variety of methods have been used to treat this complication, including the use of hormones, vitamins, and prostaglandin synthetase inhibitors, but there are no data establishing the effectiveness of any of these measures.

The relative risk of pelvic infection in IUD users ranges from 1.7 to 9.3. A variety of microorganisms have been implicated, including *Actinomyces* in rare cases. Prompt removal of the device and antibiotic therapy are recommended when there is any evidence of salpingitis. However, in parous women who have used the IUD, the risk of infertility caused by pelvic infection is no greater than in patients who have never used an IUD.^[151]

Although the overall risk of ectopic pregnancy is lower in women using the IUD when compared with women using no contraception, the chances that a pregnancy will be ectopic is 7 to 10 times higher in the IUD user.

There has been some enthusiasm for insertion of the IUD during the immediate postpartum period. Surprisingly, this practice is associated with fewer perforations than are insertions between 1 and 8 weeks. Not surprising, however, is the finding that much higher expulsion rates are noted (10 to 21 percent).^[152]

The IUD has been found to be a satisfactory method of birth control in women who are breast-feeding. In a multicenter study, Cole et al.^[153] observed that breast-feeding did not increase the risk of expulsion or other complications regardless of the time of insertion of the device.

Sterilization

Tubal sterilization is the most frequently used method of contraception in the United States.^[154] The puerperium is a convenient time for tubal ligation procedures to be performed in women who desire sterilization. The procedure can be performed at the time of a cesarean delivery or within the first 24 to 48 hours after delivery. In some hospitals the operation is performed immediately after delivery in uncomplicated patients, especially when epidural anesthesia was given for labor analgesia. With the use of small paraumbilical incision, the procedure seldom prolongs the patient's hospitalization.

The 10-year failure rate of postpartum partial salpingectomy is 0.75 percent.^[155] There are several modifications of this procedure: the Pomeroy, Parkland, Uchida, and Irving (see Chapter 19).^[156], ^[157] There are also reports of immediate postpartum sterilization with the laparoscope,^[160] but this method lacks widespread enthusiasm. Because of the relaxed abdominal wall and the easy accessibility of the fallopian tubes, the minilaparotomy has the advantages of convenience and speed without the possible risks of visceral injury that might occur with the trocar of the laparoscope.

Perhaps more important than the type of procedure is the decision about the timing of the procedure or whether it should be performed at all. Puerperal sterilization compared with interval sterilization is associated with increased incidence of guilt and regret.^[161] With increasing frequency, couples are postponing tubal ligation procedures until 6 to 8 weeks after delivery. This provides time to ensure that the infant is healthy and to review all the implications of the decision. In most patients, laparoscopic tubal ligation can be accomplished as an outpatient procedure with a minimum of morbidity or loss of time from work or family.

The risks of tubal ligation procedures, whether performed in the puerperium or as an interval procedure, include the short-term problems of anesthetic accidents, hemorrhage, injury of the viscera, and infection. These complications are infrequent, and deaths from the procedure occur in 2 to 12 per 100,000 procedures. Long-term complications are less well defined and more controversial. About 10 to 15 percent of patients will have irregular menses and increased menstrual pain after tubal sterilization. This so-called posttubal syndrome is sufficiently severe in some cases to require hysterectomy. Well-controlled prospective studies, however, have failed to provide convincing evidence that these symptoms occur more commonly after tubal sterilization than in control patients of the same age and previous menstrual history.^[162], ^[163]

There has also been concern about poststerilization depression.^[164] Because depression is common in women of childbearing age and is even more common in the puerperium, it is difficult to know whether sterilization procedures are independent risk factors for depression. It is obvious, however, that the loss of fertility associated with a sterilization procedure will have important conscious and subconscious implications for many women. It is therefore not surprising that some patients manifest transient grief reactions in response to tubal ligation. The loss of libido that may occur in such situations may be frightening to some women and

equally disturbing to their partners. Reassurance that such reactions are temporary and are not necessarily symptoms of a seriously disturbed psyche is an important means of support during this crisis. Both partners must be aware of the dynamics of this situation to avoid a sense of estrangement.

Obstetricians must remember that vasectomy is often a more advisable and desirable alternative for a couple considering sterilization. ^[165], ^[166] It can be performed as an outpatient procedure under local anesthesia with insignificant loss of time from work or family. Furthermore, almost all the failures (about 3 to 4 per 1,000 procedures) can be detected by a postoperative semen analysis. This is a decided advantage over the tubal ligation, in which failures are discovered only when a pregnancy occurs. Furthermore, vasectomy is less expensive and overall is associated with fewer complications. In addition, women whose husbands undergo vasectomy are less likely to have hysterectomies than are women who have had tubal sterilization. ^[167] Studies of long-term health effects of vasectomy found no evidence of an increased risk of atherosclerotic heart disease or other chronic illnesses. ^[165], ^[168]

Tubal ligation can be reversed, but a patient should not undergo sterilization if she is contemplating reversal. Success as measured by the occurrence of pregnancy following tubal reanastomosis varies from 40 to 85 percent, depending on the type of tubal ligation performed and on the length of functioning tube that remains. Success rates for vas reanastomosis vary from 37 to 90 percent, with higher success rates being associated with shorter intervals from the time of vas ligation.

Hysterectomy has been advocated as a means of sterilization that has the advantage of protecting the patient from future uterine or cervical cancer. However, the morbidity of cesarean or puerperal hysterectomy operations is sufficiently great to preclude their consideration for elective sterilization. ^[169]

POSTPARTUM PSYCHOLOGICAL REACTIONS

The psychological reactions experienced following childbirth include the common, relatively mild, physiologic, and transient "maternity blues" (50 to 70 percent of women). True depression occurs in 8 to 20 percent, and frank puerperal psychosis occurs in 0.14 to 0.26 percent. Although the specific etiology of these psychological disorders is unknown, they are not a continuum of progressively severe manifestations of a single underlying disorder. Although psychologic and psychiatric symptoms often fall along a continuum, the specific diseases of postpartum depression and postpartum psychosis are quite different.

Maternity Blues

Maternity blues is a common psychological manifestation of the puerperium. It is manifest by a transient state of tearfulness, anxiety, irritation, and restlessness, variously described as "maternity blues" or "postpartum blues." As it occurs in up to 70 percent of parturients,^[170] it might well be considered a normal involutonal phenomenon. The symptoms may appear on any day within the first week after delivery and usually have resolved by postpartum day 10. Occasional patients will note transient recurrence of the symptoms, especially weeping, for several weeks after delivery.^[171] Also, as might be expected, the disruptive sleep patterns in the first weeks following delivery have been shown to contribute to an increase in dysphoric mood experienced by women during this time.^[172]

Patients suffering from maternity blues manifest a wide range of symptoms, including weeping, depression, restlessness, elation, mood lability, headache, confusion, forgetfulness, irritability, depersonalization, insomnia, and negative feelings toward their infants. Not every patient experiences all these symptoms.

There appear to be no obstetric, social, economic, or personality correlates for maternity blues. While it is tempting to ascribe the symptoms of this syndrome to the changes in steroid hormone levels that occur immediately following delivery, no such correlation has been found.^[173] However, lower than expected tryptophan levels have been documented in association with the depressive symptoms in the immediate postpartum period, suggesting a role for neurotransmitters in the elaboration of puerperal mood changes.^[174] Hyperactivity of the hypothalamic-pituitary-adrenal axis, blunted responsiveness of the hypothalamic-pituitary-thyroid axis, and altered central neurotransmitter function characterize postpartum depression as well as nonpuerperal major depression.^[175] Behavioral psychiatrists have theorized that the "blues" may represent a transient response to the rapid role changes and psychologic tasks that occur after delivery.

Because the syndrome is transient and of short duration, no therapy is indicated. Some of the symptoms may be exacerbated by sleep deprivation, and increased rest may be helpful. Anticipatory explanation and a sympathetic and understanding attitude on the part of family members and those caring for the patient are all that are required for this troublesome and common mood change.

Postpartum Depression

The incidence of postpartum major depression varies from 8 to 20 percent.^[176]^[177]^[178] This affective disorder occurs after pregnancies of all duration, from spontaneous abortions to full-term deliveries. The depression varies from mild to a suicidal depression. It may occur

anytime after delivery up to 1 year postpartum. Symptoms most commonly begin in the first 4 to 6 weeks after delivery. Pitt^[179] was one of the first to document the incidence of neurotic depression in the puerperium. He found that 11 percent of the patients studied at 28 weeks' gestation and at 6 weeks after delivery developed new cases of depression during the postpartum period.

Much research has been done in an attempt to clarify the etiology of postpartum depression. Significant alterations in levels of estrogen, progesterone, prolactin, and cortisol are not different in women suffering from depression and controls. However, changes in the hypothalamic-pituitary-adrenal axis, including corticotropin-releasing hormone, may occur in women with postpartum depression.^[179]^[180] In a study of 128 women randomly selected and interviewed on several occasions during their pregnancies and for 1 year after birth, Watson et al. found that it was unusual for postpartum depression to occur in a patient with an otherwise psychologically uncomplicated pregnancy and past history. They also confirmed a lack of association between postnatal depression and social class, marital status, or parity. Not surprisingly, several authors have found an increased incidence of postpartum depression after pregnancy loss.^[182]

The signs and symptoms of postpartum depression are not different from those in nonpregnant patients, but may be difficult to differentiate from normal involutonal phenomena (e.g., weight loss, sleeplessness) or from the transient "maternity blues."^[183] However, in addition to the more common symptoms of depression, the postpartum patient may manifest a sense of incapability of loving her family and manifest ambivalence toward her infant.

There is a high risk of recurrence (50 to 100 percent) of postpartum depression in subsequent pregnancies and a 20 to 30 percent risk of postpartum depression in women who have had a previous depressive reaction not associated with pregnancy. Consequently, it is important to inquire about depression as well as psychiatric illness when taking the prenatal history. Importantly, a family history of depression is also a risk factor.

There are a number of questionnaires that may help to identify the antepartum patient who is at high risk for postpartum major depression.^[184] Several investigators have found that one or more of the characteristics listed [in the box \(Characteristics of Antenatal Patients that Increase the Risk For Major Postpartum Depression\)](#) should be a cause for concern that a patient is at increased risk for postpartum major depression.^[185]^[186] It is appropriate that questions addressing some of these risk factors as well as the simple inquiry "Are you happy?" be incorporated into the antenatal history.

In addition to a family or personal history of depression, and difficult social situations, adverse pregnancy outcomes are also associated with an increased incidence of postpartum depression. Behavioral psychiatrists have postulated that the increased stress associated with complications leads to a greater strain on the mother's compensatory defenses and thus depression develops. Pregnancy complications associated with postpartum depression include miscarriage, fetal demise, and neonatal death. Cesarean delivery is not associated with an increased risk.

Characteristics of Antenatal Patients that Increase the Risk for Major Postpartum Depression

- Under 20 years of age
- Unmarried
- Medically indigent
- Comes from a family of six or more children
- Separated from one or both parents in childhood or adolescence
- Received poor parental support and attention in childhood
- Had limited parental support in adulthood
- Has poor relationship with husband or boyfriend
- Has economic problem with housing or income
- Is dissatisfied with amount of education
- Shows evidence of emotional problem, past or present
- Has low self-esteem

Data from Posner et al.^[185]

Puerperal hypothyroidism often presents with symptoms including mild dysphoria; consequently, thyroid function studies may be useful in patients presenting with suspected postpartum depression. However, the onset associated with thyroid disease is often a few months after delivery.^[187]

Early recognition of the signs and symptoms and supportive care and reassurance from family and health care professionals are the first line of treatment. The most well-validated tool for identifying patients in the puerperium who are high risk for depression is the Edinburgh Postnatal Depression Scale (EPDS).^[188] This is a short, 10-question scale. Because of the long-term effects of postpartum depression, as well as the high incidence of this disease, some authors have called for population-based screening using the EPDS.^[189] Women with a score of 12 or greater are very likely to have major depression and deserve careful clinical assessment to establish the diagnosis. Also, women with risk factors such as a family history of depression, or difficult social situations, should be cautioned about symptoms

718

of depression, and visits at 2 and or 4 weeks postpartum should be considered.

Edinburgh Postnatal Depression Scale (EPDS)

(Not Available)

From Cox JL, Holden JM, Sagovsky R: *Detection of postnatal depression. Development of the 10-item Edinburgh Postnatal Depression Scale. Br J Psychiatry 150:782, 1987, with permission.*

Treatment for postpartum depression should be begun early. Optimal treatment includes both counseling and medications. In the past, tricyclic antidepressants (nortriptyline or desipramine) have been noted to be helpful, but recent studies suggest that serotonin uptake inhibitors (fluoxetine, paroxetine, or sertraline) are equally effective and have fewer side effects.^[190],^[191] These agents are considered safe for breast-feeding. Other treatments include the estrogen patch.^[192] In women with a previous episode of postpartum depression, it has been suggested that prophylactic serotonin selective reuptake inhibitor (SSRI) medications be started 2 to 3 weeks prior to delivery. This approach allows these drugs to achieve an effective level by the postpartum period.^[193] If there is no prompt response to general supportive measures and initial use of medication, psychiatric consultation is advisable. The prognosis for treated postpartum depression is good, although symptoms may persist for up to a year. Unfortunately, untreated postpartum depression has significant consequences. Depression may progress to frank suicidal psychosis. Less severe depression has been noted in multiple studies to have long-term effects on the infants of depressed mothers. These effects include behavioral changes, cognitive changes, and emotional reactions that are different than control infants and children.^[186],^[194] Vandenberg^[195] emphasizes the importance of

719

the family in the therapy of postpartum depression. Being physically and emotionally drained from the stresses of pregnancy and childbirth and further burdened by the incessant demands of her infant, the postpartum patient may be unable to meet the demands of her husband and the other children. This will compound her feeling of self-worthlessness. Helping the husband and other family members to understand the nature of the patient's illness and mobilizing resources to provide the patient with help with her home chores and the care of the other children will help to prevent her sense of entrapment and isolation.

If a patient is at high risk for developing postpartum depression or if suspicious signs or symptoms develop during the immediate postpartum period, it is mandatory that the postpartum visits be scheduled sooner than the traditional 6 weeks. The moderately depressed mother will often experience such guilt and embarrassment secondary to her sense of failure in her mothering role that she will be unable to call her physician or admit the symptoms of her depression.^[195] Consequently, ample time must be set aside to explore in depth even the slightest symptoms or sign of depression. Home visits in this situation may be appropriate to assess the patient. When a patient calls with a seemingly innocuous question, she should be asked two or three open-ended questions about her general status. These questions allow the patient to open up if there is an underlying depression that she is too guilty or afraid to express initially; for example:

1. How do you feel things are going?
2. How are things with the baby?
3. Are you feeling like you expected?

Because nursing staff often triage phone calls for physicians and midwives, it is important that such personnel be instructed to be alert to this protocol. Additionally,

we recommend that both parents be warned prior to hospital discharge that if the maternity blues seem to be lasting longer than 2 weeks, or become "too tough" to handle, then either partner should call.

Postpartum Psychosis

Schizophrenia is seen with increased frequency in the puerperium, suggesting that there is a psychosis specific to the postpartum condition. It may occur in up to 0.1 percent of women with a past history of psychosis or a family history. Symptoms usually become manifest in the first 2 to 3 days postpartum, but may occur up to several months after delivery. In a study of all patients giving birth in 1966 and 1967 in Southampton, England, Nott ^[196] documented a significant increase in psychiatric referrals for specific psychoses in the 16 weeks after delivery. This confirmed the observation by Kendall et al., ^[197] who found a significant increase in admission to psychiatric hospitals during the puerperium compared with the antepartum or the nonpregnant state.

There is considerable debate as to whether the psychotic reactions that occur in the puerperium represent a unique psychiatric entity. ^[198] The signs and symptoms differ only slightly from those of acute, nonpuerperal psychosis. Postpartum psychosis is usually manifest by an increased degree of anxiety and a more "organic sense" of symptomatology versus nonpuerperal psychosis, which appears much more as a purer thought disorder. The frequency of symptoms differs substantially as well. Some patients with puerperal psychosis are manic-depressive. Women with bipolar disease have a higher than expected recurrence in the postpartum period. They may present with confusion and disorientation as prominent features of the clinical presentation. Furthermore, the psychotic reactions occurring in the puerperium appear to have a more favorable prognosis than the nonpuerperal psychosis. If the duration of the illness is only 2 or 3 months, and manifest by greater affective symptoms, then the prognosis is more favorable for long-term recovery.

During the immediate postpartum period, the early signs of depression may be difficult to distinguish from "maternity blues," but if suicidal thoughts or attempts occur, or if frankly delusional thoughts are expressed, the diagnosis of postpartum psychosis can be made. ^[195]

Clearly, all patients with puerperal psychosis require hospitalization for at least initial evaluation and institution of therapy. However, specific therapeutic management of puerperal psychotic disorders is a matter of controversy because of the lack of properly conducted treatment trials in these disorders. ^[199] Antipsychotic agents, electroconvulsive therapy, antidepressants, neuroleptic, and lithium carbonate have all been recommended for specific subgroups of puerperal psychosis, but none has been proven to enhance recovery. There is recent evidence, however, that sublingual estradiol (1 mg 36 times daily) results in substantial improvement in patients with postpartum psychosis. ^[199] Whatever therapy for these conditions is instituted, it should be conducted or supervised by a psychiatrist.

Women with postpartum psychosis should be supervised at all times. These patients have a 5 percent rate of suicide, and a 5 percent rate of infanticide!

MANAGING PERINATAL GRIEVING

For the most part, perinatal events are happy ones and are occasions for rejoicing. When a patient and her family experience a loss associated with a pregnancy,

720

special attention must be given to the grieving patient and her family.

The most obvious cases of perinatal loss are those in which a fetal or neonatal death has occurred. Other more subtle losses can be associated with a significant amount of grieving, such as the birth of a critically ill or malformed infant, an unexpected hysterectomy performed for intractable postpartum hemorrhage, or even a planned postpartum sterilization procedure. Grief will occur with any significant loss whether it is the actual death of an infant or the loss of an idealized child in the case of the birth of a handicapped infant. ^[200]

Mourning is as old as the human race, but the clinical signs and symptoms of grief and their psychological ramifications as they relate to loss suffered by women during their pregnancies have been given special consideration in recent years. In studying the relatives of servicemen who died in World War II, Lindemann ^[201] recognized five manifestations of normal grieving. These include somatic symptoms of sleeplessness, fatigue, digestive symptoms, and sighing respirations; preoccupation with the image of the deceased; feelings of guilt; feelings of hostility and anger toward others; and disruption of the normal pattern of daily life. He also described the characteristics of what is now recognized as pathologic grief, which may occur if acute mourning is suppressed or interrupted. Some of the manifestations of this so-called morbid grief reaction are overactivity without a sense of loss; appearance or exacerbations of psychosomatic illness; alterations in relationships with friends and relatives; furious hostility toward specific persons; lasting loss of patterns of social interaction; activities detrimental to personal, social, and economic existence; and agitated depression.

Kennel et al. ^[202] studied the reaction of 20 mothers to the loss of their newborn infants. Characteristic signs and symptoms of mourning occurred in all the patients, even in situations in which the infant was nonviable. Similar grief reactions occurred in most of the parents of 101 critically ill infants who survived after referral to a regional neonatal intensive care unit, ^[203] showing that separation from a seriously ill newborn is sufficient to provoke typical grief reaction.

It is important that the characteristics of the grieving patient be recognized and understood by health professionals caring for such patients; otherwise, substantial misunderstanding and mismanagement of the patient will occur. For example, if the patient's reaction of anger and hostility is not anticipated, a nurse or physician may take personally statements or actions by the patient or her family and avoid the patient at the very time she needs the most consolation and support. Because of their own discomfort with the implications of death, physicians, nurses, and others on the postpartum unit often find it uncomfortable to deal with patients whose fetus or infant has died. As a consequence, there is a reluctance to discuss the death with the patient and a tendency to rely on the use of sedatives or tranquilizers to deal with the patient's symptoms of grief. ^[204] ^[205] ^[206] What is actually beneficial at such a time is a sympathetic listener and an opportunity to express and discuss feelings of guilt, anger, and hopelessness and the other symptoms of mourning.

It is not surprising that postpartum depression is more common and more severe in families that have suffered a perinatal loss. In one study, the prolonged grief response occurred more often in those women who became pregnant within 5 months of the death of the infant. ^[207] This finding suggests that in counseling women after the loss of an infant, one should avoid the traditional advice of encouraging the family to embark soon on another pregnancy as a "replacement" for the infant who died. Just how long the normal grief reaction lasts is not known, and surely it varies with different families. Lockwood and Lewis ^[208] studied 26 patients who had suffered a stillbirth; they followed several patients for as long as 2 years. Their data suggest that grief in this situation is usually resolved within 18 months, invariably with a resurgence of symptoms at the first anniversary of the loss.

Somatic symptoms of grief, such as anorexia, weakness, and fatigue, are now well recognized; other psychological manifestations are also reported. Spontaneous abortion and infertility increase among couples who attempt to conceive after the loss of an infant. ^[209] Schleifer et al. ^[210] found significant suppression of lymphocyte stimulation in the spouses of women with advanced breast carcinoma. Although the most intense suppression was noted within the month after bereavement, a modified response was noted for as long as 14 months. These investigators suggest that this may account for the increase in morbidity and mortality associated with bereavement.

The regionalization of perinatal health care has resulted in a large proportion of the perinatal deaths occurring in tertiary centers. In some of these centers teams of physicians, nurses, social workers, and pastoral counselors have evolved to aid specifically in the management of families suffering a perinatal loss. ^[211] ^[212] ^[213] ^[214] While this approach ensures an enlightened, understanding, and consistent approach to bereaved families, it suggests that the support of a grieving patient is a highly complex endeavor, to be accomplished only by a few specially trained individuals who care for postpartum patients. Enlightened and compassionate counseling of parents who have suffered a perinatal loss may be accomplished by any of the mother's health care professionals by using the guidelines listed in the box (Guidelines for Managing Perinatal Loss) (Box Not Available) . ^[214] Clearly, management of grief is not solely a postpartum responsibility. This is particularly true when a prenatal diagnosis is made of fetal death or fetal abnormality. A

721

continuum of support is essential as the patient moves from the prenatal setting, to labor and delivery, to the postpartum ward, and finally to her home. Relaxation of many of the traditional hospital routines may be necessary to provide the type of support these families need. For example, allowing a loved one to remain past visiting hours, providing a couple a private setting to be with their deceased infant, or allowing unusually early discharge with provisions for frequent phone calls and follow-up visits will often facilitate the resolution of grief.

Guidelines for Managing Perinatal Loss

(Not Available)

Modified from Kowalski K: *Managing perinatal loss. Clin Obstet Gynecol* 23:1113, 1980.

It is also important to realize that the fathers of infants who die have somewhat different grief responses than do the mothers. In a study of 28 fathers who had lost infants, Mandell et al. [\[215\]](#) found their grief characterized by the necessity to keep busy with increased work, feelings of diminished self-worth, self-blame, and limited ability to ask for help. Stoic responses are typical of men and may obstruct the normal resolution of grief.

Postpartum Posttraumatic Stress

Posttraumatic stress disorder may occur after any physical or psychological trauma. It may lead to behavioral sequelae including flashbacks, avoidance, and inability to function. Emergency operative deliveries, both vaginal and abdominal, and severe unexpected pain have been reported to have produced posttraumatic stress. The reaction may lead to fear of a subsequent delivery that may become incapacitating, as well as generalized symptoms of this disorder. Whenever an emergency procedure is indicated, debriefing afterwards, both early and a few weeks later, may help to decrease the incidence of this problem. Women with adverse outcomes frequently will experience transference of their previous experience as the next delivery approaches. [\[216\]](#) [\[217\]](#) [\[218\]](#) [\[219\]](#)

Key Points

By 6 weeks postpartum, 28 percent of women will have returned to their prepregnant weight.

Approximately 50 percent of parturients experience diminished sexual desire during the 3 months following delivery.

Postpartum uterine bleeding of sufficient quantity to require medical attention occurs in 1 to 2 percent of parturients. In patients requiring curettage, 40 percent will be found to have retained placental tissue.

Late-onset endometritis (after 7 days) is frequently caused by *Chlamydia trachomatis*.

Candida infection is a common cause of persistent nipple soreness in women who are breast-feeding.

Most women with puerperal mastitis can be adequately prepared with penicillin V, ampicillin, or dicloxacillin while they continue to breast-feed their infants.

Breast-feeding will result in 98 percent contraceptive protection for up to 6 months following delivery, provided there is little or no supplemental feeding of the infant.

Progestin-only contraceptive medication (norethindrone 0.35 mg daily) does not diminish lactation performance.

Postpartum, major depression occurs in 8 to 20 percent of parturients.

Puerperal hypothyroidism often presents with symptoms that include mild dysphoria; consequently, thyroid function studies are suggested in the evaluation of patients with suspected postpartum depression that occurs 2 to 3 months after delivery.

Section 5 - Complicated Pregnancy

729

Chapter 22 - Fetal Wastage

Joe Leigh Simpson

Not all conceptions result in a liveborn infant. Of clinically recognized pregnancies, 10 to 15 percent are lost. Of married women in the United States, 4 percent have experienced two fetal losses and 3 percent have experienced three or more. ¹ It is accepted that a subset of women genuinely manifest repetitive spontaneous abortions as opposed to merely representing random untoward events. This chapter considers the causes of fetal wastage, the management of couples experiencing repetitive losses, and the topic of ectopic gestations.

FREQUENCY AND TIMING OF PREGNANCY LOSSES

Pregnancy is not generally recognized clinically until 5 to 6 weeks after the last menstrual period, but before this time -human chorionic gonadotropin (-hCG) assays can detect preclinical pregnancies. Wilcox et al. ^[2] performed daily urinary hCG assays beginning around the expected time of implantation (day 20 of gestation). Of pregnancies detected in this fashion, 31 percent (61 of 198) were lost; the preclinical loss rate was 22 percent (43 of 198), and the clinically recognized loss rate was 12 percent (19 of 155). These rates are consistent with data gathered by this author and colleagues ^[3] in a National Institute of Child Health and Human Development collaborative study in which serum -hCG assays were performed 28 to 35 days after the previous menses. The total fetal loss rate (preclinical and clinical) for pregnancies detected at 4 to 5 weeks or approximately 10 days later than those ascertained by Wilcox et al. ^[2] was 16 percent.

Clinically recognized first-trimester fetal loss rates of 10 to 12 percent overall are well documented in both retrospective and prospective cohort studies. ^[4] The higher loss rates reported in some older studies probably reflect unwitting inclusion of surreptitious illicit abortions, a common occurrence during the era in which legal termination was proscribed. Loss rates reflect many factors that will be discussed in this chapter, but two associations are worth emphasizing here. First, maternal age greatly increases risk, a 40-year-old woman carrying twice the risk of a 20-year-old woman. Second, prior pregnancy history is pivotal. Loss rates are lowest (6 percent) among nulliparous women who have never experienced a loss^[5] rising to 25 to 30 percent after three or more losses. Most recurrence risk data were derived from studying women whose losses were usually not recognized until 9 to 12 weeks' gestation. However, the same counseling figures are appropriate for couples whose pregnancies are ascertained in the fifth week of gestation. ^[6]

Abortion rates may be lower when conception occurs on days other than the date of ovulation or day prior (optimal interval). In couples with prior abortions, loss rates were 7 percent when conception occurred on the day of ovulation or 1 day earlier, but 23 percent when conception occurred on other (nonoptimal) days of the cycle. ^[7] Wilcox et al. ^[8] studied a cohort of 189 pregnancies of which 141 lasted beyond 6 weeks. Among the implantations leading to a clinical pregnancy, 84 percent did so on days 8, 9, or 10 after ovulation. No pregnancies occurred when implantation occurred beyond day 12. The loss rate was 13 percent if implantation occurred by day 9, increasing to 26 percent, 52 percent, and 82 percent and on the next 3 days, respectively.

Studies utilizing ultrasonography have now made it clear that fetal demise occurs before overt clinical signs are manifested. This conclusion is based on cohort

studies showing that only 3 percent of viable pregnancies are lost after 8 weeks' gestation. ^[9] Given an accepted clinical loss rate of 10 to 12 percent, fetal viability must cease weeks before maternal symptoms appear; thus, most fetuses aborting clinically at 9 to 12 weeks must have died weeks previously. Most pregnancy losses after 8 weeks likely occur in the next 2 gestational months, as loss rates are only 1 percent in women confirmed by ultrasound to have viable pregnancies at 16 weeks. Overall, almost all losses are "missed abortions" (retained in utero for an interval prior to clinical recognition); thus, the term is archaic.

ETIOLOGY OF PRECLINICAL LOSSES

Establishing an etiology for preclinical losses is not easy, but the one proven explanation is morphologic and genetic abnormalities in the early embryo. Decades ago, Hertig and Rock^[10] ^[11] ^[12] examined the fallopian tubes, uterine cavities, and endometria of women undergoing elective hysterectomy. These women were of proved fertility, with a mean age of 33.6 years. Coital times were recorded before hysterectomy. Eight preimplantation

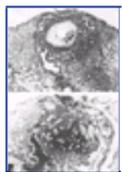

Figure 22-1 Cross section of endometrium containing an abnormal 14-day-old embryo (A) compared with a normal 11-day-old embryo. E. In the abnormal embryo no embryonic disk is present and only syncytiotrophoblasts are identifiable. (From Hertig A, Rock J: *A series of potentially abortive ova recovered from fertile women prior to the first missed menstrual period. Am J Obstet Gynecol* 58:968, 1949, with permission.)

731

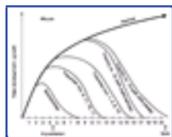

Figure 22-2 Timing for loss of murine autosomal monosomy and murine autosomal trisomy. (From Gropp A: *Chromosomal animal model of human disease. Fetal trisomy and development failure. In Berry L, Poswilllo DE [eds]: Teratology. Berlin, Springer-Verlag, 1975, p 17, with permission.*)

embryos (<6 days from conception) were recovered. Four of these eight embryos were morphologically abnormal. The four abnormal embryos presumably would not have implanted or, if implanted, would not have survived long thereafter. Nine of 26 implanted embryos (6 to 14 embryonic days) were morphologically abnormal (Fig. 22-1).

The frequency of chromosomal abnormalities in human preimplantation embryos normal and abnormal is very high.^[13] ^[14] Of morphologically normal embryos, 25 percent show abnormal metaphases (usually aneuploidy). This percentage is consistent with the 25 to 30 percent aneuploidy rate on the basis of studies using fluorescent in situ hybridization (FISH) using chromosome-specific probes for chromosomes 13, 18, and 21.^[15] The 25 percent aneuploidy rate in morphologically normal embryos is also consistent with aneuploidy observed in 6 percent of sperm from ostensibly normal males^[16] and in perhaps 20 percent of oocytes.^[17] ^[18]

Chromosomal abnormalities are even more frequent in morphologically abnormal embryos. Using metaphase analysis, Plachot et al.^[13] found chromosomal abnormalities in 78 percent of fragmented embryos, compared to 12.5 percent in morphologically normal embryos. Pellestor et al.^[19] reported 90 percent abnormalities in 118 poor quality embryos. Using FISH with chromosome-specific probes, abnormality rates of 50 to 75 percent are observed even with a limited number of chromosomes tested.^[19] Given the above, it has been accepted for over a decade that chromosomal abnormalities would be expected to be the next frequent explanation for the morphologically abnormal embryos recovered by Hertig et al.^[10] ^[11] ^[12]

Consistent with this conclusion are elegant studies in the mouse by Gropp.^[20] Mice heterozygous for a variety of robertsonian translocations were mated to produce various monosomies and trisomies. By selective mating and sacrifice of pregnant animals at varying gestational ages, both survivability and phenotypic characteristics of the aberrant complements could be determined. In mice, as presumably in humans, autosomal monosomy proved inviable. Most monosomes aborted around the time of implantation (4 to 5 days after conception) (Fig. 22-2). Most trisomies survived longer, but only rarely to term. These findings are analogous to those observed in aneuploid human fetuses.

CYTOGENETIC ETIOLOGY IN CLINICALLY RECOGNIZED LOSSES

The major cause of clinically recognized pregnancy losses is chromosomal abnormalities. At least 50 percent of clinically recognized pregnancy losses result from a chromosomal abnormality.^{[21] [22] [23]} The frequency is probably even higher. If one analyzes chorionic villi after ultrasound diagnosis of fetal demise, rather than relying on later recovery of spontaneously expelled products, the frequency of chromosomal abnormalities proves to be 75 to 90 percent.^{[24] , [25]}

Among second-trimester losses, one also observes chromosomal abnormalities similar to those observed in liveborn infants: trisomies 13, 18, and 21; monosomy X; and sex chromosomal polysomies. Among third-trimester losses (stillborn infants) the frequency of chromosomal abnormalities is approximately 5 percent.^[26] This frequency is less than that observed in earlier abortuses, but still higher than found among liveborns (0.6 percent).

Autosomal Trisomy

Autosomal trisomies comprise the largest (approximately 50 percent) single class of chromosomal complements in cytogenetically abnormal spontaneous abortions. Frequencies of these trisomies are listed in Table 22-1. Trisomy for every chromosome except chromosome 1 has been reported, and trisomy for that chromosome has been observed in an eight-cell embryo.^[27] The

most common trisomy is trisomy 16. Most trisomies show a maternal age effect, but the effect is variably marked among certain chromosomes. The maternal age effect is especially impressive for double trisomies.

Various attempts have been made to correlate morphologic abnormalities with specific trisomies,^[28] ^[29] but relationships are imprecise. Trisomies incompatible with life predictably show slower growth than trisomies compatible with life (trisomies 13, 18, and 21). For example, the mean crown-rump length in abortuses shown to be trisomic (13, 18, and 21) is 20.65 mm compared with only 10.66 mm for trisomies that virtually never survive to term (e.g., trisomy 10 or 16).^[29] Either the former survive longer or the latter show greater intrauterine growth retardation, or both. Potentially viable trisomies tend to show anomalies consistent with those found in full-term liveborn trisomic infants.^[29] ^[29] The malformations present have been said to be more severe than these found in induced abortuses detected after prenatal diagnosis.

Aneuploidy usually results from errors of meiosis I, specifically arising in maternal meiosis. Most trisomies are accounted for by maternal meiotic errors. In trisomy 13 and trisomy 21, 90 percent of these maternal cases arise at meiosis I; almost all trisomy 16 cases arise in maternal meiosis I.^[30] A notable exception is trisomy 18, in which two thirds of the 90 percent maternal meiotic cases arise at meiosis II.^[31] ^[32]

Errors of maternal meiosis I are associated with advanced maternal age and in turn correlate with decreased to absent meiotic recombination.^[31] ^[32] ^[33] The cytologic hypothesis invoked to explain this relationship generally is the product-line hypothesis, which states that oocytes ovulated earlier in life are characterized by more recombinants and, hence, less likelihood for nondisjunction.^[34] The clinical significance is that adverse periconceptual events (e.g., exposure to toxins, potentially fertilization involving gametes aged in vivo) are unlikely to play a major etiologic role in human trisomies. Thus, failure to find increased frequency of Down syndrome in pregnancies conceived on days other than the day of ovulation or the day before is not surprising.^[35] ^[36]

Errors in *paternal* meiosis account for 10 percent of acrocentric (13, 14, 15, 21, and 22) trisomies.^[37] In trisomy 21, paternal meiotic errors are equally likely to arise in meiosis I or II,^[38] a circumstance that contrasts with the situation in maternal meiotic errors.

Among nonacrocentric chromosomes, paternal contribution to aneuploidy is even less than 10 percent.

Polyploidy

In polyploidy, more than two haploid chromosomal complements exist. Triploidy ($3n = 69$) and tetraploidy

733

($4n = 92$) occur often in abortuses. Triploid abortuses are usually 69,XXY or 69,XXX, resulting from dispermy.^[39] ^[40] Pathologic findings in triploid placentas include a disproportionately large gestational sac, cystic degeneration of placental villi, intrachorial hemorrhage, and hydropic trophoblasts (pseudomolar degeneration).^[28] ^[29] Malformations include neural tube defects and omphaloceles, anomalies reminiscent of those observed in triploid conceptuses progressing to term. Facial dysmorphism and limb abnormalities have also been reported. An association exists between triploidy and hydatidiform mole, a "partial mole" said to exist if molar tissue and fetal parts coexist. The more common "complete" hydatidiform mole is 46,XX, of androgenetic origin.^[41]

Tetraploidy is uncommon, rarely progressing beyond 2 to 3 weeks of embryonic life.

Monosomy X

Monosomy X is the single most common chromosomal abnormality among spontaneous abortions, accounting for 15 to 20 percent of abnormal specimens (Fig. 22-3). Monosomy X embryos usually consist of only an umbilical cord stump. Later in gestation, anomalies characteristic of the Turner syndrome may be seen, specifically cystic hygromas and generalized edema. Although liveborn 45,X individuals usually lack germ cells, 45,X abortuses show germ cells; however, these germ cells rarely develop beyond the primordial germ cell stage. The pathogenesis of 45,X germ cell failure thus involves not so much failure of germ cell development as more rapid attrition in 45,X than in 46,XX embryos.^[42] ^[42] Incidentally, this observation makes plausible the rare but well-documented pregnancies occurring in 45,X individuals.^[43]

Monosomy X usually (80 percent) occurs as a result of paternal sex chromosome loss.^[44] This observation is consistent with the lack of a maternal age effect in 45,X or possibly even an inverse effect.

Structural Chromosomal Rearrangement

Structural chromosomal rearrangement account for 1.5 percent of all abortuses (Table 22-1). Rearrangements (e.g., translocation) may either arise de novo during gametogenesis or be inherited from a parent carrying a "balanced" translocation or inversion. Phenotypic consequences depend on the specific duplicated or deficient chromosomal segments. Although not a common cause of sporadic losses, inherited translocations are an important cause of *repeated* fetal wastage.

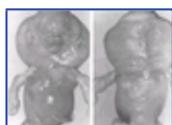

Figure 22-3 Photograph of a 45,X abortus. (From Simpson CL, Bombard AT: *Chromosomal abnormalities in spontaneous abortion: frequency, pathology and genetic counseling*. In Edmonds K, Bennett MJ [eds]: *Spontaneous Abortion*. London, Blackwell, 1987, p 51, with permission.)

734

Sex Chromosomal Polysomy (X or Y)

The complements 47,XXY and 47,XYY each occur in about 1 per 800 liveborn male births; 47,XXX occurs in 1 per 800 female births. X or Y polysomies are only slightly more common in abortuses than in liveborns.

MENDELIAN AND POLYGENIC/MULTIFACTORIAL ETIOLOGY

The 30 to 50 percent of first-trimester abortuses that show no chromosomal abnormalities could still have undergone fetal demise as a result of other genetic etiologies. Neither mendelian nor polygenic/multifactorial disorders show chromosomal abnormalities. Many excellent anatomic studies of abortuses have demonstrated structural abnormalities, but lack of cytogenetic data on the dissected specimens makes it nearly impossible to determine the precise role of noncytogenetic mechanisms in early embryonic maldevelopment. Doubtless pivotal to early development are many mendelian genes, mutation of which would be expected to result in embryonic death and pregnancy loss.

Novel Cytogenetic Mechanisms

Beyond the scope of this chapter are several novel cytogenetic mechanisms that have been shown to explain certain placental abnormalities and, hence, fetal losses in conceptuses with a diploid number of chromosomes.

One possibility is mosaicism restricted to the placenta, the embryo per se being normal. This phenomenon is termed "confined placental mosaicism." Losses caused by this mechanism may already be reflected in extant data because most studies have involved analysis only of villous material. Related to confined placental mosaicism (CPM) is the phenomenon of uniparental disomy (UPD). In UPD, both homologues for a given chromosome are derived from a single parent, probably as a result of expulsion of a chromosome from a trisomic zygote. The karyotype would appear normal (46,XX or 46,XY), but genes on the involved chromosome would actually lack contribution of one parent. For example, uniparental disomy for chromosome 21 has been detected in an embryonic abortus. ^[45]

Genes acting in novel fashion can also cause spontaneous abortions. One hypothesis is that highly skewed X-inactivation is associated with recurrent abortions. Of 48 women having two prior losses without explanation, 7 (14.6 percent) had highly skewed X-inactivation, defined as 90 percent of their X chromosomes originating from one specific parent (expected 50 percent); only 1 of 67 controls (1.5 percent) showed skewed X-inactivation). ^[46] Male offspring of a woman with skewed X-inactivation might be aborted. A pedigree consistent with this hypothesis has been reported. ^[47]

GENETIC COUNSELING AND RECURRENT RISKS

The obstetrician faced with a couple experiencing spontaneous abortion has several immediate obligations: (1) inform the couple concerning the frequency of fetal wastage (10 to 12 percent clinically recognized pregnancies) and its likely etiology (at least 50 percent cytogenetic), (2) provide recurrence risk rates, and (3) determine the necessity of a formal clinical evaluation.

Patient Information

The responsibility of informing patients can be fulfilled by summarizing the salient facts cited in this chapter and emphasizing common etiologies responsible for fetal losses. Worth citing explicitly is the positive correlation between loss rates and both advancing maternal age and prior losses (see below). The maternal age effect is not solely the result of increased trisomic abortions, but presumably reflects endometrial factors as well.

Recurrence Risks

Loss rates are definitely increased among women who have experienced previous losses, but not nearly to the extent once thought (Table 22-2). For decades, obstetricians fervently believed in the concept of "habitual

TABLE 22-2 -- APPROXIMATE RECURRENCE RISK FIGURES USEFUL FOR COUNSELING WOMEN WITH REPEATED SPONTANEOUS ABORTIONS*

	Prior Abortions	Risk (%)
Women with liveborn infants	0	510
	1	2025
	2	25
	3	30
	4	30
Women without liveborn infants	3	3040

Based on data from Warbuton and Fraser,^[49] Poland et al.,^[50] and Regan^[5]

* Recurrence risks are slightly higher for older women and for those who smoke cigarettes or drink alcohol and for those exposed to high levels of selected chemical toxins.

abortion." After three losses, the risk of subsequent losses was thought to rise sharply. Such beliefs were based on calculations made in 1938 by Malpas,^[48] who concluded that following three abortions the likelihood of a subsequent one was 80 to 90 percent. Occurrence of three consecutive spontaneous abortions was thus said for decades to confer upon a woman the designation of "habitual aborter." These risk figures not only proved incorrect but also were and unfortunately still seem subconsciously to be used as "controls" for clinical studies evaluating various treatment plans. This practice led to unwarranted acceptance of certain interventions, the most famous of which was diethylstilbestrol (DES) treatment.

In 1964, Warburton and Fraser^[49] showed that the likelihood of recurrent abortion rose only to 25 to 30 percent, irrespective of whether a woman had previously experienced one, two, three, or even four spontaneous abortions. This concept has been confirmed in many subsequent studies, with the additional observation that if no previous liveborns have occurred the likelihood of fetal loss is somewhat higher.^[50] Lowest risks (5 percent) are observed in nulliparous women with no prior losses.^[5] Women who smoke cigarettes or drink alcohol moderately are probably at slightly higher risk.^[51] Recurrence risks are higher if the abortus is cytogenetically normal than cytogenetically abnormal.^[52]

Taking all the above into account, the prognosis is reasonably good even without therapy, the predicted success rate being 70 percent. Indeed, Vlaanderen and Treffers^[53] reported successful pregnancies in each of 21 women having unexplained prior repetitive losses but subjected to no intervention. Other groups reached similar conclusions, including the control (placebo) group in a recent well-publicized immunotherapy study.^[54],^[55] To be judged efficacious, therapeutic regimens must achieve successes greater than 70 percent.

Necessity of Formal Evaluation

Every couple experiencing a fetal loss should be counseled and provided recurrence risk rates, but not every couple requires formal assessment. Infertile couples who are in their fourth decade may choose to be evaluated after only two losses. After three losses, all couples should be offered formal evaluation. Once a couple enters evaluation, they should undergo all tests standard for a given practitioner. There is no scientific rationale for performing some studies after three losses but deferring others until after four losses. Any couple having a stillborn or anomalous liveborn infant should undergo cytogenetic studies unless the stillborn was known to have a normal chromosome complement. Parental chromosomal rearrangements (i.e., translocations or inversions) should be excluded.

ETIOLOGY AND CLINICAL EVALUATION OF REPETITIVE ABORTIONS

Translocations

Structural chromosomal abnormalities are generally accepted as one explanation for repetitive abortions. The most common structural rearrangement encountered is a translocation, found in about 5 percent of couples experiencing repeated losses. ^[56] ^[57] ^[58] Individuals with balanced translocations are phenotypically normal, but abortuses or abnormal liveborns may show chromosomal duplications or deficiencies as a result of normal meiotic segregation. About 60 percent of the translocations detected are reciprocal, and 40 percent are robertsonian. Females are about twice as likely as males to show a balanced translocation. ^[56]

The clinical significance of translocations is illustrated in Figure 22-4. If a child has Down syndrome as a result of such a translocation, the rearrangement will prove to have originated de novo in 50 to 75 percent of cases. That is, a balanced translocation will not exist in either parent. The likelihood of Down syndrome recurring in subsequent offspring is minimal. On the other hand, the risk is significant in the 25 to 50 percent of families in which individuals have Down syndrome as the result of a balanced parental translocation (e.g., parental complement 45,XX,-14,-21,+t[14q; 21q]). The theoretical risk of having a child with Down syndrome is 33 percent, but empirical risks are considerably less. The likelihood is only 2 percent if the father carries the translocation and 10 percent if the mother carries the translocation. ^[59] ^[60] If robertsonian (centric-fusion) translocations involve other chromosomes, empirical risks are lower. In t(13q; 14q), the risk for liveborn trisomy 13 is 1 percent or less.

Reciprocal translocations are those that do not involve centromeric fusion. Empirical data for specific translocations are usually not available, but useful generalizations can be made on the basis of pooled data derived from many different translocations. Studies of sperm chromosomes ^[61] theoretically might provide data specific for a given translocation in a specific individual, but this is not readily available. Of interest is that sperm of fathers experiencing repeated losses show no more than the expected 10 percent of cytogenetic abnormalities. ^[62]

Irrespective, theoretical risks for abnormal offspring (unbalanced reciprocal translocations) are far greater than empirical risks. Overall, the risk is 12 percent for offspring of either female heterozygotes or male heterozygotes. ^[59] ^[60] Detecting a parental chromosomal rearrangement thus profoundly affects subsequent pregnancy

736

management. Antenatal cytogenetic studies should be offered in subsequent pregnancies. The frequency of unbalanced fetuses is lower if parental balanced translocations are ascertained through repetitive abortions (3 percent) than through anomalous liveborns (nearly 20 percent). ^[59]

A few translocations preclude the possibility of normal liveborn infants, namely, translocations involving homologous chromosomes (e.g., t[13q13q] or t[21q21q]). If the father carries such a structural rearrangement, artificial insemination may be appropriate. If the mother carries the rearrangement, donor oocytes or donor embryos (assisted reproductive technologies) should be considered.

Inversions

A less common parental chromosomal rearrangement responsible for repetitive pregnancy losses is an inversion. In inversions the order of genes is reversed. Analogous to translocations, individuals heterozygous for an inversion should be normal if their genes are merely rearranged. However, individuals with inversions suffer abnormal reproductive consequences as a result of normal meiotic phenomena, namely, crossing-over in their

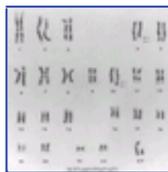

Figure 22-4 Balanced translocation detected in a woman experiencing multiple abortions. (From Simpson JL, Tharapel AT: Principles of cytogenetics. In Philip E, Barnes J [eds]: Scientific Foundations of Obstetrics and Gynaecology, 4th ed. London, Heinemann Medical Books, 1991, p 27, with permission.)

gametes, yielding unbalanced gametes. Pericentric inversions (see Chapter 9) are present in perhaps 0.1 percent of females and 0.1 percent of males experiencing repeated spontaneous abortions. Paracentric inversions are even rarer.

Counseling a couple having an inversion is complex. Inversions involving only a small portion of the total chromosomal length paradoxically may be less significant clinically because the large duplications or large deficiencies that follow crossing-over are usually lethal. By contrast, inversions involving only 30 to 60 percent of the total chromosomal length are relatively more likely to be characterized by duplications or deficiencies compatible with survival. ^[63]

Overall, females with a *pericentric* inversion have a 7 percent risk of abnormal liveborns; males carry a 5 percent risk. Pericentric inversions ascertained through phenotypically normal probands are less likely to result in abnormal liveborns.

Few data are available on recurrence risks for *paracentric* inversions. Theoretically, there should be less risk for detecting unbalanced products at chorionic villus sampling (CVS) or amniocentesis than with pericentric inversions because paracentric recombinants are usually lethal. On the other hand, abortions and abnormal

737

liveborns have been observed within the same kindred, and the risk for unbalanced viable offsprings has been tabulated at 4 percent. ^[64] Antenatal cytogenetic studies should be offered.

Recurrent Aneuploidy

Already discussed at length as the most common overall cause for sporadic abortions, numerical chromosomal abnormalities (aneuploidy) may be responsible for both recurrent as well as sporadic losses. This reasoning is made on the basis of observations that the complements of successive abortuses in a given family are more likely to be either recurrently normal or recurrently abnormal (Table 22-3). If the complement of the first abortus is abnormal, the likelihood is 80 percent that the complement of the second abortus also will be abnormal.^[65] The recurrent abnormality usually is trisomy.

These data suggest that certain couples are predisposed toward chromosomally abnormal conceptions. Although it can be argued that corrections for maternal age render the ostensible nonrandom distribution non-significant, this author counsels increased risks compared with normal women of comparable age. If couples are predisposed to recurrent aneuploidy, they might logically be at increased risk not only for aneuploid abortuses but also for aneuploid liveborns. The trisomic autosome in a subsequent pregnancy might not always confer lethality, but rather might be compatible with life (e.g., trisomy 21). Indeed, the risk of liveborn trisomy 21 following an aneuploid abortus is about 1 percent.^[66]

Information concerning fetal chromosomal status may be lacking for couples having repetitive abortions. Antenatal diagnosis then may or may not be appropriate. Risks for abnormal offspring are probably increased, but the risk of amniocentesis or CVS is especially troublesome to couples who have had difficulty achieving pregnancy. Finally, there is some evidence that abortion rates are lowest in couples with prior losses when conception occurred in midcycle.^[67] Midcycle fertilization is recommended in subsequent pregnancies.

Luteal Phase Defects

Implantation in an inhospitable endometrium is a plausible explanation for spontaneous abortion. The hormone usually hypothesized to be deficient is progesterone, a deficiency of which might fail to prepare the estrogen-primed endometrium for implantation. Luteal phase defects (LPDs) is the term used to describe the endometrium manifesting an inadequate progesterone effect. Progesterone secreted by the corpus luteum is necessary to support the endometrium until the trophoblast produces sufficient progesterone to maintain pregnancy, an event occurring around 7 gestational (menstrual) weeks or 5 weeks after conception. Plausible pathogenic mechanisms underlying LPD include decreased gonadotropin-releasing hormone (GnRH), decreased follicle-stimulating hormone (FSH), inadequate luteinizing hormone (LH), inadequate ovarian steroidogenesis, or endometrial receptor defects.

Once almost universally accepted as a common cause for fetal wastage, LPD now seems to be considered an uncommon cause. Although plausible clinically, there are no randomized studies verifying efficacy of treatment. Moreover, histology identical to that observed with luteal phase "defects" exists in fertile women. When regularly menstruating fertile women with no history of abortions were biopsied in serial cycles, the frequency of LPD was 51.4 percent in any single cycle and 26.7 percent in sequential cycles.^[67]

A major difficulty in determining the frequency as well as validity of LPD is lack of standard diagnostic criteria. LPD was originally defined on the basis of an endometrial biopsy lagging at least 2 days behind the actual postovulation date. This was determined by counting backward from the next menstrual period, assuming

TABLE 22-3 -- RECURRENT ANEUPLOIDY: THE RELATIONSHIP BETWEEN KARYOTYPES OF SUCCESSIVE ABORTUSES

Complement of First Abortus	Complement of Second Abortus					De Novo Rearrangement
	Normal	Trisomy	Monosomy	Triploidy	Tetraploid	
Normal	142	18	5	7	3	2
Trisomy	31	30	1	4	3	1

Triploidy	7	4	1	4	0	0
Tetraploidy	3	1	0	2	0	0
De novo rearrangement	1	3	0	0	0	0

* Tabulation by Warburton et al.^[65]

14 days from the date of ovulation to menses. However, the original reports of Noyes et al.^[68] showed a mean error of 1.81 days in dating, suggesting that an endometrial biopsy should be designated "out-of-phase" only if it lags 3 or more days behind the actual postovulation date. Not surprisingly, interobserver variation is considerable. Endometrial biopsies (n = 62) read by five different pathologists resulted in differences in interpretation that would have altered management in approximately one third of patients.^[69] Reading coded endometrial biopsy slides a second time, the same pathologist agreed with his or her initial diagnosis in only 25 percent of samples.^[70] At a minimum, at least two out-of-phase biopsies are necessary to make the diagnosis of LPD. Other diagnostic criteria have been proposed, such as integrated serum progesterone (three values) levels.^[71] However, most investigators believe hormone levels are no better than endometrial biopsy. (Indeed, in patients with two or more spontaneous abortions, a low serum progesterone in the luteal phase is only 71 percent predictive of an LPD as defined on the basis of an abnormal endometrial biopsy.^[72])

Attempting to characterize gonadotropin and progesterone secretion in LPD, Soules et al.^[73],^[74] concluded that diagnosis is best made on the basis of a single assay of three pooled blood samples; a level of 10 ng/ml connotes LPD.^[75]

A major shortcoming is that no randomized studies have proved LPD to be a genuine entity. Efficacy of treatment is even less well established. Studies by Tho et al.^[76] and Daya and Ward^[77] are among those cited as evidence of efficacy, but actually their experimental designs are not optimal,^[78] because concurrent control groups were not recruited. Meta-analysis by Karamardian and Grimes^[79] showed no beneficial effect of progesterone treatment. Thus, LPD is an arguable entity, and if valid, may or may not be treated successfully with progesterone or progestational agents.

Of interest are observations suggesting a relationship between fetal loss and either oligomenorrhea^[80] or clinically evident polycystic ovary disease.^[81] These observations could be consistent with the studies described above showing pregnancy loss is lowest when conceptions occur in midcycle.^[7] The pathogenesis could be endometrial dyssynchrony mediated through perturbations of LH. Regan et al.^[82] reported increased pregnancy loss in 20 women with elevated LH; however, treatment to lower LH failed to decrease pregnancy loss rate.^[83] Neither Carp et al.,^[84] nor Tulppala et al.,^[85] nor Bussen et al.^[86] observed elevated LH.

Thyroid Abnormalities

Decreased conception rates and increased fetal losses are associated with overt hypothyroidism or hyperthyroidism. Subclinical thyroid dysfunction has generally not been considered an explanation for repeated losses,^[87] but the situation may be more complex. Bussen and Steck^[88] studied 22 habitual aborters and like numbers of nulligravid and multigravid controls. Thyroid antibodies were increased in the former. Stagnaro-Green et al.^[89] and Glinoe et al.^[90] concluded that antithyroid antibodies and mild thyroid disease were associated with spontaneous abortions, whereas Singh et al.^[91] thought that thyroid antibodies were a useful marker for clinical losses in the ART population. Pratt et al.^[92] reported increased antithyroid antibodies in euthyroid women experiencing first trimester losses, but the same group^[93] also concluded that the ostensible association was secondary to nonspecific organ antibodies. Rushworth et al.^[94] followed women in a repetitive abortion clinic who had antibodies against thyroglobulin or thyroid microsomal factors. The overall prevalence of antibodies in 164 women was 19 percent. However, subsequent outcomes were not significantly different whether thyroid antibody-positive or -negative.

Overall, asymptomatic thyroid antibodies would still not seem to be a major cause of early pregnancy loss.

Diabetes Mellitus

Women whose diabetes mellitus is poorly controlled are at increased risk for fetal loss.^[93] In one study, women whose glycosylated hemoglobin level was greater than 4 SD above the mean showed higher pregnancy loss rates than women with lower glycosylated hemoglobin levels. This finding was also found in retrospective studies.^[99] Poorly controlled diabetes mellitus should be considered one cause for early pregnancy loss, but well-controlled or subclinical diabetes is probably not a cause of early miscarriage.

Intrauterine Adhesions (Synechiae)

Intrauterine adhesions could interfere with implantation or early embryonic development. Adhesions may follow overzealous uterine curettage during the postpartum period, intrauterine surgery (e.g., myomectomy), or endometritis. Curettage is the usual explanation, with adhesions most likely to develop if curettage is performed 3 or 4 weeks after delivery. Individuals with uterine synechiae usually manifest hypomenorrhea or amenorrhea, but 15 to 30 percent show repeated abortions. If adhesions are detected in a woman experiencing repetitive losses, lysis under direct hysteroscopic visualization should be performed. Postoperatively, an intrauterine device or inflated Foley catheter may be inserted in the uterus to discourage reapposition of healing uterine surfaces. Estrogen administration should also be initiated. Approximately 50 percent of patients conceive after surgery, but the frequency of abortions remains high.

739

C, Uterus arcuatus (broadening and medial depression of a portion of the uterine septum). D, Uterus septus (persistence of a complete uterine septum). E, Uterus bicornis unicollis (two hemiuteri, each leading to same cervix). (From Simpson JL: *Disorders of Sexual Differentiation, Etiology and Clinical Delineation*. San Diego, Academic Press, 1976, with permission.)

Incomplete Müllerian Fusion

Müllerian fusion defects (Fig. 22-5) are an accepted cause of *second*-trimester losses and pregnancy complications. Low birth weight, breech presentation, and uterine bleeding are other abnormalities associated with müllerian fusion defects. Ben Rafael et al.^[96] confirmed these conclusions after comparison with women with hysterosalpingogram-proven normal uteri; however, most other reports lack controls.^[97]^[98]^[99]^[100]^[101]^[102]^[103] A few studies claim that the worst outcomes are associated with either septate uteri^[99] or T-shaped uteri,^[98] but others discern few differences among various anomalies.^[102] Some authors^[104] believe that minor structural defects may be just as deleterious as overt defects, but this does not seem completely plausible.

The major problem in attributing cause and effect for second-trimester complications and uterine anomalies is that the latter are so frequent that adverse outcomes could often be coincidental. For example, Stampe-Sorensen^[105] found unsuspected bicornuate uteri in 1.2 percent of 167 women undergoing laparoscopic sterilization; 3.6 percent had a severely septate uterus, and 15.3 percent had fundal anomalies. Simon et al.^[106] found müllerian defects in 3.2 percent (22 of 679) of fertile women; 20 of the 22 defects were septate. Treatment has traditionally involved surgical correction, such as metroplasty. Ludmire et al.^[107] wondered if conservative treatment might not be just as efficacious as surgical correction, following 101 women with an uncorrected malformation through a standardized protocol to decrease physical activity. Fetal survival rates in both bicornuate and septate groups (58 and 65 percent, respectively) did not differ significantly from rates in the same patients prior to institution of the protocol (52 and 53 percent, respectively).

First-trimester abortions might also be caused by müllerian fusion defects. Septate uteri might raise the risk of poor implantation on a poorly vascularized and inhospitable surface. Abortions occurring after ultrasonographic confirmation of a viable pregnancy at 8 or 9 weeks may properly be attributed to uterine fusion defects if the latter is present; however, losses having no confirmation of fetal viability at that time are statistically more likely to represent missed abortions in which fetal demise occurred prior to 8 weeks. Women experiencing second-trimester abortions can be assumed to benefit from uterine reconstruction, but reconstructive surgery is not necessarily advisable if losses are restricted to the first trimester.

Leiomyomas

Although leiomyomas are very frequent, relatively few affected women with leiomyomas develop symptoms requiring medical or surgical therapy. That leiomyomas cause pregnancy wastage per se rather than obstetric complications like prematurity is thus plausible but probably rare. Analogous to uterine anomalies, the coexistence of uterine leiomyomas and reproductive losses need not necessarily imply a causal relationship. Location of leiomyomas is probably more important than size, submucous leiomyomas being most likely to cause abortion. Postulated mechanisms leading to pregnancy loss include (1) thinning of the endometrium over the surface of a submucous leiomyoma, predisposing to implantation in a poorly decidualized site; (2) rapid growth caused by the hormonal milieu of pregnancy, compromising the blood supply of the leiomyoma and resulting in necrosis ("red degeneration") that in turn leads to uterine contractions and eventually fetal expulsion; and (3) encroachment of leiomyomas upon the space required by the developing fetus, leading to premature

740

delivery through mechanisms presumably analogous to those operative in incomplete müllerian fusion. Relative lack of space can also lead to fetal deformations (i.e., positional abnormalities arising in a genetically normal fetus).

Surgical procedures to reduce leiomyomata may occasionally be warranted for women experiencing repetitive second-trimester abortions, but more often leiomyomata will have no etiologic relationship to pregnancy loss. Surgery should be reserved for women whose abortuses were both phenotypically and karyotypically normal and in which viability until at least 9 to 10 weeks was documented.

Incompetent Internal Cervical Os

A functionally intact cervix and lower uterine cavity are obvious prerequisites for a successful intrauterine pregnancy. Characterized by painless dilation and effacement, cervical incompetence usually occurs during the middle second or early third trimester. This condition frequently follows traumatic events like cervical amputation, cervical lacerations, forceful cervical dilatation, or conization. A relationship to various connective tissue disorders is plausible but yet unproved. The various surgical techniques to correct cervical incompetence are discussed [in Chapter 23](#).

Infections

Infections are accepted causes of late fetal wastage and logically could be responsible for early fetal loss as well. Microorganisms and conditions reported to be associated with spontaneous abortion include variola, vaccinia, *Salmonella typhi*, *Vibrio fetus*, malaria, Cytomegalovirus, *Brucella*, *Toxoplasma*, *Mycoplasma hominis*, *Chlamydia trachomatis*, and *Ureaplasma urealyticum*. Transplacental infection doubtless occurs with each of these microorganisms, and sporadic losses could logically be caused by any. However, verification at these logical deductions has not been forthcoming. Other studies have found no difference in outcome between women treated and not treated with antibiotics. Unanswered also is whether the infectious agents were causative in the fetal losses or merely arose secondarily after demise caused by a noninfectious etiology. Confounding variables (e.g., maternal age, prior pregnancy history) are also rarely taken into account. Overall, a purported association between a common microorganism and pregnancy loss could easily reflect chance findings or be explained by other factors.

Of all organisms mentioned, *Ureaplasma* and *Chlamydia* are not only the most commonly implicated in *repetitive* abortion but also fulfill certain prerequisites necessary to assume a causal relationship. Both can exist in an asymptomatic state, and neither necessarily is so severe as to cause infertility. From 46 women with histories of three or more consecutive losses of unknown etiology, Stray-Pedersen et al.^[108] recovered *Ureaplasma* significantly more often among women with

repetitive abortions (28 percent) than among female controls (7 percent). Infected women and their husbands ($n = 43$) were then treated with doxycycline, with subsequent cultures confirming eradication of *Ureaplasma*. Nineteen of the 43 women became pregnant; of the 19, three experienced another spontaneous abortion and 16 had normal full-term infants. Among 18 women with untreated *Ureaplasma*, only 5 full-term pregnancies occurred.

Because of the presence of chlamydial antibodies in the sera of women who experienced repeated losses, an association has been claimed on the basis of presence of high titers.^[109], ^[110] However, other data show no relationship.^[111], ^[112] An immunohistochemical study found no difference in the frequency of cytomegalovirus antigen in karyotypically normal and abnormal abortuses, suggesting no causal association.^[113] Pauku et al.^[114] found no differences in the frequencies of IgG-IgA antibodies to *C. trachomatis* in a study of 70 Finnish women with multiple losses. Toxoplasmosis antibodies have been observed in Mexican and in Egyptian women having repetitive losses,^[115], ^[116] but whether frequencies are higher in those general populations is unclear. The most recent studies have not concluded that toxoplasmosis is not a significant cause of pregnancy loss.^[117]

A key question is whether infectious agents *cause* fetal losses or merely arise following fetal demise for a host of other etiologies. Cohort surveillance for infections beginning in early pregnancy is necessary in order to determine the etiologic role of infections in pregnancy loss. To this end, Simpson et al.^[118] analyzed data collected prospectively on clinical infections in 818 women followed frequently from early in the first trimester. No clinical evidence was found that infection occurred more often in the 112 subjects experiencing pregnancy loss compared to the 706 having successful pregnancies. This observation held both for the 2-week interval in which a given loss was recognized clinically as well as in the prior 2-week interval. These data suggest that the attributable risk of infection in first-trimester spontaneous abortion is low.

What evaluation and management is recommended? Culturing the endometrium for *U. urealyticum* seems reasonable, with culture-positive women having such infections treated. Alternatively, tetracycline therapy can be reasoned to be so innocuous that empiric treatment with doxycycline (100 mg orally twice a day for 10 days, both husband and nonpregnant wife) could be recommended.

Antifetal Antibodies

Perturbations of the immune system can be responsible for fetal wastage. However, the nature of the immunologic

741

process responsible for maintaining pregnancy has proved to be complex. Several different immunologic processes may play a role.

In one immunologic process, an otherwise normal mother produces antibodies against her fetus on the basis of genetic dissimilarities. Fetal loss is well documented in Rh-negative (D-negative) women having anti-D antibodies. More apropos for early pregnancy loss is the presence of anti-P antibodies. Most individuals are genotype Pp or PP, but one may be homozygous for p (pp). If a woman of genotype pp has a Pp or PP mate, resulting offspring may or must be Pp. If the mother develops anti-P antibodies, Pp fetuses will be rejected (aborted) early in gestation. Plasmapheresis and other modalities may be therapeutically efficacious.^[119], ^[120]

Hill and colleagues^[121] proposed that perturbations of cytokines cause repetitive abortions in women through T-helper cell abnormalities. The rationale is based on T-helper 1 (Th1) cytokines being deleterious, but Th2 cytokines not. The former includes tumor necrosis factor (TNF), interleukin (IL) -2, and interferon (IFN)- γ ; the latter includes IL-4, IL-5, IL-6, and IL-10, all secreted by activated T cells expressing the CD4 phenotype. Natural killer cells expressing CD56 also produce salutary cytokines. In women with recurrent loss, immune cell responsiveness becomes activated to produce increased IFN- and TNF.^[122] Supporting the hypothesis that Th1 cytokines are deleterious, down-regulation of Th1 cytokines in certain mammalian species improves pregnancy outcome.^[123], ^[124] Progesterone therapy is said by some to mitigate against the deleterious effects.

Autoimmune Disease

An association between second-trimester pregnancy loss and certain autoimmune disease is generally accepted.^[125], ^[126] Antibodies found in women with pregnancy loss encompass nonspecific antinuclear antibodies (ANAs) as well as antibodies against such cellular components as phospholipids, histones, and double- or single-stranded DNA. Antiphospholipid antibodies in turn represent a broad category that encompasses lupus anticoagulant (LAC) antibodies and anticardiolipin antibodies (aCL). Most investigators^[127] agree that midtrimester fetal death is increased in women with LAC or aCL; in fact, dramatically so. Controversy centers on the role of these antibodies in first-trimester losses.

Descriptive studies initially seemed to show increased anticardiolipin antibodies in women with first-trimester pregnancy losses. However, frequencies of various antiphospholipid antibodies (LAC, aCL, aPL) soon were shown to be similar in women who experience and who do not experience first-trimester abortions.^[128] ^[129] ^[130] ^[131] A major pitfall in assessing the role of these antibodies in first-trimester losses is the unavoidable selection bias in studying couples only after they have presented with spontaneous abortions. That antibodies did not arise until *after* the pregnancy loss can not be excluded in most experimental designs. To address this pitfall, Simpson et al.^[132] analyzed sera prospectively obtained from women within 21 days of conception. A total of 93 women who later experienced pregnancy loss were matched 2:1 with 190 controls who subsequently had a normal liveborn offspring.^[132] No association was observed between pregnancy loss and presence of either aPL or aCL.

Although neither aCL nor aPL would seem to contribute greatly, if at all, to first-trimester pregnancy loss in the general population, the issue remains open in the opinion of some. For example, some believe that results would be different if more specific assays were performed, such as antiphosphatidylethanolamine.^[133] Another pitfall is that marked variation in antiphospholipid antibodies occurs during pregnancy.^[134] Another subset consists of women successfully achieving pregnancy by in vitro fertilization, who in some reports show increased prevalences of aCL.^[135] Power calculations are also inadequate to exclude an effect limited to selected subsets, like the 3 to 4 percent of women with three or more repetitive losses; however, one third of women in the cohort study of Simpson et al.^[132] experienced at least one prior loss, and in that group the frequency of aCL and aPL was not increased compared to those of women without prior losses.^[136]

It has also been claimed that even if aCL and aPL are not present, antibodies to b2 glycoprotein (a2GP-1) might still be increased in repetitive aborters. However, Balasch et al.^[137] found no increase. Only 1 of 100 women having repetitive abortions and not having LAC or aCL showed elevated a2GP-1. No relationship is likely to exist between a2GP-1 and failure of implantation in the in vitro fertilization population, despite earlier claims of Stern et al.^[138]

In conclusion, a relationship between first-trimester loss and aPL and aCL seems unlikely to be applicable to more than a small subset of cases. Given this, treatment regimens should be offered hesitantly and only with nontoxic agents (e.g., aspirin and heparin, but not steroids). Similarly, treating aborters with intravenous immunoglobulin is not recommended.^[139]

Alloimmune Disease (Shared Parental Antigens)

If fetal rejection occurs as a result of diminished fetal/maternal immunologic interaction (alloimmune factors), immunotherapy might be beneficial to stimulate beneficial blocking antibodies generated at the few loci differing from father and mother and, hence, potentially fetus. The first prospective randomized trial produced impressive results,^[140] but later studies have been far less so. In 1994 a multicenter U.S. effort pooling results of immunotherapy by injection of paternal leukocytes into the mother reported a scant 11 percent increased pregnancy

742

rate in the immunized group.^[141] Meta-analysis by Fraser et al.^[142] found the odds ratio to be only 1.3 in favor of a beneficial effect. In 1999, Ober et al.^[143] definitively reported a NICHD collaborative effort involving six U.S. and Canadian centers. Women with three or more spontaneous abortions of unknown cause were randomized into one arm ($n = 91$) that underwent immunization with paternal mononuclear cells; women in the other arm were given saline (controls) ($n = 92$). Pregnancy beyond 28 weeks occurred in 46 percent (31 of 68) of the immunized group versus 65 percent (41 of 63) in the nonimmunized group. These findings were the opposite of expectation if immunotherapy were salutary.

In conclusion, parental human leukocyte antigen (HLA) sharing leading to fetal rejection seems to be valid, with HLA-B the locus showing the strongest association. However, the attributable role of HLA sharing in pregnancy losses in the general population must be low, and immunotherapy is clearly not useful.

Drugs, Chemicals, and Noxious Agents

Various exogenous agents have been implicated in fetal losses. Indeed, women are exposed frequently to relatively low doses of ubiquitous agents. However, few agents can be implicated with confidence. Rarely are data adequate to determine the true role of these exogenous factors in early pregnancy losses.

Outcomes following exposures to exogenous agents are usually deduced on the basis of case-control studies. In such studies, women who aborted claimed exposure to the agent in question more often than controls. However, case-control studies suffer certain inherent biases, as reviewed [in Chapter 8](#). The primary bias is that controls have less incentive to recall antecedent events than subjects experiencing an abnormal outcome (recall bias). Employers attempt to limit exposure of women in the reproductive age group; thus, exposures to potentially dangerous chemicals are usually unwitting and, hence, poorly documented. Moreover, pregnant women usually are exposed to many agents concurrently, making it nearly impossible to attribute adverse effects to a single agent. Given these caveats, physicians should be cautious about attributing pregnancy loss to exogenous agents. On the other hand, common sense dictates that exposure to potentially noxious agents be minimized.

X-Irradiation

Irradiation and antineoplastic agents in high doses are acknowledged abortifacients. Of course, therapeutic x-rays or chemotherapeutic drugs are administered during pregnancy only to seriously ill women whose pregnancies often must be terminated for maternal indications. On the other hand, pelvic x-ray exposure of up to perhaps 10 rad places a woman at little to no increased risk. Exposure doses are usually far less (1 to 2 rad). Still, it is prudent for pregnant hospital workers to avoid handling chemotherapeutic agents and minimize potential exposures during diagnostic x-ray procedures.

Cigarette Smoking

Smoking during pregnancy is accepted as associated with spontaneous abortion, but this could be explained partly on the basis of confounding variables. Kline et al.^[144] found increased abortion rates in smokers, independent of maternal age and independent of alcohol consumption. Ness et al.^[145] studied the relationship between pregnancy loss and tobacco use, as assessed by urinary cotinine levels. Four hundred women with spontaneous abortions were compared with 570 who experienced ongoing pregnancies. Women with urinary cotinine had increased risk of abortion, but the odds ratio only reached 1.8 (95 percent confidence interval [CI] 1.3 to 2.6).

Caffeine

The consensus has long been that no deleterious effects of caffeine exist, whereas most studies were retrospective and case-control in design. Data gathered in cohort fashion by Mills et al.^[146] are reassuring. The odds ratio for an association between caffeine (coffee and other dietary forms) was only 1.15 (95 percent CI 0.89 to 1.49).^[146] Additional data from women exposed to very high levels (>300 mg caffeine daily) would be useful, as shown by the reports of Klebanoff et al.^[147] showing an association between pregnancy losses and caffeine ingestion, 7 mg daily and by Cnattinguis et al.^[147] A problem with the latter studies is difficulty in being able to separate the effects of nausea, which typically is more common in successful pregnancies. However, in general reassurance can be given concerning moderate caffeine exposure and pregnancy loss.

Alcohol

An association between alcohol consumption and fetal loss once seemed generally accepted. In one study,^[144] 616 women suffering spontaneous abortions were compared with 632 women delivering at 28 gestational weeks or more. Among women whose pregnancies ended in spontaneous abortion, 17 percent drank at least twice per week; only 8.1 percent of controls drank similar quantities of alcohol. Harlap and Shiono^[148] also found a slightly increased risk for abortion in women who drank in the first trimester. More recent studies have not reported a relationship in moderate drinkers. Halmesmärki et al.^[149] found that alcohol consumption was nearly identical in women who did and did not experience an abortion; 13 percent of aborters and 11

percent of control women drank on average three to four drinks per week; other investigations have reached a similar conclusion.^{[145], [150]}

Alcohol consumption should be avoided or minimized during pregnancy for many reasons, but abstinence may only minimally if at all decrease pregnancy loss rate. Avoidance has other benefits that can be better substantiated.

Contraceptive Agents

Conception with an intrauterine device in place clearly increases the risk of fetal loss. However, if the device is removed prior to pregnancy, there is no increased risk of spontaneous abortions. Use of oral contraceptives before or during pregnancy is not associated with fetal loss, nor is spermicide exposure either prior to or after conception ([see Chapter 9](#)).

Environmental Chemicals

Limiting exposure to potential toxins in the workplace is recognized as prudent for pregnant women. The difficulty lies in defining the precise effect of lower exposures and attributing a specific risk. False alarms concerning potential toxins are frequent. Among the many chemical agents variously claimed to be associated with fetal losses, consensus seems to be evolving around a selected few.^[151] These include anesthetic gases, arsenic, aniline dyes, benzene, solvents, ethylene oxide, formaldehyde, pesticides, and certain divalent cations (lead, mercury, cadmium). Workers in rubber industries, battery factories, and chemical production plants are among those at potential risk ([see Chapter 7](#)).

Trauma

Women commonly attribute pregnancy losses to trauma, such as a fall or blow to the abdomen. However, fetuses are actually well protected from external trauma by intervening maternal structures and amniotic fluid. The temptation to attribute a loss to minor traumatic events should be avoided.

Psychological Factors

That impaired psychological well-being predisposes to early fetal losses has been claimed but never proved. Certainly, neurotic or mentally ill women experience losses just like normal women. Whether the frequency of losses is higher in the former is less certain because potential confounding variables have not been taken into account.

Investigations cited as proving a benefit of psychological well-being are those of Stray-Pedersen et al.^[152] Pregnant women who previously experienced repetitive abortions received increased attention but no specific medical therapy ("tender loving care"). These women ($n = 16$) proved more likely (85 percent) to complete their pregnancy than 42 women not offered such close attention (36 percent successful outcome). One potential pitfall was that only women living "close" to the university were eligible to be placed in the increased-attention group. Women living farther away served as "controls"; however, these women may have differed from the experimental group in other ways as well.

Other studies have also reported a beneficial effect of psychological well-being.^{[153] [154] [155] [156]} However, the biologic explanation for this effect remains obscure.

Severe Maternal Illness

Many debilitating maternal diseases have been implicated in early abortion. Pathogenesis is not necessarily independent of mechanisms discussed previously, specifically endocrinologic or immunologic. Symptomatic maternal diseases established as causes of fetal wastage include Wilson's disease, maternal phenylketonuria, cyanotic heart disease, hemoglobinopathies, and inflammatory bowel disease. Actually, any life-threatening disease would be expected to be associated with an increased abortion rate. Seriously ill women rarely become pregnant, but the disease process may deteriorate after the onset of pregnancy. Overall, relatively few fetal losses will be the result of severe maternal disease, with the same even more applicable for repetitive losses.

Gabbe: *Obstetrics - Normal and Problem Pregnancies, 4th ed.* , Copyright © 2002 Churchill Livingstone, Inc.

ECTOPIC PREGNANCY

In ectopic pregnancy, implantation occupies a site other than the endometrium. Ectopic pregnancies are responsible for approximately 10 percent of all maternal mortality.^[157] Moreover, the prognosis for future reproduction is poor. Only one half of women having an ectopic pregnancy are eventually delivered of a liveborn infant. Most of these never become pregnant, and up to 25 percent of those who do suffer a repeat ectopic pregnancy.^[158] Various factors contribute to ectopic pregnancies, the most common being infection. Unlike intrauterine spontaneous abortions, genetic factors are not paramount in the etiology of ectopic pregnancy. Ectopic embryos show chromosomal abnormalities no more often than predicted on the basis of embryonic age.^[159]

Incidence

The incidence of recorded ectopic gestation is increasing. Some of this increase seems real and some spurious. A true increase can be hypothesized as a result of

744

(1) improved treatment for pelvic inflammatory disease, a condition that in the past would have conferred sterility; (2) an increase in surgical corrections of fallopian tube occlusion; and (3) a greater number of elective sterilizations, some of which are later reversed surgically. However, there is also an artificial increase related to improved diagnostic techniques. Ectopic pregnancies that in the past would have been mislabeled as unexplained abdominal pain or bleeding are readily recognized today because pregnancy tests have become very sensitive.

Most ectopic pregnancies (96 percent) are tubal. The remainder are interstitial uterine ectopic pregnancies and, rarely, cervical, abdominal, or ovarian pregnancies.^[160] Most tubal pregnancies are located in the distal (ampullary) two thirds of the tube. A few ectopic pregnancies are isthmic, located in the proximal portion of the extrauterine part of the tube. On rare occasions both intrauterine and extrauterine gestations can coexist (heterotopic pregnancy).

Signs and Symptoms

Abdominal pain and irregular vaginal bleeding are the most common presenting symptoms in ectopic pregnancy.^[161] In a 1983 report of 328 patients presenting with ectopic pregnancy, 94 percent had pain, 89 percent had a missed menstrual period, 80 percent had vaginal bleeding, and 20 percent had hypotension.^[162] An abdominal mass is palpable in only one half of patients with an ectopic pregnancy. Of course, passage of a decidual cast in association with vaginal bleeding nearly unequivocally indicates ectopic pregnancy, but this is uncommon. The Arias-Stella phenomenon is frequently found in the endometrium in association with ectopic pregnancies; however, this phenomenon is also seen in 70 to 80 percent of therapeutic and spontaneous abortions,^[163] so it is not specific for ectopic gestation.

Ectopic pregnancies should be diagnosed before the onset of hypotension, bleeding, pain, and overt rupture. Patients with a history of tubal surgery, pelvic inflammatory disease, tubal disease, or previous ectopic pregnancy are at special risk for ectopic pregnancy and would benefit not only from their physicians' vigilance but also from routine hormone screening of the type discussed below. Fortunately, early diagnosis of ectopic gestation is now quite feasible. Ectopic pregnancy can be detected by 6 weeks' gestation, often as early as at 4½ gestational weeks.

Chronic ectopic pregnancy is a distinct entity. Diagnosis may be difficult because normal anatomic landmarks are distorted by the formation of adhesions resulting from chronic inflammatory processes. Chronic ectopic pregnancies present a management quandary because the significance of the associated declining -hCG levels is difficult to determine. The dilemma is whether resolution will occur spontaneously or require surgical intervention to prevent catastrophic hemorrhage and permanent adhesion formation resulting in tubal damage.

Diagnosis

Direct vision by laparoscopy has been the diagnostic standard for ectopic pregnancy. However, if the pregnancy is early and the gestational sac small, the gestation may not be visualized. Thus, algorithms incorporating a single measurement of serum progesterone, serial measurement of the -subunit of hCG, pelvic ultrasonography, and uterine curettage are accepted.^[164] [Figure 22-6](#) shows a useful approach.

Single Measurement of Serum Progesterone

Serum progesterone reflects production of progesterone by the corpus luteum, which is stimulated by a viable pregnancy. Measurement of progesterone is an inexpensive screening test that can identify patients who need to undergo further testing. Ectopic pregnancy can be excluded and viable intrauterine pregnancy diagnosed with 97.5 percent sensitivity if serum progesterone levels are 25 ng/ml (79.5 nmol/L) or higher, obviating the need for further testing. Conversely, serum progesterone can identify nonviable pregnancies with 100 percent sensitivity if progesterone levels are 5 ng/ml (15.9 nmol/L) or lower.^[165] ^[166] ^[167] ^[168] If a single progesterone level is 5 ng/ml or lower, diagnostic uterine evacuation can be performed even if ectopic pregnancy cannot otherwise be distinguished from a spontaneous intrauterine abortion. Progesterone values above 5 but below 25 ng/ml necessitate establishing viability by ultrasonography.

Serial Serum -hCG Measurements

-hCG is produced by trophoblastic cells. In normal pregnancies, -hCG concentration increases 67 percent over a 2-day interval.^[169] Abnormal intrauterine or ectopic pregnancies have impaired -hCG production and, hence, a prolonged hCG doubling time. Thus, serial -hCG measurements can be used to assess the viability of pregnancy, signal the optimal time for ultrasonography, and document the effectiveness of diagnostic curettage.

Transvaginal Ultrasound

If -hCG is greater than 1,500 mIU/ml and the pregnancy is intrauterine, a gestational sac should be visualized

745

Figure 22-6 Algorithm for the diagnosis of unruptured ectopic pregnancy without laparoscopy. Progesterone measurements increase the sensitivity of the algorithm by inexpensively screening large numbers of patients during the first trimester of pregnancy. The definitive diagnosis is made by transvaginal ultrasound or uterine curettage and does not depend on the serum progesterone concentrations obtained during screening. (From Carson SA, Buster JE: *The ectopic pregnancy: new advances in diagnosis and treatment*. *N Engl J Med* 329:1174, 1993, with permission.)

by transvaginal ultrasound. By transabdominal ultrasound the gestational sac may not be identified until -hCG reaches 6,000 mIU/ml. If -hCG is greater than these levels but the gestational sac cannot be visualized, an ectopic location should be assumed. Conversely, intrauterine pregnancies may also be confirmed by ultrasound, specifically excluding ectopic pregnancy. ^{[165] [166] [167] [168]}

Widely available in gynecologic offices and emergency rooms, ultrasonography with a 5-mHz transvaginal ultrasound probe can document intrauterine gestation earlier than transabdominal ultrasonography. Transvaginal color Doppler sonography may further enhance early diagnostic sensitivity and specificity through the identification of characteristic uterine and adnexal flow patterns. ^[170]

Uterine Curettage

Villi float in saline, a characteristic permitting identification of tissue obtained by curettage. If no villi are recognized and a decrease in the -hCG level of 15 percent or more 8 to 12 hours occurs after curettage, a completed abortion can be assumed to exist. If villi are not visualized and -hCG titers plateau or rise, trophoblasts can be assumed *not* to have been removed by the uterine curettage; thus, an ectopic pregnancy can be presumed to be present.

Surgical Treatment

Salpingectomy by laparotomy has long offered almost a 100 percent cure. However, current emphasis is not just to prevent death but also to facilitate rapid recovery, preserve fertility, and reduce costs. Laparoscopic salpingostomy and partial salpingectomy are thus rapidly replacing laparotomy. Laparotomy should be performed only when a laparoscopic approach is too difficult, the surgeon is not trained in operative laparoscopy, or the patient is hemodynamically unstable.

Linear salpingostomy is the standard laparoscopic operation when an ectopic mass is unruptured yet more than 4 cm in length by ultrasound. ^{[169] [171] [172] [173] [174] [175]} Over the bulging antimesenteric border of the implantation site, a longitudinal incision is made by electrocautery, scissors, or laser. The products of conception are removed by forceps or suction. After hemostasis is achieved, the incision is allowed to heal by secondary intention. Alternatively, sutures can be placed. Approximately 95 percent of laparoscopic salpingostomies are successful (i.e., no additional procedures are needed). ^[165] Of the 93 women evaluated in one study, 86 percent were later shown to have patent oviducts; 66 percent of 430 women who were followed subsequently became pregnant, with 23 percent of those pregnancies being ectopic. ^[176]

Segmental resection is necessary if ectopic pregnancies

are located in the isthmus (the midportion of the oviduct). Subsequent laparotomy is then necessary for reanastomosis of the surgically divided oviduct. Laparoscopic salpingectomy is also desirable for patients who do not wish to become pregnant again.

Postoperative bleeding, elevated -hCG levels indicative of persistent viable trophoblastic tissue, and other symptoms occur in up to 20 percent of cases after conservative laparoscopic surgery. Excision of the involved oviduct or medical therapy may then be necessary.

Medical Treatment

Although operative laparoscopy has substantially fewer complications than laparotomy, there remains irreducible morbidity intrinsic to surgery and anesthesia. Medical treatments can greatly reduce this morbidity. To supplant surgery, however, medical therapies must match the high success rates, low complication rates, and good reproductive potential achieved with laparoscopic operations. This appears to be true. ^{[165] [177]} The agent used is the folic acid antagonist methotrexate, which inhibits synthesis of purines and pyrimidines and thus interferes with DNA synthesis and cell multiplication. Actively proliferating trophoblasts have long been known to be vulnerable to methotrexate, as illustrated by its successful use in the treatment of gestational trophoblastic disease.

Hemodynamically stable patients with ectopic pregnancies are eligible for treatment with methotrexate if the mass is unruptured and measures 4 cm or less in diameter by ultrasound. ^[165] Patients with larger ectopic masses, embryonic cardiac activity, or evidence of acute intra-abdominal bleeding (acute abdomen, hypotension, or falling hematocrit) are not eligible for methotrexate therapy. ^[165] Outcome of treatment with systemic methotrexate (Table 22-4) ^{[165] [178]} compares favorably with that of laparoscopic salpingostomy; 94 percent of women successfully treated with systemic methotrexate needed no subsequent therapy. Of women tested, 81 percent had patent oviducts; 71 percent subsequently became pregnant, with 11 percent of those being ectopic.

High doses of methotrexate can cause bone marrow suppression, acute and chronic hepatotoxicity, stomatitis, pulmonary fibrosis, alopecia, and photosensitivity. Fortunately, these side effects are not only infrequent with the shorter treatment schedules used for an ectopic pregnancy but can be mitigated against by the administration of leucovorin (citrovorum factor). Experience with methotrexate in gestational trophoblastic disease provides little reason for concern about the risks of subsequent neoplasia or congenital anomalies in later pregnancies. ^[179]

Safeguards are necessary to enhance the success and

TABLE 22-4 -- SUMMARY OF THE METHOTREXATE REGIMENS USED

Regimen	Monitor
Multiple dose	Serum -hCG weekly until undetectable; blood count, platelet count, liver enzyme levels
Methotrexate, 1 mg/kg of body weight intramuscularly every other day (days 1, 3, and so on)	
Leucovorin, 0.1 mg/kg intramuscularly every other day (days 2, 4, and so on)	
Continue treatment until -hCG drops 15% in 48 hours or 4 doses of methotrexate have been given	
Single dose	Serum -hCG level days 4 and 7, then weekly until undetectable; initial blood count, platelet count, liver enzyme levels
Methotrexate, 50 mg/m ² of body surface area intramuscularly	
No leucovorin	

From Carson SA, Buster JE: *The ectopic pregnancy: new advances in diagnosis and treatment*. *N Engl J Med* 329:1174, 1993, with permission.

minimize the toxicity of systemic methotrexate. First, the patient should undergo a pelvic examination by only a single examiner and then only once. Self-control concerning this part of management should be similar to that employed with placenta previa. Second, both physician and patient must recognize that transient pain is common, usually occurring 3 to 7 days after initiation of methotrexate therapy. The pain, presumably caused by tubal abortion, normally lasts 4 to 12 hours. Perhaps the most difficult aspect of methotrexate therapy is distinguishing the transient abdominal pain associated with successful therapy from that of rupturing ectopic

pregnancy. Surgical intervention becomes necessary only when pain is accompanied by orthostatic tachycardia, hypotension, or a falling hematocrit. If uncertainty exists concerning the patient's hemodynamic stability, physicians may prefer to hospitalize the patient with pain for observation. Because colicky abdominal pain is common during the first 2 or 3 days of methotrexate therapy, patients should also be warned to avoid gas-producing foods such as leeks and cabbage. Patients should also avoid exposure to the sun because of the photosensitivity methotrexate produces.

Intramuscular methotrexate is not the only route of therapy, but less experience exists with other methods. These include the direct injection of methotrexate into the ectopic, methotrexate administered by tubal cannulation, or prostaglandins by direct injection.

Finally, few medical advances evolve without negative consequences. As ectopic pregnancy is detected earlier and more efficiently, some pregnancies that would

otherwise have been spontaneously absorbed are now treated, in retrospect, needlessly. Identifying early ectopic pregnancies that are destined for spontaneous remission would thus be useful, although efforts to do so have so far been unsuccessful. "Overtreatment" of ectopic pregnancy will thus be the inevitable corollary of early intervention.

Relative Benefits of Surgical Versus Medical Therapy

Conservative laparoscopic surgery is very efficacious, as is that of systemic methotrexate therapy. Systemic methotrexate therapy is less expensive than operative laparoscopy, and patients lose less time from work. On the other hand, some patients prefer surgical therapy because they wish to avoid the possible side effects of systemic chemotherapy and a more protracted course of treatment. However, even after laparoscopic removal of ectopic tissue, residual tissue remains to cause hemorrhage and other complications in 20 percent of cases. With either surgical or medical treatment, weekly blood tests are thus necessary until -hCG becomes undetectable. Only a small subgroup of patients treated with either medical or surgical therapy have been followed to determine subsequent reproductive capabilities; thus, it is difficult to state conclusively whether the rates of pregnancy, tubal patency, and recurrent ectopic pregnancy differ between medical and surgical treatment. Not until a prospective randomized study is conducted will the optimal choice of the therapy for each patient be known.

In conclusion, removal of the ectopic pregnancy by salpingostomy is recommended when laparoscopy is needed for diagnosis. We recommend systemic methotrexate when laparoscopy is not required for diagnosis. Laparoscopic surgery is also preferable when the ectopic mass is larger than 4.0 cm. A laparotomy is performed only for catastrophic hemorrhage or hemodynamic instability.

RECOMMENDED EVALUATION FOR RECURRENT PREGNANCY LOSSES

1. Couples experiencing only one first-trimester abortion should receive pertinent information, but not necessarily be evaluated formally. Mention the relatively high (10 to 15 percent) pregnancy loss rate in the general population and the beneficial effects of abortion in eliminating abnormal conceptuses. Provide the relevant recurrence risks, usually 20 to 25 percent subsequent loss in the presence of a prior liveborn and somewhat higher in the absence of a prior liveborn. Risks are higher for older women. If a specific medical illness exists, treatment is obviously necessary. Intrauterine adhesions should be lysed. Otherwise, no further evaluation need be undertaken, even if uterine anomalies or leiomyomas are detected. On the other hand, occurrence of an anomalous stillborn or liveborn warrants genetic evaluation irrespective of the number of pregnancy losses.
 2. Investigation may or may not be necessary after two spontaneous abortions, depending on the patient's age and personal desires. After three spontaneous abortions, evaluation is usually indicated. One should then (a) obtain a detailed family history, (b) perform a complete physical examination, (c) discuss recurrence risks, and (d) order the selected tests cited below.
 3. Parental chromosomal studies should be performed on all couples having repetitive losses. Antenatal chromosomal studies should be offered if a balanced chromosomal rearrangement is detected in either parent or if autosomal trisomy occurred in any previous abortus.
 4. Although it is impractical to karyotype all abortuses, cytogenetic information on abortuses may exist. Detection of a trisomic abortus suggests the phenomenon of recurrent aneuploidy, justifying prenatal cytogenetic studies in future pregnancies. Performing prenatal cytogenetic studies solely on the basis of repeated losses is more arguable, but not unreasonable among women aged 30 to 34 years.
 5. The validity of LPD as a discrete entity increasingly seems arguable. To detect LPD, timed endometrial biopsies should be performed late in the luteal phase in two or more cycles. Results should be correlated with the date of ovulation. If histologic dating reveals an endometrium 2 or more days less than expected, the diagnosis can be made. Diagnosis on the basis of progesterone levels is preferred by some. Progesterone therapy has been proposed, but its efficacy has not been proved.
 6. Other endocrine causes for repeated fetal losses include poorly controlled diabetes mellitus (hyperglycemia) and possibly thyroid dysfunction.
 7. To determine the role of infectious agents, the endometrium may be cultured for *Ureaplasma urealyticum*. Alternatively, a couple could be treated empirically with doxycycline (100 mg two times per day for 10 days) before pregnancy. Of other infectious agents, only *Chlamydia trachomatis* seems plausible. These agents are more likely to cause sporadic than repetitive losses.
 8. If an abortion occurs after 8 to 10 weeks' gestation, a uterine anomaly or submucous leiomyoma should be considered. The uterine cavity should be
-

explored by hysteroscopy or hysterosalpingography. If a müllerian fusion defect (septate or bicornuate uterus) is detected in a woman experiencing one or more second-trimester spontaneous abortions, surgical correction may be warranted. A large submucous leiomyoma may also justify myomectomy or reduction. However, the same statements do not necessarily apply following first-trimester losses. Cervical incompetence should be managed by surgical cerclage during the next pregnancy.

9. To exclude autoimmune disease involving antiphospholipid antibodies, assessment should include aPL and aCL. Women with antibodies who experience midtrimester losses may benefit from treatment with heparin and aspirin, but the same does not necessarily hold when these antibodies are detected in asymptomatic women having first-trimester pregnancy losses. This recommendation also holds for women undergoing assisted reproductive technologies (ART). Testing for other autoantibodies (e.g., DNA) is not indicated.
10. There is some deleterious effect of HLA sharing (HLA-), but not enough to alter clinical approach. Determining parental HLA types in the absence of other immunologic testing is not recommended. Immunotherapy (by inoculation of the mother with her husband's leukocytes) has been unequivocally shown to be ineffective.
11. One should discourage exposure to cigarettes and alcohol, yet remain cautious in ascribing cause and effect in individual cases. Similar counsel should apply for exposures to other potential toxins.

Gabbe: *Obstetrics - Normal and Problem Pregnancies, 4th ed.* , Copyright © 2002 Churchill Livingstone, Inc.

Key Points

Approximately 22 percent of all pregnancies detected on the basis of urinary hCG assays are lost, usually before clinical recognition.

The clinical loss rate is 10 to 12 percent. Most of these pregnancies are lost before 8 weeks' gestation. Only 3 percent of pregnancies are lost after an ultrasonographically viable pregnancy at 8 to 9 weeks, and only 1 percent are lost after 16 weeks' gestation.

Pregnancy losses may be recurrent, 4 percent of U.S. women experiencing two losses and 3 percent three or more losses. Although increasing after one loss, the recurrence risk generally reaches no more than 25 percent after three or four losses. Loss rates for 40-year-old women are approximately twice that of 20-year-old women.

By far the most common causes of pregnancy losses are chromosomal abnormalities. At least 50 percent of clinically recognized pregnancy losses show a chromosomal abnormality. The types of chromosomal abnormalities differ from those found in liveborns, but autosomal trisomy still accounts for 50 percent of abnormalities. A balanced translocation is present in about 5 percent of couples having repeated spontaneous abortions.

Many nongenetic causes of repetitive abortions have been proposed, but few are proved. It is reasonable to evaluate couples for these conditions, but efficacy of treatment remains uncertain and relatively few pregnancy losses are caused by these factors.

Uterine anomalies are accepted causes of second-trimester pregnancies. Couples experiencing such losses may benefit from metroplasty or hysteroscopic resection of a uterine septum. Uterine anomalies are less common causes of first-trimester losses.

Drugs, toxins, and physical agents are associated with spontaneous abortion, but usually not in repetitive pregnancies. Avoiding potential toxins is obviously desirable, but one should not assume that such exposures explain repetitive losses.

LAC antibodies, aPL, and aCL are clearly associated with second-trimester losses, but their role in first-trimester losses is more arguable. Immunotherapy for couples sharing HLA antigens or otherwise showing blunted maternal response to paternal antigens (alloimmune disease) is not recommended. Determining parental HLA types in the absence of other immunologic evaluations is not recommended.

Management of ectopic pregnancy has undergone significant modification over recent years. The condition is less commonly an acute emergency and more easily diagnosed early in gestation on the basis of maternal serum progesterone, maternal -hCG, transvaginal ultrasound, and uterine curettage. The earlier detection of an unruptured ectopic pregnancy has greatly modified treatment. Laparotomy is now rarely necessary. Laparoscopic procedures (linear salpingostomy) are commonly used, with an increase

in subsequent pregnancy rates and a decrease in repeat ectopic gestations. About one third of women with ectopic pregnancies prove eligible for medical treatment (methotrexate). Patients at high risk for ectopic pregnancy may benefit from a screening serum progesterone determination at the time of initial pregnancy test.

Chapter 23 - Preterm Birth

Jay D. Iams

In developed nations, complications of prematurity account for the majority of perinatal mortality and morbidity in nonanomalous infants. In the United States, prematurity-related disorders cause more than 70 percent of fetal and neonatal deaths.^[1] Long-term sequelae of prematurity disproportionately contribute to developmental delay, visual and hearing impairment, chronic lung disease, and cerebral palsy.^[2]

Advances in neonatal care have led to increased survival and reduced short- and long-term morbidity for infants born before 37 weeks of pregnancy, but the rate of low-birth-weight deliveries actually increased between 1989 and 1997^[3] (Fig. 23-1). In 1997, 11.4 percent of births occurred before 37 weeks, up from 11.0 percent in 1996. These rates represent increases of 8 percent since 1990 and 20 percent since 1981. There are two notable trends in the data. The first is the racial difference in the rate of preterm birth before 37 and 32 weeks' gestation: 9.9 and 1.49 percent for white; 11.2 and 1.68 percent for Hispanic; and 17.6 and 4.19 percent for black women, respectively.^[3] The rate of preterm birth has been falling slowly among blacks, rising slowly among whites, and stable in the Hispanic population, but the black-white differences are persistent and largely unexplained. The second major trend is the increased number and rate of preterm births among multiple gestations. The rate of twins has increased 11 percent since 1990, from 22.6 to 26.8 per 1,000 births. The rate of higher order (more than two fetuses) multiple gestations has more than doubled since 1991, from 81.4 to 173.6 per 100,000, and has quadrupled since 1980, from a rate of 37.0 per 100,000.^[3] These increased rates of multiple gestation have fueled the rise in preterm births in both the United States and Canada.^[4] In the United States, the rate of preterm birth in 1997 was 10.0 percent for singletons, 54.9 percent for twins, and 93.6 percent for higher order multiples.^[3]

Three other factors may also explain the rise in preterm birth: (1) greater willingness to deliver preterm infants when maternal complications occur; (2) increased use of ultrasound to date pregnancy, which tends to correct menstrual dates in most cases by reducing gestational age; and (3) increased registration of extremely immature deliveries before 20 to 22 weeks.^[5] Efforts to identify and treat the conditions leading to prematurity have been largely disappointing, fulfilling the prophetic words of Nicholson Eastman in 1947: "Only when the factors underlying prematurity are completely understood can any intelligent attempt at prevention be made."^[6] Significant progress has been made toward understanding the factors that underlie preterm birth, but the goal remains elusive.

THE PROBLEM OF PREMATURITY

Definitions

Discussion of the problems of premature and low-birth-weight infants are complicated by use of data that incorrectly interchange the definitions of *prematurity*, defined by the duration of pregnancy, and *low birth weight*, defined by the size of the infant at birth.

Preterm or premature: Infants born before 37 weeks' gestation (259 days from the first day of the mother's last menstrual period, or 245 days after conception).

Low birth weight (LBW): Infants who weigh less than 2,500 g at birth, regardless of gestational age.

756

Very low birth weight (VLBW): Infants who weigh less than 1,500 g at birth.

Extremely low birth weight (ELBW): Infants who weigh less than 1,000 g at birth

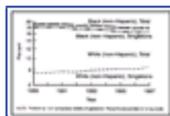

Figure 23-1 Rate of preterm birth by plurality and race/Hispanic origin of mother: United States, 1989-1997. (From Ventura SJ, Martin JA, Curtin SC, Mathews TJ: *Births: Final data for 1997. Natl Vital Stat Rep* 47:1, 1999.)

Obviously, age does not equal size. For example, infants born after 37 weeks whose birth weight is below 2,500 g are low birth weight but not preterm. The confusion first occurred because gestational age could not be determined with confidence prior to the availability of sensitive serologic and ultrasonographic means of pregnancy dating. It is now possible to determine gestational age very accurately by correlation of menstrual history with sensitive pregnancy tests and by measurements of fetal size with ultrasound in the first half of pregnancy. Unfortunately, these methods of pregnancy dating are not available for some pregnancies. Because gestational age and birth weight are directly correlated throughout most of gestation, birth weight has been used as an indirect indicator of gestational age in many studies, especially when gestational age is determined retrospectively. Interchanging the two measures may lead to erroneous interpretation of clinical and epidemiologic data because the problems of LBW infants may be the result of prematurity in some instances, of poor intrauterine growth in others, and of both in still others. Similarly, problems due to prematurity in preterm infants whose birth weight exceeds 2,500 g may go unrecognized because of their apparently "full-term" appearance.

The proportion of LBW infants who are preterm versus term varies widely between developed and underdeveloped nations. In underdeveloped areas, most LBW infants are born after 37 weeks, their low birth weight the result of poor intrauterine nutrition and chronic maternal illness and/or malnutrition. In developed nations, most LBW infants are premature, although there are wide variations within the United States according to race, parity, fetal sex, and environmental factors such as maternal cigarette smoking and altitude. The birth weight data in Figure 23-2 from Brenner^{7]} is based on a racially mixed population near sea level. Ideally, each region or state should generate a birth weight versus gestational age chart for its own population. In the absence of such data, a published chart based on a similar population can be used.

The incidences of LBW and VLBW deliveries have changed little since 1970. [9] The LBW rate was 6.00 percent of liveborn infants in 1989, 5.93 percent in 1992, and 6.08 percent in 1997. The rate of VLBW (<1,500 g) was 1.15 percent in 1980 and increased slowly to 1.42 percent in 1997. This small increase is more important than it may seem. In 1996, VLBW infants accounted for slightly more than 1 percent of all births, but 50 percent of all infant deaths. Rates of LBW and VLBW newborns in blacks are consistently about twice as high as corresponding rates in nonblacks (Fig. 23-3). Even when corrected for age and educational level, black women continue to deliver more LBW infants than do white women.

Perinatal Mortality and Morbidity

Analysis of perinatal mortality and morbidity statistics has long been confounded by the various definitions of fetal, perinatal, neonatal, and infant time periods that have been used across the United States and around the world. The definitions endorsed by the American College of Obstetricians and Gynecologists (ACOG) are used here. [8] A *perinatal death* is one that occurs between

757

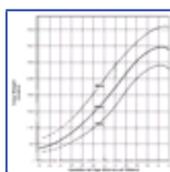

Figure 23-2 Percentage of low birth weight infants by race: 1975-1992. (From Brenner WE, Edelman DA, Hendricks CH: *A standard of fetal growth for the United States of America. Am J Obstet Gynecol* 126:555, 1976, with permission.)

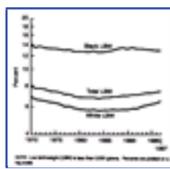

Figure 23-3 Percent low birth weight by race: United States, 1970-1997. (From Ventura SJ, Martin JA, Curtin SC, Mathews TJ: *Births: Final data for 1997. National Vital Stat Rep* 47:1, 1999.)

22 weeks, or 500 g if gestational age is not known, and 28 days following delivery, and includes both deaths in utero before delivery (fetal deaths) and deaths from

birth through 28 days of neonatal life. An early neonatal death occurs between birth and 7 days of life; a late neonatal death occurs between 8 and 28 days of life. Infant mortality occurs between 28 days of life and 1 year of age.

Perinatal mortality and morbidity for preterm infants are inversely related to both gestational age and birth weight: the greater the gestational age and birth weight, the lower the perinatal mortality and morbidity. Because the goals of prenatal care are maintenance of maternal well being and delivery of an infant with the lowest possible chance of mortality and morbidity, obstetricians frequently weigh the risks of preterm birth for the infant against the potential risks of prolonging the pregnancy for the mother. Knowledge of the gestational age-related risks for the baby of preterm birth is therefore an important part of obstetric practice.

Significant improvements in survival rates for all preterm infants have been documented for the past 40 years, and have been especially important for infants born before 28 weeks. In 1970, most hospitals did not expect infants born at or before 28 weeks or who weighed less than 1 kg to survive. Major improvements in the survival of extremely preterm (<26 weeks) infants

758

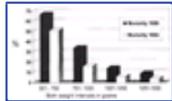

Figure 23-4 Mortality and very low birth weight infants born in 1988 and 1994 in the NICHD NICU Network. (Data from Stevenson DK, Wright LL, Lemons JA, et al: *Very low birth weight outcomes of the National Institute of Child Health and Human Development Neonatal Research Network, January 1993 through December 1994. Am J Obstet Gynecol 179:1632, 1998.*)

weighing less than 1,000 g have occurred over the last three decades. Data from 1982 to 1986, before the introduction of neonatal artificial surfactant, show survival rates of only 1.8 percent at 23 weeks', 9.9 percent at 24 weeks', 15.5 percent at 25 weeks', and 54.7 percent at 26 weeks' gestation.^[9] After the introduction of neonatal surfactant therapy, recent data show survival to hospital discharge rates of greater than 20 percent for infants born at 23 weeks', 50 percent at 24 weeks', 60 percent at 25 weeks', and 80 percent at 26 weeks' gestation for infants born in 1993 to 1994^[10] (Fig. 23-4) (Fig. 23-5) (Fig. 23-6). Neonatal reports do not include data from all fetuses who were alive at the time of maternal hospital admission, and may therefore be more optimistic than obstetric reports. However, obstetric series have also shown similar trends of improved survival. A report of neonatal outcomes among 799 nonanomalous infants born in 1992 to 1993 at 22 to 26 weeks in 11 American tertiary perinatal centers found that survival to 120 days was 2 percent at 21 weeks', 14 percent at 22 weeks', 26 percent at 23 weeks', 33 percent at 24 weeks', and 68 percent at 25 weeks' gestation.^[11] However, this study followed infants only until hospital discharge or 120 days of life, as shown in Table 23-1. Long-term follow-up was performed for a cohort of 138 nonanomalous infants born at 24 to 26 weeks' gestation between 1990 and 1994; 94 infants (68 percent) survived to hospital discharge. The increase in survival by week of gestation was dramatic, from 43 percent at 24 weeks to 74 percent at 25 weeks and 83 percent at 26 weeks^[12] (Table 23-2). When

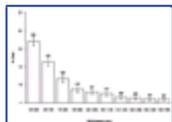

Figure 23-5 Mortality rate before discharge by birth weight among infants born in the NICHD NICU Network Centers between January 1, 1993, and December 21, 1994. Data expressed as number, percentage who died, and 95 percent confidence interval for each 100-g birth weight interval. (From Stevenson DK, Wright LL, Lemons JA, et al: *Very low birth weight outcomes of the National Institute of Child Health and Human Development Neonatal Research Network, January 1993 through December 1994. Am J Obstet Gynecol 179:1632, 1998.*)

759

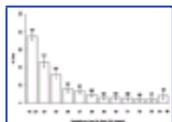

Figure 23-6 Mortality rate before discharge by gestational age, as estimated by best obstetric estimate among infants born in the NICHD NICU Network Centers between January 1, 1993, and December 21, 1994. Data expressed as number, percentage who died, and 95 percent confidence interval for each gestational age group. Thirty-six babies had missing gestational age data. (From Stevenson DK, Wright LL, Lemons JA, et al: *Very low birth weight outcomes of the National Institute of Child Health and Human Development Neonatal Research Network, January 1993 through December 1994. Am J Obstet Gynecol 179:1632, 1998.*)

When these infants were examined at a mean age of 32 months, developmental outcomes other than cerebral palsy were also related to gestational age at birth. The percentage who survived without neurologic deficit rose from 28 percent at 24 weeks' to 47 percent at 25 weeks' and 63 percent at 26 weeks' gestation^[13] (Table 23-3).

TABLE 23-1 -- OUTCOME AT 120 DAYS FOR INFANTS BORN WEIGHING LESS THAN 1,000 g ACCORDING TO GESTATIONAL AGE AT BIRTH

From Bottoms SF, Paul RH, Iams JD, et al: *Obstetric determinants of neonatal survival: Influence of willingness to perform cesarean delivery on survival of extremely low birth weight infants. Am J Obstet Gynecol 176:960, 1997, with permission.*

When data from the initial cohort of 138 fetuses are combined (Table 23-4), the same trends are evident. However, the percentage of intact survivors falls as a result of the inclusion of fetal, perinatal, and infant deaths. Because they include fetal and neonatal outcomes, these data may be the most appropriate for perinatal decision making before delivery (see last section of chapter). The survival rates cited in these studies

come from tertiary perinatal care centers, and do not necessarily reflect the experience in the general population. For example, a population-based study from the north of England described the outcome for births before 28 weeks between 1983 and 1994.^[14] As in the United States, survival increased over time, but the survival rates are much lower at the margins of viability. This is a reflection more of the broadly inclusive data-set (all births in a region of the country vs. selected births at regional centers) than of any differences in perinatal care between the United Kingdom and the United States. Data from the last 2 years of this report are shown in [Table 23-5](#).

Perinatal care can clearly influence mortality statistics. A study of 1126 infants who weighted between 501 and 800 grams at birth^[15] confirmed earlier observations,^[16] that in addition to birth weight (odds ratio [OR], 0.38; 95 percent confidence interval [CI], 0.29 to 0.49), variables such as female gender (OR, 0.42; 95 percent CI, 0.29 to 0.61), small for gestational age (OR, 0.58; 95 percent CI, 0.38 to 0.88), and antenatal

Data from Tin W, Wariyar U, Hey E, et al: Changing prognosis for babies of less than 28 weeks' gestation in the north of England between 1983 and 1994. *BMJ* 314:107, 1997.

treatment with corticosteroids (OR, 0.52; 95 percent CI, 0.36 to 0.76) have a favorable effect on mortality ([Fig. 23-7](#)). Neonatal treatment with surfactant (favorable effect) and intrauterine infection (unfavorable effect) also influence survival significantly.^[17]

Twins have in the past been thought to have higher rates of mortality than singletons born at the same gestational age, but recent reports from single institutions^[18] and from multicenter studies^[19] indicate rates of neonatal mortality and morbidity for liveborn twins that do not differ significantly from singletons born at the same gestational age.

There are significant but unexplained differences in survival and morbidity rates for LBW babies reported

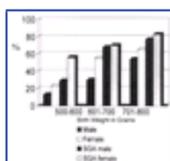

Figure 23-7 Intact survival by birth weight, SGA, and gender in extremely low birth weight infants. (Redrawn from Tyson JE, Younes N, Verter J, et al: Viability, morbidity, and resource use among newborns of 501- to 800-g birth weight. *JAMA* 276:1645, 1996. Copyright 1997 American College of Obstetricians and Gynecologists.)

by apparently similar neonatal intensive care units.^[20] Thus, when available, it is best to use local statistics when counseling patients.

Despite marked improvements in neonatal survival, the United States compares relatively unfavorably with other developed countries with respect to neonatal mortality. In the past, this poor international ranking was blamed on an excess of LBW infants at all gestational ages in the United States. However, a study^[21] of linked birth and perinatal death records from 105,084 Norwegian and 7,445,914 American births found that the higher rate of perinatal death in the United States is due almost entirely to a small excess of preterm births in the United States (2.9 percent) versus Norway (2.1 percent). The authors noted that a reduction in preterm delivery in the United States to the rate observed in Norway would produce the same perinatal mortality rate in both countries. They concluded that prevention of

perinatal mortality in the United States depends more on prevention of prematurity, especially extreme prematurity, than of low birth weight.

Preterm infants are at risk for specific diseases related to the immaturity of various organ systems. Common complications in these very premature infants include respiratory distress syndrome (RDS); intraventricular hemorrhage (IVH); bronchopulmonary dysplasia (BPD); patent ductus arteriosus (PDA); necrotizing enterocolitis (NEC); and sepsis, apnea, and retinopathy of prematurity (ROP). Extremely preterm infants are at greatest risk. There is wide geographic variation in the frequency of these sequelae, which may reflect differences in definitions as well as clinical practices. [29] Robertson et al. [23] reported gestational age-specific morbidities for 20,662 infants born from well-dated pregnancies, 1,539 of whom were born before 36 weeks. Rates of neonatal morbidities by gestational age are shown in Figure 23-8. [24]

Long-Term Morbidity

During the 1950s, preterm infants were found to be at increased risk for neurodevelopmental handicaps such as severe mental retardation (IQ or DQ [developmental quotient] <70), cerebral palsy, seizure disorders, blindness, and deafness. Since then, concern about long-term neurologic sequelae has focused on smaller and smaller infants of increasingly earlier gestational age. The rate of intact survival has steadily increased for VLBW and ELBW infants (Fig. 23-9). Despite fears to the contrary, the proportion of survivors within each birth weight group who have serious handicaps has not increased since the introduction of neonatal intensive care. However, the increased number of survivors has increased the absolute number of individuals who survive with long-term morbidities of prematurity. [23] [24] [25]

Long-term outcomes for infants with birth weights below 1,000 g have been reported as these children have reached adolescence. A 1994 study of school-age outcomes found higher rates of cerebral palsy, severe visual impairment, and reduced head size and height for children with birth weights under 750 g when compared with children with birth weights 750 to 1,499 g and children born at term (Fig. 23-10). [2] Abnormal cognitive, academic, visual motor, gross motor, and adaptive performance was also more frequent among children with birth weights below 750 g (Fig. 23-11). A study of 141 adolescents who weighed less than 1,000 g at birth reported significantly more self-perceived limitations in cognition, sensation, self-care, and pain at 12 to 16 years of age compared with controls. However, the median self-perceived health scores for subjects and controls were similar. [26] Among 72 adolescents born before 33 weeks and studied at 14 to 15 years of age, researchers found neurologic magnetic resonance imaging (MRI) abnormalities in 40. Abnormal MRI findings were significantly related to reading, adjustment, and neurologic impairment. [27] These reports describe children who were born before the introduction of surfactant and before the aggressive use of antenatal corticosteroids. A recent report described outcomes for ELBW infants born in 1993 to 1994 when surfactant was more commonly used. Factors significantly associated with neurodevelopmental disability among survivors at 18 to 22 months include chronic lung disease, grades 3 to 4 intraventricular hemorrhage and periventricular leukomalacia, necrotizing enterocolitis, male gender, lower maternal education, and nonwhite race. [28]

The relationship between prematurity and long-term morbidity is apparently more complex than can be explained only by immature organ systems. Recent clinical and pathologic studies have linked chorioamnionitis to neonatal morbidities other than neonatal infections, especially including cerebral palsy and bronchopulmonary dysplasia. [29] [30] [31] [32] [33] [34] [35] [36] [37] [38] [39] These investigations indicate that a chronic intrauterine inflammatory process is responsible not only for much of the neonatal morbidity traditionally attributed simply to prematurity, but for the occurrence of preterm birth itself in many cases. [30] Amniotic fluid cytokines have been related to neonatal brain lesions (e.g., IVH and periventricular leukomalacia) thought to be precursors for cerebral palsy, [29] [36] to the development of cerebral palsy, [39] and to bronchopulmonary dysplasia. [31] [32] Umbilical cord blood levels of interleukin-6 (IL-6) obtained at delivery have been found to predict neonatal brain lesions and subsequent cerebral palsy. [34]

In addition to prolonged hospitalization at birth, many VLBW infants are rehospitalized during the first year of life. [40] Although less well studied, there is concern that preterm birth disrupts maternal-infant bonding, which can have a major impact on family function,

762

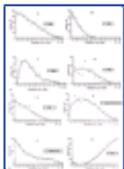

Figure 23-8 Incidence of various neonatal morbidities by gestational age at birth in infants born between 1982 and 1986 in a five-center prospective trial. A, Rates of respiratory distress syndrome (RDS; A), intraventricular hemorrhage (IVH; E), sepsis (C), and necrotizing enterocolitis (NEC; D). B, Rates of patent ductus arteriosus (PDA; A), hyperbilirubinemia (E), hypoglycemia (C), and of no morbidity (D). (From Robertson PA, Sniderman SH, Laros RK, et al: Neonatal morbidity according to gestational age and birth weight from five tertiary care centers in the United States 1983 through 1986. *Am J Obstet Gynecol* 166:1629, 1992, with permission.)

763

with increased likelihood of child abuse and family separation. Sudden infant death syndrome is also more frequent among prematurely born infants.

OVERVIEW OF THE PATHOGENESIS OF PREMATURITY

The Epidemiology of Preterm Birth

The list of maternal and fetal diagnoses antecedent to preterm deliveries is both long and diverse. Preterm labor, preterm ruptured membranes, preeclampsia, abruptio placentae, multiple gestation, placenta previa, fetal growth restriction, excessive or inadequate amniotic fluid volume, fetal anomalies, amnionitis, incompetent cervix, as well as maternal medical problems such as diabetes mellitus, asthma, drug abuse, and pyelonephritis may all lead to preterm delivery.

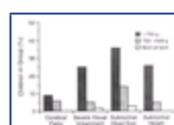

Figure 23-10 Percentage of children with cerebral palsy, severe visual impairment, subnormal head size, and subnormal height in infants born less than 750 g birth weight, 750 to 1499 g birth weight, and at term. (From Hack M, Taylor HG, Klein N, et al: School-age outcomes in children with birth weights under 750 g. *N Engl J Med* 331:756, 1994, with permission.)

associated with preterm delivery are equally numerous: maternal race (black greater than nonblack), a history of previous preterm birth, low socioeconomic status, poor nutrition, low prepregnancy weight, absent or inadequate prenatal care, age less than 18 or over 40, strenuous work, high personal stress, anemia, cigarette smoking, bacteriuria, genital colonization or infection (e.g., bacterial vaginosis, *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, *Mycoplasma*, and *Ureaplasma*), cervical injury or abnormality (e.g., in utero exposure to diethylstilbestrol, a history of cervical conization, or second-trimester induced abortion), uterine anomaly or fibroids, excessive uterine contractility, and premature cervical dilation of more than 1 cm or effacement greater than 80 percent. The list of risk factors is so long that it is hard to see any common thread.

The multitude of clinical disorders and risk factors has been usefully organized into two broad categories, called *spontaneous* and *indicated* preterm births, based upon the clinical presentation, the health of the mother

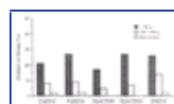

Figure 23-11 Percentage of children with subnormal cognitive function, academic skills, visual and gross motor function, and adaptive function in infants born less than 750 g birth weight, 750 to 1499 g birth weight, and at term. and fetus, and the epidemiologic profile of affected pregnant women.^{[41] [42] [43] [44]} Approximately 75 percent of preterm births occur "spontaneously" after preterm labor (PTL), preterm premature rupture of membranes (preterm PROM), or related diagnoses such as amnionitis and incompetent cervix (PROM refers to rupture of membranes before the onset of labor at any gestational age, hence the apparently redundant "preterm PROM"). Complications of PTL and preterm PROM may lead to an "indication" for delivery (e.g., intrauterine infection), but these births are nevertheless termed "spontaneous" because they follow spontaneous preterm labor or preterm PROM. Risk factors for PTL and preterm PROM are similar, with a few exceptions. Women with preterm PROM are more likely to be indigent,^[41] to smoke,^[45] and to have experienced bleeding in the current pregnancy^[46] than are women who present with preterm labor.

Indicated preterm births follow medical or obstetric disorders that place the fetus at risk (e.g., acute or chronic maternal hypertension, diabetes mellitus, placenta previa or abruption, and intrauterine growth restriction). Indicated preterm births account for 20 to 30 percent of births before 37 weeks in most series.^{[42] [43]} Some risk factors are associated with both spontaneous and indicated prematurity (e.g., multiple gestation, prepregnancy weight <55 kg, nulliparity, black race, and bleeding in the first or second trimester), and some clinical risk factors are primarily related to one or the other (Table 23-6).

The distinction between spontaneous and indicated preterm births rests on an assumption that fetal growth

Indicated and spontaneous preterm birth. *Am J Obstet Gynecol* 173:597, 1995; Meis PJ, Goldenberg RL, Mercer BM, et al: The preterm prediction study: Risk factors for indicated preterm birth. *Am J Obstet Gynecol* 178:562, 1998; Goldenberg RL, Iams JD, Mercer BM, et al: The preterm prediction study: The value of new vs. standard risk factors predicting early and all spontaneous preterm births. *Am J Public Health* 88:233, 1998.

and well-being have been satisfactory before the spontaneous occurrence of preterm labor or PROM. Most data support this premise, but poor intrauterine growth may be more common in preterm infants, even in the absence of apparent maternal disease.^{[47] [48] [49]} These clinical observations have been supported by studies that showed decidual and placental vascular lesions^{[50] [51] [52]} and increased impedance in the uterine arteries^[53] of women who delivered after preterm labor.

Fetal stress may initiate preterm labor by uteroplacental production of corticotropin-releasing hormone (CRH), a peptide produced by the placenta, amniochorion, and decidua and known to enhance prostanoic acid production in these same cells.^[54] These reports provide a biologically plausible mechanism by which abnormalities of the placenta and uteroplacental blood flow may lead to spontaneous preterm birth, either directly, through decidual and/or membrane injury, or indirectly by inducing fetal stress.

The Epidemiology and Pathogenesis of Spontaneous Preterm Birth

Just as epidemiologic observations provide clues to the distinction between the causes of spontaneous and indicated preterm births, so also does epidemiology provide clues to pathogenesis of spontaneous prematurity. Ultimately, the final steps of the parturitional process are the same at any gestational age, regardless of the initiating cause. Whether preterm parturition is just normal labor that is initiated too soon, or follows a distinctly different pathway until the final stages of labor, has been the subject of great debate. Increasingly, the evidence favors the latter interpretation, with several pathologic processes capable of initiating the process.

The epidemiology of preterm birth reveals several major trends. The first is that early preterm birth (<32 weeks) and late preterm birth (>32 weeks) have a different epidemiology. Another is that some risk factors are associated with recurrent preterm birth, while others appear to be unique to the affected pregnancy.^[44] Risk factors for recurrent and nonrecurrent preterm birth are similar but not identical to those for early and later prematurity, respectively, suggesting at least two general pathways. Early preterm birth is more likely to recur, is more strongly associated with a short cervix and the presence of fetal fibronectin in cervicovaginal secretions, and is more often accompanied by clinical or subclinical evidence of infection and by long-term morbidity for the infant.^[44] Later preterm birth is more likely to be associated with increased uterine contraction frequency and with a rise in maternal excretion of estriol (an indicator of increasing maturation of the fetal hypothalamic-pituitary-adrenal axis), and thus to mimic normal labor at term.^[55]

Nonrecurrent Preterm Birth

Risk factors for nonrecurrent spontaneous preterm birth include second-trimester bleeding, abnormal amniotic fluid volume, multiple gestation, substance abuse, and trauma. These events have in common that they may lead to ischemia, injury, or disruption to the junction of the maternal decidua with the fetal chorion. Premature contractions or membrane rupture may result from decidual hemorrhage with thrombin generation, which in turn may stimulate uterine contractions and proteases that affect membrane integrity (see the section Preterm Premature Rupture of the Membranes, below).

Excessive uterine volume, as may occur with polyhydramnios or multiple gestation, is another pathway to increased uterine activity via increased formation of gap junctions, oxytocin receptors, and prostaglandin and collagenase production.

There is increasing evidence, however, that preterm birth in multiple gestation is more complex than can be explained simply by uterine distention. Women who carry a multifetal gestation beyond 34 weeks are more likely to have conceived spontaneously (without assisted reproductive technology)^[56] and to have a cervical length above the 50th centile at 24 to 26 weeks' gestation.^[57] Increased levels of maternal serum relaxin following superovulation^[58] and the potential for intrauterine inoculation with vaginal microorganisms during cervical instrumentation are potential mechanisms under investigation.^[59] Also, spontaneous or induced fetal loss in higher order multiple gestation has been associated with an increased risk of preterm birth, perhaps mediated by decidual hemorrhage or necrosis.

Recurrent Preterm Birth

Recurrent spontaneous preterm birth is associated with prior preterm births, especially before 32 weeks, African-American race, maternal genital tract infection, maternal cervical length less than the 10th percentile, and the presence of fetal fibronectin in cervicovaginal mucus.^{[44] , [60] [61] [62] [63]} The interrelationship of these risk factors has begun to explain some of the mechanisms of preterm delivery.

Obstetric History and Preterm Birth

The risk of spontaneous preterm birth is increased by a history of prior preterm delivery. The recurrence risk rises as the number of prior preterm births increases.^[64] As can be seen in [Table 23-7](#), the most recent birth is the most predictive. The likelihood of recurrent preterm birth also increases as the gestational age of the prior preterm birth decreases. The earlier the prior preterm birth, the greater the recurrence risk.^[62] A population-based

cohort study of births over 15 years in Georgia found that, of second deliveries between 20 and 31 weeks' gestation, 29.4 percent for white and 37.8 percent for black women were preceded by a preterm delivery.^[63]

The biologic variable most consistently related to recurrent spontaneous preterm birth is cervical length when measured by transvaginal sonography.^{[44] , [60] , [61]} These reports suggest that cervical function is at least in part a constitutional factor that influences preterm birth risk in successive pregnancies.

Maternal Race and Preterm Birth

African-American women have a rate of preterm delivery that is approximately twice that of women of other races. In 1996, 16.3 percent of non-Hispanic black women delivered before 37 completed weeks' gestation, compared with 10.1 percent for Hispanic women and 8.1 percent of non-Hispanic white women.^[65] Although the rate of preterm birth declines with advancing education among African-Americans, it is higher than the rate among nonblack women at all educational levels. In fact, the ratio of black to white preterm birth rates in 1995 was 1.95 for women with some college education and 1.74 for women who did not finish high school.^[66] Black women born outside the United States do not share this increased risk of preterm delivery.^[67]

Sociodemographic factors also do not explain the higher rate of preterm birth in U.S.-born African-American women. A study of 1,029 black and 462 white parous indigent women in Alabama found that black women delivered preterm and low-birth-weight infants more frequently than white women, even though white indigent women in the population studied had greater sociodemographic risk. [68] One small study of 125 women suggested that cervical length might be an explanation for the observed racial differences. [69] However, among 2,929 women in the Preterm Prediction

Data from Iams JD, Goldenberg RL, Meis PJ, et al: *The length of the cervix and the risk of spontaneous premature delivery. N Engl J Med 334:567, 1996.*

Study, cervical length was related to preterm birth but not to race [70] (Table 23-8). This study controlled for bacterial vaginosis in relating cervical length to preterm birth, an important consideration because bacterial vaginosis is itself related to risk of preterm birth [44] and to cervical length. [71]

The higher prevalence of bacterial vaginosis among African-American women is a potential explanation for racial differences in preterm birth rates. A series of studies have linked bacterial vaginosis to preterm birth, particularly among African-Americans. The Vaginal Infections in Pregnancy (VIP) Study, a large observational study of vaginal microflora in pregnancy, found organisms associated with bacterial vaginosis more often in black women, even when differences in health behaviors were controlled. [72] The Preterm Prediction Study [44] revealed that the relationships between preterm birth, black race, and bacterial vaginosis (BV) were mediated by fetal fibronectin. The relation between preterm birth before 32 weeks and bacterial vaginosis was significant only in black women, where the population-attributable risk for BV was 40 percent for births before 32 weeks. In contrast, for nonblack women, a low body mass index (<19.8 kg/m²) had the strongest association with early preterm birth. [44]

Infection and Prematurity

The association between preterm birth and infection has been reported for more than 50 years. [73], [74] Evidence relating infection to preterm labor and birth comes from multiple sources: epidemiologic, microbiologic, histologic, and clinical. Maternal and neonatal infections occur more frequently after preterm than term birth. Numerous microorganisms, including *Ureaplasma urealyticum*, *Mycoplasma* species, *Chlamydia trachomatis*, *Trichomonas*, *Escherichia coli*, group B *Streptococcus*, and especially anaerobes such as *Fusobacterium*, *Bacteroides*, anaerobic streptococci, and *Mobiluncus*, have been recovered from the lower and upper genital tract and amniotic fluid of women with preterm labor and preterm ruptured membranes. [75] [76] [77] [78] [79] [80] [81] [82] [83]

The strength of the association between both clinical infection and histologic amnionitis increases as the gestational age at delivery decreases, especially before 30 to 32 weeks. A study of placental histology revealed that membrane inflammation was nearly universal at 21 to 24 weeks and declined as gestational age advanced to a rate of 10 percent at term. [79] In a study that related cultures of the fetal membranes to gestational age at delivery, positive cultures were found in more than 70 percent of births before 30 weeks compared with 20 percent at term. [79] Positive amniotic fluid cultures have been reported in 20 to 30 percent of women with preterm labor, especially before 30 weeks' gestation and when the labor is refractory to tocolytic drugs. [75] [76] [77], [83] The same inverse relationship between gestational age and positive amniotic fluid cultures was reported in study of amniotic fluid cultures obtained from women with preterm labor who did not have overt clinical chorioamnionitis [83] as shown in Figure 23-12. The most common organisms recovered were *Fusobacterium nucleatum*, *Bacteroides* species, and *Ureaplasma urealyticum*. Another study (Fig. 23-13) (Figure Not Available) [84] found that both positive membrane cultures and increased amniotic fluid

IL-6 levels occurred more frequently in spontaneous than indicated preterm births. [84]

Infections outside the genital tract have also been related to preterm birth, most commonly urinary tract and intra-abdominal infections (e.g., pyelonephritis and appendicitis). Recently, maternal periodontal infections have been associated with increased risk of spontaneous preterm birth. [85]

Pregnant women treated with antimicrobial drugs effective against *Ureaplasma*, *Mycoplasma*, and *Chlamydia* had reduced rates of preterm birth in some studies. [86] [87] [88] However, prospective trials of the same antibiotics to prevent preterm birth in women colonized with *Ureaplasma* and *Chlamydia* found no difference in the incidence of premature delivery [89], [90] (Table 23-9). The failure of these trials fostered reconsideration of the relationship between infection and prematurity, and particularly of the association between maternal BV and spontaneous preterm birth. [79] [80] [81], [91], [92] Rather than a specific infection caused by a single organism, BV is an alteration of the maternal vaginal flora in which gram-negative anaerobic bacteria and *Mycoplasma* species largely replace the normally predominant lactobacilli. The association between BV and prematurity has been noted in microbiological, histological, and clinical studies. In a report from the Vaginal Infections and Prematurity Study, maternal bacterial vaginosis with mycoplasma and bacteroides colonization was significantly related to low birth weight (OR, 2.1; 95 percent CI, 1.5 to 3.0) but neither organism was related to low birth weight when BV was not present. [92] The authors cited other work showing an association between BV and elevated levels of endotoxin, IL-1, mucinase, and sialidase, and suggested that BV may result in the production of cytokines with biologic effects on the uterus, cervix, and membranes.

Two prospective trials of antibiotic treatment reported reduced rates of preterm birth in women who had a history of preterm birth and BV, but there was no benefit for women who had either risk factor alone. [93], [94] However, the rate of preterm birth was not affected by treatment with metronidazole in a placebo-controlled trial that enrolled 1,900 women with asymptomatic bacterial vaginosis. [95] The rates of birth before 37, 35, and 32 weeks were not reduced by treatment, nor were the rates of LBW or VLBW infants. Analysis of subsets of women according to their obstetric history of preterm birth, race, gestational age at initiation of treatment, eradication of BV, and prepregnancy weight did not reveal any subgroup for whom the antibiotic produced a reduced preterm birth rate. Remarkably, a

Figure 23-14 (Figure Not Available) Potential pathways from choriodecidual bacterial colonization to preterm delivery. (From Goldenberg RL, Hauth JC, Andrews WW: *Intrauterine infection and preterm delivery*. *N Engl J Med* 342:1500, 2000, with permission.)

companion study conducted simultaneously in women with *Trichomonas vaginalis* reported an increase in the rate of preterm birth in those randomized to receive metronidazole.^[99]

These trials indicate that the relationship between infection and prematurity is more complex than can be

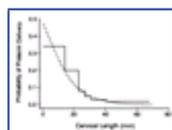

Figure 23-15 Estimated probability of spontaneous preterm delivery before 35 weeks' gestation from the logistic regression analysis (dashed line) and observed frequency of spontaneous preterm delivery (solid line) according to cervical length measured by transvaginal ultrasonography at 24 weeks. (From Iams JD, Goldenberg RL, Meis PJ, et al: *The length of the cervix and the risk of spontaneous premature delivery*. *N Engl J Med* 334:567, 1996, with permission.)

explained by the ascent of organisms from the lower to the upper genital tract during pregnancy. Recent research has examined the roles played by host defense, including the cervix and the maternal and fetal immune response, in the occurrence of preterm birth. Andrews and Goldenberg have argued that microorganisms responsible for preterm birth, especially early, recurrent preterm birth, are actually present in the endometrium before conception, and become clinically manifest as preterm labor, PROM, or even incompetent cervix only in the second and early third trimester.^[97] The pathways by which intrauterine infection may lead to spontaneous preterm birth are indicated in Figure 23-14 (Figure Not Available).^[98]

Cervical Length

The length of the uterine cervix as measured by transvaginal ultrasonography is inversely and continuously related to the risk of preterm birth in both singleton^[99] and multiple gestation.^[100] The shorter the cervical length at 18 to 28 weeks' gestation, the greater the risk of spontaneous prematurity^[99],^[101],^[102] (Fig. 23-15). This relationship has been observed throughout the entire range of cervical length, not only for cervical length below the 10th percentile (Fig. 23-16). Cervical length is also strongly related to a history of spontaneous preterm birth, especially before 32 weeks' gestation. In one study, the gestational age at delivery in prior pregnancies was related to cervical length in a subsequent

769

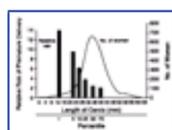

Figure 23-16 Distribution of subjects by percentile of cervical length measured by transvaginal sonography at 24 weeks (solid line) and relative risk of spontaneous preterm birth before 35 weeks according to percentiles of cervical length (bars). Relative risk of spontaneous preterm delivery for women at the 1st, 5th, 10th, 25th, 50th, and 75th percentiles are compared with the risks among women with cervical lengths above the 75th percentile. (From Iams JD, Goldenberg RL, Meis PJ, et al: *The length of the cervix and the risk of spontaneous premature delivery*. *N Engl J Med* 334:567, 1996, with permission.)

pregnancy: the earlier the gestational age at delivery, the shorter the cervix in the next pregnancy.^[60] Cervical length is also related to the risk of recurrent preterm birth.^[61],^[103] For women with a prior preterm birth, the likelihood of recurrent preterm birth before 35 weeks fell from 31 percent when the cervical length at 24 weeks was 25 mm or less to 16 percent when the cervical length was 26 to 35 mm, and to 8 percent when the cervical length was 36 mm or more (>50th centile). In contrast, among women whose only prior birth(s) were at term, the rate of birth less than 35 weeks was 8 percent when the cervix was 25 mm or less, 4 percent when it was 26 to 35 mm, and 2 percent when it was 36 mm or more.^[61]

The correlation between cervical length and preterm birth risk may be explained by the physical strength or resistance of the cervix to factors such as intrauterine weight or volume, biochemical influences arising from infectious or other inflammatory stimuli,^[71],^[105],^[106] or biophysical effects of uterine activity. Whatever the explanation, these investigations indicate that cervical length is a marker for cervical competence, and that cervical competence operates as a continuum. These data contradict the previous understanding of the cervix as a categorical rather than a continuous variable (i.e., either competent or incompetent). If the cervix has degrees of "competence," then cervical incompetence is simply the lowermost end of a spectrum.^[99] That cervical length is related to gestational age at delivery in both previous and future pregnancies indicates that cervical length is an independent risk factor for prematurity.^[104]

Fibronectin

Fibronectin is an extracellular matrix protein that is best described as the "glue" that attaches the fetal membranes to the underlying uterine decidua.^[107] Fibronectin is normally found in the cervicovaginal secretions before 20 to 22 weeks of pregnancy, and again at the end of normal pregnancy as labor approaches. It is not normally present in cervicovaginal secretions between 22 and 37 weeks. The presence of fibronectin in cervicovaginal secretions after 22 weeks is a marker of disruption of the decidual-chorionic interface. In the NICHD Preterm Prediction Study, multivariate analysis revealed that the strongest predictors of spontaneous preterm birth (SPTB) were cervicovaginal fibronectin,^[108] transvaginal sonographic cervical length,^[99] an obstetric history of previous preterm birth,^[109] and presence of BV,^[91] respectively. Fibronectin status at 22 to 24 weeks was strongly correlated with the presence of BV and with subsequent histologic chorioamnionitis, postpartum endometritis, and neonatal sepsis.^[110] Almost all BV-positive women who delivered before 32 weeks were fibronectin positive at 22 to 24 weeks, suggesting that BV

either causes or is a marker for disruption of the choriodecidual interface.^[44] The relative risk of preterm birth before 32 weeks was 14.1 (CI 9.3, 21.4) for fibronectin-positive versus -negative women, compared with 2.7 (CI 1.6, 4.6) for BV-positive versus -negative women. Among women with lower tract BV, the presence of fibronectin in cervical and vaginal fluid therefore distinguishes women with upper tract infection from those with only lower tract colonization, and thus to identify those with the highest risk of early preterm birth. Why do some women with BV have upper tract involvement while others do not? The difference may lie in the timing of upper tract colonization, in the maternal and fetal immune response to the presence of organisms in the uterus, or both.

Clear linkages between the most consistent risk factors for preterm birth have emerged from recent research and produced alternate explanations for prematurity that begin with the observation that maternal lower genital tract colonization is much more common than upper tract colonization, and both are more common than preterm birth. Older hypotheses to explain the presence in the upper genital tract of microorganisms from the lower tract have had to be reexamined. Theories that begin either with idiopathic uterine contractions that open the cervix to allow ascent of organisms into the uterus^[111] or with cytokines produced in the decidua that initiate prostaglandin production leading to cervical ripening and uterine contractions have

been challenged by reports that suggest an indolent role for microorganisms in the pathogenesis of preterm birth. An ascending route from the vagina through the cervix is consistent with reported relationships between spontaneous preterm birth and cervical dilation.^{[112] [113] [114]} and length.^{[99] , [101]} However, reports indicating that intrauterine colonization and infection precede cervical effacement and dilation suggest another explanation for the presence of microorganisms within the uterus, based in part on a report of chronic plasma cell endometritis in endometrial biopsy specimens from 10 of 22 women with BV, compared to only 1 of 19 controls (OR, 15; 95 percent CI, 2 to 686).^[115] Chronic intrauterine colonization of the endometrium with BV before conception, with subsequent proliferation of these low-virulence organisms within the uterus in the altered immune environment of pregnancy is an attractive theory to explain the above reports that relate BV and fibronectin to preterm birth risk. This pathway is further supported by observations of increased levels of cytokines released in response to infection^{[116] , [117]} or ischemia^[118] in amniotic fluid samples obtained at midtrimester genetic amniocentesis from women who experienced spontaneous preterm labor weeks later.

The Spontaneous Preterm Birth Syndrome

When information about fibronectin, cervical length, maternal infection, and second-trimester amniotic fluid cytokines are considered together with data presented earlier in the chapter about intrauterine infection and neonatal morbidity, a model of early preterm birth as an indolent rather than acute process emerges.^[119] Romero et al. have termed this the "preterm labor syndrome".^[120] In response to a chronic intrauterine inflammatory insult (usually infectious or ischemic), and influenced by both the maternal and fetal immune response,^[30] the fetal membranes and decidua produce cytokines (tumor necrosis factor- [TNF-], IL-1, and IL-6). This cytokine-mediated process ultimately leads to one or more of the following: (1) continued leakage of fetal fibronectin from the decidua-membrane interface, (2) elaboration of uterotonic bioactive lipids (prostaglandin E₂ [PGE₂], prostaglandin F₂ [PGF₂], thromboxane A₂, leukotrienes B₄ and C₄,^[121] hydroperoxyeico-satetraenoic acid [5-HETE] and others) that (3) stimulate myometrial contractions and (4) initiate release of proteases that are capable of injuring the membranes and underlying decidua that (5) incites prostaglandin stimulation that results in (6) cervical ripening, dilation, and/or membrane rupture, and (7) in utero injury to the fetal brain, lung, or gut.

In this model, most women with microorganisms in the lower or upper tract or other sources of inflammation experience neither preterm birth nor neonatal morbidity. That some do while most do not may be attributed to differences in behavioral (physical or sexual activity, smoking) and/or genetic (e.g., cervical length, immune response) factors or both.

Other potential initiators of the process may include premature activation of the maternal-fetal hypothalamic-pituitary axis and/or pathologic uterine distention (as shown in Fig. 23-17) (Figure Not Available),^[122] both of which are more likely to cause later preterm births and less likely to cause major neonatal neurologic morbidity.

PREVENTION AND TREATMENT OF PRETERM BIRTH

Prevention and treatment strategies for prematurity may be described according to the public health concepts of primary, secondary, and tertiary care. ^[119], ^[123] *Primary* care or prevention is the elimination or reduction of risk in an entire population. Effective primary care requires a good understanding of the pathophysiology of the disease, and public health educational efforts to modify behaviors and eliminate risk factors. For preterm birth, the target population is clear (preteens and women of childbearing age), but effective primary interventions have not been demonstrated. A primary program to reduce the incidence of prematurity might include efforts to prevent smoking and sexually transmitted diseases, to avoid unplanned pregnancies through use of birth control, to plan pregnancy to reduce stress and improve nutrition, to avoid higher order multifetal gestation, and to foster employment policies that promote the needs of pregnancy over the workplace. ^[124], ^[125] *Secondary* care selects individuals with increased risk for surveillance and/or prophylactic treatment. Effective secondary care requires both accurate screening tests and effective interventions to prevent or reduce risk. Examples of secondary care for preterm birth are screening for preterm birth risk, early diagnosis and patient education programs, prophylactic medications (e.g., tocolytic drugs, progesterone supplementation, or antibiotics) and lifestyle changes such as reduced physical or sexual activity. Unfortunately, none of these has led to a decline in prematurity. ^[126] *Tertiary* care is treatment of an individual patient after an index illness has occurred. Tertiary care has no effect on the incidence of the disease, but rather is aimed at reducing morbidity and mortality after the diagnosis has been made. For preterm birth, tertiary care includes prompt and accurate diagnosis, referral to an appropriate care site, and specific treatment (e.g., tocolytic drugs to arrest preterm labor, antibiotics for group B -hemolytic streptococcal

771

Figure 23-17 (Figure Not Available) Major pathogenic pathways of preterm delivery resulting in preterm rupture of membranes, preterm labor, or both. HPA, hypothalamic-pituitary-adrenal; CRH, corticotropin-releasing hormone; E₁, estrone; E₃, estriol; TNF, tumor necrosis factor; IL-1, IL-6, and IL-8, interleukins-1, -6, and -8, respectively; PG, prostaglandin. *Activation of the maternal and/or fetal HPA axis:* Maternal and fetal stress lead to increased expression of placental-amniochorion-decidual CRH and placental estrogen expression. CRH enhances PG production in placental-amniochorion-decidual cells, while estrogens activate the myometrium. *Inflammation:* Ascending genital tract and severe systemic infections lead to activation of genital tract cytokine networks generating IL-1 and TNF-1, which enhance production of myometrial-decidual-amniochorionic-cervical uterotonins (i.e., prostaglandins, endothelins, leukotrienes) and proteases (e.g., matrix metalloproteinases-collagenases, plasmin). These parturition effects are amplified by IL-1-TNF-mediated induction of (a) IL-6, which further enhances PG production; and (b) IL-8, a granulocyte chemotactant and activator, which causes the release of elastases and collagenases. *Decidual hemorrhage:* Abruptions lead to local generation of thrombin, which binds to cellular receptors in the decidua to enhance local protease and PG production. *Pathologic uterine distention:* Multifetal gestation, hydramnios, and uterine abnormalities resulting from diethylstilbestrol exposure and congenital müllerian duct defects promote excessive stretching of the fetal membranes, the myometrium, or both, which causes myometrial activation (enhanced gap junctions, oxytocin receptors, PGF₂, synthase) and fetal membrane cytokine (IL-8) production. *Final common pathway:* Each of these four pathogenic mechanisms has a unique set of biochemical initiators but shares a final common pathway: enhanced expression of fetal membrane, decidual, and cervical proteases and uterotonins (e.g., prostaglandins). This leads to membrane rupture, cervical change and progressive uterine contractions, and preterm delivery. (From *The American College of Obstetricians and Gynecologists. Preterm labor and delivery. Precis: Obstetrics, 2nd ed. Washington, DC, 1999. Copyright ACOG, 1999, with permission.*)

sepsis prophylaxis or amnionitis, and corticosteroids to reduce neonatal mortality and morbidity).

Prevention: Secondary Care of Preterm Birth

Secondary care strategies require identification of pregnancies at risk and effective interventions to prevent or reduce the morbidity of preterm birth. There has been more progress on the former than the latter. Care of prematurity as a clinical problem to be solved has been described either as a pointless exercise: "Only when the factors causing prematurity are clearly understood can any intelligent attempt at prevention be made" ^[6] or as a social problem beyond the purview of obstetricians: "I do not think that . . . prematurity can be reduced . . . by better obstetrics These problems are social, not obstetric." ^[127] These sentiments were challenged as unduly nihilistic by some ^[128], ^[129] who argued that premature birth could be addressed proactively, even though the pathophysiology is not entirely clear, and despite the frustrating social correlates that so often accompany preterm birth. Although screening and intervention programs have not been effective in

772

reducing preterm birth in this country, ^[128] researchers have continued to look for tests that can identify women with increased risk and for therapies to reduce that risk. ^[130] ^[131] ^[132]

Clinical Risk Factors for Preterm Birth

Because clinical risk factors for spontaneous preterm birth have relatively high prevalence but low sensitivity and positive predictive value, efforts to create scoring systems to identify pregnancies at risk have faltered. ^[133] ^[134] ^[135] ^[136] Scoring systems for preterm birth risk have been abandoned by most centers as insensitive. Nevertheless, women with these major risk factors should be considered to be at risk of preterm birth:

1. *Prior preterm delivery.* A history of prior preterm birth between 16 and 36 weeks carries a three- to fourfold increase in risk of recurrent preterm birth. The magnitude of risk increases as the gestational age of the previous preterm birth decreases. ^[63], ^[109]
2. *Multiple gestation.* Twin pregnancies are five to six times more likely than singletons to deliver preterm. Higher order multiples have even higher risk of prematurity. Twins account for 2 to 3 percent of births, but 12 percent of preterm births and 15 percent of neonatal mortality. ^[137] The increased number of pregnancies achieved with assisted reproductive technologies has produced a significant increase in twin and higher order multiple gestations. ^[3], ^[4]
3. *Low prepregnancy weight* manifested by a body mass index below 19.8 kg/m² has been consistently associated with preterm delivery, particularly in white women. ^[44], ^[136], ^[138]
4. *Vaginal bleeding in the second or third trimester* has been reported to have a relative risk for preterm birth ranging from 1.6 ^[136] to as much as 15, ^[46] especially for preterm prematurely ruptured membranes.

These historical risk factors are easily elicited, but identify less than half of women who will deliver prematurely. Just as screening for preeclampsia is part of routine prenatal care, all pregnant women should receive care and education aimed at the problem of prematurity. Other possible risk factors that have been studied as screening tests for preterm birth risk include uterine contraction frequency, digital and ultrasound examination of the cervix, vaginal microbiology, serologic markers, and the presence of fetal fibronectin in cervicovaginal secretions.

Uterine Contractions

Uterine activity increases as pregnancy progresses ^[139], ^[140] and is slightly more frequent in women destined to deliver prematurely. ^[139], ^[141] A cross-sectional study of

uterine activity recorded during antenatal fetal heart rate testing in 2,446 women after 30 weeks found that uterine activity increased by 4.7 percent per week.^[139] Women who delivered preterm had more and those who delivered postterm had fewer contractions per 10-minute window of observation. A longitudinal study^[140] of 109 normal women who recorded 24-hour uterine activity profiles twice a week between 24 weeks and delivery found that no contractions were recorded in 73 percent of monitored hours; 96 percent of hours had fewer than four contractions per hour (Fig. 23-18). Contraction frequency was similar in nulliparous and parous subjects. Contraction frequency was increased at night and with gestational age. The 95th percentile of uterine activity was 1.3 ± 0.5 (SD) contractions per hour at 21 to 24 weeks, 2.9 ± 1.0 at 28 to 32 weeks, and 4.9 ± 1.7 at 38 to 40 weeks ($p < 0.0001$). The night/day ratio of contractions per hour was 1.8:1 at 21 to 24 weeks, 2.3:1 at 28 to 32 weeks, and 2.0:1 at 38 to 40 weeks ($p < 0.001$). A few women recorded more than 15 contractions per hour, yet delivered at term without intervention. Contraction frequency decreased after recumbency and increased after coitus.

Another longitudinal study compared uterine activity in 254 women with historical risk factors for preterm birth and 52 low-risk women.^[141] Contraction frequency did not differ according to risk status, but women destined to deliver preterm had more contractions than did women delivered at term. Although statistically significant, the difference was too small to be clinically valuable. The sensitivity and positive predictive value of contraction frequency to predict preterm birth before 35 weeks were both less than 25 percent. Sensitivity for and prediction of birth before 32 weeks were even lower.

Initial hopes that ambulatory monitoring of contractions could select women with increased risk of preterm

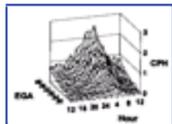

Figure 23-18 Mean hourly frequency of monitored uterine contractions by gestational age and time of day in 109 normal pregnant women who delivered at term after uncomplicated pregnancies. 773

birth for further diagnostic assessment or treatment to reduce the incidence of preterm birth have not been fulfilled, perhaps because of the low sensitivity and predictive value of contraction frequency. Numerous studies^{[142] [143] [144] [145] [146] [147] [148] [149]} and analyses^{[150] [151] [152] [153] [154]} of this strategy have been performed with variable results. The definitive assessment of ambulatory contraction monitoring was provided by a large trial published in 1998. Dyson et al.^[155] enrolled 2,422 women with risk factors for preterm birth. Subjects were assigned randomly to receive weekly contact with a nurse, daily contact with a nurse, or daily contact with a nurse together with uterine contraction monitoring. There were no differences in the occurrence of preterm birth before 35 weeks, in cervical dilation at the diagnosis of preterm labor, or in any neonatal outcomes. The failure of the contraction detection and suppression strategy to reduce the rate of preterm delivery is instructive. First, although contraction frequency is increased in women destined for preterm birth, this association did not translate into an effective screening test. Second, the theory behind this strategy may be false. If premature labor begins with excessive uterine contractile activity, then early detection and suppression of contractions should have been an effective strategy. The inability to demonstrate benefit for contraction detection and suppression indicates either that this theory is incorrect, or that it is applicable to relatively few cases of preterm labor. As will become evident in the following paragraphs, these same observations may be made about other prematurity prevention strategies.

Cervical Examination

An association between preterm delivery and cervical dilation of 2 cm or more and/or effacement of 80 percent or more has been reported in several studies.^{[112] [113] [114] [136]} As with uterine contractions, however, the observation of an association has not led to a reduced incidence of preterm delivery. A randomized study^[156] found no difference in rates of preterm birth among 2,803 women who were followed with serial cervical exams as compared with 2,799 women in whom examination was not routinely performed.

Digital examination of the cervix is reasonably accurate in active labor, but is subject to great interexaminer variation when dilation is less than 3 cm and/or effacement is less than 80 percent.^[157] Endosonographic measurement of the cervix is more reproducible than digital or transabdominal examination.^{[158] [159]} Moreover, this technique has provided information not previously available about the nature and timing of cervical changes preceding delivery (see also later section regarding cervical competence). The cervix effaces or thins from the internal os caudad toward the external os. The length of the cervix varies normally in the second trimester from less than 1 cm (below the first percentile) to values in excess of 4.5 cm, above the 95th percentile, with a median value of about 3.5 cm.^[70] The risk of preterm birth increases as cervical length decreases throughout the entire range^{[70] [101]} (Fig. 23-15) and (Fig. 23-16). Not only do women with the shortest cervical length have the greatest risk of preterm birth, but those whose cervical length is at the 50th percentile have more risk than do women whose cervical length is above the 75th percentile.^[70] A comparison of digital and ultrasonographic assessment of the cervix at 24 weeks to predict spontaneous preterm birth before 35 weeks is shown in the Table 23-8, using data from the NICHD MFMU Preterm Prediction Study.^[70] The data in the table indicate that neither test is an especially sensitive predictor of preterm birth, nor is sonography superior to a carefully performed Bishop score to predict risk. However, sonographic cervical length was significantly more reproducible than either Bishop score or funneling in this study. As expected, the positive predictive values rise as the cervical length threshold declines, accompanied by a corresponding decline in sensitivity.

Although cervical sonography has been useful in redefining the contribution of cervical factors to the pathogenesis of early preterm birth, there is no evidence that interventions such as maternal rest or cerclage based on a finding of a short cervix can be translated into a reduced rate of preterm birth. One nonrandomized study found fewer births after 32 weeks among 42 women with cervical length less than or equal to 1.5 cm at 23 weeks who were treated with cerclage compared with expectant management, but there was no significant difference in neonatal survival.^[160] In another study of endovaginal sonography conducted in 97 women with a history of preterm birth, both a cervical length less than 25 mm and a funneling of the internal os were strongly correlated with preterm birth (relative risk, 4.8; 95 percent CI, 2.3 to 10.1).^[161] The incidence of preterm birth and interval from detection of cervical changes to delivery was not different for those treated by cerclage compared with expectant management. Finally, neither of two recent randomized trials of cerclage in women treated on the basis of obstetric history and cervical sonography found an advantage for the cerclage group.^{[162] [163]}

Genital Colonization with Microorganisms

The association of maternal colonization with various genital microorganisms and risk of preterm birth has led to investigations of screening tests to identify and treat women at risk. In the VIP Study,^{[89] [164]} parturients who were culture positive for various microorganisms were randomly assigned to receive placebo or antibiotic treatment (Table 23-9). No reduction in preterm birth was associated with screening and treatment for *Chlamydia*

774

trachomatis, *Ureaplasma urealyticum* or group B *Streptococcus* (GBS), despite preliminary data suggesting an association of these organisms with increased risk of preterm birth for *Ureaplasma*^[89] and for GBS.^[164] Antibiotic treatment was employed after 25 weeks in this trial; the authors speculated that earlier treatment might have been more successful. Another randomized trial of antibiotic treatment in women with a history of preterm birth found benefit, but only for women who also had bacterial vaginosis.^[93] Treatment with metronidazole and erythromycin resulted in a significantly reduced rate of spontaneous preterm birth, from 49 percent in the placebo group to 31 percent in the antibiotic group. Unlike the VIP Study, in which all colonized subjects were eligible for randomization, the trial of BV treatment was limited to women with a history of prior preterm birth. The epidemiologic association of BV with preterm delivery (PTD) in multiple regression analyses^[91] together with reports of reduced preterm birth following treatment of BV-positive women at risk^[93] has led some to recommend routine screening and treatment, at least for high-risk women. However, this conclusion was not supported by a larger, multicenter trial of metronidazole treatment for women with BV.^[95] At present, the American College of Obstetricians and Gynecologists suggests that physicians "consider" BV screening and treatment only in women with a history of preterm birth.^[165] The value of microbiologic screening and treatment to reduce preterm birth remains unsettled.

Biochemical Markers

Maternal blood assays for progesterone, prolactin, relaxin, major basic protein, C-reactive protein, interleukins, and collagenase have all been tested in attempts to

identify pregnancies with increased risk. In each, a biologic correlation has been observed, but correlation does not translate into prediction. Among the serum assays collected in the Preterm Prediction Study, three were found to correlate with preterm birth before 32 weeks: -fetoprotein greater than the 90th percentile, alkaline phosphatase greater than the 90th percentile, and granulocyte-colony stimulating factor greater than the 75th percentile. ^[166] Increased levels of estriol in maternal saliva have also been reported to correlate with the risk of preterm birth after 32 weeks' gestation. ^[167] IL-6 has been associated with preterm birth and intra-amniotic infection. ^[168]

Assays of cervical fluid for fetal fibronectin have shown promise as markers for preterm birth, particularly for births before 30 weeks. Data from 2,929 women enrolled in the NICHD Preterm Prediction Study revealed that a single positive fibronectin assay performed at 24 to 26 weeks may identify up to 60 percent of women destined to deliver before 30 weeks' gestation. ^[44], ^[109] However, the sensitivity of the 24- to 26-week fibronectin assay to predict spontaneous preterm birth before 35 weeks was just 25 percent. Once again, there are no studies in which treatment of fibronectin-positive women has led to decreased prematurity. Based on the reported association of fibronectin and BV, ^[110] randomized trials of antibiotic prophylaxis in fibronectin-positive women are ongoing.

A study that compared multiple tests, including maternal symptoms, contraction frequency, Bishop score, cervical ultrasound, and fibronectin, to predict preterm birth enrolled 254 high-risk and 52 low-risk pregnant women at 11 sites. ^[141] Although each variable was significantly and independently related to risk of preterm birth, none performed well as an efficient screening test for preterm birth before 32, 35, or 37 weeks (Table 23-10 shows results for data collected at 22 to 24 weeks).

The low sensitivity of individual tests for spontaneous preterm birth prompted a search for a combination of tests that could improve both sensitivity and positive predictive value. Among the 28 different tests evaluated as potential markers in the Preterm Prediction Study, seven were available at 24 weeks and identified by multiple regression as significantly related to spontaneous birth before 35 weeks (listed in descending order of the strength of the odds ratio between cases and controls): fetal fibronectin (OR, 6.6), alkaline phosphatase above

TABLE 23-10 -- PREDICTION AT 22 TO 24 WEEKS OF SPONTANEOUS PRETERM BIRTH BEFORE 35 WEEKS

Test	Sensitivity	Specificity	Predictive Value	
			Positive	Negative
Multiple PTL symptoms	50.0%	63.5%	21.4%	86.4%
Uterine contractions 4/hr	6.7%	92.3%	25.0%	84.7%
Bishop Score 4	32.0%	91.4%	42.1%	87.4%
Cervical length 25 mm	40.8%	89.5%	42.6%	88.8%
Fibronectin 50 ng/ml	18.0%	95.3%	42.9%	85.6%

Data from Iams JD, for the NICHD MFMU Network: Home uterine monitoring to predict preterm birth. Uterine contraction frequency and preterm birth [abstracts 2 and 670]. Am J Obstet Gynecol 178:S2 and S188, 1998; and Self perceived symptoms to predict preterm birth [abstract 47]. Am J Obstet Gynecol 182:S32, 2000.

the 90th percentile (4.0), a prior spontaneous preterm birth (4.0), cervical length less than or equal to 25 mm (3.9), -fetoprotein above the 90th percentile (3.9), granulocyte colony-stimulating factor above the 75th percentile (3.1), and vaginal bleeding (2.2). ^[169] Individually, these tests suffer from the same low sensitivity and positive predictive value as the other markers previously described. Because few women were positive for more than one of the listed markers, it is possible that a combination or "multiple marker" test could be applied at 24 weeks that might have sufficient collective sensitivity to be clinically useful. It is unlikely, however, that a single interventional strategy will be effective for women identified by such disparate tests.

Interventions to Prevent Preterm Birth

Attempts to prevent prematurity have been based on a traditional medical model of identifying and correcting a potential "cause" of preterm birth, with the expectation that the rate of preterm birth would decline. Intervention trials have addressed early identification of preterm labor through patient education, pharmacologic suppression of uterine contractions, antimicrobial therapy of vaginal microorganisms, cerclage sutures to bolster the cervix, reduction of maternal stress, improved access to prenatal care, and reduced physical activity. Some trials have enrolled women with the risk factor in question without regard to obstetric history (e.g., the VIP Studies ^[89], ^[164]), while others have been limited to women with a prior preterm delivery (e.g., the European cerclage trials ^[169], ^[170], ^[171]). In no case has a study that focused on elimination of a single risk factor led to a decrease in preterm birth, but there have been hopeful trends identified in some of them. In virtually every trial, reports of an association between a risk factor and SPTB have been followed by small trials, usually observational in design, that describe promising early results, only to find minimal if any benefit when carried out in larger populations.

Education of At-Risk Women About the Signs and Symptoms of Preterm Labor

Initial studies ^[133] described reductions in SPTB, but subsequent reports showed inconsistent results. ^[134], ^[135], ^[172] In a multicenter investigation, the March of Dimes Collaborative Trial found significant benefit in two centers, but no benefit at three other sites. ^[135]

Antibiotics to Prevent Preterm Birth

The serendipitous observation ^[173] of a reduced frequency of preterm birth in women who received tetracycline as prophylaxis for urinary tract infection has been followed by a mixed literature of success and failure (Table 23-9). Clearly, there is a relationship between genital microorganisms and preterm birth, but the results of these trials just as clearly indicate that infection does not operate independently as a cause of preterm birth.

Social Support and Improved Access to Prenatal Care

Prenatal care is correlated with the rate of SPTB in both black and white women but the reason is not clear. Prospective interventions designed to reduce preterm birth through better access to care, reduced stress, and the like, have been unsuccessful, ^[174], ^[175] but one trial found reduced preterm births for indigent black women age 19 and older. ^[176]

Prophylactic Cerclage for Women with a Prior Preterm Birth

A historical study ^[177] described significant improvements in pregnancy outcome for women with a history of early preterm birth, but subsequent attempts to reduce the incidence of preterm birth with cerclage have been mixed. Two studies ^[178], ^[179] found no benefit, while another ^[180] reported a reduction in the incidence of early preterm births, but no effect on the overall rate of SPTB. More recent reports of cerclage for women with a history of preterm birth who also had ultrasound evidence of a short or funneled cervix have been mixed. ^[180], ^[161], ^[162], ^[163]

Prophylactic Medications

Tocolytic agents have been widely used as prophylaxis, but this has not been associated with either a reduction in preterm or low-birth-weight deliveries. ^[132] Parenteral progesterone (17-hydroxyprogesterone caproate) was used for prophylaxis against preterm labor after reports ^[178] suggested a decreased incidence of preterm births in treated women. Another study in an active-duty military population failed to demonstrate any reduction in preterm delivery rates compared with a placebo group. ^[179]

Bed Rest/Activity Modification

Although there is a modest relationship between maternal physical activity and preterm birth risk, ^[180], ^[181] there is no evidence from properly conducted trials that bed

rest offers any benefit for pregnant women. [\[182\]](#)

TERTIARY CARE

Diagnosis and Treatment of Spontaneous Preterm Birth

776

Clinical Assessment of Spontaneous Versus Indicated Preterm Delivery

The distinction between indicated and spontaneous prematurity, although helpful to understand the pathogenesis of prematurity, can be difficult to apply in practice. Evaluation of a woman with apparent preterm labor or ruptured membranes begins with a search for the underlying cause and an assessment of fetal well-being. The reason for preterm labor and the well-being of the fetus are always considered simultaneously, because they are interrelated in both diagnosis and treatment. The factor(s) that led to preterm labor may also lead to fetal compromise, as might occur in a patient with placental abruption or oligohydramnios. Conversely, a decision to treat the mother with drugs to arrest labor implies that further intrauterine growth and maturity will occur in a safe intrauterine environment. Preterm labor associated with infection or ischemia is more likely to result in perinatal morbidity than preterm labor for which no cause is found.^[183] There is evidence that restriction of fetal growth occurs more commonly among infants delivered after preterm labor or preterm PROM, even in apparently otherwise uncomplicated pregnancies.^[184] Therefore, a careful evaluation of fetal growth and well-being must precede and accompany any treatment to prolong pregnancy. For example, preterm labor and preterm PROM may be accompanied by abnormal amniotic fluid volume and/or bleeding. A patient with light bleeding and oligohydramnios may have spontaneously ruptured membranes, a growth-restricted fetus and occult preeclampsia, or a fetal renal anomaly. In a patient with polyhydramnios, preterm labor may be the result of fetal anomaly, maternal diabetes, or an intrauterine viral infection. In summary, clinical management of preterm labor is based on a careful assessment of the risks for mother and infant of continuing the pregnancy versus delivery.

After causes of preterm labor have been evaluated, the gestational age must be considered. The intensity of treatment to delay delivery is inversely related to the expected neonatal morbidity and mortality: the earlier the gestational age, the greater the risk of prematurity-related problems for the newborn. This assessment in turn determines the degree of risk and discomfort the mother may be asked to accept on behalf of her fetus. Decisions made prior to spontaneous preterm birth typically focus on assessment of risks for the infant, but maternal interests must always be considered.

Diagnosis of Preterm Labor

The diagnosis of preterm labor is traditionally made when persistent uterine contractions are accompanied by dilation and/or effacement of the cervix detected by digital examination.^[185] Symptoms of preterm labor are nonspecific and are not necessarily those of labor at term. Women treated for preterm labor report symptoms of pelvic pressure, increased vaginal discharge, backache, and menstrual-like cramps, all of which may occur in normal pregnancy. Contractions may be painful or painless, and are distinguished from the benign contractions of normal pregnancy (called Braxton-Hicks contractions) only by their persistence. The accuracy of these criteria has been questioned by studies suggesting poor sensitivity and specificity. In placebo-controlled trials of drugs to arrest preterm labor, 40 percent of subjects treated with placebo delivered at term.^[186] Conversely, other studies have found rates of preterm birth of 20 percent in women who were sent home without treatment after evaluation for possible preterm labor.^[187] Difficulty in accurate diagnosis is the product of the high prevalence of the symptoms and signs of early preterm labor among normal healthy women, and the imprecision of the digital examination of the cervix. Observational studies of ambulatory women with risk factors for preterm birth have found that symptoms are poorly predictive because of the common occurrence of the same symptoms in women who do not develop preterm labor.^{[114], [141], [188]} Uterine contraction frequency varies considerably in normal pregnancy according to gestational age, time of day, and maternal activity^[140] (Fig. 23-18). Contraction frequency alone is therefore insufficient to establish the diagnosis of preterm labor. The practice of initiating tocolytic drugs for contraction frequency without additional diagnostic criteria results in unnecessary treatment of women who do not actually have preterm labor.^[189] Overdiagnosis might be acceptable if treatment were clearly effective, but that is not the case (see paragraphs to follow on the efficacy of each tocolytic drug). Although digital assessment of cervical dilation of 3 cm or more is straightforward, the reproducibility of digital examination when dilation is less than 3 cm and/or effacement is less than 80 percent is low.^[190] Despite their imprecision, these symptoms and subtle changes in the cervix remain the basis of the early diagnosis of preterm labor.^[185]

Among symptomatic women, the best clinical predictors of preterm delivery within 24 hours to 7 days include initial cervical dilation greater than 3 cm or effacement of 80 percent or more, vaginal bleeding, and ruptured membranes.^{[189], [191], [192]} Surprisingly, contraction frequency of 4 or more per hour has low positive predictive value for preterm birth within 7 to 14 days of presentation.^{[193], [194]} For this reason, symptomatic

777

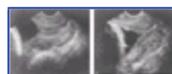

Figure 23-19 A, Transvaginal ultrasound image of the cervix at 28 weeks in a normal pregnancy. Calipers (+) are placed at the notches marking the internal and external os where the anterior and posterior walls of the cervical canal touch. B, Transvaginal ultrasound image of the cervix at 28 weeks in a patient with preterm labor. The (X) calipers mark the length of the cervical canal that is used for clinical evaluation. The (+) calipers are placed at the outer edges of the cervix; this length is not useful clinically because of wide variation among patients.

women whose cervical dilation is less than 2 cm and/or whose effacement is less than 80 percent present a diagnostic challenge. Diagnostic accuracy may be improved in these patients with transvaginal sonographic measurement of cervical length,^{[195], [196], [197], [198], [199], [200]} and/or testing for fetal fibronectin in cervicovaginal fluid.^{[193], [194], [201]} Cervical sonography is useful to exclude preterm labor in some patients, and may add sensitivity to the diagnosis in others. In a review of cervical sonography as a marker for preterm birth, a sonographic cervical length of 18 mm had the optimal positive predictive value, and 30 mm the optimal negative predictive value for the diagnosis of preterm labor in symptomatic women.^[200] These studies were performed with transvaginal sonography. Transabdominal sonography has poor reproducibility for cervical measurement and should not be used clinically without confirmation by a transvaginal ultrasound^{[159], [202]} (Fig. 23-19). Cervical sonography may also be useful to evaluate patients whose contractions are accompanied by vaginal bleeding of uncertain origin (Fig. 23-20). Fetal fibronectin is described earlier in the chapter. As the gestational sac implants and attaches to decidua in the first half of pregnancy, fibronectin is normally present in cervicovaginal fluid. The presence of fibronectin in the cervix or vagina after the 22nd week is uncommon (<5 percent of pregnancies),^[109] and indicates disruption of the attachment of the membranes to the decidua. Fibronectin commonly reappears in cervicovaginal secretions as labor approaches at term. A positive fibronectin test between 22 and 37 weeks is associated with an increased risk of preterm birth, especially in symptomatic women.^{[193], [194], [203]} A positive test result in a patient with persistent contractions and cervical dilation of less than 3 cm has better sensitivity (90 percent) and positive predictive value for delivery less than 7 to 14 days than standard clinical markers, but the positive predictive value is just 18 percent in accumulated series, depending on the population studied (Table 23-11) and (Table 23-12).^{[193], [194], [203], [204], [205], [206]} The clinical value of the test in symptomatic women is primarily its high negative predictive value, as a test to avoid overdiagnosis and unnecessary treatment, (e.g., similar to cardiac enzymes in the evaluation of chest pain).

Two studies have evaluated the effect of introduction of the fibronectin test into clinical care algorithms. In one, admissions for preterm labor, duration of hospitalization, and use of tocolytic medication were reduced without affecting neonatal outcome.^[207] In the other, the test had no benefit for women whose cervical dilation was greater than or equal to 3 cm, but a negative test in women without significant dilation allowed a 90 percent reduction in maternal transfer to a tertiary care facility.^[208] Both reports indicate that to be clinically useful in the acute management of preterm labor, the test must be rapidly available, and the clinician must be willing to act on a negative test result by not initiating treatment. The results of a trial conducted in 200 symptomatic women at a center in which tocolysis was not employed may therefore be reassuring.^[209] The sensitivity, specificity, and positive and negative predictive values for delivery at less than or equal to 7 days were

Figure 23-20 Midline sagittal image from transvaginal ultrasound showing a blood clot at the internal cervical os in a patient with contractions and vaginal bleeding.

62.5, 87.0, 16.7, and 98.2 percent, respectively. Three of 170 fibronectin-negative women (1.8 percent) delivered at 7 days or earlier at this center. Although the studies cited above suggest that overdiagnosis can be reduced with this test, fibronectin is not helpful when the patient has overt symptoms of preterm labor accompanied by cervical dilation greater than 3 cm.^[208] It is also not clear how a positive result should influence clinical management protocols. It may on occasion improve sensitivity by identifying women at risk who did not meet traditional criteria for tocolysis and/or steroids.

Fibronectin has been compared to contraction frequency, cervical dilation greater than 1 cm, and vaginal bleeding (Table 23-12) and to the clinician's diagnosis of preterm labor (Table 23-13) in data drawn from two U.S. studies.^[193],^[194] When masked fibronectin results

TABLE 23-11 -- FETAL FIBRONECTIN AND PREDICTION OF PRETERM BIRTH WITHIN 7 DAYS IN SYMPTOMATIC WOMEN¹

Negative	6	945	951
Total	52	1,152	1,204

Summary of six studies in symptomatic women with cervix dilation <3 cm: Lockwood et al.,^[203] Iams et al.,^[193] Senden and Owen,^[206] Bartnicki et al.,^[204] Malak et al.,^[205] and Peaceman et al.^[194]

* Sensitivity, 88.5%; specificity, 82.0%; positive predictive value, 18.2%; negative predictive value, 99.3%.

were compared to the clinician's decision to use tocolysis (Table 23-13) in symptomatic women with cervical dilation less than 3 cm, the fibronectin assay improved both sensitivity and specificity. Sixteen of 68 women (23.5 percent) treated with tocolysis and who had a positive fibronectin delivered within 7 days. Of 146 women treated for preterm labor who had a negative fibronectin, four (2.7 percent) delivered within 7 days, a rate similar to that seen in untreated women. This suggests that treatment might have been safely withheld in 142 patients. Interestingly, 16 women not deemed to be in labor by clinical criteria were identified with fibronectin testing.^[210]

Combined use of fibronectin and cervical sonography in the evaluation of symptomatic women has been evaluated in two studies. One found the tests to be complementary in improving the accuracy of diagnosis.^[211] The

other found that the combination was not superior to either one alone.^[212]

The suggested protocol for evaluation and treatment of women with possible preterm labor in the box incorporates fibronectin into current clinical care patterns, and should always be preceded by an evaluation of the etiology of SPTD. Transvaginal sonography can be used as an adjunctive test in patients with persistent contractions and cervical dilation of 2 cm or less. Because of variation introduced by maternal bladder filling, transabdominal sonography is not sufficiently reproducible to be useful.^[203]

Clinical Evaluation of Patients with Possible Preterm Labor

1. Patient presents with signs/symptoms of preterm labor:

Persistent contractions (painful or painless)
Intermittent abdominal cramping, pelvic pressure, or backache
Increase or change in vaginal discharge
Vaginal spotting or bleeding

2. General physical examination:

Sitting pulse and blood pressure
Temperature
External fetal heart rate and contraction monitor

3. Sterile speculum examination

pH
Fern
Pooled fluid
Fibronectin swab (posterior fornix or external cervical os, avoiding areas with bleeding)
Cultures for *Chlamydia* (cervix), and *N. gonorrhoeae* (cervix), and group B *Streptococcus* (outer one third of vagina and perineum)

4. Transabdominal ultrasound examination:

Placental location
Amniotic fluid volume
Estimated fetal weight and presentation
Fetal well-being

5. Cervical examination (after ruptured membranes excluded):

Cervix 3 cm dilation / 80 percent effaced Preterm labor diagnosis confirmed. Evaluate for tocolysis
Cervix 2 to 3 cm dilation and <80 percent effaced Preterm labor likely but not established. Monitor contraction frequency and repeat digital examination in 30 to 60 minutes. Preterm labor diagnosis if cervical change. If not, send fibronectin or obtain transvaginal cervical ultrasound. Evaluate for tocolysis if any cervical change, cervical length <20 mm or positive fibronectin.
Cervix <2 cm dilation and <80 percent effaced Preterm labor diagnosis uncertain. Monitor contraction frequency, send fibronectin and/or obtain cervical sonography, and repeat digital examination in 1 to 2 hours. Evaluate for tocolysis if there is a 1-cm change in cervical dilation, effacement >80 percent, cervical length <20 mm or positive fibronectin.

6. Use of Cervical Ultrasound:

Cervical length <20 mm and contraction criteria met = preterm labor
Cervical length 20 to 30 mm and contraction criteria met = probable preterm labor
Cervical length >30 mm = preterm labor very unlikely regardless of contraction frequency

7. Treatment of Symptomatic Fibronectin-Positive Patients:

Parenteral tocolysis
Steroids
Maternal transfer if appropriate
Group B *Streptococcus* prophylaxis

8. Care for Symptomatic Fibronectin-Negative Patients:

When tocolysis initiated before fibronectin returned (risk of delivery 7 days = 1.7 to 3.5 percent)
Conclude course of tocolysis
Reduce hospital stay
When tocolysis not initiated (risk of delivery 7 days = 0 to 1.8 percent)
Observe in outpatient setting
Cervical sonography should be considered in these patients to assess risk of SPTD

To summarize, the diagnosis of preterm labor is often uncertain, and as can be seen in the next section, the treatment is not always benign. In order to increase the sensitivity of diagnosis without treating unnecessarily, it is best to be *liberal* in looking for preterm labor, but *conservative* in diagnosis and treatment. The goal of first contact with a patient who may have preterm labor should be sensitivity, while the goal of evaluation in labor and delivery should be specificity. We recommend the following maxims:

1. Invite any patient complaining of possible symptoms of preterm labor to come in for contraction monitoring and cervical exam. Severity of symptoms bears little relation to their clinical significance.
2. Wait for cervical change of at least 1 cm in dilation, dilation of 2 cm or more, or a positive fibronectin before accepting the diagnosis of preterm labor in a patient

with persistent contractions.

3. Use cervical sonography (cervix 30 mm) as a test to support continued observation.

4. Be wary of "incidental" diagnosis of preterm labor, especially in the afternoon and early evening. Remember the wide range of contraction frequency and the normal increase in contractions in the late afternoon and evening in normal pregnancy.

Premature Birth and Assessment of Fetal Maturity

The goal of care for preterm labor and PROM is to reduce perinatal morbidity and mortality, most of which is caused by immaturity of the respiratory, gastrointestinal, coagulation, and central nervous systems of the premature infant. Fetal pulmonary immaturity is the most frequent cause of serious newborn illness, and is the only organ system whose function is directly testable before delivery. If the quality of obstetric dating is good and intrauterine fetal well-being is not compromised, the likelihood of neonatal respiratory distress syndrome can often be satisfactorily estimated from the gestational age (Fig. 23-8).

Amniotic fluid studies of fetal pulmonary maturity are important in two settings: (1) when dates are uncertain (e.g., fetal size larger than expected for dates, suggesting a more advanced gestation or maternal glucose intolerance, or size less than expected, suggesting fetal growth restriction); and (2) when fetal jeopardy is not now present (prompt delivery would be indicated) but may occur during the remaining days or weeks of pregnancy (e.g., when membranes have ruptured, fetal heart patterns are nonreassuring, or growth restriction is suspected). Occasionally, amniocentesis may be indicated for other studies such as fetal karyotype in patients with polyhydramnios, or culture, glucose, and Gram stain when amnionitis is suspected.

Treatment of Preterm Labor: Goals and Efficacy of Treatment

The ultimate goal for pregnancies complicated by preterm labor is delivery of an infant who suffers none of the sequelae of prematurity. Given the uncertain accuracy of the diagnosis, the treatment of women without true preterm labor in studies of tocolysis, and the relative infrequency of serious neonatal morbidity after 32 to 34 weeks, it has been difficult to demonstrate that treatment of preterm labor achieves this end point. The surrogate end point for neonatal outcome in clinical trials is usually prolongation of gestation to 32, 34, 35, 36, or 37 weeks. Other surrogate end points studied include respiratory distress syndrome, days and/or cost of neonatal intensive care, or more recently, composite or combined morbidities. Putting issues of accurate diagnosis aside, the efficacy of tocolytic drugs has been addressed through studies that compare one tocolytic drug to another, or less commonly, to a placebo. Most studies have been too small to allow firm conclusions. That in turn has led to reviews or meta-analyses wherein several studies of similar design are combined in an attempt to reach a definitive conclusion.^[186],^[213] These studies indicate that tocolytics do not prevent preterm birth but can delay delivery for at least 48 hours, an important interval during which effective antenatal interventions to reduce neonatal morbidity and mortality may be accomplished:

1. Antepartum transfer of the mother and fetus to the most appropriate hospital, especially when the estimated birth weight is expected to be less than 1,500 g.^[214],^[215]
2. Antibiotic prophylaxis of neonatal group B streptococcal infection.^[216]
3. Antepartum administration of corticosteroids to the mother to reduce the risk of death, respiratory distress syndrome, and intraventricular hemorrhage in the preterm neonate.^[217]

A recent meta-analysis of the effect of acute treatment of preterm labor^[213] evaluated the results of 16 randomized controlled trials that enrolled women with intact membranes and focused on three outcome measures: prolongation of pregnancy in days, gestational age at delivery, and birth weight. Studies of agents from each major class of tocolytic drugs (-mimetics, calcium channel blockers, magnesium sulfate, and the nonsteroidal anti-inflammatory drugs [NSAIDs]) were

781

Figure 23-21 Meta-analysis of 16 randomized controlled trials of the effect of acute tocolytic treatment on delivery 37 weeks' gestation in women with preterm labor, analyzed by type of tocolytic drug. NSAIDs = Non-steroidal anti-inflammatory drugs. (From Evidence Report/Technology Assessment No. 18: Management of Preterm Labor [AHRQ Publication No. 01-E021]. October 2000. Access at www.ahrq.gov/clinic/epcix.htm.)

combined in a meta-analysis suggesting that all four are associated with a decline in the occurrence of birth before 37 weeks. For each type of tocolytic drug, the odds ratios were greater than 1, with 95 percent confidence intervals that did not cross unity (Fig. 23-21). The authors cautioned that the number of subjects in the NSAID trials is small, and confidence limits, although significant, are wide. This analysis of acute use of tocolytic drugs was not able to address directly whether the observed prolongation of pregnancy was accompanied by reduced neonatal mortality.

Initial Evaluation of Preterm Labor

The initial evaluation of the patient in preterm labor is focused on the risks and benefits of continuing the pregnancy for both mother and fetus. Common maternal contraindications to tocolysis include hypertension, bleeding, and cardiac disease (see the box "Contraindications to Tocolysis"). Preterm labor accompanied by maternal hypertension places both mother and fetus at risk of acute hypertensive crises, and may occur in response to fetal stress or distress, uterine ischemia, or occult placental abruption. Although vaginal spotting may occur in women with preterm labor because of cervical effacement or dilation, any bleeding beyond light spotting is rarely due to labor alone. Placenta previa and abruption must be considered, because both may be accompanied by uterine contractions. In general, both diagnoses contraindicate tocolytic treatment. However, in rare instances prophylactic use of tocolysis in women with these dangerous diagnoses may be considered to achieve time for corticosteroids in the setting of extreme prematurity when the bleeding is believed to occur in response to contractions. Such treatment is fraught with difficulty, because even low doses of some tocolytic agents can be hazardous in a patient with bleeding. -Mimetic agents and calcium channel blockers may hamper maternal cardiovascular response to hypotension, and prostaglandin inhibitors are known to impair maternal platelet function. Cardiac disease is a contraindication because of the risks of tocolytic drug treatment in these patients.

Potential causes of preterm labor should be sought in the initial evaluation and reassessed during the course of treatment. An underlying cause of preterm labor may be found that requires delivery (e.g., abruptio placentae or chorioamnionitis), that may affect the choice of tocolytic (e.g., a degenerating myoma often

782

responds best to a prostaglandin synthetase inhibitor), or that requires adjunctive treatment (e.g., antibiotics for pyelonephritis or therapeutic amniocentesis for polyhydramnios).

Contraindications to Tocolysis

Maternal Contraindications to Tocolysis

Significant hypertension (eclampsia, severe preeclampsia, chronic hypertension)
Antepartum hemorrhage
Cardiac disease
Any medical or obstetric condition that contraindicates prolongation of pregnancy
Hypersensitivity to a specific tocolytic agent

Fetal Contraindications to Tocolysis

Gestational age <37 weeks
Advanced dilation effacement
Demise or lethal anomaly
Chorioamnionitis
In utero fetal compromise
Acute: fetal distress

Chronic: IUGR or substance abuse

Myometrial Contractility and Tocolytic Action

A brief review of myometrial activity ([see the box "Uterine Muscle Physiology"](#)) and the site(s) of action of the various tocolytic agents is appropriate. [Figure 23-22](#) summarizes the current knowledge of the regulatory mechanisms of uterine smooth muscle contractility. The key process in actinmyosin interaction, and thus contraction, is myosin light-chain phosphorylation. This reaction is controlled by myosin light-chain kinase (MLCK). The activity of tocolytic agents can be explained by their effect on the factors regulating the activity of this enzyme, notably calcium and cyclic adenosine monophosphate (cAMP) ([Fig. 23-22](#)). Calcium is essential for the activation of MLCK and binds to the kinase as calmodulin-calcium complex. Intracellular calcium levels are regulated by two general mechanisms: (1) influx across the cell membrane and (2) release from intracellular storage sites. Entry of calcium into cells occurs by at least two mechanisms. Depolarization leads to calcium influx through specific calcium channels that are voltage dependent. This is the site of action of the calcium channel blockers. Calcium can also enter through voltage-independent mechanisms, most notably the calcium-magnesium-adenosine triphosphatase (ATPase) system. Magnesium ions may interact here and also may compete with calcium for the voltage-dependent channels. Calcium is stored within cells in the sarcoplasmic reticulum and in mitochondria. Progesterone and cAMP promote calcium storage at these sites, while PGF_2 and oxytocin stimulate its release ([Fig. 23-22](#)). MLCK is also regulated by cAMP, which directly inhibits MLCK function via phosphorylation. Levels of cAMP are increased by the action of adenylate cyclase, which in turn is stimulated by β -adrenergic agents. Therefore, β -mimetic tocolytics act through adenylate cyclase to increase cAMP, which inhibits MLCK activity both by direct phosphorylation and by reducing intracellular free calcium (by inhibiting calcium release from storage vesicles) ([Fig. 23-22](#)). β -Mimetics also interact with surface receptors on the trophoblast, leading to increased cAMP, which in this tissue increases production of progesterone. [\[218\]](#) Hormonal production is a lengthy process, and significant production is not seen for at least 18 hours. For the myometrium to contract in a coordinated and effective manner (i.e., labor, whether term or preterm), individual smooth muscle cells must be functionally interconnected and able to communicate with adjacent cells. The key element of intercellular coordination of effective labor contractions is the gap junction. Estrogens and progesterone regulate formation of gap junctions and the concentration of oxytocin receptors. [\[218\]](#)

Uterine Muscle Physiology

Actin plus myosin (myosin light chain kinase [MLCK]) contraction
MLCK becomes active in presence of free intracellular calcium
Increased free intracellular calcium Increased MLCK contractions
Decreased free intracellular calcium decreased contractions

Choosing a Tocolytic Agent

Tocolytic drugs are reasonably safe when used according to standard protocols. However, their apparent safety is due more to the youth and general good health of the patients treated than to the inherent safety of the drugs. The choice of tocolytic requires consideration of the efficacy, risks, and side effects for each individual patient.

Magnesium Sulfate

Intravenous magnesium sulfate has been used for seizure prophylaxis in preeclampsia for decades, but was not used for the inhibition of preterm labor until the 1970s. [\[219\]](#) Because of its safety and familiarity, magnesium has displaced the β -mimetic drugs ritodrine and terbutaline to become the most commonly used tocolytic. The mechanism of tocolytic activity of magnesium is unclear. In vitro studies of uterine muscle strips show reduced contractility in the presence of magnesium ion. It has been suggested that magnesium acts by competition with calcium either at the motor end plate, reducing excitation, or at the cell membrane, reducing calcium influx into the cell at depolarization.

Efficacy of Magnesium Sulfate

The efficacy of magnesium to arrest labor has been studied in small clinical trials. In one study, 24 of 31 women treated with magnesium sulfate remained undelivered 24 hours after beginning therapy, compared to 14 of 31 treated with intravenous ethanol. [\[219\]](#) In an observational study of magnesium-treated women with singleton pregnancies with intact membranes and cervical dilation of 3 to 4 cm, 64 percent of subjects were undelivered at 48 hours and 56 percent were undelivered at 7 days. [\[220\]](#) A study in which 120 subjects with preterm labor were randomly assigned to receive either

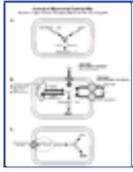

Figure 23-22 Control of myometrial contractility; myosin light-chain kinase (MLK) is the key enzyme. See text for details.

ritodrine or magnesium reported that only 4 percent and 8 percent of subjects, respectively, were delivered within 48 hours; and only 17 percent and 20 percent of ritodrine- and magnesium-treated subjects had delivered at 7 days.^[221] More than 45 percent of subjects in each group remained undelivered at 37 weeks, suggesting that many enrolled subjects did not have true preterm labor. In the only trial that compared magnesium to no therapy,^[222] 156 women between 24 and 34 weeks' gestation were randomly assigned to receive either magnesium or no tocolysis. There was no difference in duration of pregnancy, birth weight, neonatal morbidity or perinatal mortality. The rate of delivery within 24 hours of enrollment was about 30 percent in each group. Delivery within 7 days of enrollment occurred in 47 percent of magnesium-treated subjects compared to 37 percent of controls. About 35 percent of subjects in each group delivered more than 28 days after enrollment, again suggesting overdiagnosis of preterm labor in one third of subjects. One review of tocolytic agents concluded that there was insufficient evidence to support magnesium as an effective tocolytic,^[223] but a meta-analysis^[213] reached a favorable conclusion. Magnesium has become the first choice for tocolysis more because of its relative safety than for its efficacy.

Maternal Side Effects

Magnesium has a low rate of serious side effects compared with other tocolytic drugs.^[224] However, flushing, nausea, vomiting, headache, generalized muscle weakness, diplopia, and shortness of breath are not rare. Major and life-threatening complications, including chest pain and pulmonary edema, also occur rarely. Side effects were noted in 7 percent of 355 patients treated with magnesium.^[220] Four patients (1.1 percent)

784

developed pulmonary edema, a rate similar to that seen with β -mimetics. Side effects are significantly more common when magnesium and β -mimetics are administered simultaneously.^[221] Most centers avoid combined use for this reason.

Neonatal Side Effects

Although magnesium crosses the placenta and achieves serum levels comparable to maternal levels, serious neonatal complications are uncommon. Lethargy, hypotonia, and even respiratory depression may occur. Neonatal bony anomalies were reported in 6 of 11 infants who were exposed to magnesium for more than 7 days, but the clinical significance of this phenomenon is unknown.^[225]

For reasons that remain unclear, antenatal maternal magnesium treatment has also been related to improved neonatal outcome in several recent studies. A case-control study found that maternal magnesium treatment for either preeclampsia or preterm labor was associated with lower rates of cerebral palsy (CP).^[226] Only 7.1 percent of 42 children with cerebral palsy had been exposed to antenatal magnesium, compared to 36 percent of 75 controls without CP (OR, 0.14; 95 percent CI, 0.05 to 0.51). Another cohort study followed 519 infants whose birth weight was less than 1,500 g. The relationship of in utero magnesium exposure was related to CP at 1 year of age. At 3 to 5 years of age, none of 52 infants exposed to magnesium had CP and one was mentally retarded, compared to 29 with CP and 21 with mental retardation born to 337 mothers who did not receive magnesium.^[227] The odds ratios and 95% confidence intervals were 0.00 (0.00 to 0.92) for cerebral palsy and 0.31 (0.04 to 2.34) for mental retardation. However, there has also been a report of increased perinatal mortality and morbidity associated with antenatal magnesium.^[228] Prospective studies to evaluate the possible benefits of perinatal magnesium are ongoing.

Dosage of Magnesium Sulfate

Magnesium sulfate must be given parenterally to elevate serum levels above the normal range. Therapeutic dosage and serum levels have not been formally established but empirically are similar to those used for intravenous treatment of preeclampsia. A loading dose of 4 to 6 g is given over 20 to 30 minutes, followed by an infusion of 2 to 4 g/hr.^[229] The relationship of serum magnesium levels to therapeutic effect is controversial. A review of 101 episodes of preterm labor treated with magnesium sulfate found no difference in the rate of tocolytic success when serum levels were less than 6 mg/dl, compared with levels of greater than 6 mg/dl.^[229] Mean serum magnesium levels in patients with successful tocolysis were similar to those in patients in whom tocolysis failed. The investigators concluded that serum magnesium levels alone should not serve as the end point of therapy and that the drug should be titrated on the basis of clinical efficacy and toxicity.

Provided renal function is normal, the kidney rapidly excretes excess magnesium. In patients with evidence of renal impairment (e.g., oliguria or serum creatinine levels >0.9 mg/dl), magnesium therapy should be approached cautiously, and the patient should be followed with serum levels, and doses adjusted accordingly. Magnesium sulfate should not be used in patients with myasthenia gravis because the magnesium ion competes with calcium.

A clinical protocol for magnesium sulfate as a tocolytic is shown in the box.

Summary of Magnesium

Magnesium sulfate is a safe agent with limited tocolytic effectiveness. Because of its favorable safety profile, magnesium may be an especially useful choice when the diagnosis of preterm labor is early and uncertain, and in patients for whom other agents are contraindicated (e.g., type 1 diabetes mellitus).

Indomethacin

Prostaglandins are mediators of the final pathways of uterine muscle contraction. Labor at term is associated with increased concentrations of arachidonic acid, and PGE_2 and PGF_2 , in amniotic fluid. Prostaglandins given to pregnant women can ripen the cervix and/or induce labor, depending on the dosage and route of administration. Prostaglandins cause an increase in free intracellular calcium levels in myometrial cells and increased activation of MLCK, resulting in uterine contractions. Myometrial gap junction formation, an important step in synchronized uterine activity, is enhanced by prostaglandins. Prostaglandin synthetase, also known as cyclo-oxygenase (COX), is the enzyme that converts arachidonic acid to PGG_2 . Prostaglandin synthesis is increased when the COX-2 form of this enzyme is induced by cytokines, bacterial products such as phospholipases and endotoxins, and corticosteroids. Inhibition of prostaglandin synthetase by NSAIDs leads to reduced synthesis of prostaglandins. The NSAID agents vary in their activity, potency, and side-effect profile. Indomethacin is the most widely used agent in this class, which also includes sulindac, naproxen, aspirin, and fenoprofen.

The potential for clinical use of these agents was noted in studies showing prolonged pregnancy and

785

longer mean duration of labor in women taking therapeutic doses of salicylates.^[230]

Protocol for Magnesium Sulfate Tocolysis

1. Administer loading dose of 6 g magnesium sulfate in 10 to 20 percent solution over 20 to 30 minutes.
2. Maintenance dose of 2 g/hr (40 g of magnesium sulfate added to 1 L D5 0.9 normal saline or lactated Ringer's at 50 ml/hr).
3. Increase magnesium sulfate by 1 g/hr until the patient has one or less contraction per 10 minutes or a maximum dose of 4 to 5 g/hr is reached.
4. Limit intravenous fluid to 125 ml/hr. Follow fluid status closely with an indwelling urinary catheter if needed.
5. Maintain magnesium sulfate tocolysis for 12 hours after contractions have stopped or decreased to less than one per 15 minutes. Therapy may be stopped without tapering the dose.
6. Recurrent contractions require reevaluation to look for an underlying cause of the preterm labor such as amnionitis or occult abruption. Amniocentesis should be considered. The accuracy of the original diagnosis of preterm labor should be reconsidered with cervical sonography or fibronectin.
7. Patients treated with magnesium sulfate should be followed with
 - a. Deep tendon reflexes and vital signs hourly.
 - b. Intake and output every 2 to 4 hours.
 - c. Magnesium levels if infusion exceeds 4 g/hr or if clinical concern about toxicity.

Efficacy of Indomethacin

Indomethacin was first reported to delay delivery by more than 7 days in 80 percent of treated subjects.^[231] In randomized, placebo-controlled trials, indomethacin was superior to placebo in delaying delivery for 48 hours (80 percent vs. 33 percent in one trial^[232] and 95 percent vs. 23 percent in the other).^[233], ^[234] After 7 days, 83 percent of the indomethacin-treated subjects were undelivered, compared with 16 percent for the placebo group.^[233], ^[234] Additional randomized trials have produced mixed results. A randomized comparison of indomethacin to ritodrine^[235] found no difference in prolongation of pregnancy, but the indomethacin group had significantly fewer maternal side effects. In a randomized, placebo-controlled trial of indomethacin, pregnancy was prolonged beyond 48 hours in 13 of 16 (81 percent) of the indomethacin-treated subjects versus 10 of 18 (56 percent) in the placebo arm.^[236] However, serious neonatal morbidity occurred in twice as many of the indomethacin-treated infants. An observational study compared neonatal outcome among infants born after maternal treatment with ritodrine with infants born after combined treatment with ritodrine and indomethacin.^[237] Gestation was not significantly prolonged, but neonatal respiratory complications were increased in the indomethacin group. Because indomethacin was used in this trial only for patients with persistent contractions, the complications observed may relate more to the underlying cause of preterm labor than to the medication.

Maternal Side Effects of Indomethacin

Prostaglandin inhibition may have multiple and diverse side effects because of the abundance of prostaglandin-mediated physiologic functions. Nevertheless, the principal advantage of this agent is the relative infrequency of serious maternal side effects when the agent is used in a brief course of tocolysis. As with any NSAID, gastrointestinal side effects such as nausea, heartburn, and vomiting are the most common, but usually mild. More serious complications include gastrointestinal bleeding, alterations in coagulation, thrombocytopenia, and asthma in aspirin-sensitive patients. Lunt et al.^[238] reported normal prothrombin and activated partial thromboplastin times, but found abnormal prolonged bleeding times in 65 percent of women treated for 48 hours. Prolonged treatment can lead to renal injury, especially when other nephrotoxic drugs are employed. Hypertensive women may rarely experience acute increased blood pressure after indomethacin treatment. Drugs of this class are antipyretic agents and may obscure a clinically significant fever. Maternal contraindications to indomethacin tocolysis include renal or hepatic disease, active peptic ulcer disease, poorly controlled hypertension, asthma, and coagulation disorders.

Fetal and Neonatal Side Effects

In contrast to the generally favorable maternal side-effect profile, the potential for fetal and neonatal complications of indomethacin tocolysis is worrisome. In actual practice, serious complications have been rare, but there is potential for injury to the fetus if treatment protocols are not followed carefully. Before the pathologic mechanisms of fetal injury were recognized, there were case reports of neonatal death following maternal

indomethacin tocolysis. Three principal side effects of indomethacin have been of concern: constriction of the ductus arteriosus, oligohydramnios, and neonatal pulmonary hypertension. The ductal constriction occurs because formation of prostacyclin and PGE₂, which maintain ductal vasodilation, is inhibited by indomethacin.^[239] Doppler evidence of ductal constriction was found in 7 of 14 fetuses of women treated with indomethacin between 27 and 31 weeks of pregnancy.^[240] Tricuspid regurgitation occurred in three fetuses; all ductal abnormalities resolved within 24 hours after the medication was discontinued. The likelihood of ductal constriction increased after 32 weeks of pregnancy.^[239] Prior to 32 weeks, the incidence of ductal constriction was 5 to 10 percent. At 32 to 35 weeks, the incidence increased to 50 percent after 48 hours of indomethacin exposure. Although potentially serious, ductal constriction is usually transient, and responds to discontinuation of the drug. However, persistent ductal constriction and irreversible right heart failure have been reported.^[241] A review of fetal echocardiographs obtained from 61 women treated with indomethacin for preterm labor found evidence of ductal constriction in 50 percent of fetuses.^[242] Constriction was detected at an average of 30.9 ± 2.3 weeks after an average of 5.1 ± 6.0 days of indomethacin therapy, and reversed in all fetuses after cessation of medication.

Oligohydramnios associated with indomethacin tocolysis is common, dose related, and reversible, but there is a report of neonatal renal insufficiency and death after prolonged administration.^[243] Oligohydramnios is a consequence of reduced fetal urine production, due in turn to reduction by indomethacin of the normal prostaglandin inhibition of antidiuretic hormone, and by direct effects on fetal renal blood flow.

Primary pulmonary hypertension in the neonate is a potentially fatal illness that has also been associated with prolonged (>48 hours) indomethacin therapy.^[244], ^[245] Primary neonatal pulmonary hypertension has not been reported with 24 to 48 hours of therapy, but the incidence may be as high as 5 to 10 percent with long-term therapy.^[235]

Other complications, including necrotizing enterocolitis, small bowel perforation, patent ductus arteriosus, jaundice, and intraventricular hemorrhage, have been observed when indomethacin was outside of standardized protocols that did not limit the duration of treatment and/or employed the drug after 32 weeks.^[246] Fetuses treated in utero with indomethacin have been followed in childhood without evidence of significant long-term effects.^[247], ^[248], ^[249]

Sulindac is an alternate NSAID that has been favorably compared to indomethacin as a tocolytic. Placental transfer of this drug is less than with indomethacin, but the tocolytic efficacy of sulindac has not been studied in large numbers.^[250] One study^[251] found fewer fetal cardiovascular effects detected by Doppler ultrasound with sulindac than with indomethacin.

Because of the effect on fetal urine production and amniotic fluid volume, indomethacin may be an appropriate tocolytic when preterm labor is associated with polyhydramnios. Indomethacin has been used successfully to treat preterm labor in women with polyhydramnios,^[252] and for polyhydramnios without labor.^[253], ^[254] Uterine activity and pain associated with degenerating uterine fibroids in pregnancy also respond well to indomethacin.

Dosage of Indomethacin

Indomethacin is well absorbed orally or per rectum. The usual dose is a 50-mg loading dose by mouth or 50 to 100 mg per rectum. Subsequently, 25 to 50 mg is administered orally every 6 hours, depending on the response. Therapy is usually limited to 2 to 4 days because of concern about side effects of oligohydramnios and neonatal pulmonary hypertension (see the box "A Protocol For Indomethacin Tocolysis").

Summary of Indomethacin

Indomethacin is an effective tocolytic agent that is well tolerated by the mother. Concern about fetal side effects

787

has appropriately limited use of indomethacin to brief courses of therapy in patients experiencing preterm labor before 32 weeks. A review of tocolytic efficacy and safety concluded that indomethacin was the only tocolytic for which there was convincing evidence of effectiveness, and that there was little risk to the fetus when used before 32 weeks according to published protocols.^[223] However, indiscriminate use of prostaglandin inhibitors (e.g., for patients beyond 32 weeks or who have frequent contractions in the absence of a positive fibronectin or cervical dilation >2 cm) does not have a favorable risk/benefit ratio for the fetus.

A Protocol for Indomethacin Tocolysis

1. Limit use to preterm labor before 32 weeks' gestation in subjects with normal amniotic fluid volume and normal renal function.
2. Loading dose of 50 mg rectally or orally; repeated in 1 hour if no decrease in contractions.
3. Give 25 to 50 mg every 6 hours for 48 hours.
4. Check amniotic fluid volume prior to initiation and at 48 to 72 hours. If oligohydramnios is present, the drug should be discontinued.
5. Use the drug for no longer than 48 to 72 consecutive hours. Treatment for >48 hours requires extraordinary circumstances. Ductal flow should be evaluated with Doppler echocardiography.
6. Discontinue therapy promptly if delivery seems imminent.
7. Fetal contraindications to use of indomethacin include growth restriction, renal anomalies, chorioamnionitis, oligohydramnios, ductal dependent cardiac effects, and twintwin transfusion syndrome.

The -Mimetic Tocolytics

The -mimetic tocolytic drugs have been widely used for 30 years. They are structurally related to epinephrine and norepinephrine, and include ritodrine, terbutaline (marketed in the United States only as a drug for asthma but often used as a tocolytic), albuterol, fenoterol, hexoprenaline, isoxuprine, metaproterenol, nylidrin, orciprenaline, and salbutamol. The U.S. Food and Drug Administration (FDA) approved ritodrine as a parenteral tocolytic in 1980, but it is used less often than terbutaline because of a perceived higher rate of maternal side effects. Terbutaline use continues despite not only the lack of FDA approval but also the specific FDA disapproval of its use as a tocolytic.^[255]

Efficacy of -Mimetics

There is evidence that the -mimetic agents are successful in prolonging pregnancy for at least 48 hours and perhaps longer. A meta-analysis^[186] of the randomized trials of -mimetic drugs found that treated subjects were less likely to deliver within 24 (OR, 0.29; 95 percent CI, 0.21 to 0.41), and 48 (OR, 0.59; 95 percent CI, 0.42 to 0.83) hours of admission. There was a reduction in preterm births less than 37 weeks in treated subjects in 3 of 15 studies (OR, 0.71; 95 percent CI, 0.53 to 0.96). There was no advantage for the treated group compared to placebo controls in the frequency of low birth weight below 2,500 g (OR, 0.75; 95 percent CI, 0.55 to 1.02), severe RDS (OR, 1.07; 95 percent CI, 0.71 to 1.61), or perinatal death (OR, 0.96; 95 percent CI, 0.55 to 1.68). A Canadian prospective randomized trial of ritodrine compared with placebo reported similar results.^[256] A reduction in deliveries within 2 to 7 days of diagnosis was noted, but there was no significant difference in births before 37 weeks. A trend toward fewer deliveries before 32 weeks did not achieve statistical significance. Any benefit of tocolysis evident in these analyses would seem to be conferred by the opportunity to administer steroids, antibiotics, and the like, and not by prolongation of pregnancy to allow further intrauterine growth and maturation of the fetus.

Long-term use of -mimetic drugs, given by mouth or subcutaneous infusion, has been championed by investigators whose approach to prematurity prevention is based on detection and suppression of contractions. This approach is supported by observational studies^[257] that have not been confirmed in randomized placebocontrolled trials.^[258] These and other studies^[186] support the use of -mimetic agents only for the acute suppression of contractions. The concern expressed by the FDA Advisory relates specifically to subcutaneous infusion for prevention and treatment of preterm labor:

Published studies on the safety of this use (subcutaneous infusion) are seriously limited by methodologic inadequacies. In the absence of data establishing the effectiveness and safety of the drug/device (for subcutaneous infusion) the FDA is alerting practitioners . . . and others that continuous administration of subcutaneous terbutaline sulfate has not been demonstrated to be effective and is potentially dangerous.^[255]

The agency was responding to reports of maternal cardiac symptoms and one reported maternal death that occurred during outpatient use of terbutaline infusion. It should be noted that the incidence of such serious side effects is low. In a report of 8,709 women treated with a continuous subcutaneous infusion, only 0.54 percent had cardiopulmonary symptoms.^[261] However, any risk is unacceptable in the absence of benefit.

The remaining value for terbutaline in the care of preterm labor may lie in its rapid onset of action and ease of administration via a single subcutaneous injection. This use has been helpful to reduce contractions during transfer to a regional facility or in a protocol for triage evaluation of women with possible preterm labor.^[262] The subject of long-term suppression of contractions is reviewed further for all tocolytics later in the chapter.

Pharmacology of -Mimetics

Sympathomimetic drugs act through either α - or β -receptors. Stimulation of α -receptors leads to contraction of smooth muscles, while β -receptor stimulation carries the opposite effect, leading to smooth muscle relaxation at all sites: vascular, gastrointestinal, and uterine. The presence of β -receptors in other tissues (e.g., the heart) accounts for the side effects of -mimetics. β -Receptors are divided into β_1 - and β_2 -subtypes. The β_1 -receptors are largely responsible for the cardiac effects, while β_2 -receptors mediate the smooth muscle relaxation as well as hepatic glycogen production and islet cell release of insulin. All -mimetics are structurally related to epinephrine, with two carbons separating a benzene ring from an amino group. Relative

788

β_2 activity appears to be associated with large alkyl substitutions on the amino group while maintaining hydroxyl groups at the 3 or 5 position on the benzene ring.^[263] It should be noted that when drugs are referred to as β_2 -selective or β_2 -specific, the selectivity is relative, not absolute. β -Receptors are not distributed on an all-or-none basis; variable ratios of β_2 - to β_1 -receptors occur in various tissues. For example, the heart is primarily stimulated by β_1 -agonists, but 14 percent of its β -receptors are β_2 . In addition, not all β_2 -specific drugs are perfectly selective and will stimulate β_1 -receptors to some degree, especially when serum concentrations are elevated.

Pharmacokinetics

Ritodrine is conjugated in the liver to inactive glucuronic and sulfuric esters. Both unconjugated and conjugated drugs are then excreted in the urine. Actual serum ritodrine levels vary greatly at a given infusion rate. [264] The variability in serum levels among individuals at the same infusion rates appears to be related to differences in hepatic blood flow or serum concentrations of protein rather than maternal weight. [265] Concentrations of 80 ng/ml or more are commonly required initially to inhibit preterm labor. Ritodrine crosses the placenta readily. Fetal concentrations average 30 percent of maternal levels after a 2-hour infusion and are equal to those of the mother after longer infusions. In kinetics studies, serum ritodrine levels reach 75 percent of maximum levels within 20 minutes of a constant intravenous infusion. [265] The manufacturer's recommended protocol for intravenous therapy starts at 0.1 mg (100 g)/min and is increased by 0.05 mg (50 g) every 10 minutes until contractions cease, side effects occur, or the maximum rate (0.35 mg (350 g)/min) is reached. The infusion is then maintained at the effective level for 12 hours after contractions cease. Side effects occur most often when the infusion rate and concentration of ritodrine are increasing. [264] The rate of change in the infusion rate or drug concentration is more important than absolute drug level in causing side effects. [265] An alternative protocol with equal efficacy and fewer side effects begins with an initial infusion of 50 g/min, increasing by 50 g/min every 20 minutes only if contractions are more frequent than every 10 minutes. Once labor is stopped, the infusion rate is maintained for 1 hour and then reduced every 20 minutes to the lowest rate that inhibits contractions adequately. This rate is then maintained for 12 hours.

Terbutaline has a longer half-life than ritodrine, and as a result has been associated with fewer side effects. Terbutaline levels are 30 percent lower in pregnant patients than in nonpregnant volunteers given the same dose. The onset of action is rapid with both intravenous bolus (1 to 2 minutes) and subcutaneous administration (3 to 5 minutes). Because terbutaline is not FDA approved, there is no manufacturer's protocol for preterm labor. Nevertheless, there is abundant clinical and published information about tocolytic use of terbutaline. Currently published protocols often employ subcutaneous administration, with a usual dose of 0.25 mg (250 g) every 3 to 4 hours. [266] A single subcutaneous dose of terbutaline to arrest contractions during the initial evaluation of preterm contractions was found in one report to be an efficient method of evaluating women presenting with possible preterm labor. [262] None of three options studied affected pregnancy outcome, but women treated with a single subcutaneous dose of terbutaline had shorter, less expensive triage visits than women who received either intravenous or oral hydration. Intravenous administration of terbutaline has been employed in some centers, beginning at 2.5 g/min and increasing by 2.5 g/min every 20 minutes in a manner similar to ritodrine until a maximum of 17.5 to 20 g/min is reached. [267]

Tachyphylaxis with -Mimetic Drugs

Tachyphylaxis or desensitization of the adrenergic receptor occurs throughout the body after prolonged exposure to -agonists, and affects the clinical use as tocolytics. Animal studies suggest that contractions resume after only several hours of *continuous* intravenous therapy with high-dose -mimetic therapy; the myometrium remains quiescent longer with *pulsatile* administration of lower doses of the same tocolytic agent. [268] Caritis et al. observed reduced -receptor sensitivity to continuous versus intermittent administration of ritodrine [269] , [270] and showed that the mechanism of this altered sensitivity occurs via reduced receptor density and adenyl cyclase activity. Interestingly, dexamethasone treatment ameliorated these effects and preserved the tocolytic effect. These observations led to studies of intermittent administration of -mimetic agents.

Side Effects and Complications of Parenteral -Mimetic Tocolysis

Maternal side effects of the -mimetic drugs are common and diverse, as shown in [Table 23-14](#) . Most side effects are mild and of limited duration, but serious maternal cardiopulmonary and metabolic complications have been reported, including maternal death when -adrenergic agents were given to mothers with unrecognized or occult cardiac disease. A thorough history and review of possible cardiac symptoms before initiating treatment should be performed. Prompt attention to any patient with persistent symptoms during treatment is important to prevent complications. Some centers obtain

TABLE 23-14 -- SIDE EFFECTS AND COMPLICATIONS OF -MIMETIC TOCOLYSIS

Maternal	Fetal and Neonatal
<i>Physiologic</i>	<i>Fetal</i>
Apprehension	Tachycardia
Jitteriness	Cardiac arrhythmia
Headache	Myocardial and septal hypertrophy
Nausea and vomiting	
Fever	
Hallucinations	Myocardial ischemia
<i>Metabolic</i>	Heart failure
Hyperglycemia	Hyperglycemia
Hyperinsulinemia	Hyperinsulinemia
Hyperlactacidemia	Death
Hypokalemia	<i>Neonatal</i>
Hypocalcemia	Tachycardia
Antidiuresis, water retention	Hypoglycemia
Altered thyroid function	Hypocalcemia
Elevated transaminases	Hyperbilirubinemia
<i>Cardiac</i>	Tachycardia
Tachycardia	Myocardial ischemia
Pulmonary edema	Hypotension
Hypotension	Intraventricular hemorrhage
Arrhythmias/palpitations	
Heart failure	Decreased myocardial contractility
Myocardial ischemia, altered ECG and chest pain	
Shortness of breath	
<i>Other</i>	
Skin rash	
Pruritis	
Ileus	
Death (cardiac)	

routine electrocardiograms before beginning treatment with -mimetic agents, but a normal electrocardiogram (ECG) does not exclude underlying cardiac disease and is probably not cost-effective in women without a worrisome history or persistent symptoms.

Cardiopulmonary Complications

The -mimetic drugs have the potential for serious complications, but have an acceptable margin of safety if used with care and contraindications are strictly observed. Side effects are frequent with high-dose therapy. About 20 to 30 percent of patients experience nausea, and more than 50 percent of patients develop tachycardia greater than 120 bpm.^[267], ^[271] Pulmonary edema is serious but can often be prevented.^[272] Pulmonary edema in association with tocolysis was once thought to be secondary to volume overload with left heart failure. However, evaluation of cardiac function with Swan-Ganz catheters and echocardiography has failed to demonstrate left ventricular failure in all but a few cases of pulmonary edema, most of which were associated with underlying hypertension.^[273] Noncardiogenic contributing causes include decreased colloid oncotic pressure and increased pulmonary vascular permeability, especially when premature labor is associated with amnionitis.^[274] Most patients with pulmonary edema have received either physiologic saline solutions or lactated Ringer's solution, which further decreases colloid oncotic pressure and expands vascular volume. A patient treated with -mimetics should be considered as having a compromised cardiovascular system and should not receive large amounts of saline or lactated Ringer's solution.

It is uncommon for pulmonary edema to develop in the first 24 hours of -mimetic therapy unless one of the predisposing factors ([see the box "Contraindications and Relative Contraindications to -Mimetic Tocolytics"](#)) is present. In fact, more than 90 percent of reported cases of pulmonary edema occur after 24 hours of -mimetic therapy. Glucocorticoids have been suggested to be a predisposing factor, but neither beta-methasone nor dexamethasone have mineralocorticoid activity. Their association with maternal pulmonary edema is probably coincidental. Pulmonary edema has been reported without concomitant use of corticosteroids, and with tocolytics other than the -mimetics.

Symptomatic cardiac arrhythmias and myocardial ischemia have occurred during -agonist tocolytic therapy. Myocardial infarction with resultant maternal death has also been reported.^[275] Ischemia appears to be localized to the subendocardial region. The subendocardial ratio of oxygen supply to demand can be reduced

by two factors that are known to be operative during pregnancy and -mimetic therapy: the normal placental arteriovenous shunt that diminishes aortic diastolic blood pressure, and the drug-induced tachycardia that shortens diastole, the time for myocardial perfusion.

Contraindications and Relative Contraindications to -Mimetic Tocolytics
Contraindications to -Mimetic Tocolytics
Maternal cardiac disease (structural, ischemia, or dysrhythmia)
Eclampsia, severe preeclampsia, or other significant hypertensive disease
Significant antepartum hemorrhage
Uncontrolled diabetes mellitus
Maternal hyperthyroidism
Relative Contraindications to -Mimetic Tocolytics
Diabetes, both diet and insulin controlled
Hypertension
History of severe migraine headaches
Fever
Increased risk of pulmonary edema

If a patient develops chest pain during tocolytic therapy, tocolysis should be discontinued and oxygen administered. With severe pain, treatment with nitrates may be necessary. Premature ventricular contraction, premature nodal contractions, and atrial fibrillation have been noted in association with -mimetic therapy.^[271] These usually respond well to discontinuation of the drug and oxygen administration. The most important steps to prevent these cardiac complications are (1) excluding patients with prior cardiac disease and (2) limiting infusion rates so that maternal pulse does not exceed 130 bpm. Baseline or routine electrocardiograms before or during treatment are not helpful. There is a very poor correlation between symptoms of myocardial ischemia and electrocardiographic changes in these patients.^[276] Nonetheless, an electrocardiogram is indicated if there is no response to oxygen and cessation of -mimetic therapy.

The -mimetic agents produce a mild (5 to 10 mm Hg) fall in diastolic blood pressure, and the extensive peripheral vasodilatation makes it difficult for the patient to mount a normal response to hypovolemia. This is one of the reasons -mimetics may be dangerous in women with antepartum hemorrhage. Another is that the important early signs of excessive blood loss (e.g., maternal and fetal tachycardia) are masked by these drugs.^[271]

Metabolic Complications

-Mimetic agents may induce transient mild hyperglycemia in nondiabetic pregnant women,^[267] lead to gestational diabetes with prolonged oral use,^[276], ^[277] elevate blood glucose sufficiently to require insulin patients with diet-controlled gestational diabetes, and seriously compromise glucose control in type 1 and type 2 maternal diabetes. Increased glycogenolysis with resultant hyperglycemia, increased lactic acid release from skeletal muscles, and ketone formation from fat stores, as well as a fall in bicarbonate, markedly increase the risk of ketoacidosis. These drugs should in general be avoided in women with diabetes. If it is absolutely necessary to use -mimetics, a simultaneous intravenous insulin infusion should be employed to avoid ketoacidosis. -Mimetics also lead to potassium flux from plasma into cells, thereby causing a fall in serum measurements without a change in excretion. Hence, there is no change in total body potassium. Measurement of glucose and potassium before initiating therapy and on occasion during the first 24 hours of treatment is appropriate. This surveillance will ensure that the patient with unrecognized gestational diabetes and the occasional normal patient in whom significant hyperglycemia (>180 mg/dl) develops will not be missed. After 24 hours of therapy, both the serum glucose and potassium levels will have begun to return to baseline even without specific therapy.^[278] No potassium replacement is needed unless the serum potassium level falls below 2.5 mEq/L.

In most women treated for 24 to 48 hours with -agonist tocolytics, these metabolic changes are mild and transient. Prolonged treatment, however, has the potential to induce significant alterations in maternal blood glucose, insulin levels, and energy expenditure.^[279] The risk of abnormal glucose metabolism is further increased by simultaneous treatment with corticosteroids,^[280] a common combination for threatened preterm labor. Subcutaneous infusion has been found to induce fewer new cases of gestational diabetes than oral terbutaline.^[281] However, the same study found that 100 percent of women who already had gestational diabetes required insulin to maintain euglycemia during treatment with subcutaneous terbutaline infusion.

Neonatal Side Effects of -Mimetics

-Mimetic tocolysis has been linked to an increased risk of neonatal intraventricular hemorrhage.^[282] This and the other maternal complications cited above led many centers to replace the -mimetic drugs with magnesium, nifedipine, or indomethacin as the tocolytic agent of first choice. Neonatal hypoglycemia and ileus have also been reported with -mimetics, and can be clinically significant if the maternal infusion is not discontinued more than 2 hours before delivery.^[283] Neonatal

hypocalcemia may also occur. With all tocolytic drugs, and particularly -mimetics and magnesium sulfate, adverse neonatal effects are greatest when the fetus is born close to a period of high-dose parenteral therapy. These drugs must be used with great caution if at all when there is advanced cervical dilatation and delivery appears inevitable. Situations in which the patient is at increased risk for -mimetic complications (relative contraindications) are listed in box above. Careful risk/benefit evaluation needs to be performed on an individual basis in these cases.

Summary of -Mimetic Tocolysis

-Mimetic drugs were the tocolytics of first choice for a long time, but have been replaced by other drugs with better safety and side-effect profiles. Although ritodrine is still the only FDA-approved tocolytic agent, it is not commonly used in the United States. Terbutaline is a familiar choice that, when used as a single subcutaneous injection of 0.25 mg to facilitate maternal transfer or to initiate tocolysis while another agent with a

791

slower onset of action is being given, has relatively few serious side effects. Long-term oral or subcutaneous treatment has not been shown to reduce either prematurity or neonatal morbidity in controlled trials.

Calcium Channel Blockers

Inhibitors of intracellular calcium entry affect the contraction of smooth muscle, and thus have potential use as tocolytics. Calcium channel blockers are marketed for treatment of hypertension, angina, and arrhythmias, but have been used off-label as tocolytic drugs. The pharmacologic effect is believed to occur via inhibition of the voltage-dependent channels of calcium entry into smooth muscle cells, resulting in a direct decrease in intracellular calcium as well as decreased release of calcium from intracellular storage sites. Nifedipine and nicardipine have been studied as tocolytic agents because they selectively inhibit uterine contractions compared to others such as verapamil. Unlike other tocolytics, calcium channel blockers are rapidly absorbed after oral administration. The pharmacokinetics in pregnancy are apparently similar to that seen in non-pregnant individuals, with appearance of nifedipine within plasma within just a few minutes, peak concentrations at 15 to 90 minutes, and a half-life of 81 minutes after oral administration.^[284] Placental transfer of nifedipine was documented in this study in two patients who delivered 2 to 3 hours after receiving nifedipine. The duration of action of a single dose can be as long as 6 hours.

Efficacy

Nifedipine was reported in a small observational study^[285] to be effective in suppressing contractions and well tolerated by mother and fetus. There are no placebo-controlled trials of calcium channel blockers. When nifedipine has been compared with -mimetics,^[286]^[287]^[288]^[289] its efficacy has been comparable or superior, and side effects lower than with -mimetics. In a comparison with magnesium, nifedipine was equally effective in delaying delivery for 72 hours.^[290] Hypotension was common (almost 40 percent) with nifedipine, but all other side effects occurred more often with magnesium. Another calcium channel blocker, nicardipine, was compared with magnesium in a randomized trial of 122 subjects.^[291] There were no differences in neonatal outcomes, gestational age at delivery, or delay in delivery, but side effects were more common with magnesium.

Side Effects

As noted above, maternal side effects are less common with nifedipine and nicardipine than -mimetics. A decrease in blood pressure and rise in pulse have been noted by most authors, with occasional cases of significant hypotension.^[286] Unlike the -mimetics, nifedipine is not associated with a decrease in serum potassium, although modest increases in glucose have been noted. Maternal symptoms are often related to hypotension and include headache (20 percent), flushing (8 percent), dizziness, and nausea (6 percent). Pretreatment with fluids may reduce their incidence. Most effects have been mild, but there are reports of serious complications. A 29-year-old healthy woman treated with intravenous ritodrine followed by oral nifedipine had a documented myocardial infarction 45 minutes after her second dose of nifedipine.^[292] Whether her illness was due solely to the nifedipine or to the sequential use of a -mimetic and calcium channel blocker is not known, but simultaneous or immediately sequential use of calcium channel blockers and -mimetics is not recommended. Two reports describe skeletal muscle blockade when used in conjunction with magnesium sulfate,^[293]^[294] so this combination therapy should be avoided. Both reports describe a prompt response to cessation of magnesium and/or treatment with calcium gluconate. A case of hepatotoxicity requiring discontinuation of the drug has also been reported.

Widespread acceptance of nifedipine as a tocolytic was limited by initial animal studies that reported reduction in uteroplacental blood flow, fetal bradycardia, and hypoxic myocardial depression with other calcium channel blockers, including verapamil, nicardipine, and diltiazem. However, animal studies of nifedipine have not shown such effects unless large doses were infused. Reports of Doppler ultrasound assessment of fetal and uteroplacental circulation during nifedipine use in women for treatment of preterm labor have also been reassuring.^[295] No changes in the fetal middle cerebral artery, renal artery, ductus arteriosus, umbilical artery, or maternal vessels were noted in one study of 11 women treated with nifedipine for preterm labor. In an observational series of 102 mothers and 120 neonates treated with nifedipine, fetal well-being and neonatal complications such as low Apgar scores and cord pH less than 7.20 were typical for premature infants.^[296] Ray et al.^[297] found no significant differences in Apgar scores or umbilical venous blood gas values in infants exposed to nifedipine compared with infants not exposed to any tocolytic medicines. These human studies have provided sufficient reassurance, and some centers now use nifedipine as the tocolytic of first choice.^[298]

Dosage

Nifedipine is usually given as a 10- to 20-mg dose every 6 to 8 hours by mouth ([see the box "Nifedipine Tocolysis"](#)). *Sublingual administration is not recommended* for general medical or obstetric patients because of reports

792

of profound hypotension and myocardial ischemia.^[292]^[299]

Nifedipine Tocolysis
10 to 20 mg <i>orally</i> as initial dose, then 20 mg
orally every 6 hours for 24 hours, then 20 mg
orally every 8 hours (<i>do not use sublingual route</i>)

Summary of Calcium Channel Blockers

Nifedipine has become the tocolytic agent of choice at some hospitals because of the low incidence of significant maternal side effects and ease of administration. There are few remaining concerns about fetal side effects because animal studies suggesting fetal compromise were performed with agents other than nifedipine, and because of an increasing number of reports of safe use in humans. Nifedipine should not be combined with magnesium or -mimetics. Use should follow published dosage schedules closely until more extensive clinical experience has been reported.

New Tocolytic Agents

The oxytocin antagonist atosiban has been investigated in a randomized, placebo-controlled trial in which 501 subjects with acute preterm labor were randomized to

receive either intravenous and subcutaneous atosiban or intravenous and subcutaneous placebo. Subjects who continued to exhibit contractions and progressive cervical change after 1 hour of initial treatment in either the placebo or atosiban arms were treated with an openlabel "rescue" tocolytic agent of the clinician's choice, thus confounding any direct comparison of efficacy. ^[300] A significantly greater number of subjects remained undelivered without an alternate tocolytic at 24 hours (73 percent vs. 58 percent; OR, 1.93; 95 percent CI, 1.30 to 2.86), at 48 hours (67 percent vs. 56 percent; OR, 1.62; 95 percent CI, 1.62 to 2.37), and at 7 days (62 percent vs. 49 percent; OR, 1.70; 95 percent CI, 1.17 to 2.46). These differences were confined to subjects enrolled after 28 weeks; there were no advantages over placebo for subjects enrolled between 20 and 28 weeks. Unexpectedly, a significantly greater number of babies born to subjects enrolled into the atosiban arm died. The explanation for this observation is unclear, but the excess perinatal deaths all occurred among infants enrolled before 26 weeks. This suggests that enrollment may have been biased toward enrollment of early preterm labor subjects into the treatment arm. Maternal side effects of atosiban were few except for injection site inflammation. Although the differences in pregnancy prolongation were significant, the FDA did not approve atosiban. As in other placebo-controlled tocolytic trials, the rate of "successful" treatment in the placebo group was 50 percent or more, confirming the high rate of false-positive diagnosis of preterm labor based on contraction frequency and digital examination of the cervix. A companion trial compared subcutaneous infusions of atosiban to placebo. ^[301] The interval from the start of maintenance infusion therapy to the first recurrence of preterm labor was longer for the atosiban group, but there were no differences in the rate of preterm birth before 28, 32, or 37 weeks' gestation. An international study group compared the efficacy and side-effect profile of atosiban with ritodrine. ^[302] Efficacy to delay delivery for 48 hours (about 85 percent for both drugs) and 7 days (about 75 percent for both drugs) was similar, but cardiovascular side effects were much less common for atosiban (4 percent) than for ritodrine therapy (84 percent).

The nitric oxide donor glyceryl trinitrate has been studied in a trial in which 245 women with acute preterm labor were randomly assigned to receive either transdermal glyceryl trinitrate or standard ritodrine tocolysis. ^[303] The rate of prolongation to 37 weeks was 74 percent in both treatment arms. Headache occurred in 30 percent of the patients who received glyceryl trinitrate.

Clinical Use of Tocolytic Drugs

Tocolytic therapy is employed in several clinical circumstances. In a patient who presents in active labor with advanced cervical effacement, the diagnosis is not in question, and the goal is prompt treatment to allow maternal transfer and time for corticosteroids and GBS prophylaxis. In this setting, oral nifedipine or subcutaneous terbutaline may be the best initial choice to stop contractions promptly, with either additional nifedipine or magnesium to suppress contractions for 8 to 24 hours. When the clinical presentation is more indolent, with persistent contractions and cervical effacement less than 80 percent, a slower acting agent such as magnesium is often chosen as the initial drug. Acute treatment for preterm labor is typically continued for some period of time, usually 6 to 12 hours, after contractions have stopped, or occur less than four times per hour without additional cervical change. When labor has been difficult to stop in a patient with complete cervical effacement, acute treatment is sometimes continued until a full course of steroid therapy is completed (48 hours).

If contractions persist despite therapy, the wisdom of tocolytic treatment should be reconsidered. The cervix should be reexamined; if cervical dilation has progressed beyond 4 cm, tocolytic therapy in most cases should be discontinued. Fetal well-being and the possibility of placental abruption or intra-amniotic infection should be reevaluated. If these concerns can be excluded,

793

the accuracy of the original diagnosis should be reevaluated, remembering that significant effacement and development of the lower uterine segment are the features of the digital exam that most reliably indicate preterm labor. If a fibronectin swab was collected before therapy was begun, it should be sent for analysis. A positive result is not confirmatory, but a negative fibronectin, if collected before performance of a digital examination, provides evidence that the patient's contractions are benign. ^[201] Alternately, a transvaginal cervical ultrasound examination may be performed. A length of 30 mm or more essentially excludes the diagnosis. ^[200]

It should also be remembered that the definition of "successful" tocolysis does not necessarily require that *no* contractions occur, only that the frequency be reduced to less than 4 to 6 per hour without further cervical change. If these issues can be resolved, the adequacy of the tocolytic medication may be an issue. Unlike other drugs, serum levels are not clinically helpful to adjust the dose of tocolytics. A change to a second agent, or combination therapy with multiple agents, may improve efficacy, but often result in increased side effects as well. If magnesium was the initial agent, a supplemental dose of subcutaneous terbutaline 0.25 mg is appropriate for patients with active preterm labor. This combination is reasonably effective and is safe if supplemental terbutaline is given only once or twice. Sustained treatment with both magnesium and a -mimetic has been found to increase the risk of significant side effects and should be avoided. ^[304], ^[305] Both -mimetics and magnesium sulfate cause increased cardiac output and decreased peripheral vascular resistance, so the high rate of side effects is not surprising.

Combined use of either -mimetics or magnesium sulfate with calcium channel blockers should be avoided. Although many centers employ indomethacin as a second-line agent when magnesium fails, a recent trial found no additional neonatal benefit when indomethacin was added to ritodrine. ^[237] Such reports at first suggest ineffective treatment, but there is increasing evidence that occult chorioamnionitis may be responsible not only for persistent contractions but also for short- and long-term neurologic morbidity reported after combination tocolytic drug therapy. ^[306], ^[307] These findings emphasize the importance of careful evaluation of the preterm labor patient whose contractions do not respond promptly to tocolysis, especially before 30 weeks' gestation ([see the box "Management of Persistent Contractions Despite 12 to 24 Hours of Tocolysis"](#)).

Amniocentesis can be helpful in the management of some women with preterm labor. In addition to evaluation for infection, amniotic fluid studies for fetal pulmonary maturity may be helpful in the following circumstances:

1. When the gestational age is in doubt.
2. When the size of the fetus suggests poor or excessive intrauterine growth.
3. When there is any question of a chronic hostile intrauterine environment (e.g., maternal hypertension, decreased amniotic fluid volume, substance abuse).
4. When the gestational age is between 34 and 37 weeks. ^[307], ^[308]

Routine use of amniocentesis to assess pulmonary maturity in all patients with preterm labor is not practiced in most hospitals, but may be justified in centers that care for populations with poor dates, high rates of maternal substance abuse, or fetal growth restriction.

Management of Persistent Contractions Despite 12 to 24 Hours of Tocolysis

1. Is the patient infected? Repeat clinical exam, white blood cell counts, and fetal assessment. Consider amniocentesis for glucose, Gram stain, and culture.
2. Is the fetus compromised? Review the fetal heart tracings and do a biophysical assessment.
3. Is there evidence of abruption? Is there a suspicion of uterine anomaly with implantation of the placenta on the septum? Repeat hemoglobin, hematocrit, and coagulation profile, and abdominal sonography for placental implantation site.
4. Is the diagnosis of preterm labor correct? Is the cervix changing? Perform a transvaginal cervical ultrasound to measure cervical length and look for funneling or separation of the membranes from the lower segment. Send a fibronectin swab.
5. If infection, fetal compromise, and abruption can be excluded, stop parenteral tocolysis for 24 hours and observe. Most patients will stop contracting spontaneously.

Continued suppression of contractions after acute tocolysis has been studied in multiple placebo-controlled trials ^[310] ^[311] ^[312] ^[313] ^[314] (see Table 23-15), none of which found a significant reduction in the rate of preterm birth. Other studies that compared oral medications to no treatment also found no reduction in preterm birth. ^[315] ^[316] ^[317] ^[318] Because many of the trials are small, several meta-analyses have been performed. ^[213] ^[260] ^[319] All have found no benefit in any outcome studied, including prolongation of pregnancy, frequency of preterm birth, and reduction in

TABLE 23-15 -- PLACEBO-CONTROLLED TRIALS OF ORAL TOCOLYSIS AFTER ACUTE TREATMENT OF PRETERM LABOR

recurrent preterm labor associated with oral medication to suppress contractions. The evidence showing no benefit is important because oral terbutaline continues to be prescribed, and because chronic administration of -mimetic tocolytics can have significant side effects, both fetal and maternal. One case report ^[320] describes a woman whose fetus developed hypertrophy of the myocardial septum, apparently as a result of prolonged -mimetic-induced fetal tachycardia. Other studies have documented a clear deterioration in glucose tolerance after more than 5 days of oral -mimetics. ^[276] ^[277] Continuous administration of terbutaline via a subcutaneous infusion pump has been proposed to reduce the occurrence of tachyphylaxis ^[321] and side effects. Descriptive studies have found fewer side effects than with oral terbutaline, ^[257] but these studies lack control groups and cannot be used to judge efficacy. Two randomized placebo-controlled trials of subcutaneous terbutaline to prolong pregnancy after acute treatment of preterm labor found no benefit to this treatment. ^[258] ^[259]

There are several possible reasons for the inability of maintenance tocolytics to improve outcome. First, oral -mimetics and magnesium do not achieve levels in the blood comparable to levels produced by parenteral therapy. ^[322] The Canadian ritodrine study ^[256] reported prolongation of pregnancy for 2 to 5 days while the drug was given parenterally, but there was no additional prolongation of pregnancy when the medication was administered orally. The dose was insufficient to achieve therapeutic blood levels. Another explanation of the failure of maintenance tocolysis is the evidence cited previously that preterm labor is a usually chronic process that develops over weeks or months, not days. This conclusion is also consistent with studies that found no decrease in prematurity for women followed with ambulatory or home uterine contraction monitoring, a strategy based on detection and suppression of uterine contractions. None of three randomized trials of home contraction monitoring after acute treatment of preterm labor found a benefit for the monitored group. ^[323] ^[324] ^[325] A meta-analysis of these three trials found no advantage to home monitoring for delivery before 37 weeks, birth weight, or gestational age at delivery. ^[213] A multicenter randomized trial in which uterine activity was monitored but the data were ignored in one group also found no improvement in preterm birth rate when contraction data were used. ^[149]

The duration of hospitalization for an episode of preterm labor will vary according to several factors including the dilation, effacement, and sonographic length of the cervix; ease of tocolysis; gestational age, obstetric history; distance from hospital; and the availability of home care and family support. Women with complete cervical effacement at a gestational age at the margins of perinatal viability are more likely to benefit from prolonged hospital care. Associated risk factors that may complicate or increase the risk of recurrent preterm labor, such as a positive genital culture for GBS, chlamydia, or gonorrhea; urinary tract infection; or anemia should be controlled before discharge from hospital care. Social issues such as homelessness, availability of child care, or protection from an abusive partner are important determinants of a patient's ability to comply with medical care, and must be considered before the patient is discharged from the hospital.

Adjunctive Treatment for Women with Preterm Labor

The initial goal of treatment of women with preterm labor is to delay delivery long enough to allow three adjunctive interventions that have been shown to reduce the neonatal morbidity and mortality related to prematurity:

1. Transfer of mother and fetus to a hospital equipped to care for a premature infant. ^[214] ^[215]
2. Administration of glucocorticoids to decrease neonatal morbidity and mortality. ^[217] ^[326]
3. Administration of antibiotic prophylaxis to prevent neonatal GBS infection. ^[216] ^[327]

These three interventions are effective. The only questions about their use relate to selection of the appropriate women for treatment. Other potential interventions

currently being investigated include antibiotics to enhance the effectiveness of tocolysis and antenatal magnesium to reduce neonatal neurological morbidity.

Maternal and Neonatal Transfer

Regionalized neonatal and maternal care has been shown to improve the rates of morbidity and mortality for LBW and especially for VLBW infants. Neonatal transfer of the LBW infant led to marked improvements in neonatal outcome. When it was recognized that some VLBW infants died before a regional center's neonatal care team could arrive, transfer of the mother with the fetus in utero became the preferred alternative whenever possible. In recognition of the advantages of concentrating care for VLBW infants in special centers, most states have adopted systems of regionalized perinatal care. Hospitals and birth centers caring for normal mothers and infants are designated as Level I. Larger urban hospitals that care for the majority of maternal and infant complications are designated as Level II centers; these hospitals have neonatal intensive care units staffed and equipped to care for most infants with birth weights above 1,000 to 1,250 g. Level III centers typically provide care for the sickest and smallest infants, and for maternal complications requiring intensive care.

Antenatal Corticosteroids

In 1972, Liggins and Howie ^[328] reported a reduction in hyaline membrane disease or RDS in infants born to women treated with antenatal corticosteroids. Since then, many studies have confirmed the benefit of maternal steroid treatment to reduce the incidence and severity of RDS and other neonatal morbidity including intraventricular hemorrhage, necrotizing enterocolitis, and patent ductus arteriosus. Most important, meta-analyses indicate that antenatal glucocorticoid treatment has led to decreased perinatal mortality, with odds ratios ranging from 0.32 to 0.9 ^[217] ^[329] (Fig. 23-23).

Physiologic Effects of Antenatal Corticosteroids

Antenatal steroids influence the synthesis of fetal proteins and peptides. In general, glucocorticoids act to enhance cell differentiation and maturation rather than cell growth. In the fetal lung, steroids induce several changes that favorably affect neonatal pulmonary performance. Production of surfactant is enhanced by the effect of glucocorticoids on enzymes important in the synthesis of phosphatidylcholine, a major component of surfactant; neonatal lung compliance is increased; production of

proteins that enhance surfactant activity is increased; and alveolar protein leakage is decreased. Steroids also affect other organ systems, inducing maturation in the fetal brain, skin, and gastrointestinal tract. Animal studies have suggested that steroids promote maturation of the germinal matrix and thereby reduce the occurrence of perinatal intraventricular hemorrhage. [330]

Therapeutic Effects of Antenatal Corticosteroids

PERINATAL MORTALITY.

Perinatal mortality has been reduced in infants born to steroid-treated mothers in

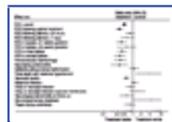

Figure 23-23 Summary of meta-analysis of 15 trials of the effect of corticosteroid use before preterm delivery on maternal and newborn outcome. RDS, respiratory distress syndrome. (From Crowley PA: Antenatal corticosteroid therapy. A meta-analysis of the randomized trials. *Am J Obstet Gynecol* 173:322, 1995, with permission.)

796

most reported trials. In a meta-analysis of multiple studies, [217] the odds ratio for neonatal mortality after antenatal steroid treatment was 0.61 (95 percent CI, 0.49 to 0.78). This figure is consistent with the original report [328] and subsequent analyses [329] showing a 40 percent reduction in neonatal mortality after steroid treatment.

Pulmonary Function

The original study reported a 50 percent reduction in RDS in steroid-treated neonates. [328] A meta-analysis [217] of 15 trials found an odds ratio of 0.51 (95 percent CI, 0.42 to 0.61) in the cumulative data for the occurrence of RDS in infants born to mothers treated with antepartum steroids compared with placebo-treated controls (Fig. 23-23). Questions remain about the efficacy of steroids in reducing RDS in patients with preterm PROM, but the magnitude and the consistency of the benefit across multiple trials have eliminated any doubt of reduced RDS in patients with intact membranes. Questions raised by earlier trials [331] that the effectiveness of steroids might be limited to certain subgroups (e.g., female and/or black infants, or infants only between 28 and 32 weeks) have been answered by the larger numbers accumulated in meta-analyses. Reduction in RDS occurs for male and female and for black and nonblack infants across a wide range of gestational ages from 24 through 34 weeks. Earlier questions about efficacy in subgroups were the result of inadequate statistical power due to small sample sizes for subgroup analysis in the initial trials. However, two principal unresolved issues about clinical use of antenatal steroids remain: (1) appropriate use of multiple courses of steroids, and (2) use in women with preterm PROM.

Maternal steroid treatment is not uniformly effective in eliminating RDS, but has been shown to ameliorate the severity of RDS when it does occur, manifested by reduced ventilator pressure settings and fewer neonatal intensive care unit (NICU) days. [332] Exogenous surfactant, an effective *postnatal* treatment for RDS, does not replace the respiratory benefits of antenatal steroid treatment. Rather, the effects of antenatal steroids and postnatal surfactant have been found to be additive for infants who receive both treatments, including significant reduction in mortality compared with those who received either therapy alone. [333] [334] [335] [336] Despite the clear effect on RDS, the impact of antenatal steroids on the incidence of bronchopulmonary dysplasia is uncertain. [217]

INTRAVENTRICULAR HEMORRHAGE.

Placebo-controlled trials have shown that antenatal steroid treatment is associated with a 50 percent reduction in the incidence of intraventricular hemorrhage [217], [329], [337], [338] (Fig. 23-23). The mechanism by which steroids produce this benefit was originally attributed entirely to the reduced frequency and severity of RDS, but effects independent of RDS have been postulated based on studies that controlled for RDS severity [339] and cranial ultrasound studies of neonates performed shortly after birth. [340] A study confined to patients treated between 24 and 28 weeks [332] in which the severity but not the incidence of RDS was reduced nevertheless found a reduction in IVH from 25 percent in untreated to 3 percent ($p = 0.012$) in treated infants. A reduction in the size of cerebral infarction has been shown in animals treated with dexamethasone prior to but not after an experimental hypoxic brain injury. [330] The neurologic benefits of antenatal corticosteroids for VLBW were supported by a retrospective cohort analysis of 1,604 infants who weighed between 500 and 1,500 g at birth. [341] The rate of postnatal ventriculomegaly when examined at mean intervals of 1, 7, and 22 days of life was reduced by half in infants who had received either a full or partial course of antenatal corticosteroids compared with those who had not received steroids. One report found that betamethasone was more effective than dexamethasone in reducing the occurrence of periventricular leukomalacia. [342]

OTHER BENEFITS.

Antenatal steroid treatment has been associated with other favorable effects on neonatal outcome, including a 65 percent reduction in the incidence of necrotizing enterocolitis (OR, 0.35; 95 percent CI, 0.18 to 0.68). [217] Reductions in the incidence of patent ductus arteriosus and circulatory instability, and improved Apgar scores [343] have also been reported.

DOSAGE OF CORTICOSTEROIDS.

Two glucocorticoid regimens have been found effective: *betamethasone*, given as a mixture of 6 mg each of betamethasone phosphate and betamethasone acetate (Celestone) 12 mg intramuscularly every 24 hours for 2 doses, and *dexamethasone* (Decadron) 6 mg, also given intramuscularly, every 12 hours for 4 doses. The oral preparation of dexamethasone should not be used. A randomized trial of oral versus intramuscular dexamethasone was halted after a blinded review found an unexplained increase in intraventricular hemorrhage and neonatal sepsis in babies whose mothers were in the oral treatment arm. [344] Other steroid preparations (e.g., prednisone) are not effective because of poor placental transfer and should not be used. In studies of neonatal respiratory morbidity, betamethasone and dexamethasone produce similar clinical benefits. However, there may be important differences. Dexamethasone, but not betamethasone, was associated with altered neurobehavioral development in mice. [345] In another study that evaluated the occurrence of cystic periventricular leukomalacia among infants born between 24 and 31 weeks' gestation, the rate of periventricular leukomalacia was 4.4 percent among 361 infants who were treated antenatally with betamethasone, 11.0 percent among 165 infants

797

who received dexamethasone, and 8.4 percent among 357 infants who were not treated with antenatal glucocorticoids. [342] Betamethasone, but not dexamethasone, transiently alters the fetal biophysical profile, inducing absent fetal heart variability and decreased tone and breathing movements for 48 to 72 hours. [346], [347]

Several issues about the appropriate dosage schedules remain unresolved. It is not known whether steroids accelerate the normal maturational process transiently or permanently. The issue is difficult to study because the interval between treatment and delivery in clinical trials is variable, and because some effects may be transient while others are permanent. Neonatal benefit has been most easily observed when the interval between the first dose and delivery exceeds 48 hours, but benefit also accrues for babies born after a partial or incomplete course. The initial studies [348] seemed to indicate that the respiratory benefits were limited to the first week after treatment. However, there were very few cases of RDS among infants delivered more than 7 days after treatment, limiting the power of this observation. In contrast, a large multicenter trial [349] found evidence of benefit for as long as 18 days after the initial course of antenatal steroids.

RISKS OF ANTENATAL CORTICOSTEROID TREATMENT.

Concerns about both short- and long-term adverse effects of corticosteroids have arisen as the frequency of antenatal therapy increased after the 1994 NICHD Consensus Conference. [350] Short-term concerns include possible reduced resistance to infection for both the mother and infant, impaired glucose tolerance,

suppression of maternal or neonatal adrenal function, and alteration of the fetal biophysical profile following steroid treatment. The largest studies ^[331], ^[351], ^[352] did not find any increased incidence of neonatal or maternal infections. Infection is a greater concern when steroids are given to women with preterm PROM, but even in that subgroup, an increase in infectious morbidity has not been definitively shown. Increased fetal jeopardy in pregnancies complicated by proteinuric hypertension was suggested by the original ^[335] study, but was not confirmed in subsequent series. ^[353], ^[354]

In women with insulin-dependent diabetes mellitus, steroid treatment virtually always results in 48 to 96 hours of increased blood glucose that can be difficult to control with standard insulin regimens. Intravenous infusion of insulin is often necessary. In women without diabetes, impairment of maternal glucose tolerance may also occur, especially in women treated with -mimetic drugs^[280] or when traditional risk factors for gestational diabetes such as maternal age, obesity, or family history are present. Therefore, maternal glucose testing should be considered when repeated courses of glucocorticoids are administered.

Whether antenatal steroids inhibit adrenal response in the mother or newborn in a clinically relevant manner is uncertain. Transient suppression of neonatal cortisol levels has been reported. ^[361] The doses given produce levels of corticoids comparable to those endogenously produced by the neonatal adrenal gland in response to the stress of RDS. Women treated with multiple courses of steroids during pregnancy were found to have a blunted response to adrenocorticotrophic hormone (ACTH) stimulation later in pregnancy or during the puerperium. ^[356]

Maternal treatment with betamethasone^[357] but not dexamethasone^[346], ^[347] has been associated with transient reduction in fetal heart rate variability and body and breathing movements in several studies. When it occurs, typically between 48 and 72 hours after the first dose, the alteration in fetal biophysical behavior is striking. Both short- and long-term heart rate variability is reduced, and fetal body and breathing motion may be absent or significantly reduced. The effects resolve spontaneously by the 4th day. Doppler ultrasound studies are unaffected by corticosteroid administration and may therefore provide reassurance about fetal well being. ^[358]

Concern about long-term fetal effects is founded upon the observation that corticosteroids act to accelerate fetal cellular and organ maturation at the expense of cell and organ growth. ^[359] Data about long-term risks are mostly but not wholly reassuring, and must be viewed against the overwhelming evidence of neonatal benefit. Studies in mice^[360] and sheep^[361] have reported decreased fetal size after repeated doses of steroids. Antenatal steroid therapy given in a rodent model at a gestational age analogous to the early third trimester in humans was associated with reduced brain cell number and decreased brain DNA content. ^[362] In the sheep, repeated injections of corticosteroids were associated with a significant delay in myelination of the optic nerve. ^[363] Slotkin ^[364] cautioned that "therapeutic use of antenatal steroids ... occupies precisely the timeframe of maximum vulnerability of the central nervous system (CNS) ... (and) ... low doses of glucocorticoids that lie at or below the threshold for eliciting changes in lung surfactant production are capable of altering CNS development." He also noted that steroids could possibly affect tissue response to hypoxia in organ systems other than the CNS. Additional concern about repeated courses has been raised by reports in humans of reduced growth associated with multiple courses of antenatal steroids. An Australian study found that 17 percent of infants who received a single in utero course of antenatal steroids had birth weights below the 10th percentile, compared with 35 percent of infants exposed to more than three antenatal courses. ^[365] There was also a significant association between multiple courses and reduced head circumference in this study. In view of these concerns, it is reassuring to note that the original cohorts of infants treated with a single course of antenatal steroids have displayed no differences

when compared with gestational age-matched controls in physical or mental function. ^[352], ^[366]

Clinical Use of Antenatal Corticosteroids

Despite the impressive evidence of both medical and economic benefit, ^[367], ^[368] maternal steroid treatment preceded only 26 percent of low-birth-weight deliveries in a 1990 survey. ^[369] Fewer than half of treated infants in this review had received a full course of treatment. The underutilization apparently occurred for diverse reasons. Some did not receive treatment for unavoidable causes such as presentation in advanced labor or maternal illness requiring immediate delivery (e.g., eclampsia or significant obstetric hemorrhage). Others were not treated because of underestimation of neonatal survival rates for ELBW babies, concern about maternal or neonatal risks of infectious morbidity, or questions about the effectiveness of partial treatment or of population subsets such as white male fetuses.

In response to these concerns, the NICHD convened a Consensus Development Conference on Antenatal Steroids in 1994. ^[370] The recommendations of this conference were reviewed by the Committee on Obstetric Practice Opinion (No. 210) of the American College of Obstetricians (ACOG) and Gynecologists. ^[326] Both NICHD and ACOG recommend antenatal steroids for mothers expected to deliver before 32 weeks' gestation to reduce mortality and the incidence of RDS and IVH, regardless of the status of the fetal membranes. At 32 to 34 weeks, both recommend antenatal steroid treatment for mothers with intact membranes who were likely to deliver within 7 days, but noted that the benefit for infants born to women with ruptured membranes after 32 weeks is still controversial. The controversy centers on whether a large trial^[371] that found a substantial benefit of steroids should be included in meta-analyses. The results of this trial may have been confounded by concomitant treatments and by a remarkably high rate of RDS in the control group. When meta-analyses of steroid trials in patients with PPRM exclude the data from this trial, the beneficial effect of steroids on the incidence of RDS is lost, but the effect on intraventricular hemorrhage is retained.

In addition to the preterm PROM issues, questions regarding the need for and risk of repeated courses of steroids remain unanswered. The opportunity for long-term risk would seem to be greater with repeated dosing. The 1994 NICHD Consensus Panel reconvened in August 2000. The Panel recommended that repeat dosing not be used in clinical practice pending data from ongoing research studies. The risk and consequences of imminent preterm birth, in contrast, are immediate and real, and will vary in individual ways as the pregnancy continues. A weekly reassessment of the need for steroids, rather than a policy of routinely administering steroids each week to high-risk patients, is probably the wisest course.

The NICHD Consensus Panel's successful campaign to increase the use of steroids has also led to new unanswered questions about the indications for steroid treatment of high-risk patients. What risk of imminent preterm delivery is sufficient to treat the patient with antenatal corticoids? Is actual preterm labor or preterm PROM required, or is a history of a previous preterm delivery and/or a dilated or effaced cervix enough? At our center, we have used admission to the hospital as the principal criterion for steroid treatment. Asymptomatic women with historical risk factors who inquire about receiving prophylactic corticosteroids may be reassured by a negative fibronectin test or cervical ultrasound examination, thus avoiding indiscriminate use of steroids.

Antibiotics for Women with Preterm Labor

There are two potential uses for antibiotics in women with preterm labor. The first is prophylaxis of neonatal GBS infection, an intervention that is clearly effective ([see Chapter 40](#)). The second is antibiotic therapy aimed at prolonging gestation in women with preterm labor by targeting a broad range of microorganisms that have been implicated in the pathogenesis of spontaneous preterm birth. Administration of antibiotics to women being treated for preterm labor has been studied extensively with disappointing results. ^[372] ^[373] ^[374] ^[375] ^[376] ^[377] Results from the largest trial^[378] are shown in [Table 23-16](#).

Given the extensive and persuasive literature that links genital tract colonization and infection with spontaneous prematurity, ^[98] what can be the reasons for the failure of supplemental prophylactic antibiotics to enhance tocolysis? The first is the problem that has hampered all studies of preterm labor, the overdiagnosis of preterm labor. The inclusion of women who do not actually have preterm labor in trials of interventions for preterm labor confounds interpretation of the results. Antibiotic

TABLE 23-16 -- SUPPLEMENTAL ANTIBIOTIC TREATMENT IN WOMEN WITH PRETERM LABOR*

Outcome	Antibiotic Rx (n = 131)	Placebo (n = 144)
Delivery <37 weeks (%)	53	52
Entry to delivery (days)	35	32
Mean birth weight (g)	2,535	2,883
Preterm PROM (%)	19	15
Amnionitis (%)	2	5

Data from Romero R, Sibai B, Caritis S, et al: Antibiotic treatment of preterm labor with intact membranes: a multicenter, randomized, double-blinded, placebo-controlled trial. *Am J Obstet Gynecol* 169:764, 1993.

* Prospective, randomized trial by NICHD MFMU network; ampicillin + erythromycin vs. placebo; 277 subjects with PTL at 24-34 wk, intact membrane.

trials limited to subjects who are fibronectin-positive might produce different results. The second reason is that the clinical diagnosis of preterm labor, even when accurate, may occur so late in the pathologic sequence that it is simply too late for antibiotics to exert any favorable effect. Regardless of the explanation, it is clear that supplemental antimicrobial therapy for reasons other than treatment of a specific pathogen such as gonorrhea or prophylaxis of GBS is not justified at present for women with preterm labor.

Other Adjunctive Antenatal Treatment to Reduce Fetal Morbidity

The persistence of cases of RDS among infants born to women treated with steroid therapy has led to investigation of alternative treatment approaches to further enhance pulmonary maturation. Neonatal treatment with surfactant is an effective adjunctive therapy that adds independently and synergistically to the benefit of corticosteroids in reducing RDS-related morbidity. Three large randomized, placebo-controlled trials of maternal treatment with antenatal thyrotropin-releasing hormone (TRH) to reduce neonatal lung disease have found no benefit over corticosteroids alone. ^[379] ^[379] ^[380] Together, these trials enrolled 1,771 subjects.

Studies of other agents given to the mother before delivery to reduce or prevent neonatal neurologic morbidity have been reported for phenobarbital and vitamin K. Initial studies of both agents appeared promising but larger placebo-controlled trials have found no benefit to treatment with these agents. Rates of grade III and IV intraventricular hemorrhage, of any IVH, and of neonatal mortality did not differ between 181 infants born to mothers who received placebo and 191 whose mothers received both vitamin K and phenobarbital. ^[381] Another randomized trial found no difference between antenatal phenobarbital and placebo in either intracranial hemorrhage or early death in 610 preterm infants. ^[382]

A reduced incidence of intraventricular hemorrhage and cerebral palsy in premature infants exposed to antepartum maternal magnesium sulfate treatment for both preterm labor tocolysis and seizure prophylaxis has been noted in retrospective analyses. ^[226] , ^[227] This association is unexplained, and is currently being tested in randomized trials.

ABNORMAL CERVICAL COMPETENCE

Definition

Few topics in obstetrics have been the subject of greater controversy than has cervical incompetence. The diagnosis of incompetent cervix has traditionally been made and is still most confidently established by an obstetric history of passive and painless dilation of the cervix in the second trimester. The controversy has centered on whether this classic picture is the only true presentation for this disorder, or whether there are other clinical presentations. A history of the amniotic sac found bulging through a well-effaced and partially dilated cervix in the absence of contractions, bleeding, infection, or amniorrhexis is classic but is not common.

Arguments about the presentation and incidence of incompetent cervix derive from two different theories. According to the traditional view, the cervix operates as a categorical variable in which it is either fully functional (competent), or nonfunctional (incompetent). Preterm labor, ruptured membranes, bleeding, or intra-amniotic infection in women presenting at 16 to 26 weeks are assumed to be primary etiologic diagnoses in which a competent cervix changes only in response to uterine activity, whether overt or occult. This understanding of cervical competence as either categorically competent or incompetent is based on studies of the cervix in which digital examination was used to assess cervical dilation and length. The authors of a 1961 study "... wondered whether there can be any degrees in the incompetence of the internal os. If an incompetent os can cause abortion, is it possible that a lesser degree of incompetency ... can lead to premature labour?"^[383] They performed digital examination of the cervix in 655 subjects and concluded that "A degree of incompetence of the internal os that would lead to a premature labour does not seem to exist." This once dominant conclusion was challenged by studies suggesting that women with a history of second-trimester delivery might benefit from prophylactic cerclage.^[169],^[177] These investigations indicated that the traditional clinical presentation of incompetent cervix may be simply fortuitous (i.e., that some women with a passively dilated cervix and bulging amniotic sac might develop contractions, infection, or membrane rupture as the consequence of incompetent cervix).

Subsequent studies of the cervix with ultrasound have revealed that the cervix functions along a continuum of "competence."^[101] One study used transvaginal ultrasound to measure cervical length in three groups of pregnant women: (1) women with an obstetric history typical of incompetent cervix, (2) women with a history of a prior spontaneous preterm birth, and (3) women who had normal obstetric histories and normal current pregnancies.^[63] The hypothesis was that if cervical function were categorical, cervical length would be short in women with incompetent cervix but would be similar in both normal pregnancies and in the women who delivered preterm. Alternately, if cervical function were continuous, cervical length would decrease as the gestational age at delivery in the previous pregnancy decreased. The results were consistent with the latter hypothesis: the

earlier the gestational age at delivery in the prior pregnancy, the shorter the cervix in the current pregnancy. Two prospective studies correlated transvaginal sonographic measurements of the cervix in the late second and early third trimesters with risk of preterm delivery. In a cross-sectional study of 178 women,^[101] the risk of preterm delivery increased as cervical length decreased. A multicenter observational study^[79] of 2,915 pregnant women found that the risk of preterm birth increased as cervical length decreased across the whole range of cervical length (Fig. 23-15) and (Fig. 23-16).

The same cervical changes (shortened cervix, funneled internal os) that are associated with increased risk of spontaneous preterm birth have been described in women who present with typical cervical incompetence.^[384] The only difference is the duration of pregnancy at the time of examination. The same changes have been noted as early as 16 weeks.^[385] However, although the risk of preterm birth is increased approximately six fold in women whose cervical length is below the 10th percentile (25 mm), the majority of women in whom these changes are observed do not present with typical incompetent cervix, or even deliver preterm.^[79],^[102]

These studies have changed our understanding of the cervix from a categorical concept of cervical "incompetence" versus "competence" to one of variable competence, wherein cervical function is described by a bell-shaped curve that roughly corresponds to length. The risk of spontaneous preterm birth increases as cervical length decreases. Women whose cervical length lies below the 5th or 10th centile clearly have the greatest risk for spontaneous preterm birth (Fig. 23-16), but the clinical presentation is not uniform. Some will present with preterm labor, others with PPRM, and still others with the classic picture of incompetent cervix.

If cervical length correlates with risk of preterm birth, is it possible to define reduced cervical competence according to a cervical length below, for example, the 5th percentile? The answer is no. Cervical length is influenced by several factors, including biologic or inherent differences (the ratio of muscle to collagen is increased in women with incompetent cervix),^[386] by the duration of pregnancy (the cervix elongates in the first and early second trimesters and shortens slowly thereafter as the volume of the uterus increases), by the action of cytokines and prostaglandins,^[71],^[387] and finally by uterine contractions. The contribution of each of these to any individual cervical length measurement is uncertain.

Despite the unanswered questions, this much is clear: cervical competence is variable, and so is the clinical presentation. The only clearly diagnostic presentation is still a history of painless dilation, but any patient with a history of early preterm birth before 26 weeks may have reduced cervical competence, a term that more accurately reflects the data described above.

Etiology

Reduced cervical competence may be congenital or acquired. Some women have typical histories of painless dilation in the first and every subsequent pregnancy, while others experience progressively earlier delivery with each pregnancy until a typical "incompetent" history occurs. Still others have several term births before an obstetric injury in the penultimate pregnancy creates a damaged cervix. The concept of percentiles of competence suggests that women with cervical lengths below the 25th to 50th percentiles may suffer clinically meaningful injury to the cervix as a result of obstetric or gynecologic trauma that would not have clinical consequences had the initial cervical length been longer.

Cervical trauma may occur in the course of either vaginal or cesarean delivery. The cervix may be lacerated and heal poorly, or may be stretched beyond tolerance. It is not uncommon to care for women whose typical presentation of incompetent cervix followed a prior cesarean delivery performed for disproportion after prolonged pushing in the second stage of labor. Obstetric trauma may rarely accompany dilation and curettage. Insertion of laminaria to soften the cervix before dilatation and extraction or dilatation and curettage may reduce cervical trauma. A history of prior first-trimester elective abortion carries a risk of injury so small as to be insignificant if it was performed by an experienced operator using local anesthesia only, and if laminaria were used in nulliparas.^[388] Depending on the amount of tissue removed, cervical cone biopsy may lead to reduced cervical competence, but has less risk than is commonly thought.^[389] Patients with a higher concentration of smooth muscle relative to collagen fibers in the cervix may be at increased risk for cervical incompetence.^[386] Congenital structural changes in the cervix can occur in association with Müllerian uterine malformations or after diethylstilbestrol (DES) exposure. We have followed women with prior conization, Müllerian anomalies, and in utero DES exposure with serial transvaginal sonography, and have had success in selecting candidates for cerclage when funneling or shortening below 20 mm occurs, thus

limiting cerclage to relatively few patients with these risk factors.

Diagnosis

Reduced cervical competence is a clinical diagnosis marked by gradual, painless dilatation and effacement of the cervix with membranes visible through the cervix. This history establishes the diagnosis, but is probably a fortuitous presentation; eventually, women with this cervical status may develop membrane rupture, labor,

801

or even amnionitis with intact membranes. Short labors with the delivery of an immature fetus or loss of the pregnancy at progressively earlier gestational ages in successive pregnancies is characteristic of reduced competence. Until recently, objective criteria in the absence of the typical history have been lacking. Dilators or balloons to determine cervical resistance and/or hysterosalpingograms to measure the width of the cervical canal between pregnancies are neither sensitive nor specific, and digital examination of the cervix is highly subjective.^[157], ^[390] Sonography has provided a reproducible method of evaluating the cervix.^[158], ^[391] The sonographic characteristics of reduced competence are a short cervix, with a length of less than 20 mm, before 24 weeks' gestation often but not always accompanied by funneling of the internal os. Funneling may be thought of as "effacement in progress": The process proceeds from the inside out, beginning at the internal os and moving caudad. It may be first identified on digital exam by a subtle softening of the lower segment and on ultrasound examination by a narrow funnel or echolucent proximal third of the endocervical canal (Fig. 23-24 A). As the process continues, the opening of the internal os becomes broader and the shoulders of the funnel more pronounced (Fig. 23-24 B). Eventually, the shoulders disappear, leaving only a short cervical length. Remarkably, the process is dynamic, with the internal os opening and closing in response to fundal or suprapubic pressure or assumption of the standing position. Local or coordinated uterine activity may accompany the funneling of the internal os, but more commonly there is no palpable or measurable uterine contraction. Note that these criteria are essentially identical to those seen in preterm labor, differing only in the absence of contractions and the earlier gestational age at which the reduced competence phenomenon occurs. Ziliani et al.^[392] have suggested a useful acronym to describe the process of effacement as seen by transvaginal sonography: TYVU. These letters form, in chronologic sequence, the sonographic appearance of the cervical canal and lower segment as it changes from the uneffaced *T* to the beginning funnel *Y*, with further shortening to *V*, and finally to a fully developed lower uterine segment, *U*. Because of the variation of the appearance of the upper funneled portion of the cervix, we have concentrated on accurate measurement of the residual lower cervical length as the most consistent measurement, both serially for each woman and for comparison with other centers.

A diagnosis of reduced cervical competence may be made prior to pregnancy or in the first trimester, if a typical history of painless dilatation and effacement of the cervix in a prior pregnancy can be documented. Women with a history of a previous second-trimester loss in which cervical sonography documented the classic picture of funneling and shortened cervical length are also candidates for prophylactic cerclage sutures. However, when the history is atypical or uncertain, it is more appropriate to follow the patient closely with frequent transvaginal ultrasound examinations beginning at 16 to 18 weeks' gestation, looking for the criteria noted above, and for funneling in response to fundal pressure. Funneling did not occur in response to fundal pressure in 150 normal pregnancies, but was seen in 14 of 31 women with a history suggestive of abnormal competence.^[393] Without a history of early preterm birth, the appearance of spontaneous or induced funneling after 24 weeks of pregnancy does not establish a diagnosis of cervical incompetence, nor does it require a cerclage. The obstetric history and the cervical length exclusive of any funneling are the most predictive. The appearance of a funnel with a normal residual length has little import.

When reduced cervical competence presents unexpectedly in a patient without a worrisome history, the initial symptoms may include a sense of pelvic pressure, low backache, or premenstrual molimina accompanied by an increase in vaginal discharge that may be light tan or blood streaked. Sonography at this point will usually reveal a large funnel and substantial shortening, with or without dilation of the external os. Later, overt fluid leakage or contractions may ensue.

Cerclage Technique

Prophylactic Cerclage

In 1955, Shirodkar^[394] reported successful management of cervical incompetence with a submucosal band of Mersilene tape, placed at the level of the internal os. This procedure requires anterior displacement of the bladder and submucosal dissection. The Shirodkar cerclage may be difficult to remove so that successful pregnancies may require delivery via cesarean section. Several years later, McDonald^[395] described the use of a purse-string technique that could easily be performed during pregnancy. This approach involves either four or five "bites" as high on the cervix as possible. A metal catheter may be used to help identify the margin of the bladder. The knot is placed anteriorly to facilitate removal. This operative technique is illustrated in Figure 23-25. We use two purse-string stitches of 5 Ethibond, but there are many suitable variations. The McDonald procedure has proved to be as effective as the Shirodkar technique^[396] and requires considerably less dissection. Prophylactic cerclage sutures may be placed at 10 to 15 weeks' gestation. We do not use tocolytics at the time of prophylactic cerclage, but do give perioperative antibiotics. Intercourse, prolonged (>90 minutes) standing, and heavy lifting are omitted following cerclage. We follow these patients with periodic vaginal sonography to assess stitch location and funneling.^[397] No additional

802

Figure 23-24 A, Transvaginal ultrasound image of the cervix in a woman with abnormal cervical competence showing mild separation of the canal or early evidence of funneling. Cervical length is marked by the (+) caliper; the other calipers define the funnel. B, Transvaginal ultrasound image of the cervix in a woman with abnormal cervical competence showing a marked funnel. The (-) caliper shows the length of the remaining cervix and the (x) caliper the length of the funnel.

restrictions are recommended as long as the stitches remain within the middle or upper third of the cervix without the development of a funnel, and the length of the cervix is greater than 25 mm. Some shortening of the cervix should be expected after 20 weeks. In fact, if the cervical length remains greater than 35 mm throughout the second trimester, the accuracy of the original diagnosis may be questioned.^[398] For patients who have not been successful with a vaginal suture despite aggressive ancillary care and sonographic surveillance, a transabdominal cerclage may be appropriate.^[399]

Emergency Cerclage

Care of the patient with newly detected reduced cervical competence in the second trimester is both difficult and controversial. The introduction of sonography has

803

Figure 23-25 Placement of sutures for McDonald cervical cerclage. A, We use a double-headed Mersilene band with four "bites" in the cervix, avoiding the vessels. E, The suture is placed high upon the cervix close to the cervical-vaginal junction, approximately the level of the internal os.

been helpful in making early diagnoses and avoiding the complications that accompany advanced dilation and effacement. When the diagnosis is made before cervical dilation has occurred and when there is still 10 to 15 mm or more of cervical length, we admit the patient for 24 hours of treatment with perioperative indomethacin and broad-spectrum antibiotics before placing the cerclage sutures, and observe the patient for 48 to 96 hours postoperatively. However, if the cervix has dilated to allow visualization of the membranes, the patient may remain hospitalized for several days after cerclage placement. The prognosis for these patients is better than generally expected, with many women delivering a "viable" (usually defined as >1,000 g) infant, but aggressive therapy may be required to achieve these

results. The prognosis is influenced by the gestational age at the time the heroic suture is placed. ^[400] If the sutures appear tenuous, prolonged hospitalization with Trendelenburg position may be required.

In the setting of advanced dilatation with bulging membranes, several techniques may be helpful. First, careful inspection of the membranes to identify separation or loss of the chorion from the intact amnion should be performed. If only the amnion remains, prolongation of pregnancy beyond a few days is unlikely. Precerclage amniocentesis to remove sufficient fluid to reduce the bulging membranes can be helpful. Overfilling the bladder with 1,000 ml of saline may help by elevating the membranes out of the operative field, but may also obstruct the surgeon's view. ^[401] We often place a Foley catheter balloon inside the cervix, and overfill it with at least 50 ml of saline to gently push the membranes out of the lower segment. The cerclage can then be placed and tied as the balloon fluid is evacuated. Cerclage is rarely performed after 24 to 25 weeks of pregnancy. The great risk of inducing PROM or preterm labor and the ability to prolong gestation with bed rest and suppressive medications argue against surgical intervention in such cases.

The cerclage is removed at 37 weeks' gestation or at the onset of labor.

Risks of Cerclage

Cervical injury at the time of delivery is the most commonly reported morbidity from a McDonald cerclage. While fibrous scar tissue may form at the site of the stitch, producing an abnormal labor curve, most patients will have a normal labor curve after cerclage. ^[402] A fibrous "band" may rupture, leading to a cervical laceration (1 to 13 percent), or never dilate (cervical dystocia, 2 to 5 percent), requiring cesarean birth. ^[403] Rarely, a laceration may extend to the broad ligament or corpus of the uterus, requiring extensive repair or even hysterectomy.

For elective cerclage at the beginning of the second trimester, the risk of infection is small, estimated at less than 1 percent. Later in the pregnancy, displacement of the suture also can occur (3 to 12 percent). A second cerclage has a much lower success rate. Late complications of cerclage include PROM or preterm labor and chorioamnionitis; the risk varies with the duration of gestation and the presence of cervical dilation. When fluid leakage occurs in a patient with a cerclage, removal of the suture ^[404], ^[405] to reduce the risk of infection is controversial.

Efficacy of Cervical Cerclage

There has never been a randomized prospective study documenting the benefit of cerclage for women with a "classic" history of cervical incompetence, but 80 to 90 percent of reported pregnancies in observational studies have resulted in live births of viable infants. ^[403]

Three prospective randomized trials of cerclage ^[169] ^[170] ^[171] have been conducted in patients with increased risk of preterm birth, *excluding* women with classic indications for cerclage. Two trials ^[170], ^[171] found no benefit from cervical cerclage in this patient population, and one noted an increase in the need for antepartum hospitalization. ^[171] The third, a prospective randomized study that enrolled 905 women for whom the obstetrician was uncertain about the need for cerclage, found a small decrease in the occurrence of preterm births before 33 weeks in women treated with a cerclage compared with controls (13 percent vs. 18 percent, $p = 0.03$). ^[169] There were similar statistically significant reductions in birth weight under 1,500 g and in neonatal death.

PRETERM PREMATURE RUPTURE OF THE MEMBRANES

The fetal membranes normally rupture spontaneously during labor, presumably due to the physical effects of repetitive uterine contractions. Spontaneous rupture of the fetal membranes before the onset of labor is called premature rupture of the membranes (PROM) regardless of gestational age. Preterm PROM is defined as PROM that occurs before 37 weeks' gestation.

Etiology

The fetal membranes are made up of a thin layer of amnion and a thicker outer layer of chorion that is directly apposed to maternal decidual tissue. Interspersed between the amnion and chorion is a collagen-rich connective tissue zone that serves in part to replenish the amnion. By 26 weeks' gestation, the amnion is composed of a single layer of cuboidal cells. The chorion is four to six cell layers in thickness. The amnion has greater tensile strength than the chorion, although both membrane layers together withstand greater bursting pressures than they do separately. The amount of physical stress tolerated by the membranes decreases as pregnancy progresses. Membranes supported by a closed cervix require much greater pressures to rupture than do membranes covering an open area of 3 to 4 cm in diameter.^[406] As gestational age advances, the relative concentration of collagen decreases as well.^[407] These factors help to maintain integrity of the membranes throughout pregnancy, yet allow rupture of membranes in labor at term.

Collagen maintenance and degradation are regulated in fetal membranes by the interaction of matrix metalloproteinases (MMPs) and specific tissue inhibitors (tissue inhibitor of matrix metalloproteinases [TIMPs]), so imbalances in the action of this system may be associated with preterm rupture.^[408] Both collagenase and pro-tease activity are increased in women with premature ruptured membranes.^[409] These mechanisms of collagen maintenance and degradation may be altered in the presence of clinical risk factors that have been linked to the occurrence of preterm PROM, such as maternal gene expression,^[410] ^[411] connective tissue disorders (e.g., Ehlers-Danlos syndrome), genital tract infection or colonization with various microorganisms,^[412] coitus,^[413] low socioeconomic status,^[414] uterine overdistention,^[414] second- and third-trimester bleeding,^[46] nutritional deficiencies of copper and ascorbic acid,^[405] and maternal smoking.^[46] ^[409] ^[415] One study^[416] found that a short cervical length (25 mm) at 24 weeks was associated with preterm PROM that occurred weeks later. This suggests that the process leading to preterm PROM is chronic rather than acute in many cases.

Evidence of the association of infection with preterm PROM is abundant.^[417] Naeye^[413] observed an association between preterm PROM, recent coitus, and histologic chorioamnionitis. Histologic studies of the membranes after preterm PROM often demonstrate significant bacterial contamination along the choriodecidual interface with minimal involvement of the amnion. This suggests spread of the organisms along the maternal-fetal surfaces *before* membrane rupture.^[418]

Specific genital tract pathogens have also been correlated with the occurrence of PROM. The organisms include *B. fragilis* and other anaerobes, *N. gonorrhoeae*, *C. trachomatis*, *T. vaginalis*, and group B -hemolytic streptococci.^[419] Group B streptococcal colonization was not associated with PROM in the Preterm Prediction Study.^[419] A consistent association has been found between bacterial vaginosis and spontaneous preterm births, including those following preterm PROM (see earlier section of this chapter).

Diagnosis

The most common presentation is a gush of fluid from the vagina followed by persistent, uncontrolled leakage, but some patients report only intermittent leakage or perineal wetness. Any history of passing fluid through the vagina should be evaluated by a sterile speculum examination to collect fluid for confirmatory tests. Digital examination of the cervix in women with possible preterm labor or preterm PROM should be avoided

until the diagnosis of ruptured membranes has been excluded. Because of the risk of introducing bacteria into the endocervix, digital examination for women with preterm PROM should be avoided until labor occurs or delivery is anticipated within 24 hours. Increased neonatal infection and mortality were observed when a digital examination precedes delivery by more than 24 hours in the presence of PROM.^[419] Mean interval from rupture to delivery was much shorter (2.1 days vs. 11.3 days) in 121 women who had a digital examination compared with 144 women who had only a sterile speculum examination.^[420] However, a study of 794 women with preterm PROM has challenged these traditional maxims, at least when the number of exams is less than or equal to 2.^[421] In this study of a predominantly indigent population, 161 women had one, 27 had two, and 606 had no digital exams. There were no differences in the rates of chorioamnionitis, endometritis, early neonatal sepsis, or composite neonatal morbidity according to the number of exams. To avoid a digital exam, a visual estimate at the time of sterile speculum examination can sometimes identify women with advanced dilation.^[422] The sterile speculum examination may also reveal a collection or "pool" of fluid that can be tested for pH with nitrazine paper. Since amniotic fluid is slightly alkaline (the pH is about 7.15), vaginal secretions containing amniotic fluid will usually result in pH changes in the blue-green range, 6.5 to 7.5. Nitrazine testing is accurate in 90 to 98 percent of cases.^[423] False-positive values can result from infections that raise vaginal pH (e.g., *T. vaginalis*), the presence of blood, or rarely, cervical mucus. False-negative reactions are frequent when only a scant amount of fluid is present.

When placed on a clean slide and allowed to air dry, amniotic fluid produces a microscopic crystallization in

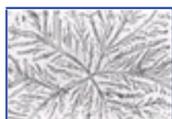

Figure 23-26 Demonstration of amniotic fluid arborization pattern. (From Reece EA, Chervenak F, Moya F, et al: Amniotic fluid arborization: Effect of blood, meconium, and pH alterations. *Obstet Gynecol* 64:248, 1984, with permission.)

a "fern" pattern. [Figure 23-26](#) demonstrates the typical appearance. This phenomenon is due to the interaction of amniotic fluid proteins and salts and accurately confirms PROM in 85 to 98 percent of cases. False-positive tests can result from the collection of cervical mucus, which also "ferns," but usually in a more floral pattern. The fern test is unaffected by meconium, changes in vaginal pH, and blood/amniotic fluid ratios of up to 1:5. The fern pattern in samples heavily contaminated with blood is atypical and appears more "skeletonized."^[424] ^[425]

An ultrasound evaluation for amniotic fluid volume should be performed in women with preterm PROM to determine fetal presentation, fetal weight, and gestational age. If the diagnosis of membrane rupture is equivocal, a finding of decreased or absent fluid by ultrasound supports a diagnosis of ruptured membranes. When abundant residual fluid is observed in women after a confirmed diagnosis of PROM, the possibility of polyhydramnios prior to rupture should be considered. In uncertain cases, a repeat sterile speculum examination after the patient has rested in a semiupright position for approximately 1 hour to allow the pooling of

secretions in the posterior vagina may be helpful. During this time, the woman may be monitored to evaluate fetal well-being and uterine contractions. Variable decelerations suggest umbilical cord compression secondary to reduced amniotic fluid volume. When all other tests are equivocal in a patient with reduced fluid and a good history, a vaginal swab for fetal fibronectin (fibronectin is abundant in amniotic fluid) may be helpful to exclude the diagnosis. In rare instances, an amniocentesis to inject a dilute solution of indigo carmine dye to look for transcervical leakage onto a tampon can be used to make an absolute diagnosis. Methylene blue dye has been associated with hemolytic anemia and hyperbilirubinemia in the infant and should not be used. Amniocentesis is seldom indicated, but its use underscores the importance of making an accurate diagnosis of ruptured membranes. Careful evaluation is required whenever PROM is suspected at any gestational age. Preterm PROM is not a diagnosis that can be made casually and should never be entirely excluded in any patient with either oligohydramnios or symptoms of persistent leakage.

Natural History

Care of women with preterm PROM is determined by estimation of the likely course of pregnancy in the absence of medical intervention. For women with preterm PROM between 20 and 34 weeks, the duration of pregnancy after PROM is inversely related to the gestational age at time of membrane rupture. When PROM occurs prior to 26 weeks' gestation, 30 to 40 percent of

cases will gain at least 1 additional week before delivery and 20 percent will gain over 4 weeks. ^[426] By contrast, 70 to 80 percent of patients who experience PROM between 28 and 36 weeks' gestation deliver within the first week after PROM and more than one half of these within the first 4 days. ^[427] Between 32 and 34 weeks, the mean interval between rupture and delivery is 4 days. ^[428] At term, 80 percent enter labor within 24 hours after rupture of the membranes. These data describe the aggregate experience for women with preterm PROM, but it is difficult to predict the clinical course of an individual patient. Some reports have linked socioeconomic status to the likelihood of delivery and infection after preterm PROM. For example, a study of 298 indigent women with preterm PROM before 34 weeks found that 93 percent were in labor within 48 hours after membrane rupture. ^[429] The rate of chorioamnionitis in those managed expectantly was 16 percent. However, a study that compared 317 indigent women with 194 insured women found no difference in either the interval from rupture to delivery or the rate of chorioamnionitis. ^[430]

Maternal Risks

Whether a cause or result of preterm PROM, intrauterine infection is a potentially serious complication to the mother. Clinical chorioamnionitis accompanies preterm PROM in approximately 10 percent of cases (range, 3 to 30 percent). ^[418] Regardless of clinical signs of infection, as many as 25 to 30 percent of women with preterm PROM (range, 15 to 45 percent) will have a positive amniotic fluid culture. Most instances of amnionitis respond well to antibiotic treatment and delivery, but maternal deaths from sepsis can occur. ^[431] Amnionitis is more common when PROM occurs before 30 3/4 weeks.

Fetal and Neonatal Risks

Infection is a major potential complication for the fetus and neonate. The same organisms responsible for maternal infection can result in congenital pneumonia, sepsis, or meningitis. However, the majority of women with clinically overt amnionitis do not deliver infants who experience serious neonatal infection. In published series, the range of neonatal sepsis in cases of preterm PROM with or without clinical amnionitis is 2 to 19 percent. Neonatal deaths caused by infection are reported in 1 to 7 percent of infants born to women with chorioamnionitis. The frequency of neonatal infection varies considerably with gestational age, race, and maternal antepartum course, as well as the criteria for infection chosen. Studies requiring positive cultures for diagnosis tend to detect lower sepsis rates than those combining clinical course, radiographic findings, and neonatal bacterial colonization for diagnosis.

Infectious Risks after Preterm PROM	
Cord prolapse	More common in non vertex presentations
Cesarean delivery	Failed induction 44 percent cesarean births, all for failed induction
Abruption:	3 studies associated prolonged PROM with abruption 5 to 6 percent of preterm PROMs; abruption rate = 25 percent if bleeding after PROM
Pulmonary hypoplasia	Correlates with gestational age at time of rupture ^[436]
	19 wk: 50 percent
	22 wk: 25 percent
	26 wk: <10 percent
Respiratory distress syndrome	Reduced rates of respiratory distress after preterm PROM have been inconsistently observed

Other noninfectious fetal complications that may occur after preterm PROM shown in the box.

There is a higher risk of frank or occult cord prolapse, particularly if the fetus is not in a cephalic presentation. Regardless of presentation, the risks of fetal distress in labor leading to cesarean delivery are significantly higher with preterm PROM than with isolated preterm labor (7.9 vs. 1.5 percent). ^[432] The most common fetal heart rate tracing leading to operative delivery is severe variable decelerations due to cord compression. Amnioinfusion may be used to prevent or reduce cord compression secondary to oligohydramnios (see Chapter 14).

Placental abruption occurs in 4 to 6 percent of cases of preterm PROM, especially when PROM is accompanied by bleeding. ^[433], ^[434] A 15 percent rate of abruption has been observed when patients with prolonged preterm PROM manifest vaginal bleeding in addition to fluid leakage. When abruption occurs after PROM, the rate of acute intrapartum fetal distress approaches 50 percent. ^[435]

Pulmonary hypoplasia is a particular concern when fetal membranes are ruptured prior to 26 weeks' gestation. About 25 percent of babies delivered after 26 weeks' gestation following PROM that occurred before 26 weeks' gestation were found to have pulmonary hypoplasia following birth. ^[426] The duration and degree of oligohydramnios are associated with the chance of pulmonary hypoplasia. The frequency of pulmonary hypoplasia

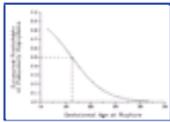

Figure 23-27 Curve relating probability of pulmonary hyperplasia to gestational age at time of rupture of membranes. (From Rotschild A, Ling EW, Peterman ML, Farquharson D: Neonatal outcome after prolonged preterm rupture of the membranes. *Am J Obstet Gynecol* 162:46, 1990, with permission.)

is most consistently correlated with gestational age at rupture.^[436],^[437] When rupture occurs before 19 weeks, approximately 50 percent of infants will have hypoplastic lungs (Fig. 23-27). The rate falls to 25 percent for infants born at 22 weeks, and to less than 10 percent at 26 weeks or later.

Prediction of pulmonary hypoplasia has been attempted by measuring residual fluid volume, lung length, comparison of the thoracic and abdominal circumferences, assessment of fetal breathing, and Doppler studies of perinatal amniotic fluid motion. None have added significantly to estimates of risk based upon the gestational age at the time of rupture.

Skeletal deformities may occur due to compression but usually resolve within 12 months. In one series, 27 percent of fetuses born after prolonged PROM before 26 weeks developed skeletal deformations.^[438]

Initial Evaluation and Management

After the diagnosis of preterm PROM has been confirmed, maternal and fetal indications for immediate delivery should be ruled out before considering other management options. The most dangerous fetal complications of PROM at any gestational age are prolapse of the umbilical cord, and fetal bradycardia caused by cord compression. The principal maternal indication for delivery is chorioamnionitis. If a firm diagnosis of chorioamnionitis can be made by the presence of maternal fever greater than or equal to 101°F, uterine tenderness, and leukocytosis greater than or equal to 20,000/mm³, delivery should be undertaken promptly regardless of the gestational age. In the absence of indications for immediate delivery, gestational age should be carefully assessed to estimate the relative risks for the fetus of delivery versus expectant management (see below). All clinical and ultrasound dating criteria should be reviewed. Because oligohydramnios may flatten the fetal head, biparietal diameter measurements to estimate fetal weight by ultrasound may be inaccurate in women with preterm PROM.^[439] Fetal tables based on head circumference, femur length, or cerebellar diameter are more reliable indicators of gestational age and fetal weight in these situations.

Before 30 to 32 weeks' gestation, the neonatal risks of prematurity will usually outweigh the in utero risks of infection and fetal compromise caused by oligohydramnios, while the reverse is usually the case after 34 to 35 weeks' gestation.^[440] A randomized trial of expectant management versus immediate delivery in 120 women with preterm PROM between 34 and 37 weeks at a university center found that both chorioamnionitis (16 percent vs. 2 percent) and the duration of maternal hospitalization (5.2 ± 6.8 vs. 2.6 ± 1.6 days) were greater in the expectantly managed group.^[441] A retrospective observational report from a private hospital of 236 women with preterm PROM between 32 and 36 weeks found no advantage to expectant management after 34 weeks. Before 34 weeks, modest benefits in neonatal hospital days and hyperbilirubinemia were observed.^[442] Consideration of individual risks forms the basis for management for women with preterm PROM and is among the most challenging tasks in obstetrics. The relative risks of prematurity, infection, and fetal well-being must be repeatedly evaluated for expectantly managed patients with preterm PROM. As will be evident in the following paragraphs, the methods of risk assessment are not uniformly satisfactory.

Amniocentesis for Women with Preterm PROM

Assessment of amniotic fluid for infection and maturity studies should always be considered in women with preterm PROM. Expectant management requires repeated assessment of mother and fetus for evidence of maternal and fetal infection, cord prolapse, and abruption. Demonstration of either fetal pulmonary maturity or intra-amniotic bacteria may allow a decision for delivery, thus obviating the difficulties of fetal and maternal surveillance. Amniotic fluid may be obtained from either free-flowing vaginal fluid or amniocentesis for studies of fetal maturity, but amniocentesis is required to obtain fluid for culture, Gram stain, and glucose tests for infection. Placing the patient in the Trendelenburg position prior to the amniocentesis may facilitate the procedure by favoring intrauterine retention of fluid. Amniocentesis has been successfully accomplished in 50^[427] to 96 percent^[443] of reported series of patients with preterm PROM. The success rate is apparently

influenced primarily by the aggressiveness of the investigators. Although the amniotic fluid pocket may be small, amniocentesis is reasonably safe when performed with ultrasound guidance. A literature review reported the risk of fetal injury to be between 0.6 and 2.0 percent and that of placenta and cord injury to be 0.3 to 1.1 percent.^[444] If there is free-flowing amniotic fluid in the vaginal vault at the time of sterile speculum examination, it may be used for lung maturity testing, but is not reliable for infection studies.^[445] Bacterial contaminants in vaginally collected fluid have been reported to produce phosphatidylglycerol, creating a false impression of fetal lung maturity with this test.^[446]

In a study^[427] of amniocentesis in women with PROM between 28 and 34 weeks, none of the 98 patients who had an amniocentesis demonstrated signs of clinical amnionitis, and none were in labor. A mature lecithin/sphingomyelin (L/S) ratio of at least 1.8:1 was found in 39 percent of samples. An additional 13 percent had Gram stains of unspun amniotic fluid that demonstrated the presence of bacteria. Thus, 52 percent of these asymptomatic women were delivered expeditiously because of amniotic fluid findings. In another study of amniotic fluid results between 32 and 36 weeks' gestation in 164 women with preterm PROM, there were 13 (7.9 percent) with immature lung studies, 12 (7.3 percent) in whom fluid could not be obtained, and 4 (2.4 percent) with chorioamnionitis.^[447] Ninety-three subjects with mature amniotic fluid studies and reassuring fetal heart rate testing consented to be randomized to either induction of labor or expectant management. Women in whom labor was induced had a lower rate of chorioamnionitis (10.9 percent vs. 27.7 percent) and shorter hospital stays (2.3 vs. 3.5 days). There was no difference in the cesarean section rate. Infants born after expectant management were treated more often for suspected sepsis, but there was no difference in neonatal survival or significant morbidity. These trials support the value of obtaining amniotic fluid maturity testing in women with preterm PROM after 32 weeks' gestation.

Tests for Infection in Patients with Preterm PROM

Expectant management of preterm PROM requires initial and continued surveillance for infection. Ultimately, the end point for tests of "infection" in this clinical setting should be clinically important maternal or fetal/neonatal infection. Intermediate end points (e.g., amniotic fluid bacteria, white blood cells, glucose, and even culture), while associated with perinatal infection, do not equate uniformly with clinical infectious morbidity or mortality. The incidence of clinical amnionitis approximates 10 percent (range, 3 to 30 percent) in women with preterm PROM. Of infants born to mothers with clinical amnionitis, only 1 to 15 percent will have positive cultures that confirm a diagnosis of neonatal sepsis. Finally, the rate of perinatal mortality caused by infection has ranged from 0 to 13 percent in studies of infants born after preterm PROM. The principal causes of perinatal morbidity and mortality after preterm PROM are still more often related to prematurity (e.g., respiratory distress syndrome, intraventricular hemorrhage) than to infection. Nevertheless, when it occurs, neonatal infection can be devastating. It is important to make an early diagnosis of infection because a two- to fourfold increase in perinatal mortality, intraventricular hemorrhage, and neonatal sepsis has been reported in infants born after amnionitis compared with gestational age-matched controls born to noninfected mothers.^[448] Importantly, antepartum treatment of maternal amnionitis clearly decreases the incidence of neonatal sepsis (Table 23-17).^[449]^[450]^[451]

Clinical surveillance of expectantly managed patients with preterm PROM includes frequent examinations for maternal heart rate, contractions, uterine tenderness, fever greater than or equal to 38°C, and biophysical profile or nonstress testing, looking for variable decelerations, tachycardia, and absent movement. An extensive review of laboratory tests to detect intrauterine infection concluded that none was wholly satisfactory.^[452] White blood cell counts are customary in patients with preterm PROM, but are not always predictive of the presence or absence of chorioamnionitis. An elevated maternal leukocyte count has a reported sensitivity of 23 to 80 percent, a specificity of 60 to 95 percent, a positive predictive value of 50 to 75 percent, and a negative predictive value of 40 to 90 percent to predict clinical or histologic amnionitis.^[453]

Nonstress testing (NST) for patients with preterm PROM is appropriate to look for evidence of cord compression, but may not be a reliable test for incipient or occult infection. A biophysical profile score of less than 6 has been related to subsequent maternal or neonatal infection.^[454] However, when compared in a randomized clinical trial, both daily nonstress and biophysical profile testing had low sensitivity (39 percent vs. 25 percent, respectively) to predict subsequent infectious

809

morbidity in 135 women with preterm PROM, all of whom received antibiotics for group B streptococcal prophylaxis. ^[455] Specificity was 85 percent for the NST and 93 percent for the biophysical profile. Clinical, laboratory, and biophysical surveillance each contribute to management, but all have suboptimal sensitivity and must be repeated frequently. Amniotic fluid obtained by amniocentesis can be used to detect amnionitis, based on demonstration of bacteria on a Gram stain of unspun fluid, amniotic fluid glucose levels, or the presence of IL-6. Approximately 10^5 organisms/ml are needed before a Gram stain will be positive. Thus, not all culture-positive fluids have positive Gram stains, though virtually all positive Gram stains result from culture-positive fluids. The Gram stain for bacteria has reported sensitivity ranging from 36 to 80 percent, and a specificity of 80 to 97 percent to predict a subsequent positive culture. Amniotic fluid culture has a reported sensitivity of 65 to 85 percent and a specificity of 85 percent to predict clinical chorioamnionitis. The presence of white blood cells in amniotic fluid has not proven helpful in predicting infection, but a low amniotic fluid glucose (16 to 20 mg/dl) has been found to correlate well with a positive fluid culture, with sensitivity and specificity of approximately 80 to 90 percent. The amniotic fluid glucose is simple, rapid, and available around the clock. A study of 108 women with preterm PROM to identify clinical characteristics that were associated with a positive Gram stain found associations with earlier gestational age, maternal temperature, and white blood cell count, and for fetal tachycardia and nonreactive fetal heart rate tracings. ^[453] Evaluation of amniotic fluid from 127 women with preterm labor and 26 with preterm PROM revealed that the combination of Gram stain and amniotic fluid glucose were superior to either test alone to predict a positive culture. ^[456] Interleukin-6 in amniotic fluid is also a good marker for intra-amniotic fluid infection. ^[457]

Management Strategies

When a thorough assessment reveals no evidence of fetal distress or infection, and fetal pulmonary maturity cannot be confirmed, three management options remain. The first is conservative or expectant management, in which the patient is hospitalized for intensive surveillance for signs of fetal compromise or infection, at which time labor is allowed or induced if necessary. This approach is associated with a low rate of cesarean delivery, but relies upon methods of fetal assessment that must be performed at least daily and, as noted, are not always accurate. An alternate choice is immediate delivery for pregnancies beyond a certain gestational age (e.g., 32 weeks) or estimated fetal weight (e.g., 1,500 to 1,800 g). This strategy avoids the need for ongoing surveillance for fetal well-being and infection, but commits to delivery some women who might have continued the pregnancy long enough to allow additional fetal development and reduced neonatal morbidity. This strategy has a high rate of cesarean delivery for failed induction. The third strategy is an attempt to delay delivery in order to influence the relative risks of prematurity and infection. For example, antibiotics have been found to reduce morbidity and prolong pregnancy ^[458] and corticosteroids are effective for reducing fetal morbidity, (especially intraventricular hemorrhage) and mortality, when given to women with PROM before 32 weeks. Any of the three strategies may be an appropriate choice, depending on the gestational age and individual assessments of the risk of infection and prematurity. For example, expectant management is often chosen for women who present before 26 to 28 weeks, immediate delivery for women after 32 to 34 weeks, with interventionist strategies employed between 26 and 34 weeks. Adherence to a single strategy for all women with preterm PROM ignores the important individual differences among patients' risk of infection and immaturity.

Corticosteroids and Antibiotics

Antenatal corticosteroids appear to reduce the risk of intraventricular hemorrhage for infants born before 32 weeks, regardless of the status of the membranes before delivery. Because grades III and IV intraventricular hemorrhages are rare after 32 weeks, the decision to use steroids after 32 weeks depends on analyses of the effect of steroids on morbidity other than IVH. As noted above, randomized trials of the effect of corticosteroids on RDS in the presence of PROM have revealed conflicting results.

It is not clear whether women with preterm PROM should receive more than one course of antenatal steroids. A significant increase in early-onset neonatal sepsis was observed in 72 infants born to women with preterm PROM who had received multiple courses of steroids when compared with 99 who received one course, and 203 who did not receive steroids. ^[460] Multiple courses were also significantly related to chorioamnionitis and postpartum endometritis. The 1994 NICHD Consensus Conference encouraged more study of steroids for reduction of RDS in preterm PROM after 32 weeks. ^[370] The ACOG also advocates caution in using steroids for preterm PROM after 32 weeks. ^[326] At our center, we currently administer a single course of antenatal steroids to expectantly managed patients with preterm PROM up to 34 weeks.

Because the risk of perinatal group B streptococcal infection is associated with both premature birth and duration of membrane rupture before delivery, women with preterm PROM prior to 37 weeks should be treated presumptively with an appropriate antibiotic. The

810

importance of maternal antibiotics for group B streptococcal prophylaxis in preterm PROM has been well established and is endorsed by both the ACOG ^[327] and by the American Academy of Pediatrics. ^[461]

Antibiotic prophylaxis has also been studied as a method of prolonging the interval from rupture to delivery in an effort to reduce perinatal morbidity and mortality due to infection and prematurity. A multicenter trial enrolled 614 women with preterm PROM between 24 and 32 weeks in a study that compared combined neonatal morbidity and mortality in subjects randomly assigned to receive treatment with either antibiotics or placebo within 72 hours of amniorrhexis ^[459] (Table 23-18). The antibiotic group received 48 hours of intravenous ampicillin and erythromycin, followed by oral amoxicillin and erythromycin for 5 days or until delivery. Erythromycin was combined with ampicillin to treat *Mycoplasma* and *Ureaplasma urealyticum*. None of the subjects in this trial received antenatal corticosteroids. Women in both groups who were colonized with group B streptococcus were treated with open-label ampicillin or erythromycin in addition to their assigned study regimen; these 118 subjects were analyzed separately. The primary outcome was composite mortality and morbidity including sepsis within 72 hours of birth, RDS, grade III to IV intraventricular hemorrhage, and stage 2 to 3 necrotizing enterocolitis. The mortality rate was 5 percent in both groups, but the antibiotic group had significantly less morbidity as shown in Table 23-18. Latency was prolonged in the antibiotic group. Infants born to women who were treated for positive group B streptococcus cultures did as well as the antibiotic study group. As might be expected in a study that enrolled a largely indigent population, chorioamnionitis was relatively common in both groups.

The combined use of antibiotics and corticosteroids appears to confer greater benefit than either treatment alone for women with preterm PROM. One study randomized women with preterm PROM who were expectantly managed and treated with ampicillin-sulbactam to receive either betamethasone or no steroids. ^[462] There were no differences in neonatal or maternal infectious morbidity, but the group that received steroids had fewer cases of respiratory distress, 18.4 percent vs. 43.6 percent, than the no-steroid group. However, this trial had a small sample size ($n = 77$), did not employ a placebo, and observed a relatively high rate of RDS in the control group. Another trial enrolled and randomly assigned 112 women with preterm PROM, all of whom were treated with corticosteroids, to treatment with one of two antibiotic regimens or placebo. ^[463] Neonatal mortality, sepsis, and respiratory morbidity were less common in the combined antibiotic groups compared with the placebo group.

In summary, prophylactic antibiotics should be given to all women with preterm PROM to reduce the risk of neonatal group B streptococcal infection. Significant reductions in composite neonatal morbidity can also be achieved with broad-spectrum antibiotic treatment, especially in populations with a high prevalence of chorioamnionitis. Furthermore, combined treatment with corticosteroids benefits infants born after preterm PROM before 32 weeks of pregnancy.

Use of Tocolytics

There is currently little evidence to support routine use of tocolytic agents in women with preterm PROM. A report from the National Institutes of Health Collaborative Study on Antenatal Steroids noted an association between tocolytic use in PROM and a higher rate of RDS. ^[464] Prospective randomized trials of prophylactic tocolysis revealed no consistent benefit to adjunctive tocolytics for these patients. ^[465], ^[466] However, the studies cited above that suggest benefit for adjunctive antibiotics and steroids have raised anew the question of short-term tocolysis in order to allow a course of steroids and antibiotics.

TABLE 23-18 -- EFFECT OF PROPHYLACTIC ANTIBIOTICS ON PERINATAL MORBIDITY IN INFANTS BORN TO WOMEN WITH PRETERM PROM

	Ampicillin + Erythromycin (n = 239)	Placebo (n = 257)	RR	95% CI
All morbidity	45%	55%	0.82	0.690.98

Preterm PROM in Special Circumstances

Preterm PROM before 26 weeks of pregnancy has diverse etiologies that may alter management. For instance, PROM may occur following amniocentesis. If the amniocentesis was performed for genetic studies or evaluation of rhesus disease, a good outcome should be expected. A brief course of bed rest and expectant management until the leakage stops and does not resume is usually all that is required. However, infection and/or delivery are likely if the amniocentesis was performed to evaluate a patient with advanced cervical dilation or preterm labor. When preterm PROM occurs in a woman who has experienced persistent second-trimester bleeding, especially when accompanied as well by a history of prerupture oligohydramnios and/or an elevated maternal serum -fetoprotein, the prognosis for a surviving infant is poor. These patients often have had abnormal placental implantation noted on ultrasound evaluation. Management of these patients should include a thorough history and placental evaluation, to detect placental trauma or loss of a blighted twin, and an attempt to obtain both placental and fetal samples for karyotype. Other possible diagnoses for second-trimester losses (e.g., fetal anomaly or aneuploidy, uterine anomalies, DES, incompetent cervix, and maternal trauma), both exogenous and self induced, should all be considered.

When preterm PROM occurs before 26 weeks, risks for both mother and fetus are higher than for PROM later in pregnancy and decisions are more difficult. Because neonatal outcome for infants born before 24 to 25 weeks is poor, immediate delivery is not an easy choice. On the other hand, expectant management carries concern about maternal risks and an uncertain outcome for the fetus. Maternal risk is the first concern. A review ^[467] of 898 women with early preterm PROM reported in 11 observational studies found that only six women (0.7 percent) developed sepsis; however, there was a single maternal death. Other maternal risks of expectant management include the consequences of activity restriction: muscle wasting, bone demineralization, venous thromboembolism, and its prophylaxis (e.g., heparin-induced thrombocytopenia). In the collected series cited above, 15 percent of infants were stillborn, 39 percent died before 28 days of life, and 46 percent (417 of 914) survived the neonatal period. Among 195 infants who were followed for 3 to 36 months, 119 (61 percent) had normal neurologic examinations. ^[467]

A 1990 report found that the strongest determinant of survival was the occurrence of pulmonary hypoplasia, which in turn was related principally to gestational age at the time of rupture. ^[436] Only 8 of 74 infants without pulmonary hypoplasia (11 percent) died, compared with 10 of 14 (71 percent) of infants with evidence of pulmonary hypoplasia. Improved neonatal and 2-year outcomes for infants born after extremely preterm PROM were reported from Sweden in 1998. ^[468] Among 53 pregnancies complicated by PROM at 14 to 28 weeks, neonatal survival rates were 40 percent ($n = 10$) when rupture occurred between 14 and 19 weeks and 88 percent when rupture occurred between 20 and 25 weeks ($n = 24$). At 2 years of age, three of four surviving infants born after PROM at 14 to 19 weeks, and 13 of 20 survivors born after PROM at 20 to 25 weeks had no neurologic impairment. The mean age at delivery in both groups was 27 weeks, with mean latent periods of 70 and 19 days. This encouraging report may not apply to many North American populations. Given the data cited here, it is easy to see why decisions about management in this setting are so complex. Fortunately, the literature supports the maternal safety of a period of observation for these women to allow time for an informed decision.

An observational study of 18 women with preterm PROM complicated by a history of maternal genital herpes simplex infection estimated that the theoretical maximum risk of neonatal HSV was no greater than 19 percent. ^[469] Prophylactic treatment with an antiviral agent such as acyclovir may be appropriate for these patients.

The question of whether to retain or remove a cerclage suture in women who later develop preterm PROM is controversial. One report favored removal, ^[404] but latency and perinatal outcome were not related to retention or removal of the cerclage suture in another study of 81 women with preterm PROM before 34 weeks. ^[405]

CONDUCT OF LABOR AND DELIVERY FOR THE PRETERM INFANT

Intrapartum care for women in labor before term is often accompanied by concerns unique to the preterm mother and her fetus. Many relate to the underlying reason(s) for preterm delivery. Complications such as maternal hypertension or fetal growth restriction may increase the chance of intrapartum fetal compromise because of poor placental function. Reduced or absent amniotic fluid may lead to umbilical cord compression during labor after preterm PROM, or when oligohydramnios occurs with intrauterine growth restriction (IUGR) or preeclampsia. When labor is induced preterm for maternal or fetal indications, the lower uterine segment and cervix may not be well prepared for labor, leading to a prolonged latent phase. When the cause of preterm labor is unclear, the possibility of occult abruption must be considered. Labor in women with amnionitis may be complicated by fever, fetal tachycardia, or

812

inefficient contractions, any of which may lead to fetal compromise. Because digital examination of the cervix is avoided in women with expectantly managed preterm PROM, labor may not be recognized in these patients until it is well established. This recurrent problem can never be entirely avoided and requires constant vigilance by both nurses and physicians. Spontaneous preterm labor that begins at home may not be easily recognized by the woman, her family, or the medical care team. Finally, labor in women with reduced cervical competence may be relatively painless, again leading to delayed intrapartum surveillance of the preterm fetus.

Estimation of Gestational Age-Specific Neonatal Mortality and Morbidity

Infants born after 26 weeks experience intact survival rates in excess of 60 percent, but concerns about both the likelihood and quality of survival are important in the conduct of labor before 26 weeks. As neonatal and perinatal care has improved, the lower limit of "viability" has been a progressively earlier gestational age. Regionalized perinatal care, broader use of antenatal corticosteroids, and advances in neonatal care (e.g., surfactant treatment) have led to steady improvements in perinatal, neonatal, and infant morbidity and mortality. As many as 15 percent of infants born at 23 weeks, 56 percent at 24 weeks, and 80 percent at 25 weeks may now survive to hospital discharge in the postsurfactant era.^[470] Several studies have reported that the expectation by the medical team of survival for the ELBW infant actually influences the likelihood of survival. A study of 66 infants with birth weights between 500 and 749 g found that after controlling for birth weight and gestational age, fetuses who were considered "viable" (i.e., likely to survive) were 18 times more likely to survive than fetuses who were deemed pre-viable.^[471] Another study of 713 infants with birth weights below 1,000 g found that, although cesarean delivery did not itself influence the rate of neonatal survival, the willingness to perform cesarean delivery was associated with higher rates of both intact and morbid survival for ELBW infants.^[11] Parents and medical professionals often do not share the same beliefs about the quality of life^[472] or the potential for intact survival in premature infants. The likelihood of survival is often underestimated by medical personnel^[473] but, due to well-publicized but uncommon cases of intact survival among ELBW infants, may be overestimated by the patient and her family. Health care providers also may not invite parental and family participation in the decisions surrounding the birth of an extremely preterm infant.^[474]

These observations underscore the importance of accurate information about neonatal outcome during labor management before 26 weeks of pregnancy. The "best obstetric estimate of gestational age," combining menstrual history and laboratory confirmation of pregnancy with earliest ultrasound biometry, is a more reliable antenatal predictor of neonatal survival than either estimated fetal weight or biparietal diameter (BPD).^[475],^[476] One study identified ultrasound biometric thresholds (femur length <40 mm, BPD <54 mm, estimated weight <382 g, or estimated gestational age <22 weeks) below which there were no survivors, regardless of gestational age.^[476] Unfortunately, infants who survived to 120 days with markers of serious long-term morbidity could not be distinguished before delivery from those who survived without morbidity markers by any antenatal information. Each patient's situation is unique. Kilpatrick and Piecuch developed a useful algorithm based on both literature and experience to begin discussions of intrapartum care and neonatal resuscitation, as shown in Table 23-19.^[12],^[13] Information available after delivery (e.g., actual birth weight) more accurately predicts outcome than information before birth, so it is always important to remind parents that a neonatal reassessment of the very preterm infant's prognosis is appropriate.

Intrapartum Fetal Assessment

Fetal monitoring is especially important when the fetus is premature. The preterm fetus may tolerate labor poorly, and the cause of the preterm birth may create additional intrapartum risk. Careful fetal surveillance has been associated with significantly improved outcome. One study showed that attentive nursing care (one on one) for preterm fetuses with auscultation every 15 minutes gives perinatal mortality results equal to those with electronic fetal heart rate monitoring.^[477] However, the same authors subsequently found that electronic monitoring provides better information about fetal and neonatal well-being.^[478] Ominous heart rate

813

tracings have the same associations with fetal acidosis as they do later in gestation. Prompt intervention can minimize their effect on perinatal morbidity and mortality.^[479],^[480] Mean fetal heart rate falls continuously, from 160 bpm at 22 weeks' gestation, to 140 bpm at term. This is apparently due to a gradual increase in parasympathetic tone. At no age after 26 to 28 weeks should the normal baseline heart rate be above 170 bpm. Changes in fetal heart rate variability in the preterm fetus carry the same or greater significance for risk of acidosis as in term infants. Although the concept that the preterm fetus may tolerate hypoxia in utero and after delivery may have some validity, particularly in considering prognosis, it should not affect management of preterm labor. Premature infants may sustain hypoxic-ischemic insults. Ominous patterns should be viewed with the same or greater level of concern as in term labor.

Anesthesia and Analgesia

There is no one method of anesthesia or analgesia in labor with a preterm fetus that is superior for all conditions. The goal of intrapartum care is to provide the neonatologist with the least traumatized, least depressed, and least acidotic fetus consistent with maternal health. Epidural anesthesia offers the advantage of pelvic

floor and outlet muscle relaxation, minimizing an important source of resistance to the soft premature fetal head. Hypotension sometimes associated with this method can largely be avoided by adequate preloading with a crystalloid and more gradual onset of the block. Paracervical block is undesirable because of the risk of fetal bradycardia secondary either to transplacental passage of the anesthetic agent causing direct myocardial depression or to local uterine vascular vasospasm with diminished uteroplacental perfusion. The use of parenteral narcotics, even early in labor, is generally minimized because of concern for respiratory depression and because of the uncertain duration of preterm labor. Analgesia that allows maternal self-control is particularly helpful in the second stage of labor.

Anesthesia for cesarean delivery creates special concerns for each potential method when the fetus is preterm. The epidural technique requires a deeper, more intense block, involving more spinal segments than vaginal delivery. This may increase the chance of hypotension. General anesthesia is quicker to administer in an emergency situation and usually involves fewer changes in uteroplacental perfusion. However, it does entail greater risks to the mother, can lead to fetal depression if the surgery is difficult, and deprives the mother of perhaps her only chance to see and bond with a sick premature infant during its first hours of life.

Labor

The course of labor in a preterm gestation is often significantly shorter than that of term pregnancy. Of particular importance are the rapidity of the active phase and the short second stage of labor. Care should be taken to ensure that the fetus does not have a precipitous delivery without control of the fetal head.

Delivery

The principal goals of intrapartum management of the preterm infant are avoidance of perinatal acidosis and birth trauma. The role of perinatal acidosis was demonstrated by a study^[481] of 136 neonates of less than 32 weeks' gestation in which the 1-minute Apgar score was highly correlated with survival. Preterm babies with 1-minute Apgar scores of 4 or more had a 95 percent survival, while infants with a score of 3 or less had only a 56 percent survival rate. The authors concluded that initial condition at birth affects survival. Although a generous episiotomy has been recommended to minimize the effect of perineal resistance on the small soft fetal head, data that demonstrate improved outcome associated with the use of episiotomy are difficult to find.^[482] When delivering a VLBW infant, an early episiotomy is appropriate if there is perineal resistance. Few multiparous women will be in this group. Forceps may be employed for premature infants for the customary indications, but should not be used prophylactically. Studies of prophylactic forceps to protect the preterm infant's head from pressure during delivery have not shown benefit.^[482]

Cesarean Delivery

Routine cesarean delivery of all preterm or VLBW infants is not justified by current literature.^[483],^[484],^[485] Several large studies have failed to note improvement in perinatal morbidity or mortality with cesarean birth for indications other than classic obstetric ones.^[483],^[485] Trends favoring cesarean delivery disappear after adjustment for confounding factors.^[483] Kitchen et al.^[485] found that the only antenatal intervention that was associated with improved outcome at 2 years of age was antenatal treatment with corticosteroids. Grant et al. reviewed six trials that addressed immediate neonatal and maternal morbidities after vaginal versus cesarean delivery for infants born between 24 and 36 weeks.^[486] This review found increased risk of maternal morbidity with cesarean section without clear benefit for the infant. Neonatal intracranial hemorrhage appears to occur as often before and after cesarean as it does during labor and vaginal delivery.

For infants in breech presentation, there are intuitive reasons for cesarean birth, particularly to avoid trapping of the aftercoming head and other manipulations that could lead to trauma or hypoxia. Older retrospective studies that suggested a benefit for cesarean delivery led to the current custom of cesarean delivery for preterm breech fetuses, but support for this practice remains weak. Wolf et al. compared rates of survival without disability at 2 years for two cohorts of preterm (26 to 31 weeks) infants born between 1984 and 1989. At one hospital, the custom was vaginal delivery ($n = 101$), while the other preferred abdominal birth ($n = 46$). Multivariate analysis found that footling presentation was associated with a greater likelihood of poor outcome (OR, 0.4; 95 percent CI, 0.2 to 0.9) and antenatal steroid treatment more than 24 hours before birth with improved outcome (OR, 2.7; 95 percent CI, 1.1 to 6.8) but no effect of mode of delivery.^[487]

When cesarean delivery for the preterm breech is chosen, it is illogical to avoid a traumatic vaginal delivery only to encounter a difficult cesarean birth because of an undeveloped lower uterine segment or an inadequate incision. Clearly, the operation must be carried out in a way that will fulfill its purpose: atraumatic delivery through a generous incision. While some have recommended routine use of a low vertical or classic incision, the exact uterine incision can depend on the fetal position and on the anatomy of the individual patient. If the lower uterine segment is well developed and the fetus is in the lower one third of the uterus, a transverse incision is reasonable.

In a study that carefully separated out "high-risk" VLBW labor (e.g., preeclampsia, vaginal bleeding, abnormal heart rate tracing) from "low-risk" VLBW (e.g., preterm labor, incompetent cervix), cesarean delivery was of no value in the low-risk group, but was associated with significantly improved survival rates in the high-risk group.^[488] Thus there are situations requiring delivery in the face of a long closed cervix that may lead to a decision to cesarean delivery for VLBW fetuses rather than a long and potentially morbid induction of labor.

CONCLUSION

Only when the factors underlying preterm birth are understood will prevention occur. Tocolytics, glucocorticoids, and antibiotics are effective tertiary therapies, but can never be wholly effective in eliminating the morbidity and mortality due to prematurity. Inaccurate diagnosis of preterm labor is a major impediment to appropriate care for premature labor.

Key Points

Preterm birth is the single greatest cause of perinatal morbidity and mortality in nonanomalous infants, responsible for 70 percent of fetal, neonatal, and infant deaths.

The outcome for premature and low-birth-weight infants is better than most medical professionals believe it to be.

Spontaneous preterm birth is a syndrome in which multiple risk factors operate collaboratively via injury to the maternofetal interface to produce several related clinical disorders.

Preterm labor may be initiated by infection, ischemia/hemorrhage, uterine distention, or endocrine factors.

Major risk factors for preterm birth are a prior history of preterm delivery, multifetal gestation, bleeding after the first trimester of pregnancy, and a low maternal body mass index (BMI), but these factors precede no more than 50 percent of preterm births. Every pregnancy is potentially at risk.

Cervical "competence" is not an absolute or categorical property of the cervix, but rather is a continuum. The risk of spontaneous preterm birth increases as the length of the cervix decreases.

Accurate early diagnosis of preterm labor is a major problem. Up to 50 percent of patients diagnosed with preterm labor do not actually have preterm labor, yet as many as 20 percent of symptomatic patients diagnosed as not being in labor will deliver prematurely.

Effective therapies that can reduce perinatal morbidity and mortality are (1) transfer of the mother and fetus to an appropriate hospital, (2) administration of antibiotics to prevent neonatal group B streptococcus infection, (3) administration of corticosteroids to reduce neonatal respiratory distress syndrome and intraventricular hemorrhage, a treatment that has been underutilized in the past, and (4) administration of labor-arresting (tocolytic) medications to allow the above to occur.

There is no truly reliable test for fetal well-being or infection in women with preterm PROM.

Prevention of preterm birth will require prevention of risk in the population.

Chapter 24 - Multiple Gestations

Usha Chitkara
Richard L. Berkowitz

The phenomenon of twinning has fascinated mankind throughout its recorded history. Twins have often been regarded as being inherently "different" from singletons, and societal responses to their birth have ranged from awe to fear. Researchers have been interested in exploiting their uniqueness in an attempt to separate the influences of genetic and environmental factors on both fetal and postpartum development.^[1] Obstetricians have long been aware that pregnancies complicated by twinning are by their very nature at higher risk than those of most singletons. Finally, parents and future siblings are often overjoyed or overwhelmed when they are told that twins are expected but are virtually never neutral in their response.

Twins are either monozygotic (MZ) or dizygotic (DZ). In the former case, a single fertilized ovum splits into two distinct individuals after a variable number of divisions. Such twins are almost always genetically identical and therefore of the same sex. On rare occasions, mutations can cause genetic discordance resulting in phenotypic and chromosomal dissimilarities between MZ twins. On the other hand, when two separate ova are fertilized, DZ twins result. These individuals are as genetically distinct as any other children born to the same couple. Sets of DZ twins may have the same or opposite sex. DZ half-siblings have been reported in which two ova were fertilized by different fathers, and it has been hypothesized that monovular dispermic fertilization may occur. These latter situations are very uncommon, however. In most cases, DZ twins are genetically dissimilar true siblings, while MZ twins are genetically identical.

The frequency of MZ twins is fairly constant throughout the world at a rate of approximately 4 per 1,000 births. This rate does not seem to vary with maternal characteristics such as age or parity. DZ twinning, however, is associated with multiple ovulation, and its frequency varies between races and within countries and is affected by several identifiable factors. In general, the frequency of DZ twins is low in Asians, intermediate in whites, and high in blacks. The Yorubas of western Nigeria have a frequency of 45 twins per 1,000 births, and about 90 percent are DZ.^[2]

The frequency of DZ births is affected by maternal age, increasing from a rate of 3 in 1,000 in women under age 20, to 14 in 1,000 at ages 35 to 40. Between 1980 to 1987, the greatest increase in U.S. birth rates of triplets and higher order multiple pregnancies occurred in women aged 30 to 39 an almost sevenfold increase in that time period.^[3] Above age 40, the rate declines. The frequency of DZ twinning also increases with parity independent of maternal age.^[1]

The different rates of DZ twinning may be due to racial or individual variations in pituitary gonadotropin production. Infertility patients treated with menopausal urinary gonadotropins (Pergonal) or clomiphene citrate are well known to have a dose-dependent increase in multiple births when compared with women who conceive without these agents. While DZ twins predominate in these patients, triplets and higher numbers of conceptuses may also occur. The use of in vitro fertilization (IVF) and embryo transfer has further increased the incidence of multiple pregnancies, and reports suggest that the incidence of multiple gestations in IVF patients may be as high as 22 percent.^[4], ^[5] In early 1980, the reported incidence of twins in the United States was 12 per 1,000 births, with two thirds of these being DZ.^[1] Current data suggest that since 1980, twin births have risen 52 percent and that triplet and higher order births have quadrupled. This dramatic rise in multiple births is mainly attributed to the growing popularity of IVF and other methods of assisted reproductive technology (ART).^[3]

The cause of MZ twinning is unclear. Benirschke and

Kim^[6] state that it is probably an uncommon occurrence among other mammals. In two species of armadillo, however, polyembryony regularly follows implantation of a single blastocyst. Oxygen deprivation has been experimentally shown to enhance fission in fish embryos, and some teratogens have been associated with increased MZ twinning rates in laboratory animals, but there is currently no satisfactory explanation for the fact that MZ twins occur in humans with such a constant frequency around the world. The majority of multiple pregnancies that occur after fertility treatment result from fertilization and implantation of multiple embryos, yielding polyzygotic gestations. However, MZ twinning is also increased by ovulation induction and other modern ART methods. Against a spontaneous rate of 0.4 percent MZ twinning in the general population, some studies have reported an increased incidence of MZ twins to 1.2 percent with conventional ovulation induction methods^[7] and a 3.2 percent incidence with use of other ART methods.^[8] In these cases, it is believed that alterations in either the structure or physical properties of the zona pellucida surrounding the early embryo are responsible for the increased tendency toward iatrogenic zygote splitting and resultant MZ twins.

PLACENTATION

Twin placentas are described in terms of their membranes ([Fig. 24-1](#)). The sac of a singleton pregnancy consists of an outer chorion and an inner amnion. Each DZ twin develops within a similar sac because both blastocysts generate their own placentas. If implantation of these blastocysts is not proximal to each other, two separate placentas will result, each of which will

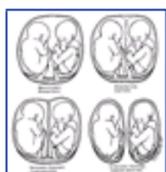

Figure 24-1 Placentation in twin pregnancies.

829

have a chorion and an amnion. Should they implant side by side, intimate fusion of the placental disks will occur, but these placentas are always diamniotic and dichorionic, and vascular anastomoses rarely occur. While MZ twins may also have placentas with two amnions and two chorions, this generally is not the case. Monochorionic placentas have a single chorion that usually surrounds two amnions, but occasionally there is only a single amnion. Regardless of whether these monochorionic placentas are diamniotic or monoamniotic, they are always a single disk and only occur in MZ twins. Triplets and quadruplets have also been delivered with monochorionic placentas and shown to be MZ. Almost all monochorionic placentas have blood vessel communications between the fetal circulations.

The type of placenta that develops in an MZ pregnancy is determined by the timing of cleavage of the fertilized ovum. If twinning is accomplished during the first 2 to 3 days, it precedes the setting aside of cells that eventually become the chorion. In that case, two chorions and two amnions will be formed. After approximately 3 days, however, twinning cannot split the chorionic cavity, and from that time on a monochorionic placenta must result. If the split occurs between the third and eighth days, a diamniotic monochorionic placenta will develop. Between the 8th and 13th days, the amnion has already formed, and the placenta will therefore be monoamniotic and monochorionic. Embryonic cleavage between the 13th and 15th days will result in conjoined twins within a single amnion and chorion; beyond that point, the process of twinning cannot occur.

The frequency of placental types within a population is influenced by the rate of DZ twinning. In the United States, approximately 80 percent of twin placentas are dichorionic, and 20 percent are monochorionic. In Nigeria, where DZ twinning is much more common, the frequency of dichorionic placentas approaches 95 percent.^[6] With triplets, quadruplets, and higher orders of multiple gestation, monochorionic and dichorionic placentations may coexist.

Because monochorionic placentas can only occur in MZ pregnancies, study of the membranes will establish zygosity in 20 percent of cases in the United States. In approximately 35 percent of cases the twins will be of opposite sex and therefore necessarily DZ. This leaves only 45 percent of cases (twins of like sex having dichorionic placentas) in which further studies are necessary in order to determine zygosity. Cameron^[9] found that this 45 percent breaks down into 8 percent MZ and 37 percent DZ. He states that "the percentage of monozygotic dichorionic pairs is inversely proportional to the completeness of the genotyping." In other words, the more genotypic markers that are studied, the greater the likelihood of demonstrating dizygosity. Cameron used six blood group markers, four red blood cell (RBC) enzymes, and placental alkaline phosphatase in order to determine zygosity. However, at present, the most accurate method for determination of twin zygosity is by analysis of DNA polymorphism.^{[10], [11]} The often-cited Weinberg rule states that in a population of twins the estimated number of MZ pairs is almost exactly equal to the total minus twice the number of twins of unlike sex. The assumption underlying this rule is that among DZ pairs the sex of one twin is independent of that of the other, resulting in almost exactly equal numbers of like and unlike sexed pairs. The small difference anticipated from exact equality is due to the fact that the sex ratio is not precisely 0.5. This rule has been questioned by several authorities who present evidence that in DZ populations there seems to be a higher frequency of like-sex than opposite-sex twins at birth.^[12] Cameron's data^[9] would favor the latter view.

PERINATAL MORBIDITY AND MORTALITY

Numerous reports have documented that perinatal morbidity and mortality are greater in twins than in singletons. A collaborative study was published by Kohl and Casey regarding 6,503 sets of twins delivered at 32 different hospitals between 1961 and 1972.^[13] The overall perinatal mortality in this series was 124 per 1,000 births. When only those twins weighing more than 1,000 g were considered, the perinatal loss was 62 per 1,000 births, which was approximately three times greater than that of comparable singletons at the same institutions.

A high incidence of low-birth-weight infants is the major cause of the increased perinatal mortality in twins. Both preterm delivery and intrauterine growth restriction (IUGR) contribute to this problem. In addition to prematurity and growth restriction, twins have an increased frequency of congenital anomalies, placenta previa, abruptio placentae, preeclampsia, cord accidents, and malpresentations.

Because of advances in both maternal-fetal medicine and neonatal care, a general decline in perinatal mortality has been reported over the past two decades from centers around the world. In general, this overall trend has also been noted for multiple gestations. Desgranges et al.^[14] reported a perinatal mortality rate of 95 per 1,000 in 213 twins delivered between 1969 and 1973 compared with 56 per 1,000 in 221 twins delivered between 1974 and 1979 at the Hopital Notre-Dame in Montreal. During these periods, there was essentially no change in the fetal death rates (28 per 1,000 vs. 32 per 1,000), but the neonatal mortality fell from 68 per 1,000 to 24 per 1,000. The frequency of anomalies

during the entire period was 23 per 1,000, and these accounted for 18 percent of all deaths. The average length of pregnancy in both study periods was identical, and the improved neonatal outcome was found to be due to increased survival rates in neonates weighing 1,000 to 1,500 g at birth.

With the routine use of antenatal fetal heart rate testing, Rattan and colleagues^[15] noted a marked reduction in fetal mortality after 32 weeks when 153 twins delivered between 1975 and 1979 were compared with 160 twins delivered between 1980 and 1983. The rate of stillbirths fell from 23 per 1,000 in the former period to 0 per 1,000 in the latter.

Despite these encouraging trends, the problems associated with multiple gestations continue to place these infants at higher risk than their singleton counterparts. Hawrylyshyn et al.^[16] reported an overall perinatal mortality rate of 91 per 1,000 births in 177 twin pairs delivered between 1975 and 1979 in Toronto. The number of cases in each year was fairly small, but there was no demonstrable decline in perinatal mortality during the study period. In this series, more than 70 percent of the deaths occurred before 30 weeks' gestation. Those deaths either took place in utero or during the neonatal period in association with respiratory distress syndrome, intracerebral hemorrhage, or necrotizing enterocolitis. These workers concluded that if obstetricians are to have a major impact on the perinatal survival of twins, they must concentrate on the period between 25 and 30 weeks' gestation.

In multifetal gestations with three or more fetuses, the most important complication again is premature delivery with its concomitant increase in perinatal morbidity and mortality. In general, delivery of multiple gestations occurs much earlier than singletons. The cumulative distribution of gestational age for singletons, twins, and triplets born in the United States during 1980 to 1994 indicated that 1.2 percent of singletons, 11 percent of twins, and 31 percent of triplets were born before 32 weeks of gestation. In the same years, infants born before 35 weeks' gestation constituted 3.1 percent singletons, 25 percent twins, and 67 percent triplets. However, when considered by the usually accepted definition of preterm as less than 37 weeks' gestation, 8.5 percent of singletons, 50 percent of twins, and 90 percent of triplets were born preterm.^[17] Accurate knowledge regarding outcome of these pregnancies remains limited because of the relatively small numbers in any reported series, especially for quadruplets and higher order births. Among three fairly large series published before 1983, Holcberg et al.^[18] reported a perinatal mortality rate of 312 per 1,000 among 31 triplet pregnancies managed in their institution between 1960 and 1979. Ron-El et al.^[19] reported a perinatal mortality of 185 per 1,000 in their series of 29 triplet and 6 quadruplet gestations managed between 1970 and 1978. Loucopoulos and Jewelewicz,^[20] in a series of 27 triplets, 7 quadruplets, and 1 quintuplet cared for from 1965 to 1981, noted a perinatal mortality rate of 148 per 1,000. Major improvements in perinatal and neonatal care over the past two decades have resulted in significantly better survival rates for triplets and perhaps higher order pregnancies. This is reflected in the results of some of the more recent published reports on multiple gestations. Lipitz et al.^[21] reported a perinatal mortality of 93 per 1,000 among 78 triplet gestations managed in their institution between 1975 and 1988. Gonen et al.,^[22] presenting their data on 30 multiple gestations (24 triplets, 5 quadruplets, and 1 quintuplet) from 1978 to 1988, reported a perinatal mortality rate of 51.5 per 1,000; and the experience of Newman et al.^[23] with 198 triplet pregnancies delivered between 1985 and 1988 was similar. Three recent publications from Britain, Switzerland, and Australia report outcome data on multiple gestations conceived spontaneously or by assisted reproductive technology. The British report^[24] contained 143 sets of triplets and 12 sets of quadruplets with perinatal mortality rates of 70 per 1,000 and 104 per 1,000, respectively. The Swiss data^[25] included 77 sets of triplets with a perinatal mortality of 89 per 1,000 and 9 quadruplet sets with a perinatal mortality of 147 per 1,000; whereas the Australian series, including 133 sets of triplets and 6 sets of quadruplets, reported perinatal mortality of 108 per 1,000 and 250 per 1,000, respectively.^[26]

A review of the subject by Alvarez and Berkowitz^[27] in 1990 concluded that although perinatal mortality rates had decreased, the risk of prematurity in multifetal gestations had not changed significantly over the past 20 to 30 years. The average gestational age at delivery for triplets consistently seems to be 33 to 35 weeks. Approximately 75 percent of these patients deliver prior to 37 weeks, and at least 20 percent deliver prior to 32 weeks. The number of reported patients with four or more fetuses remains too small for a meaningful analysis of perinatal morbidity and mortality rates. However, one can assume that at best the outcome in those pregnancies is the same as with triplets, and it probably is worse.

The infant mortality rate for multiple births is also high. Luke and Keith^[28] analyzed the National Infant Mortality Surveillance (NIMS) Project based on the 1980 U.S. birth cohort and reported an overall infant mortality rate of 8.6 per 1,000 for singletons, 56.6 per 1,000 for twins, and 166.7 per 1,000 for triplets. This represents a 6.6-fold and 19.4-fold higher mortality in twins and triplets, respectively, compared with singletons. Likewise, among survivors, the incidence of severe handicap was significantly higher among multiple births, being 19.7, 34.0, and 57.5 per 1,000 postneonatal survivors in singletons, twins, and triplets, respectively, and representing a 1.7-fold and 2.9-fold higher

rate among twins and triplets compared with singletons. Interestingly, however, the risk of death or morbidity from chronic lung disease or grade III or IV intracranial hemorrhage was found to be similar for twins and singletons that were below 28 weeks' gestation and very low birth weight (i.e., between 401 and 1,500 g).^[29]

DIAGNOSIS

It is obviously impossible to offer specialized antepartum care if multiple gestation remains undiagnosed until the intrapartum period. An often-quoted statistic in the older literature is that 50 percent of twins remain undiagnosed until the time of delivery.^[30] Because of the current widespread use of diagnostic ultrasound, this is certainly no longer true. The number of twins in the United States diagnosed during the antenatal period is currently unknown, but there must be substantial variations from one institution to another, depending on the degree to which ultrasound is used. In a report from Yale-New Haven Hospital,^[31] 91 percent of 385 twin sets delivered between 1977 and 1981 were diagnosed before the onset of labor.

Multiple gestations should be suspected whenever (1) the uterus seems to be larger than dates, (2) hydramnios or unexplained maternal anemia develops, (3) auscultation of more than one fetal heart is suspected, or (4) the pregnancy has occurred following ovulation induction or in vitro fertilization. Multiple gestation may also be diagnosed serendipitously at the time of ultrasound scanning before a genetic amniocentesis or as a result of an elevated serum -fetoprotein (AFP) level in mass-screening programs.

An argument often used in support of universal ultrasound screening for all pregnant women during the second trimester is that it would result in the early diagnosis of multiple pregnancies with almost 100 percent accuracy.^[32] Persson and Kullander^[33] reported the results of this type of screening program, which has been in effect at the Malmo General Hospital in Sweden since 1973. Originally, the program began with a single scan performed in the 30th week, but subsequently all women were offered examinations at both 17 and 33 weeks. Between 1974 and 1982, 98 percent of 254 multiple gestations were detected by ultrasound screening. There were no false-positive diagnoses, but 2 percent of multiple gestations were missed on the first examination. These authors also reported a reduction in perinatal mortality from 107 per 1,000 to 34 per 1,000 when similar numbers of twins delivered between 1970 and 1974 were compared with those delivered from 1975 to 1982. Major morbidity (e.g., cerebral palsy, mental retardation, late motor development, and hearing defects) decreased from 9.6 to 3.6 percent, and the frequency of delivery prior to 38 weeks dropped from 34 to 15.8 percent. The marked improvement in these figures was obviously due to multiple factors, but early diagnosis was among them. Results of the Routine Antenatal Diagnostic Imaging with Ultrasound (RADIUS) study from the United States indicate a similar experience.^[34] This study compared a group of low-risk pregnant women who underwent routine ultrasound screening in the second and third trimesters of pregnancy with a control group who had an ultrasound examination only when medically indicated. The diagnosis of multiple gestation, when present, was made before 26 weeks' gestation in all women who had the screening ultrasound examination. In contrast, among women in the control group, 37 percent of multiple gestations were not identified until after 26 weeks' gestation, and in 13 percent the diagnosis was not made until the delivery admission.

Separate gestational sacs can be identified ultrasonically as early as 6 weeks from the first day of the last menstrual period. With transabdominal scanning, an embryo within each sac should be visible by 7 weeks, and beating fetal hearts should be seen by 7.5 to 8 weeks.^[35] With good equipment, the fetal cranial pole is also identifiable during this period, but the intracranial landmarks used for accurate biparietal diameter measurements are usually not seen until 14 to 16 weeks. Increasing sophistication in the development and use of endovaginal scanning has made it possible to visualize these developmental landmarks 1 to 2 weeks earlier than with abdominal scanning techniques so that the embryonic pole and fetal heart can be seen by 6 weeks and the intracranial landmarks are visible by 10 to 12 weeks' gestation.^[36]

In general, the ultrasonic diagnosis of multiple gestations within the first trimester is relatively straightforward. It is mandatory, however, to visualize separate fetuses (Fig. 24-2). Retromembranous collections of blood or fluid or a prominent fetal yolk sac should not be confused with a twin gestation. Demonstration of the viability of each fetus at the time of the examination requires visualization of independent cardiac activity. Unfortunately, mistakes can be made regarding the number of fetuses present when scans are hastily interpreted. This is particularly true in the third trimester, but may also occur in the first and second trimesters, especially with four or more fetuses. It must be remembered that an ultrasound image, unlike a flat plate of the abdomen, does not provide a composite overview. The image displayed is only a tomographic slice through the area being studied. It is therefore possible to display two circular structures that may represent different fetal heads or, alternatively, the head and thorax of the same fetus in a tucked position. Misinterpretation

Figure 24-2 The scanning plane may artifactually transect a sac in such a fashion as to give the impression of multiple sacs. In this case, the three gestational sacs were all part of the single normal larger one. (From Jeanty P, Romero R: *What does an early gestation look like?* In *Obstetrical Ultrasound*. New York, McGraw-Hill, 1984, p 34, with permission.)

in this setting has resulted in the incorrect diagnosis of twins when only one fetus was present. On the other hand, rapid and careless scanning may result in failure to detect a second fetus whose head is deeply engaged in the pelvis or pushed up under the ribs. If a multiple gestation is suspected, the ultrasonologist must be compulsive in examining the entire uterine cavity. A scan should not be completed until the orientation of all the visualized fetal parts is understood.^[37]

EARLY WASTAGE IN MULTIPLE GESTATIONS

As a result of ultrasound studies performed during the first trimester, there is evidence to suggest that the incidence of multiple gestations in humans is higher than is usually appreciated and that a significant amount of early wastage occurs in these pregnancies. This has led

Figure 24-3 This scan shows an early gestational sac (GS) with a well-formed trophoblastic rim and an adjacent vanishing twin (VT). (From Jeanty P, Romero R: *What does an early gestation look like?* In *Obstetrical Ultrasound*. New York, McGraw-Hill, 1984, p 34, with permission.)

833

Figure 24-4 Vanishing twin with an incomplete trophoblastic rim (arrows) (From Jeanty P, Romero R: *What does an early gestation look like?* In *Obstetrical Ultrasound*. New York, McGraw-Hill, 1984, p 34, with permission.)

to the concept of the "vanishing twin" (Fig. 24-3) and (Fig. 24-4). Landy et al.^[39] reviewed nine series that have addressed this phenomenon. The series vary in regard to the populations studied, timing of the ultrasonography, and number of scans performed. Frequencies of twin "disappearance" in patients scanned before 14 weeks' gestation reportedly range from 13 to 78 percent. The higher rates were found in studies performed before 10 weeks' gestation.

One explanation for the disappearance of a gestational sac is resorption, which has been documented to occur in both human singleton pregnancies and lower animals (Fig. 24-5). This phenomenon has been ultrasonically described in human multiple gestations between 7 and 12 weeks. The true incidence of resorption of one or more gestational sacs is unknown, but it can occur without adverse effects on a coexisting fetus. Another explanation for sac disappearance is the presence of a blighted ovum or anembryonic pregnancy. Robinson and Caines^[39] define a blighted ovum as a gestational sac having a volume of 2.5 ml or more in which no fetus can be identified on ultrasound examination. It should be noted that the sac need not be totally anechoic, because disorganized echoes may be present in some cases. Several studies have reported that the only apparent complication of regression of a blighted ovum is slight vaginal bleeding. Regardless of whether vaginal bleeding accompanies regression of a blighted ovum, a coexisting normal pregnancy has a good prognosis for carrying to term. Furthermore, experience with patients undergoing elective first-trimester reduction of multifetal pregnancies suggests that the clinical course and outcome of these pregnancies is similar to that observed with the naturally occurring phenomenon of a blighted or "disappearing" co-twin.^{[40] [41] [42]}

Landy et al.^[39] point out that pathologic evidence to confirm "disappearance" rates as high as 78 percent is lacking. Examination of the placenta and membranes after delivery of a singleton thought to be a surviving twin rarely shows evidence of the one that disappeared. It is also true that examination of the products of an abortion is usually not helpful in verifying the presence of a sac that has "vanished." The difficulty encountered in obtaining positive pathologic confirmation of the diagnosis, however, does not mean that it is incorrect. On the other hand, false diagnoses are certainly possible as a result of poor ultrasound studies. If equipment with inferior resolution is used, or if the types of artifacts described earlier are misread as being second sacs, the presence of multiple gestations may be overdiagnosed. Particular attention should be paid to the fact that pressure from the scanning transducer can create an hourglass appearance in a normal single sac that may be incorrectly interpreted as demonstrating two separate sacs.

Aside from first-trimester bleeding, there are no reported maternal complications associated with the early disappearance of a fetus.^[39] The associated overall abortion rates in reported series range from 7 to 37 percent. However, in two studies when a vanished sac was associated with vaginal bleeding during the first trimester, spontaneous abortions occurred in 26 percent^[43] and 92 percent^[44] of cases. In a retrospective review of the first-trimester ultrasound data for 260 twin pregnancies in which one or both fetuses delivered at term, Dickey et al.^[45] found that disparities in gestational sac diameter and crown-rump length (CRL) were good predictors of eventual outcome. When disparities of 3 mm or more were observed either between the twin gestational sac diameters (at 49 days gestation) or between the twin

834

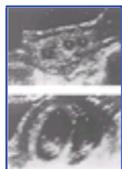

Figure 24-5 A, Three gestational sacs seen early in the first trimester. B, Two weeks later, the second sac has disappeared, and only the two lateral ones remain. (From Jeanty P, Romero R: *What does an early gestation look like?* In *Obstetrical Ultrasound*. New York, McGraw-Hill, 1984, p 34, with permission.)

CRL measurements (at 63 days gestation), these were associated with an embryo loss rate of 50 percent or more. The incidence of these disparities was lower in pregnancies resulting from assisted reproductive technologies than spontaneous conceptions and was unrelated to differences in birth weight, length, or gender of the neonate.

Landy et al.^[38] conclude that the phenomenon of the vanishing twin seems to truly exist. While on the basis of current information it is impossible to determine the exact prevalence of this occurrence, their data suggest that a reasonable figure for its incidence may be as high as 21 percent.^[46] These authors caution, however, that it is necessary to make "an accurate, faultless diagnosis" of multiple gestation in the first trimester before sharing this information with the mother because of its inevitable emotional and social impact.

GROWTH AND DEVELOPMENT

Normal individual twins grow at the same rate as singletons up to 30 to 32 weeks' gestation. After that time, they do not gain weight as rapidly as singletons of the same gestational age.^[47] Daw and Walker^[48] stated that after 32 weeks the combined weight gain of both twins is approximately equivalent to that gained by a singleton for the remaining portion of the pregnancy. The restriction in each twin's somatic growth is thought to be related to "crowding" in utero. The implication of this concept is that at some point in the third trimester the placenta can no longer keep pace with the nutrient requirements of both developing fetuses. This process occurs even earlier than 30 weeks when more than two fetuses are present.

A study of specimens obtained by induced abortion performed between 8.5 and 21 weeks showed the relationship between body weight and length in twins to be the same as that for singletons.^[49] This finding supports the concept that twins are not growth restricted during the first half of pregnancy. Fenner et al.^[50] have provided some insight into the other end of the gestational age spectrum by studying 146 twins admitted to their neonatal unit with gestational ages at birth ranging from 30 weeks to term. When data from these infants were plotted on Lubchenco's growth charts for singletons, these workers found that the twins' birth weights dropped below the mean for singletons by 32 weeks but remained within the low normal range until the 36th week, after which time they fell progressively below the tenth percentile. Twin birth lengths and head circumferences, however, remained within the low normal range for singletons throughout the entire pregnancy. The disparity between relatively normal head size and body length in association with somatic deprivation is compatible with the concept of asymmetric growth restriction. The latter is a mechanism whereby growth-restricted fetuses preferentially favor head growth at the expense of increases in body weight.^[51] These studies suggest that alterations in twin growth occur primarily in the third trimester, worsen as gestational age progresses, and are usually asymmetric in nature. In the large collaborative study conducted by Kohl and Casey,^[13] birth weights differed between 500 and 999 g in 18 percent of the twin sets and were in excess of 1,000 g in 3 percent. Obviously these discrepancies in birth weight could be due, in part, to constitutional factors. Because DZ twins are genetically distinct individuals, it is not surprising that they should be programmed to have very different weights at birth. There are, however, several pathologic situations in which twins may be born with substantial weight differences. These include the twin-to-twin transfusion syndrome, the combination of an anomalous fetus with a normal co-twin, and growth restriction, affecting only one twin because of local placental factors.^[37] IUGR, on the other hand, can affect both twins relatively equally, in which case they would both be small, but not discordant in size. Detection of differences in size in utero therefore suggests that IUGR may be present but is not diagnostic of that condition. Conversely, the demonstration that twin fetuses have similar sizes does not rule out abnormal growth. It therefore is necessary to assess each twin individually if abnormal growth in utero is to be detected.

ASSESSING FETAL GROWTH WITH ULTRASOUND

Ultrasound is the most accurate method for assessing fetal growth (see Chapter 10). Regular ultrasonic scanning permits ongoing assessment of individual growth.

Are Singleton Nomograms Applicable to Twins?

The first question to be asked is whether ultrasound nomograms devised for singletons can be used to follow twins. Conflicting data exist in the published literature regarding this issue. Some investigators have found twins to have smaller biparietal diameters (BPDs) than those of singletons at all gestational ages,^[52] while others have found mean BPD values corresponding to those of singletons until the third trimester but demonstrate progressive slowing in growth of the twin BPDs thereafter.^{[53] [54] [55] [56] [57]} When, however, 18 sets of concordant twins with verified menstrual dates were compared with values from singletons that were appropriate for gestational age (AGA) at birth, Crane et al.^[58] found the two groups to have mean BPD values that were essentially identical throughout gestation. These authors conclude that normal twin BPD growth is similar to that of AGA singletons at all stages of gestation, and the conflicting results of earlier studies are due to the inclusion of discordant twins with IUGR in the study group. A similar conclusion was reached by Graham et al.,^[59] who studied 104 twins with concordant growth, excellent gestational age assessment, and delivery after 36 weeks; they found almost identical results when BPD and femur length values were compared with those from a selected population of singletons. Other investigators^{[57] , [60]} also found no significant difference in BPD between uncomplicated singleton and twin pregnancies, suggesting that charts derived from singleton pregnancies may be reliably used to estimate gestational age of twins.

836

Neonatal anthropometric data obtained from concordant twins suggests that although there is significant reduction of birth weights of twins in late pregnancy, head circumference and body lengths are generally similar to those of normal singletons at corresponding gestational age.^{[56] , [58]} These findings are consistent with ultrasound observations showing twin femur length growth patterns similar to singletons throughout gestation,^{[55] , [59] , [61]} but a reduction in the abdominal circumference growth in twins after 32 weeks.^{[55] , [56]}

The Significance of Divergent Biparietal Diameters

In 1976, Dorros^[62] reported a case in which BPD values in a set of twins were discordant by 7 to 10 mm on three examinations performed between 38 and 41 weeks. At delivery, one infant was found to be severely growth restricted, while the other was AGA. The placenta had an infarct covering approximately 20 percent of the total surface area and was located near the origin of the growth-restricted twin's umbilical cord. Several series have subsequently shown that as the difference between twin BPDs increases, the likelihood that the smaller fetus will be growth restricted increases. Leveno et al.^[63] reported that a comparison of BPD differences of 4 mm or less with those of 5 mm or greater was associated with an increase from 7 to 22 percent in the number of twin pairs with one growth-restricted infant. Houlton^[64] noted an overall increase in small-for-gestational-age (SGA) infants from 40 to 71 percent in a comparison of BPD differentials below 6 mm with those of 6 mm or greater.

Crane et al.^[58] defined discordance in utero as an intrapair difference in BPD of 5 mm or more and a fall in BPD below 2 SD for gestational age on their normal twin curve. Twelve sets of twins met this criterion for discordancy, nine of whom were subsequently shown to have a difference in birth weight of more than 25 percent. They suggested that head circumference (HC) be measured if BPD intrapair differences exceed 5 mm. Since HC is less likely to be affected by molding in utero, an intrapair HC difference of less than 5 percent suggests that true discrepancy does not exist. Chitkara et al.^[65] also found that BPD intrapair differentials of 5 mm or greater correlated with an increased incidence of significant birth weight differences. However, estimated fetal weight and abdominal circumference measurements were found to be better predictors of discordant size. Other investigators have corroborated these observations.^[66]

This compilation of confusing and seemingly conflicting data can probably be summarized as follows. Significant differences in twin BPDs may indicate that one twin is growth restricted. However, the finding could be purely artifactual because of flattening of the head in association with malpresentation or in utero crowding. Measurements of several parameters, along with serial examinations, will help distinguish fetal growth abnormalities in most cases. Nevertheless, while major intrapair BPD differences may reflect IUGR in one fetus, it is not the only criterion that should be used to look for abnormal development in utero because it will not be present when both twins are growth restricted.

The Use of Multiple Parameters to Assess for IUGR and Growth Discordance

How then should growth in utero be followed in multiple pregnancies? BPD alone, as an isolated variable, is a poor predictor of IUGR in twins. Neilson^[67] retrospectively analyzed 66 twin pregnancies with good dates by plotting BPD values on a singleton nomogram. Only 56 percent of the 43 SGA neonates were found to have abnormal BPD growth, while 49 percent of the fetuses with abnormal BPD curves were found not to be growth restricted at delivery. Our experience^[68] and that of others^{[56] , [68] , [70]} suggest that a survey of multiple parameters on serial ultrasound examinations provides the most accurate assessment of the size of each individual fetus in twin gestations. The highest accuracy for predicting either appropriate or restricted growth is obtained by estimating the fetal weight. Among individual parameters, abdominal circumference is the single most sensitive measurement in predicting both IUGR and growth discordance.^{[65] , [66] , [69] , [70]} Recent studies suggest that an intrapair difference in abdominal circumference measurement of 2 cm or more can be effectively used as a screening test for discordant fetal growth and IUGR in the smaller twin.^{[69] , [69] , [70]} On the other hand, individual measurements of BPD, HC, or femur length are relatively poor predictors for either IUGR or growth discordance.^{[65] , [69] , [70]}

Probably the most important conclusions that can be drawn from these various studies are that it is technically feasible to measure multiple ultrasound parameters in twin pregnancies and that a consideration of as many variables as possible will maximize the effectiveness of an ultrasonic assessment of fetal size. The same general principles can be applied to the assessment of growth in triplets and higher order multiple gestations. Another point that should be stressed is that growth is a dynamic process and therefore patients with multiple gestations should be followed with serial scans. Since growth restriction is a process that usually occurs during the third trimester and the predictive accuracy of any fetal measurement in utero is inversely proportional to the scandelivery interval, we recommend that women with twins be scanned every 3 to 4 weeks after the 26th week and more frequently than that if IUGR or growth discordance is suspected.

837

Figure 24-6 A, The dividing membrane (arrow) is thick, suggestive of a DC/DA placentation. E, Visualization of four layers in the dividing membrane suggests DC/DA placentation.

Ultrasonographic Prediction of Amnionicity and Chorionicity

The risk for many of the complications occurring in multiple gestation depends on whether the placentation is monochorionic (MC) or dichorionic (DC). The incidences of IUGR and fetal death are higher in monochorionic than dichorionic twins, and the twin-to-twin transfusion syndrome (TTS) occurs only in monochorionic twins. Antenatal knowledge of the type of placentation and chorionicity is not only helpful but in some cases is critical for determining optimal management. This is true when deciding whether IUGR in one fetus of a twin gestation is due to TTS or uteroplacental insufficiency, when contemplating the selective termination of one abnormal twin, or when performing an elective first-trimester multifetal pregnancy reduction procedure. In these latter situations, if the gestation is monochorionic, a shared placental circulation could result in death or damage to a surviving fetus.

The sonographic prediction of chorionicity and amnionicity should be systematically approached by determining the number of placentas visualized and the sex of each fetus and then by assessing the membranes that divide the sacs. The pregnancy is clearly dichorionic if two separate placental disks are seen or if the twins are of different sex. When a single placenta is present and the twins are of the same sex, careful sonographic examination of the dividing membrane will usually result in a correct diagnosis. Evaluation of three features in the intertwin membrane will provide an almost certain diagnosis about the mono- or dichorionicity of a twin pregnancy. These three features are (1) thickness of the intertwin membrane, (2) the number of layers visualized in the membrane, and (3) assessment of the junction of the membrane with the placental site for what has been described as the "twin peak" sign.^[71] In dichorionic diamniotic pregnancies, the dividing membrane appears "thick"^{[72] [73] [74]} and has a measured diameter of greater than or equal to 2 mm,^[75] and either three or four layers can often be identified (Fig. 24-6).^{[76] [77]} With a monochorionic diamniotic pregnancy, only two layers of membranes will be identified, and the membrane appears to be "thin and hairlike"^[76] (Fig. 24-7). D'Alton and Dudley^[77] caution that a floating monochorionic diamniotic membrane may fold back upon itself and give a false impression of having four layers. These authors suggest that inspection of the membranes near their placental insertion will reduce this artifact. It should be mentioned that significant magnification of the image is helpful in counting the number of layers. Determination of membrane thickness allows correct identification of di- or monochorionic gestation in 80 to 90 percent of cases.^{[71] [72] [73]} Counting the number of layers adds a few extra minutes to the total scanning time but can increase the predictive accuracy to almost 100 percent.^{[76] [77]}

Initially described as the *lambda sign* by Bessis and

838

Figure 24-7 The dividing membrane (arrow) is thin and hair-like, suggestive of MC/DA placentation.

Papiernik^[78] in 1981, the twin peak sign was identified by Finberg^[79] in 15 twin and 5 triplet pregnancies undergoing ultrasound studies during the second and third trimesters. All twin pregnancies were proven to be dichorionic and all triplet pregnancies were proven to be trichorionic by placental pathology. They described the twin peak sign as a triangular projection of tissue with the same echogenicity as the placenta extending beyond the chorionic surface of the placenta. This tissue is insinuated between the layers of the intertwin membrane,

Figure 24-8 "Twin peak" sign appears as a triangular extension of placental tissue, wide at the placental surface and tapering to a point at its junction with the intertwin membrane (arrow).

839

Figure 24-9 A, In a dichorionic pregnancy with fused placentas, both the amnions (A) and the chorions (C) reflect away from the placental surface at the point of origin of the septum. This creates a potential space in direct continuity with the chorionic villi and into which they can extend. B, In a monochorionic twin pregnancy, the septum is formed by reflection of the two amnions away from the placenta. There is a continuous single chorion, which provides an intact barrier, preventing extension of placental villi into the potential interamniotic space.

wider at the chorionic surface and tapering to a point at some distance inward from that surface (Fig. 24-8). This finding is produced by extension of chorionic villi into the potential interchorionic space of the twin membrane. This space exists only in a dichorionic pregnancy and is produced by reflection of each chorion away from its placenta at the place where it encounters the chorion and placenta of the co-twin (Fig. 24-9A). The twin peak sign cannot occur in monochorionic placentation because the single continuous chorion does not extend into the potential interamniotic space of the monochorionic diamniotic twin membrane (Fig. 24-9B). In assessing the twin peak sign with ultrasonography, it is important that the zone of intersection of the membrane with the placenta be carefully scrutinized over as much length as can be detected. It should be mentioned that the absence of the twin peak sign alone does not guarantee that the pregnancy is monochorionic. Under these circumstances, evaluation of other features of the membrane previously described (i.e., thickness and number of layers) will give additional diagnostic clues regarding chorionicity and amnionicity. Chorionicity can best be determined by ultrasound examination at 6 to 9 weeks' gestation, when in dichorionic twins there is a thick septum between the chorionic sacs. After 9 weeks, this septum becomes progressively thinner to form the chorionic component of the intertwin membrane, but it remains thick and easy to identify at the base of the membrane as a triangular projection, the lambda or twin peak sign.^{[78] [79] [80] [81] [82]} At 11 to 14 weeks' gestation, sonographic examination of the base of the intertwin membrane for the presence or absence of the lambda sign provides reliable distinction between DC and MC pregnancies.^[83]

In some pregnancies with monochorionic diamniotic placentation, the dividing membranes may not be sonographically visualized because they are very thin. In other cases they may not be seen because severe oligohydramnios causes them to be closely apposed to the fetus in that sac. This results in a "stuck twin" appearance, where the trapped fetus remains firmly held against the uterine wall despite changes in maternal position (Fig. 24-10).^[71] Diagnosis of this condition confirms the presence of a diamniotic gestation, which should be distinguished from a monoamniotic gestation where dividing membranes are absent. In the latter situation, free movement of both twins, and occasionally entanglement of their umbilical cords, can be demonstrated.^[84]

Doppler Studies in Multiple Gestation

Advances in Doppler ultrasound technology within the past decade have made it possible to evaluate fetoplacental hemodynamics in normal and abnormal pregnancies (see Chapter 12) and (Chapter 25). Several studies in singleton pregnancies have demonstrated that abnormal Doppler velocimetry in the umbilical artery (UA) and other fetal vessels is often associated with fetal IUGR, pregnancy complications, and adverse perinatal outcome.^{[85] [86] [87] [88]} Although some investigators favor continuous wave systems, we think that Doppler studies in multiple gestations are best performed using a pulsed Doppler duplex system to be certain that the vessel being studied belongs to a targeted fetus.

In 32 uncomplicated twin pregnancies where both fetuses were AGA, Giles et al.^[89] found that the umbilical artery systolic/diastolic (S/D) ratios were similar to those of normal singleton AGA fetuses. Their findings were confirmed by Gerson et al.,^[90] who prospectively studied 65 normal twin pregnancies between 20 and 39 weeks' gestation. These authors reported that umbilical artery S/D ratios in normal twins decrease with advancing gestation and that the relationship between S/D ratio and

Figure 24-10 Twin gestation with severe oligohydramnios in sac of twin B. The separating membrane (arrows) is closely apposed to this fetus and was visualized with difficulty. Sac of twin A showed severe polyhydramnios. P, placenta.

suggest that the umbilical artery S/D ratios in fetuses of a twin gestation can be evaluated as if two singleton fetuses were being assessed.

Fetal growth restriction in singleton pregnancies is often associated with abnormal Doppler studies, which may precede documentation of the IUGR by sonographic biometry or abnormalities in other tests of fetal well-being.^[89] These observations are consistent with histologic evidence that abnormal umbilical artery waveforms may reflect vascular lesions in the placenta, which can be presumed to increase resistance to blood flow through the umbilical arteries.^[91] Similar alterations in umbilical artery S/D ratios have been documented in some growth-restricted twins. In their study of 76 twin pregnancies, Giles et al.^[89] had 33 patients in whom one or both twins were SGA; in 78 percent of these pregnancies at least one fetus had an elevated S/D ratio. Farmakides et al.^[92] performed Doppler studies in 43 twin pregnancies and tried to predict growth discordancy by examining S/D ratio differences in each twin pair. They found that a ratio difference of 0.4 or more between the twins was predictive of a weight difference of more than 349 g, with a sensitivity of 73 percent and specificity of 82 percent. Similar observations were reported by Saldana et al.^[93] These investigators found that an S/D ratio difference of 0.4 or more was a better predictor than ultrasound for birth weight discordancy in the SGA/AGA twin pairs, but was poor in predicting discordant weight in the SGA/SGA, AGA/AGA, or AGA/LGA twin pairs. They also suggested that in order to obtain maximal information, the absolute S/D ratios as well as differences in these ratios must be carefully evaluated in all cases.

Opinions vary regarding the usefulness of routinely performing Doppler studies in all twin pregnancies. Two studies illustrate this controversy. The first, by Giles et al.,^[94] described the clinical management and pregnancy outcome in a study group of 112 women with twin gestations in whom results of two or more Doppler studies were made available to the patients' obstetricians. These results were compared with a group of 95 patients in whom Doppler studies were performed but not reported to the clinicians. In the study group, the first test was performed at 28 to 32 weeks' gestation, and this was repeated 4 to 5 weeks later if the initial study was normal. If, however, a Doppler evaluation was abnormal, further studies were repeated as often as once a week, along with nonstress tests and sonographic studies. Patients were delivered if their nonstress tests were persistently abnormal or serial sonographic studies showed failure of fetal growth. In this series, a significant reduction in perinatal mortality and morbidity was noted in the study group. It is interesting that the improvement in outcome was achieved without any appreciable differences in gestational age at delivery or mode of delivery between the two study groups. The second study^[95] was a prospective evaluation of 89 twin pregnancies in which an attempt was made to determine the predictive value of umbilical artery Doppler studies in identifying twin fetuses destined to be SGA at birth. Serial Doppler recordings were made from each twin once a month from 22 weeks' gestation until delivery, but the results were not made available to the patients' clinicians. Thirty-two of the 178 infants in this series were SGA at birth, but only 24 of the 82 Doppler studies performed in the growth-restricted fetuses were abnormal, giving an overall sensitivity of 29 percent and a positive predictive value of 34 percent. This study, therefore, did not confirm the relatively high predictive value of Doppler

studies for SGA twins reported by other investigators.^[89],^[92]

A few more recent studies have also attempted to evaluate the usefulness of Doppler velocimetry in predicting twin fetuses that are small for gestational age, those with TTS, and those with discordant growth.^[91]^[92]^[93]^[94] In a longitudinal prospective study by Degani et al.,^[97] serial ultrasound biometry and Doppler studies were performed at monthly intervals in 37 twin pregnancies. While the overall sensitivity of Doppler alone for predicting an SGA fetus was only 58 percent, abnormal Doppler findings preceded sonographic diagnosis of SGA by about 3.7 weeks. A combination of sonographic and Doppler parameters improved the sensitivity to 84 percent, suggesting that Doppler velocimetry complements real-time ultrasonography in the early detection of abnormal growth in twin pregnancies. Gaziano et al.^[96] found an increased incidence of SGA infants in patients with abnormal Doppler studies, and the incidence of other adverse pregnancy complications, including stillbirth and major anomalies, was also found to be high in this group.

From our review of the current literature, we are not convinced that Doppler studies need to be routinely performed as part of the antepartum surveillance of women with multiple gestations. However, when IUGR is suspected in one or more fetuses, Doppler velocimetry is a useful adjunct in assessing and following these pregnancies. Our routine for the surveillance of patients with multiple gestations is as follows:

1. Ideally, an initial ultrasound is performed at 10 to 14 weeks' gestation to determine the number of fetuses and the amnionicity/chorionicity in order to differentiate monozygotic and dizygotic gestations.
2. The second ultrasound evaluation is scheduled at 18 to 20 weeks' gestation. This includes standard biometry to confirm gestational age and the size of each fetus, assessment of amniotic fluid volume in each sac, and an anatomic survey of each fetus to rule out morphologic anomalies. If the patient did not have a first-trimester ultrasound, an attempt is made to determine chorionicity by examining fetal gender, the number of placentas, the thickness as well as number of layers in the membrane separating the sacs, and the presence or absence of the lambda or twin peak sign.
3. If the first two scans are normal and suggestive of a DC/DA twinning, subsequent scans for fetal growth are performed at 24 to 26 weeks and every 3 to 4 weeks thereafter as long as fetal growth and amniotic fluid volume in each sac remains normal.
4. If the initial ultrasound is suggestive of a MC/DA placentation, and therefore a potential risk for developing TTS, subsequent scans are repeated at a minimum of 2-week intervals. Furthermore, NST's should be performed frequently after viability has been reached in patients with MC/MA placentation.
5. If there is evidence of IUGR, discordant fetal growth, or discordant fluid volumes, fetal surveillance is intensified and includes frequent nonstress testing along with biophysical profile and Doppler velocimetry studies. Because absent end-diastolic or reversed diastolic flow can be a predictor of poor outcome or imminent death in utero, serious consideration is given to delivering patients with these findings if the healthy fetus is mature enough for an elective delivery.

ABNORMALITIES ASSOCIATED WITH MULTIPLE GESTATION

Twin-to-Twin Transfusion Syndrome

Benirschke and Kim^[6] state that, as a group, MZ monochorial twins have greater disparity in weight than do dichorial twins. A comparison of dichorial MZ and DZ twins with MZ twins having a monochorial placenta shows this effect on birth weight to be due entirely to the type of placentation and not zygosity. This finding is best explained by the twin-to-twin transfusion syndrome.

To our knowledge, TTS in humans has only been reported in association with monochorionic placentas. On very rare occasions, vascular communications may exist between dichorial placentas, even in the case of DZ twins as evidenced by the occurrence of blood group chimeras,^[6] but among monochorionic twins these anastomoses are the rule rather than the unusual exception. The potential for the transfusion syndrome occurs when the arterial circulation of one twin is in communication with the venous circulation of the other through arteriovenous shunts in a "common villous district" (Fig. 24-11).^[6] In this situation, one fetus becomes a donor that transfuses its co-twin. The donor becomes anemic and growth restricted. Although occasionally it may become hydropic as a result of high-output failure, more frequently this twin is significantly smaller than the other. The recipient twin, on the other hand, becomes polycythemic and can suffer from congestive heart failure as a result of circulatory overload (Fig. 24-12). Thromboses of peripheral vessels may also develop in association with its hypertransfused state. The perinatal mortality associated with TTS may be as high as 70 percent. Several studies have shown antenatal factors that predict a poor outcome in these pregnancies, including (1) an early gestational age at

842

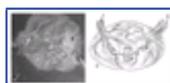

Figure 24-11 A, The placenta of a pregnancy complicated by the TTS. Milk has been injected into an artery on the "donor" side of the placenta (*black arrow*). It can be seen returning through the venous circulation on that side but is also evident in the venous circulation of the "recipient" (*white arrow*). **E**, The arteriovenous shunt shown in **A**.

diagnosis with delivery before 28 weeks, (2) severe polyhydramnios requiring multiple therapeutic amniocenteses, (3) fetal hydrops, and (4) absent or reversed diastolic flow on umbilical artery Doppler studies. If hydramnios develops early, premature labor often occurs before the third trimester.^{[109] [101] [102]} If the birth

Figure 24-12 Stillborn male twins at 31 weeks' gestation, secondary to the TTS. The plethoric twin on the left weighed 1,670 g and the anemic growth-restricted twin on the right weighed 1,300 g.

weights of MZ twins differ by less than 20 percent, the difference will usually not persist during later development. However, if the weights are discrepant by more than 25 percent, differences in height, and in some cases developmental delay, may persist into adult life.^[103]

TTS can be ultrasonically detected in utero.^[104] When severe, the syndrome usually manifests itself clinically as a result of polyhydramnios that is almost always found to exist in the sac of the larger twin. Sonographic criteria that provide an almost unequivocal antenatal diagnosis of TTS include (1) the presence of same-sex twins with a single placenta; (2) thin (two-layer) separating membrane between the sacs; (3) significant discordance in fetal growth (although this is not invariably present); (4) discordant amniotic fluid volume with polyhydramnios in the sac of the larger recipient twin and often a "stuck twin" appearance as a result of oligohydramnios in the sac of the donor twin; and (5) signs of hydrops or cardiac failure in either fetus, but this occurs more frequently in the larger twin.

When twins of unequal size are discovered on ultrasound examination, it is important to distinguish TTS from a pregnancy in which one fetus is growth restricted but the other is developing normally. In the latter situation the normal twin is usually surrounded by an appropriate quantity of amniotic fluid, and oligohydramnios may or may not be present in the other sac. In TTS, however, polyhydramnios and sonographic evidence of hydrops are often seen in association with the larger twin, while the donor is smaller than it should be and not simply smaller than its larger sibling. This

843

latter point may be useful in ruling out a third uncommon situation, namely, that of a normal fetus and a larger hydropic co-twin that is anomalous or erythroblastotic.

In addition to the usual fetal biometry and amniotic fluid volume assessment by ultrasonography, several investigators have attempted to evaluate the role of Doppler velocimetry studies in making or confirming a diagnosis of TTS. To date, these studies have only provided conflicting data. Farmakides et al.^[92] reported two cases in which umbilical artery waveforms of the twins were discordant and concluded that a simultaneous observation of high- and low-resistance S/D ratios was highly suggestive of this diagnosis. On the other hand, in eight cases where the diagnosis was documented or strongly suspected, Giles et al.^[85] found no difference in interpair S/D ratios. Pretorius et al.^[105] also reported eight cases of TTS and found no consistent pattern of umbilical artery Doppler S/D ratios. Other studies have reported similar observations on umbilical Doppler velocimetry in twin pregnancies with TTS.^{[96] , [97] , [98]} The mortality rate in the study by Pretorius et al.^[105] was very high, with five of eight pregnancies ending in fetal or neonatal death of both twins. In all five instances of perinatal loss, one or both of the twins had either absent or reversed diastolic flow. The authors concluded that, although evidence of greatly increased placental resistance (i.e., absent or reversed diastolic flow) is not helpful in identifying the donor from the recipient twin, it invariably predicts a poor outcome. Recent data from the Australian and New Zealand TTS Registry^[102] supports the observations of Pretorius et al.^[105] In their study of umbilical artery blood flow velocity waveforms, Ishimatsu et al.^[106] were also unable to identify any distinctive findings in patients with TTS. However, the presence of cardiomegaly in five recipient twins, with tricuspid regurgitation and a biphasic umbilical vein waveform in three others, led them to suggest that these findings may be more diagnostic than umbilical artery Doppler velocimetry and representative of the hemodynamic changes that occur in TTS.

Other investigators have utilized much more invasive techniques in an attempt to make a definitive prenatal diagnosis of TTS. Bruner and Rosemund^[107] performed

cordocentesis on both twins and were unable to demonstrate consistently a hemoglobin difference of 5 g or more between the recipient and donor twins. Tanaka et al.^[109] suggested the "pancuronium test," which involves cordocentesis and intravascular injection of pancuronium bromide, a nondepolarizing neuromuscular blocking agent, into one twin. Paralysis of both twins under these circumstances would confirm transplacental vascular communications and a diagnosis of TTS. The role of such invasive methods for the diagnosis of this condition is unclear and, in our opinion, the potential risks from a cordocentesis probably outweigh the benefits of definitively establishing the diagnosis.

The pathophysiology of polyhydramnios in TTS is poorly understood. Based on their observation of significantly increased concentrations of atrial natriuretic factor (ANF) in the cord blood of recipient twins compared with donor twins in three cases of TTS, Wieacker et al.^[109] suggested that chronic overload of circulatory volume in the recipient twin causes increased release of ANF from the fetal heart. This in turn results in increased fetal urine production, leading to polyhydramnios. Fries et al.^[110] on the other hand, proposed a more mechanical explanation for the presence of polyhydramnios in TTS. These authors found a high prevalence of velamentous cord insertion associated with this syndrome. They concluded that this might contribute to the development of profound disparity in amniotic fluid volume because the easy compressibility of the membranously inserted cord could result in reduced blood flow to one twin. They also suggested that removal of a large volume of amniotic fluid by amniocentesis may help reduce this compressive force on the cord insertion site, thereby leading to a reversal of the fluid imbalance.

Pregnancy outcome in patients with TTS appears to depend on the number and type of vascular anastomoses between the placentas, the pressures and directions of blood flow, and the timing of the imbalanced transfusion during the pregnancy. Even though the majority of monozygotic twins have monochorial placentas and communicating vessels, only 5 to 17 percent are reported to develop a significant transfusion syndrome.^{[111] [112] [113]} Machin and Keith^[114] suggest that intertwin vascular communications are of two main types: superficial and deep. Superficial connections form between vessels of like type (i.e., arterioarterial and venovenous). These are end-to-end anastomoses and usually not the structural basis for antenatal TTS. In fact, they usually act to protect twin pairs who might otherwise develop TTS. This is true more for the arterioarterial anastomosis, since venovenous connections operate at lower pressures and can be associated with poor outcomes. Vascular anastomoses deep in the parenchyma are arteriovenous and represent a zone of placental parenchyma supplied with arterial blood from one twin (the donor), but from which venous blood is returned to the other twin (the recipient). Indeed, when this is the only placental circulatory connection between twins, the onset of antenatal TTS is inevitable.^[114]

The actual incidence of TTS is very likely underestimated either because of the selection bias of studying liveborn twins or because the majority of dead monochorionic twins escape diagnosis at their co-twin's birth.^[113] Clinical manifestations of TTS are usually characterized by the onset of acute polyhydramnios

with or without associated preterm labor. Mortality rates associated with this presentation can range from 60 to 100 percent, the highest rates occurring in cases where the manifestation of this syndrome appears before 24 weeks' gestation.^{[6] , [113] , [115] [116] [117] [118]}

Various therapeutic maneuvers have been attempted in an effort to improve pregnancy outcome in severe cases of TTS. These approaches include therapeutic amniocenteses,^{[102] , [119] [120] [121] [122]} laser ablation of vascular anastomoses,^{[123] [124] [125]} selective feticide,^{[126] , [127]} and maternal treatment with digoxin or indomethacin.^{[128] [129] [130]} In a review of the subject in 1990, Blickstein^[131] concluded that therapeutic amniocenteses had poor efficacy in these cases. However, other reports have suggested that a much better pregnancy outcome can be achieved with the use of serial therapeutic amniocenteses.^{[102] , [119] [120] [121]} The overall survival of one or both twins in most series ranges from 74 to 83 percent.^[122] A recent study compared endoscopic laser surgery with serial amniocenteses, and concluded that laser coagulation of placental vascular anastomoses offers a more effective alternative to serial amniocenteses, with a higher fetal survival rate and lower incidence of sonographic abnormalities in the brain of surviving infants.^[132] Another study has proposed the use of amniotic septostomy (intentional puncture of the intertwin membrane) for the treatment of TTS.^[133] Excellent survival rates of 83 percent were reported in this small study consisting of 12 patients. It must be pointed out that this method, while promising, should at present be considered experimental until further studies confirm its efficacy and safety. It should also be noted that iatrogenic or spontaneous disruption of the intertwin membrane has been reported in some cases to result in subsequent cord entanglement and fetal death.^{[134] [135] [136]} Therefore, if a rent of the intertwin membrane is suspected, it is recommended that the pregnancy be managed as if it were a true monoamniotic twin pregnancy.^{[134] [135] [136]}

Isolated maternal treatment with either digoxin or indomethacin for TTS has not proven beneficial in improving fetal outcome.^{[129] [129] [130]} Selective feticide of one twin in the presence of the placental vascular communications expected in TTS can have devastating consequences, including death of the co-twin or survival with permanent damage.^[137] Fetoscopically directed Yttrium-aluminum-garnet (YAG) laser occlusion of placental vascular communications as suggested and reported by a few centers^{[124] , [125] , [132]} has tremendous appeal, since it aims to address the problem at its source. However, the technical expertise and special equipment required for this procedure limit its use to a very few specialized centers.

The weight of evidence from clinical reports and ease of performing the procedure suggest that at the present time, repeated therapeutic amniocenteses provide the best option for treatment until delivery is possible.^{[119] [120] [121]} The total number and frequency of amniocenteses must be individualized, since some patients show improvement following one or two procedures, whereas others may require that it be performed far more frequently. The volume of fluid aspirated at any one time should again be individualized, with an aim to removing as much fluid as possible from the polyhydramniotic sac and attaining a relatively "normal" fluid volume or a maximum vertical fluid pocket of about 7 cm at the end of the procedure. The role of prophylactic tocolysis in these cases remains unproven. However, our clinical observations suggest that a brief period of tocolysis at the time of amniocentesis may be helpful in reducing uterine irritability and contractions during the procedure.

CONGENITAL ANOMALIES IN MULTIPLE GESTATIONS

There is general agreement that anomalies occur more frequently in twins than in singletons, but controversy exists regarding the degree of difference. A large series from Czechoslovakia^[138] reported a rate of anomalies of 1.4 percent for singletons, 2.7 percent for twins, and 6.1 percent for triplets. Among cases of twins in which anomalies were detected, both twins were affected in 14.8 percent. There were no cases of triplets in which all three infants were affected. Hendricks^[139] found the frequency of anomalies to be more than three times higher in twins than in singletons, while in Kohl and Casey's series^[13] the frequency was 1.5 to 2 times higher. Other studies cited by Benirschke and Kim^[6] report smaller increases.

The diagnosis of a variety of morphologic abnormalities in multiple gestations has been made in utero with ultrasound. It is possible to detect anomalies of one or both fetuses or conversely to rule out specific disorders in twins who are known to be at increased risk for them. As is true for singletons, however, an ultrasonic diagnosis can only be made when a potentially detectable anatomic abnormality has become manifest at the time the fetus is studied. Neilson et al.^[140] describe four cases in which anomalies in one or both twins were heralded by elevated serum AFP values. In all these patients, the abnormalities were detected by ultrasound.

Anomalies Related to Twinning

Some anomalies such as acardia and conjoined twins are directly related to the twinning process. *Acardia* is a malformation that occurs in one of MZ twins, triplets, or even quintuplets with a frequency of approximately 1 per 30,000 deliveries.^[6] These extremely malformed

845

Figure 24-13 Acardiac twin. (Courtesy of Dr. James Wheeler, Department of Surgical Pathology, Hospital of the University of Pennsylvania, Philadelphia, PA.)

fetuses either have no heart at all (holoacardia) or only some rudimentary cardiac tissue (pseudoacardia) in association with other multiple developmental abnormalities (Fig. 24-13). These patients always have monochorial placentas and vascular anastomoses that sustain the life of the acardiac twin. Because of their isosexual status and monochorial relationship, they are considered to be MZ and therefore represent the ultimate of discordance in the development of genetically identical individuals. Controversy exists regarding the etiology of this condition. Kaplan and Benirschke^[141] believe that reversal of flow through the acardiac twin secondary to at least one artery-to-artery and one vein-to-vein connection in the placenta leads to the anomaly of twin reversed arterial perfusion (TRAP) sequence. Retrograde fetal perfusion has been documented to occur by Doppler studies in two cases.^[142], ^[143] Other authors,^[103] however, believe that acardia is a primary defect in cardiac development, and, while the placental vascular anastomoses are necessary for survival of the affected twin, these are not responsible for the abnormalities.

There is also a high incidence of chromosomal abnormalities in these pregnancies. In 6 of the 12 acardiac cases reported by Van Allen et al.,^[144] an abnormal karyotype was found in the perfused twin, while the karyotype of the pump twin was normal. The remaining six perfused twins were chromosomally normal.

Antenatal diagnosis by ultrasound of an acardiac fetus coexisting with a normal co-twin is fairly straight-forward. The anomalous twin may appear to be an amorphous mass or may show a wide range of abnormalities that depend on which organ system has failed to develop. The lower extremities and body are typically more completely developed, while the most severe abnormalities involve the upper body. The heart is frequently absent or rudimentary, and a single umbilical artery is present in approximately half the cases. A retrograde pattern of fetal perfusion can be demonstrated to occur through the umbilical arteries by Doppler studies.^[142], ^[143]

The pump twin, although structurally normal, is at increased risk for in utero cardiac failure, and mortality rates of 50 percent or higher have been reported.^[145] When the size ratio of the acardiac to that of the pump twin is less than 25 percent, the mortality rate is diminished. However, the prognosis worsens when polyhydramnios, preterm labor, or cardiac decompensation of the pump twin are present.^[145] Various techniques have been used to interrupt the vascular communication between the twins in an effort to improve outcome of the normal pump twin. These methods have included hysterotomy with physical removal of the acardiac twin,^[146] ^[147] ^[148] ultrasound-guided injection of thrombogenic materials into the umbilical circulation of the acardiac twin,^[149] ^[150] ^[151] and, more recently, ligation of the umbilical cord of the acardiac twin under fetoscopic guidance.^[153]

Nance^[103] presents evidence to suggest that a group of birth defects involving midline structures, including symmelia, extrophy of the cloaca, and midline neural tube defects, may be associated in some way with the twinning process. Symmelia is a rare severe defect that results from fusion of the preaxial halves of the developing hindlimb buds. This produces a single lower extremity with a knee that flexes in the opposite direction from normal. The incidence of this condition is 100 times higher in MZ births than in singletons. MZ twins have also been shown to have a higher frequency of neural tube defects than singletons,^[154] and they are often discordant for the abnormality. Nance^[103] suggests

846

that the MZ twinning process, with its attendant opportunities for asymmetry, cytoplasmic deficiency, and competition in utero, may favor the discordant expression of midline neurologic defects in these twins. He also cites evidence that 10 percent of all cases of extrophy of the cloaca occur in like-sex twins. In each of these instances, it is unclear whether the occurrence of a malformation somehow initiates the twinning process or whether a common factor predisposes to both events. Discordance is often, but not always, a feature of these midline defects in MZ twins.

Conjoined twins occur with a frequency of about 1 per 50,000 deliveries and in approximately 1 per 600 twin births.^[155] ^[156] ^[157] The most famous conjoined twins were Chang and Eng Bunker, who were born in Siam in 1811. These xiphopagus twins (i.e., joined by a band of tissue extending from the umbilicus to the xiphoid cartilage) lived unseparated for 63 years. P.T. Barnum exhibited them extensively for a number of years. At the age of 31, they married two sisters who bore them a total of 26 children. They died within hours of each other.^[155] ^[156] ^[157]

The precise etiology of conjoined twinning is unknown, but the most widely accepted theory is that incomplete division of an MZ embryo occurs at approximately 13 to 15 days postovulation. Most conjoined twins are female, with the ratio of females to males being reported as 2:1 or 3:1. The majority of these infants are delivered

prematurely and are still-born.^[156] They are classified according to their site of union. The most common location is the chest (thoracopagus) (Fig. 24-14), followed by the anterior abdominal wall from the xiphoid to the umbilicus (xiphopagus), the buttocks (pygopagus), the ischium (ischiopagus), and the head (craniopagus).^[156] Organs may be shared to varying degrees in different sets of twins. Major congenital anomalies of one or both twins are not uncommon and must be carefully searched for before definitive therapy is attempted. The success of surgical separation depends on the degree of union, the absence of major anomalies, and the presence of separate hearts.

In 1950, Gray et al.^[158] proposed a set of radiographic criteria for diagnosing ventrally fused twins. These include the twins facing each other with their heads at the same level and thoracic cages in close proximity, loss of the usual flexion of the fetal spines and occasionally hyperextension of the cervical spines, and no change in position of the twins relative to each other in response to external manipulations or spontaneous fetal movement. Polyhydramnios is said to be present in almost one half the reported cases of conjoined twins. Amniography or fetography and even contrast magnetic resonance has been used in establishing the diagnosis radiographically because these procedures outline the fetal body contours and can demonstrate a shared gastrointestinal

Figure 24-14 Conjoined twins attached at the chest or thoracopagus, the most common form of conjoined twins. They originate at the primitive streak stage of the embryonic plate (13 to 15 days). (Courtesy of Dr. James Wheeler, Department of Surgical Pathology, Hospital of the University of Pennsylvania, Philadelphia, PA.)

tract.^[159] Ultrasound, however, has become the safest and most reliable way to make this diagnosis in utero. Several reports have been published in which sonographic detection of this condition has been made antenatally.^{[159] [160] [161] [162] [163] [164] [165] [166] [167]} In some cases the diagnosis has been made as early as the first trimester of pregnancy by transvaginal ultrasound.^[168],^[169] Recent reports have also demonstrated that color Doppler and three-dimensional ultrasound can be effectively used to complement two-dimensional imaging, to confirm the diagnosis as well as determine the extent of organ sharing and definitive classification of conjoined twinning.^[170],^[171] Since fetal soft tissues are so well visualized with today's sonographic equipment, invasive imaging procedures such as amniography should no longer be necessary.

Once antenatal diagnosis has been established, the mode of delivery can be planned. Vaughn and Powell^[156] point out that dystocia, previously thought to be rare, since the union between conjoined twins is usually soft and pliable, may be a frequent and serious complication if vaginal delivery is attempted at term. When dystocia occurs in this setting, intrauterine surgical separation may be required that could result in devastating consequences for the fetuses and significant trauma to the mother. Craniopagus twins will not develop this type of dystocia, since it can be anticipated that they

will deliver "in series" rather than "in parallel." It is therefore recommended that most conjoined twins be delivered by cesarean section at term or if they present in premature labor and are potentially salvageable.^[156] If they are considered to have a poor chance of surviving and are small enough to pass through the birth canal without damaging the mother, vaginal delivery might be the preferable option. Compton^[172] states that with near-term-sized twins, cesarean delivery seems indicated even if the fetuses are dead. This is based on the premise that maternal morbidity from elective cesarean delivery is predictably lower than that associated with failed partial vaginal delivery necessitating an emergency operative delivery.

Chromosomal Anomalies in Twins

Most known chromosomal anomalies have been reported in twins.^[173] DZ twins are usually discordant for these anomalies and, surprisingly, MZ twins may be as well. In dizygotic pregnancies, the maternal age-related risk for chromosomal abnormalities for each twin may be the same as in singleton pregnancies. Therefore, it has been suggested that the chance of at least one fetus being affected by a chromosomal defect is twice as high as in singleton pregnancies. Furthermore, since the rate of dizygotic twinning increases with maternal age, the proportion of twin pregnancies with chromosomal defects may be higher than in singleton pregnancies.^[174] In monozygotic twins, the risk for chromosomal abnormalities is the same as in singleton pregnancies, and in the vast majority of cases, both fetuses are affected. There are, however, occasional case reports of monozygotic twins discordant for abnormalities of autosomal or sex chromosomes, most commonly with one fetus having Turner syndrome and the other fetus either a normal male or female phenotype, but usually with a mosaic karyotype.^{[175] [176] [177]}

DEATH OF ONE TWIN IN UTERO

The death of one twin in utero is not an exceptionally rare event. Hanna and Hill^[178] report a frequency of 2.2 percent over an 8-year period at their institution and cite a Swiss study in which the frequency was 6.8 percent over a period of almost 10 years. When only one twin dies in utero, it may become a fetus papyraceous. In that condition, the fluid is resorbed from the dead twin's body, and it is compressed into the adjacent membranes by the growth of the living fetus. Benirschke and Kim^[6] observed that this process can occur with any kind of placentation and that it is occasionally seen as a result of TTS.

When a dead twin remains undelivered, a legitimate medical concern is the potential for disseminated intravascular coagulation (DIC) in the mother. DIC is well known to complicate some cases of retained dead fetuses in singleton pregnancies.^[179] This is usually a chronic process that develops slowly in response to the release of thromboplastic material from the degenerating fetus into the maternal circulation. Although most cases of this type of DIC have been reported in the setting of a singleton gestation, it can occur after the death of one fetus in a multiple gestation.^[180] Romero and colleagues^[181] have reported a case in which death of one twin in utero was detected at 26 weeks' gestation (Fig. 24-15). Three and a half weeks later, the

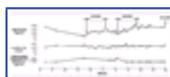

Figure 24-15 Effect of heparin therapy after 26 weeks' gestation on the platelet count and the plasma concentrations of fibrinogen and fibrin/fibrinogen degradation products in a pregnancy complicated by the death of one twin in utero. (From Romero R, Duffy TP, Berkowitz RL, et al: *Prolongation of a preterm pregnancy complicated by death of a single twin in utero and disseminated intravascular coagulation*. *N Engl J Med* 310:772, 1984, with permission.)

patient's fibrinogen level had fallen from an initial value of 370 mg/dl to 95 mg/dl. In response to an intravenous infusion of heparin, the hypofibrinogenemia was reversed. After a total of 25 days of therapy, the heparin was stopped and the patient went on to vaginally deliver a 2,040-g infant with Apgar scores of 9 and 9 and a macerated 350-g stillborn at 36 weeks. Successful reversal of maternal antepartum DIC with the use of heparin has been documented in two other patients. In each case, the pregnancy was prolonged by 10 weeks, with a normal outcome of the surviving twin.^[180],^[182] These cases demonstrate that in selected situations it may be possible to treat the chronic maternal coagulopathy associated with a retained dead twin in order to allow a premature living co-twin to continue to develop in utero. Fortunately, however, this is usually not necessary because the incidence of this complication must be very low. In our experience with several cases in which death of an anomalous twin fetus was selectively induced during the second trimester, none of the patients developed evidence of clinical DIC. Similar experiences have been reported by other groups.^[137],^[183],^[184],^[185] Therefore, as Hanna and Hill^[178] have suggested, when death in utero of one twin is detected before 34 weeks, conservative management is the wisest course. This should include weekly maternal clotting profiles and serial assessments of fetal growth and well-being. Since no coagulation disorders have been observed after spontaneous or induced first-trimester death of one or more fetuses in a multiple gestation, monitoring of coagulation factors is not necessary when fetal loss occurs prior to 13 weeks' gestation.

It should be noted that normal maternal fibrinogen levels or successful reversal of a consumption coagulopathy within the maternal circulation does not ensure that the surviving fetus will be unaffected by the process. If vascular anastomoses exist within a monochorial placenta, the shared circulation may permit embolization of thromboplastic material from the dead fetus directly into its living sibling. This phenomenon has been cited as the cause of intrauterine DIC and bilateral cortical necrosis,^[186] multicystic encephalomalacia,^[187] and other structural abnormalities^[188],^[190] in liveborn MZ twins with stillborn macerated co-twins. Another mechanism that may lead to death or damage of the living twin could be massive loss of blood from the survivor into the circulation of the other twin because of the lowered resistance that results from its death.^[191] By contrast, because of the virtual absence of shared circulations, damage to the survivor should occur far less frequently in the case of DZ twins or MZ twins with dichorionic placentas. Carlson and Towers^[192] presented a series of 17 multiple gestations in which one fetus had died and also reviewed the literature on this subject. They concluded that there is a 17 percent chance that the "surviving twin" in a monochorionic gestation will either die or suffer major morbidity, whereas these possibilities are unlikely to occur in the surviving twin in a dichorionic gestation. In a series of 43 twin pregnancies with single fetal death occurring at various times during pregnancy, Prompeler et al.^[193] observed that the loss of one of the twins in the first trimester did not impair the development of the surviving twin. If, however, fetal death occurred after 17 weeks' gestation, there was an increased risk of IUGR, preterm labor, and perinatal mortality. These authors and others also observed a high incidence of other morbidities (i.e., an increased incidence of IUGR, preterm delivery, and preeclampsia) in these pregnancies.^[194],^[195]

SELECTIVE TERMINATION OF AN ANOMALOUS FETUS

The diagnosis of discordancy for a major genetic disease before the time limit for legal termination of pregnancy in the second trimester places the parents in an extremely difficult position. Traditional choices in this setting are to terminate the pregnancy and sacrifice one normal child or to continue the pregnancy with the certain knowledge that one child will be afflicted with a devastating condition. A third choice is to perform selective termination of the affected fetus, anticipating healthy survival of the normal twin. Technical difficulties associated with this latter procedure in DZ twin gestations have, to a large extent, been resolved since its first description over a decade ago.^[196] However, several issues pertaining to technical, medical, ethical, and psychological problems related to this procedure must be carefully considered and discussed with the parents.

Several techniques that have been successfully used to perform selective terminations in the second trimester include cardiac puncture with exsanguination,^[196] removal of the affected twin at hysterotomy,^[196] cardiac puncture with intracardiac injection of calcium gluconate,^[184] air embolization through the umbilical vessels with fetoscopic guidance,^[183] and intracardiac injection of potassium chloride.^[196] The latter approach has gained acceptance because of its safety and is currently preferred both for selective termination procedures in the second trimester and for elective reduction of fetal numbers in the first trimester.^[40] ^[41] ^[42] , ^[139] , ^[185] , ^[196]

Immediate problems and complications associated with selective termination procedures include selecting the wrong fetus, technical inability to accomplish the objective of the procedure, premature rupture of the membranes, infection, and loss of the entire pregnancy. Before initiating the procedure, it is critical that the abnormal fetus be correctly identified. When the indication for selective termination is an abnormal karyotype

diagnosed by amniocentesis or chorionic villus sampling, a sonographically identifiable marker may or may not be present. If the gender of the twins is different, or the affected fetus has a gross morphologic anomaly such as hydrocephaly or omphalocele, the abnormal twin can be easily identified by sonography. However, in the absence of such visible signs, one must rely on the information provided from the original diagnostic procedure, which frequently has been performed elsewhere and several days or weeks before the patient presents herself to undergo the termination. In those cases where accurate localizing information is lacking, fetal blood sampling and rapid karyotype determination should be performed to reidentify the abnormal fetus before selective termination is attempted. Furthermore, in all cases a sample of fetal tissue must be obtained from the terminated twin to confirm that the correct fetus has been selected.

Since the procedure of second-trimester selective termination was first described over two decades ago,^[196] it has been utilized in many centers around the world. Evans et al.^[200] recently reported the experience and outcome of 402 cases from eight centers in four countries. Potassium chloride was the drug used in all cases. The overall results were excellent, with delivery of a viable infant or infants in over 90 percent of cases. There were no cases of DIC or serious maternal complications.

In considering selective termination of an abnormal twin, particular caution must be exercised to exclude the possibility of a monochorionic gestation. Vascular connections between fetal circulations occur in approximately 70 percent of MZ twins. In this situation, a lethal agent injected into the anomalous twin could enter the circulation of its normal sibling and result in death or permanent damage.^[137] To avoid this possibility, it has been suggested that pericardial tamponade with an innocuous agent such as normal saline might be attempted.^[201] However, even if this were technically successful, it is possible that the living normal twin could exsanguinate into the vasculature of its dead co-twin because of marked decrease in peripheral resistance of the shared circulations.^[137] To date, most reported attempts at selective termination in monochorionic pregnancies have been followed by death of the second twin within a short time. This has led perinatologists to attempt to occlude completely the circulation of the anomalous monochorionic twin at the time of the procedure by performing cord ligation with surgical removal of the fetus by hysterotomy^[137] , ^[202] , ^[203] or cord ligation by fetoscopy^[140] or use of a helical metal coil,^[151] or surgical silk suture soaked in 96 percent ethanol^[204] to induce thrombosis.

In summary, the therapeutic option of selective termination requires extensive counseling, the need to establish placental chorionicity prior to the procedure, significant technical competence, and verification of the diagnosis on the fetus that is terminated. When everything has been considered, selective termination may be the best choice for a particular set of parents in this unenviable predicament, but detailed and truly informed consent is mandatory.

FIRST-TRIMESTER MULTIFETAL PREGNANCY REDUCTION

The increasingly successful use of ovulatory drugs, in vitro fertilization, and related therapies has resulted in a growing incidence of multifetal pregnancies with three or more fetuses. Because of a high risk of perinatal morbidity and mortality from premature delivery in these pregnancies, first-trimester reduction^{[36] [37] [38]} of the number of fetuses has been advocated as a method to improve outcome. The original method of transcervical aspiration of gestational sacs described by Dumez and Oury^[205] has largely been abandoned. Currently, the method of choice consists of injecting a small dose of potassium chloride into the fetal thorax under real-time sonographic guidance using either a transabdominal^{[185] , [191] , [192] , [206] [207] [208]} or transvaginal^{[209] , [210]} approach.

Our experience,^[206] as well as that reported from several other centers,^{[185] , [207] [208] [209]} indicates that first-trimester pregnancy reduction is technically feasible and results in the delivery of healthy infants close to term in the majority of cases. The largest series has been reported by Evans et al.^[208] These authors combined data from 11 centers in 5 countries around the world that included 3,513 completed cases which were analyzed by the time period in which the procedures were performed, starting and finishing number of embryos/fetuses and pregnancy outcomes. With increasing experience over more than a decade the overall series loss rate was 9.6 percent, with early premature deliveries (2528 weeks) occurring in 3.7 percent. The miscarriage and severe preterm delivery rates were related to both the starting and finishing numbers of fetuses. The most recent collaborative overall loss rates (1995-1998) were 4.5 percent for patients starting with triplets, 7.3 percent for quadruplets, 11.4 percent for quintuplets, and 15.4 percent for sextuplets or higher. The data on finishing numbers confirm that reducing to twins had the lowest loss rate (6.0%), although the gap with singletons had decreased considerably from older data (6.7%). The loss rate for patients who reduced to triplets (18.4%) was considerably higher. The rates of prematurity, however, correlated directly with the finishing number. This paper, which analyzed the experience of the same operators over an extended period of time, clearly indicates that the outcome of the procedure

improves substantially with increased operator experience.

While most people would agree that perinatal morbidity and mortality are likely to improve when pregnancies with four or more fetuses are reduced to smaller numbers, the advantages of reducing triplets to twins remains far more controversial. In the absence of special circumstances, we do not believe that a first-trimester reduction from three to two fetuses can be justified on the basis of improving perinatal mortality. However, since three recently published series containing data on 198, 133, and 106 sets of triplets^{[23] , [212] , [213]} indicated that 20, 32, and 24 percent, respectively, delivered at 32 weeks or earlier, a reduction in the morbidity associated with severe prematurity may result from reducing triplets to twins. Until more detailed data are available from triplet pregnancies managed conservatively under modern circumstances, it is not possible to know whether multifetal pregnancy reduction does truly reduce perinatal morbidity in these cases.

PROBLEMS RELATED TO PLACENTATION

Benirschke and Kim^[6] note that prolapse of the cord and rupture of a vasa previa with fetal exsanguination are more common in twins than in singletons. They attribute the latter to the fact that a velamentous cord insertion occurs in 7 percent of twin placentas as opposed to 1 percent in singletons. Robinson et al.^[214] found that 7.1 percent of 72 pregnancies having a velamentous insertion of the cord had associated deformational defects of the neonate. This is defined as an alteration in shape and/or structure of a part of the fetus that has differentiated normally (e.g., clubfoot). These investigators speculate that competition for space between the developing fetus and the placenta due to mechanical factors that cause crowding in utero leads to fetal structural defects of a deformational nature and also alters the direction in which the placenta can grow. The latter situation secondarily causes velamentous insertion to occur when the bulk of the placental tissue is forced to grow laterally leaving the umbilical cord, which initially was located centrally, in an area that eventually becomes atrophic chorion laeve. The increased incidence of velamentous cord insertions in twin pregnancies may result from competition for space when two blastocysts happen to implant in close proximity. In support of this theory is the observation that velamentous insertions are more common in the most closely approximated twin placentas.

Monoamniotic twins are rare and have a high risk of fetal mortality. In a study from 1935, the survival rate of both twins was only 16 percent, while more recent series report double survival rates of 40 percent.^[215] The high fetal mortality associated with a single amniotic sac is due to prematurity, vascular anastomoses in the placenta and, most commonly, entanglement of the umbilical cords (Fig. 24-16). The latter is said to occur in as many as 70 percent of monoamniotic twins. Cord entanglement has been detected ultrasonically at 19

Figure 24-16 Entangled cords found during cesarean delivery in a case of MC/MA twins.

weeks in a case of monoamniotic twins discordant for an open neural tube defect.^[216] Inability to visualize a membrane separating two sacs in a twin gestation is suggestive of a monoamniotic pregnancy but is not diagnostic because occasionally the membrane can remain undetected even though it is present. Townsend and Filly^[217] suggest that the observation of entangled umbilical cords in the absence of a membrane separating twin fetuses provides a reliable sign for the sonographic diagnosis of monoamniotic twin gestation. They point out, though, that it is essential to trace both cords into the entangled mass before making this diagnosis. Another uncommon mishap that can result from this type of placentation is inadvertent clamping of the undelivered twin's cord after delivery of the first twin. McLeod and McCoy^[218] present just such a case in which a tight cord around the neck of twin A was clamped and divided and then found to belong to twin B. After abdominal manipulation, the second twin was rapidly delivered by forceps, and both neonates survived. These workers suggest that, whenever possible, division of a cord around the first twin's neck should be avoided. They end their paper with the reminder that if the wrong cord has been severed, "immediate extraction of the second twin is essential."

The optimal management of monoamniotic twin pregnancies with respect to timing and route of delivery remains controversial. Because of an impression of increasing morbidity and mortality rates in monoamniotic twins with advancing gestations, prophylactic preterm delivery by 30 to 32 weeks has been advocated to prevent cord-related deaths late in pregnancy.^[219] However, two recent retrospective studies^[220], ^[221] reviewing the outcome of 45 monoamniotic twin pregnancies found only one fetal death after 30 to 32 weeks' gestation. It occurred at 35 weeks' gestation. The authors of the latter study^[221] suggested that the decreased intrauterine space available in the third trimester may prevent extensive fetal movements and therefore cord entanglement. The investigators of both studies concluded that their data did not support any particular advantage to elective delivery of these pregnancies at 30 to 32 weeks' gestation. We believe that demonstration of fetal pulmonary maturity should be taken into account as an important determinant for timing of delivery and generally target a gestational age of 32 to 34 weeks for delivering monoamniotic twins. There is less controversy regarding the mode of delivery of these patients. Although anecdotal cases of a successful monoamniotic twin vaginal delivery may be mentioned, the potential for a disastrous outcome either from complications of cord entanglement or from fetal interlocking is substantial and makes vaginal delivery in these cases less than ideal. Therefore, cesarean delivery is recommended in all viable monoamniotic twin pregnancies.

AMNIOCENTESIS IN MULTIPLE GESTATIONS

When Should Both Sacs Be Tapped?

In some situations, it is obviously necessary to perform amniocentesis on each twin sac. Genetic studies must be performed on fluid surrounding each twin because, if DZ, they are genetically distinct individuals. Twins at risk of erythroblastosis fetalis must also have each sac tapped for optical density determinations, since one twin may be Rh-positive and the other Rh-negative.^[222] It should be noted that twins in Rh-sensitized pregnancies have been successfully transfused in utero.^[223]

The issue of pulmonary maturity studies in twins is more complex. Two series have found a close correlation between lecithin/sphingomyelin (L/S) ratios in amniotic fluid samples from twin sets. Spellacy et al.^[224] found no significant difference in fluids obtained from both sacs when L/S ratios were studied in 14 pregnancies. Sims and colleagues^[225] also found the L/S ratios of both sacs to be closely related in 20 sets of twins. Obladen and Gluck,^[226] however, noted significant discrepancies in postnatal phospholipid profiles of tracheal effluent in eight pairs of twins, six of whom were delivered vaginally.

Wilkinson et al.^[227] reported a case of quadruplets delivered by cesarean section at 30 weeks in which the presenting baby had amniotic fluid and pharyngeal aspirate L/S ratio values that were on the borderline of maturity, while those of the other three infants were clearly immature and almost identical to each other. The firstborn infant had mild respiratory distress, while the other three developed severe hyaline membrane disease. None of the neonates experienced birth asphyxia or postnatal hypothermia, and all the pharyngeal aspirates were collected within 10 minutes of birth. These investigators cite an earlier publication from their group in which the firstborn of triplets and quadruplets had also been found to have higher pharyngeal L/S ratios and less severe respiratory distress than those of their siblings delivered subsequently. This relationship was found regardless of whether the firstborn was delivered vaginally following spontaneous labor or was the presenting fetus in a cesarean delivery.

Norman et al.^[228] studied 30 African women with twins, all of whom had both sacs tapped immediately before cesarean delivery. Twenty-four of these patients were not in labor at the time of their delivery, and no significant intrapair differences in L/S ratio were found in this group. Six women who were in labor, however, were found to have a significant increase in the L/S ratio of their presenting twin when compared with its sibling. In addition, both free and unconjugated glucocorticoids

were found to be increased in the amniotic fluid of the presenting twin after labor had begun, but no significant difference was noted within twin sets when labor had not commenced. These latter reports suggest that the onset of labor in a multiple pregnancy may be determined by the fetus with the most mature lungs, which apparently is often the one presenting. It is possible that one twin may be significantly more stressed in utero than the other. The concept of accelerated lung maturation in response to antenatal stress has become widely accepted.^[229] It is therefore certainly conceivable that one twin may be pulmonically mature, while the other is not. Leveno et al.^[230] presented a series of 42 twin pregnancies delivered by cesarean section in which amniocentesis on each sac was performed immediately before delivery. The cesarean deliveries were done for a variety of indications, and no mention was made of the presence or absence of labor. In this group of patients, there were four instances in which one twin had an L/S ratio less than 2, while the sibling's value was 2 or greater. The pair with the greatest difference had L/S ratios of 0.7 and 3.5. However, only one of these eight neonates developed hyaline membrane disease and that was a twin whose L/S ratio was 1.4 while the sibling's was 2.2. Interestingly, in this series there were seven pairs in which only one fetus was growth restricted; IUGR was not found to increase the L/S ratio significantly in these cases. Similarly, Norman et al.^[228] compared the L/S ratios from each sac before the onset of labor in eight sets of twins with only one growth-restricted fetus and were unable to find significant differences.

It appears that the stress associated with IUGR may not be sufficient to cause a significant difference in lung maturity when only one twin is affected. There has been one case report,^[231] however, that raises the possibility that the stress associated with premature rupture of membranes for more than 16 hours in a presenting fetus may give it a pulmonary advantage over its co-twin with intact membranes. It is likely that other stressful processes could affect twins unequally and result in major differences regarding pulmonary surfactant production.

We believe it is reasonable to assume that in most cases of nonlaboring patients with twins, an L/S ratio from one sac will accurately reflect the status of both fetuses. If one twin appears to be abnormal for any reason, however, or if the patient is in premature labor, both sacs should be tapped to assess pulmonary maturity. Should the operator elect to tap only one sac in these situations, it should be that of the twin who appears to be normal in the former case and that of the second twin in the latter. The stressed twin, or the presenting twin in these two instances, can be assumed to have an L/S ratio at least as mature as that of its sibling, and probably more so.

The Technique of Tapping Multiple Sacs

Elias et al.^[232] reported that they were successful in obtaining fluid from both amniotic sacs in 19 of 20 pregnancies during the second trimester. These workers used ultrasound to identify the lie of each fetus and then introduced an amniocentesis needle into one sac using a standard insertion technique. After aspirating some fluid, they introduced a blue dye, to serve as a marker, and then removed the needle. A different needle was then inserted and the aspiration of untinged fluid indicated that the second sac had been successfully entered.

Several points should be stressed:

1. The usual precautions applying to all cases of amniocentesis must certainly be followed when multiple sacs are to be tapped. A thorough ultrasound examination should precede the amniocentesis, at which time the viability of all fetuses should be verified and their gestational ages and relative sizes assessed. The position of the placenta(s) and dividing membranes should be noted (Fig. 24-17) and (Fig. 24-18) and a search for gross fetal, uterine, and adnexal pathology performed. It is particularly important to note the position of one fetus relative to the other(s) and to label the aspirated fluids appropriately, as well as placing a drawing in the patient's chart so that at a later date it is possible to correlate a particular fetus with its fluid specimen. This becomes even more critically important in the case of genetic studies if at a later date selective termination of one fetus is to be considered.
2. Direct ultrasonic visualization of the needle tip during its insertion allows for much greater precision in guiding the needle to an optimal sampling site. It also reduces the potential for traumatizing the fetus. Jeanty et al.^[233] published a description of how this can easily be accomplished.
3. Use of a marker dye is very helpful in performing amniocentesis on more than one sac, but methylene blue has been associated with fetal hemolysis when injected intra-amniotically.^[234] Furthermore, multiple ileal obstructions^[235] or jejunal atresia^[236],^[237] have been reported in twins whose sacs have been injected with 1 percent methylene blue at the time of a diagnostic tap in the second trimester. It is therefore recommended that either indigo carmine or Evan's blue be used rather than methylene blue. Whatever dye is used, it should not be red so as to avoid confusion in the event of a bloody tap.
4. When failure to see a separating membrane between the sacs suggests the possibility of a monoamniotic twin gestation, use of a marker dye alone may not

represent reentry into the first sac. Under these circumstances, a technique described by Tabsh ^[239] may be useful in differentiating a single monoamniotic sac from separate diamniotic sacs where the membrane is simply not being visualized. Leaving the needle in place after an initial sample of fluid is withdrawn, 0.1 ml of air drawn into the syringe through a micropore filter is mixed with 0.5 ml of marker dye and 5 ml of aspirated amniotic fluid. This mixture is then injected back into the sac under firm, gentle pressure in order to create microbubbles within the amniotic fluid. The microbubbles serve as ultrasonic contrast agents within the first sac and should demarcate it from a second sac if one is present. A site for needle insertion into the second sac can then be selected. Aspiration of colorless fluid confirms that a second sac has been entered, whereas fluid colored with dye indicates that the original sac has been reentered. If the microbubbles are seen around both fetuses, a diagnosis of monoamniotic twins can be confirmed.

Figure 24-17 Sagittal scan with a single anterior placenta demonstrating a vertical membrane (arrow) separating the two sacs.

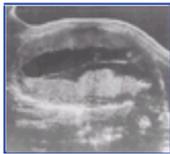

Figure 24-18 Sagittal scan revealing individual anterior and posterior placentas with the membranes running horizontally between the two sacs.

Sebire et al., in 1996, described a technique utilizing single uterine entry for genetic amniocentesis in 176 twin pregnancies. ^[239] After amniotic fluid is aspirated from the sac of one twin, the syringe is removed, the stylet replaced, and the needle advanced through the intertwin membrane under continuous ultrasound guidance into the sac of the second twin. When aspirating fluid from the second sac, they recommend discarding the first 1 ml in order to avoid possible contamination from amniotic fluid of the first sac. ^[239] While the method described by these investigators is technically feasible, we would continue to recommend the technique described earlier, using a separate needle insertion for each sac, thus eliminating any chances of contamination of fluid samples obtained from each sac. Also, it is possible that the puncture site in the membrane separating the two sacs may enlarge and lead to a cord accident later in pregnancy as has been reported when this occurred inadvertently in cases of septostomy for TTS. ^[134] , ^[136]

Although second-trimester amniocentesis for genetic indications has become a well-accepted procedure, some studies have suggested a higher postprocedural fetal loss rate in twin pregnancies than in those with singletons. ^[240] ^[241] ^[242] Loss rates as high as 4.9 percent^[241] to 16.7 percent ^[240] have been reported. These studies, however, did not address the question of whether the increased fetal wastage following amniocentesis is attributable to

the procedure or to the twin gestation itself. In a recent case-controlled study, Ghidini et al. ^[243] concluded that second-trimester amniocentesis in twin pregnancies was not associated with excess pregnancy loss and that the likelihood of fetal loss secondary to this procedure is probably of the same order of magnitude as that in singletons.

MANAGEMENT OF MULTIPLE GESTATIONS

The Antepartum Period

Specialized antenatal care cannot be offered to women with multiple gestations unless they are known to be carrying more than one fetus. In areas in which universal ultrasound screening is not performed, the early diagnosis of twins depends on maintaining a high index of suspicion whenever uterine size appears to be larger than dates. Once suspected, twins can be easily diagnosed by performing a thorough ultrasound examination. After confirmation of a multiple gestation, the issue arises as to which, if any, of the various methods used in an attempt to improve perinatal outcome in these patients is worthy of consideration.

The value of bed rest in the hospital for a patient carrying twins is controversial. Marivate and Norman ^[2] cite five studies that reported a reduction in perinatal mortality and prematurity rates and two others that found no difference in those variables when patients with twins routinely admitted to the hospital were compared with those treated on an outpatient basis. Two prospective randomized trials published in 1984 and 1985 found no benefit from late hospital admission, ^[244] ^[245] and in the latter study preterm delivery was more common among the hospitalized group.

Hawrylyshyn et al. ^[16] reported that in their series of 175 consecutive twin deliveries bed rest after 30 weeks had no effect on perinatal mortality. Since 70 percent of the perinatal deaths in their study occurred before the 30th week, these workers concluded that elective hospitalization must include the period from 25 to 30 weeks in order to exert any significant impact on both the survival and the quality of survival of twins. In support of this concept, it should be noted that Chervenak et al. ^[31] found that 81 percent of the perinatal mortality in their series of 385 twin pregnancies occurred before the 29th week of gestation.

Two other studies evaluated the role of early routine hospital admission for twin gestations and came to similar conclusions. The first was a multicenter randomized study from Australia in which 11 hospitals participated. ^[246] Of 141 women with twins in the study, 72 were assigned to outpatient care and 69 were hospitalized from 26 to 30 weeks' gestation. No differences between the groups could be demonstrated in the frequencies of major maternal complications, preterm delivery, or mean birth weights at delivery.

Surprisingly, in fact, there was a trend toward greater frequency of preterm delivery and admission of neonates to the neonatal intensive care unit (NICU) in the group admitted to the hospital. Leveno et al. ^[247] similarly observed no differences in pregnancy outcome between 134 patients with twin gestations that were hospitalized from 24 to 32 weeks versus 177 patients who were not routinely hospitalized.

Bed rest in the hospital is expensive and disrupts normal family life. Since there is no evidence to suggest that elective hospitalization is universally beneficial for patients with twins, we feel that these women should only be hospitalized for the same indications that would be used to admit women with singletons.

Prophylactic administration of tocolytic agents to women with twins has been tried with varying degrees of success. Marivate and Norman ^[2] cite one report in which pregnancy prolongation and increased birth weight was associated with this approach and three other series that found no improvement in these variables when prophylactic tocolysis was administered to patients with twins. Since an increased incidence of maternal cardiovascular complications has been reported in women with multiple gestations who have been treated with -agonists, ^[248] it seems prudent to restrict the use of these agents to women who are confirmed to be in preterm labor.

Results of studies using prophylactic cervical cerclage in women with multiple gestations have been disappointing. ^[2] Since this surgical procedure may be associated with adverse sequelae for both the mother and her fetuses, it is recommended that cerclage placement be limited to women with either a strong suggestive history or with objectively documented cervical incompetence.

In an attempt to predict the onset of labor in a series of women with twins, Houlton et al. ^[249] evaluated the effectiveness of a cervical assessment score based on the length of the cervical canal in centimeters minus the dilatation of the internal os in centimeters. These workers found a significant relationship between a cervical score of 0, or a decrease in cervical score, and the onset of labor within the subsequent 14 days. Similar effectiveness of this scoring system was reported by Neilson et al. ^[250] On the other hand, O'Connor et al. ^[251] found that routine cervical assessment and uterine activity measurements were not helpful in predicting preterm delivery. Recent studies have validated the utility of two other tests: ultrasonographic assessment of cervical length, and fetal fibronectin (FFN) as useful adjuvant tests in the prediction of preterm labor in multiple gestations. ^[252] ^[253] ^[254] ^[255]

Premature cervical shortening and cervical funneling on ultrasound have good predictive ability for preterm labor and delivery in patients with multiple gestations. These studies suggest that a cervical length measurement of greater than or equal to 35 mm by transvaginal ultrasound at 24 to 26 weeks in twin gestation will identify patients who are at low risk for delivery prior to 34 weeks' gestation. On the other hand, a cervical length of 25 mm or less with or without funneling at 24 to 26 weeks' gestation predicts a high risk for preterm labor and delivery. ^[253] ^[254] ^[255] The study reported by Goldenberg et al. ^[252] also found that a positive FFN test at 28 weeks is a significant predictor of spontaneous preterm labor prior to 32 weeks' gestation. Based on these studies, it would be reasonable to incorporate these two tests (i.e., FFN test and vaginal ultrasound for cervical length at 24 to 28 gestational weeks), as a screening test for all multiple gestations in order to identify those at high risk for preterm delivery before 34 weeks' gestation (see Chapter 23).

Another concept regarding early detection of preterm labor involves ambulatory home monitoring of uterine contractions with a mobile tocodynamometer. Although the efficacy of this method for detecting preterm labor in multiple gestations has not yet been evaluated with prospective randomized trials, clinical studies suggest that this may be a useful adjunct in the intensified antepartum surveillance of these patients. ^[23] It has been suggested that these women might benefit maximally from prophylactic bed rest in the hospital and aggressive early tocolysis for documented preterm labor. A randomized prospective study would shed some light on the efficacy of this approach, but to our knowledge this has not yet been performed.

The value of special twin clinics has been described by several investigators. ^[2] ^[251] In these clinics, where all women known to be carrying twins are seen at regular intervals by the same medical team, several advantages accrue. Patients have the opportunity in this type of clinical setting to develop rapport with a small group of caregivers. This should result in an increased awareness of their special problems and may increase compliance with therapeutic directives. The patients can also talk with other women who are expecting twins and learn that their antenatal experiences are not unique. Furthermore, the medical personnel become more adept at detecting early signs of the special problems associated with twin pregnancies. Finally, and perhaps most importantly, the team of caregivers has the opportunity to develop an antenatal management protocol that is maximally effective for their population of patients. The value of performing serial ultrasound studies to evaluate the growth and development of each fetus in a multiple gestation has been mentioned earlier in this chapter. It should also be noted that assessment of fetal well-being by simultaneous nonstress heart rate testing in twin pregnancies seems both feasible and efficacious. DeVoe and Azor ^[256] reported 24 sets of twins who underwent 120

simultaneously recorded nonstress tests in the third trimester. Technical problems in obtaining readable tracings were encountered in only 15 percent of cases. Reactive nonstress tests were found to be associated with a good prognosis if delivery occurred within 1 week, while nonreactive nonstress tests were less specific but in some cases reflected significant distress in utero. These authors concluded that nonstress tests in twins, whether reactive or nonreactive, appear to be prognostically comparable to those previously reported in singleton third-trimester pregnancies. The study of Blake et al. [257] in 94 patients with multiple gestations confirmed that antepartum nonstress testing is a highly reliable and predictive test in assessment of multiple gestations.

Before 1983, three relatively large series were published describing the management of pregnancies in which three or more fetuses were involved. Ron-El et al. [19] reported their experience with 29 triplet and 6 quadruplet pregnancies in Tel Aviv between 1970 and 1978. Seven of these pregnancies were conceived spontaneously, and the other 19 followed the administration of fertility drugs. The cesarean delivery rate was 44 percent and the mean birth weight was $1,830 \pm 536$ g. The overall perinatal mortality rate was 185 per 1,000.

In another series from Israel, Holcberg et al. [18] described the outcome of 31 triplet pregnancies managed between 1960 and 1979 at their institution in Beersheba. Twenty-one of these pregnancies were conceived spontaneously, and 10 followed the induction of ovulation. Triplet gestation was diagnosed earlier in the group with induced ovulation, and their period of hospitalization before delivery was longer than the group that conceived spontaneously. The most frequent antenatal complications for the entire group were preterm delivery (97 percent), pregnancy-induced hypertension (46 percent), and anemia (29 percent). Thirteen percent of patients required postpartum blood transfusions for excessive bleeding from an atonic uterus. The overall perinatal mortality rate was 312 per 1,000. The only neonatal death occurring in an infant born after 31 weeks was due to congenital malformations incompatible with life. The incidence of cesarean delivery was 32 percent.

Loucopoulos and Jewelewicz [29] reported the outcome of 35 pregnancies involving 27 sets of triplets, 7 sets of quadruplets, and 1 set of quintuplets at the Sloane Hospital for Women in New York between 1965 and 1981. Six patients conceived triplets spontaneously, and the remainder became pregnant after the use of ovulatory agents. The cesarean delivery rate was 42 percent, and the mean birth weight was $1,815 \pm 628$ g. The overall perinatal mortality rate was 148 per 1,000.

Four studies evaluated various management protocols

856

in multiple gestations involving three or more fetuses, Goldman et al. [259] assessed the efficacy of elective cerclage. Of 27 multiple pregnancies, 12 with triplets and 3 with quadruplets received elective cerclage, whereas 10 triplet and 2 quadruplet gestations did not. These investigators found that the cerclage group achieved a significantly longer mean gestation, higher birth weights, higher Apgar scores, lower rates of respiratory distress syndrome, and a significantly lower perinatal mortality rate. Lipitz et al. [21] however, reporting their experience with 78 triplets managed between 1975 and 1988, concluded that there was no benefit of elective cervical cerclage either in prolonging gestation or decreasing fetal loss. Their observations are supported by a recent study also evaluating the role of elective cerclage in triplet pregnancies. [259] In the report of Lipitz et al., [21] 86 percent of the patients delivered prematurely, with the mean gestational age at delivery being 33.2 weeks. The perinatal and neonatal mortality rates were 93 per 1,000 and 51 per 1,000 livebirths, respectively. A higher proportion of low Apgar scores and respiratory disorders occurred in the third infant in patients delivered vaginally. These authors recommend cesarean delivery for triplet pregnancies.

Gonen et al. [22] reported the outcome and follow-up data of 30 multiple gestations (24 triplets, 5 quadruplets, and 1 quintuplet) managed over a 10-year period from 1978 to 1988. In their study, the early neonatal mortality rate was 31.6 per 1,000, late neonatal mortality was 21 per 1,000, and the perinatal mortality was 51.5 per 1,000 live births. The incidence of respiratory distress syndrome was 43 percent, bronchopulmonary dysplasia 6 percent, retinopathy of prematurity 3 percent, intraventricular hemorrhage 4 percent, and cerebral palsy 2 percent. Follow-up of 84 infants for a period of 1 to 10 years showed 75 percent of them to be free from any neurologic or developmental handicap, 22 percent had mild functional delay, one infant was mildly handicapped, and one was moderately handicapped. Although all patients were not managed with the same protocol, the authors concluded that the most likely determinants of the excellent outcome in this series were early diagnosis, meticulous antenatal care, frequent evaluation of fetal well-being, cesarean delivery, presence of a trained neonatologist for each neonate at the time of delivery, and the resources of a highly skilled NICU.

Newman et al. [23] evaluated outpatient antepartum management and pregnancy outcome of 198 women who delivered triplets between 1985 and 1988. The study involved 24 centers, with individual patients managed at the discretion of obstetricians in both private and academic practices. All patients were managed with the assistance of ambulatory perinatal nursing to provide outpatient surveillance. Uterine activity was monitored twice a day with a portable tocodynamometer, and daily telephone contact along with around-the-clock availability of the nursing staff provided a liaison between the patient and her physician. Modified bed rest was prescribed for almost all patients, but prophylactic tocolytic agents or betamethasone were used at the discretion of the individual physician. Although patients were hospitalized for either preterm labor or other medical complications, the average stay for antepartum hospitalization was only 15 days in this series. The mean gestational age and birth weight at delivery were 33.6 ± 3 weeks and $1,871 \pm 555$ g, respectively. The corrected perinatal survival was 95 percent, leading the authors to conclude that routine hospitalization is unnecessary for patients with triplets, and intensive outpatient surveillance is justifiable and is associated with excellent outcomes in these pregnancies.

In a recent report, 10 cases of quadruplet pregnancies managed over a 5-year period were reported by Elliott and Radin, [260] with unusually excellent outcomes, including a perinatal mortality rate of zero. Their protocol involved prophylactic use of low-dose aspirin, home contraction monitoring, terbutaline pump tocolysis, and bed rest at home starting at 16 weeks' gestation. The superb results obtained by this group of clinicians merit further assessment of their management approach in a larger group of patients with higher order multiple gestations.

Based on a review of the published studies and our own clinical experience, we believe that management of multifetal gestations with three or more fetuses can be achieved on an outpatient basis in most cases, but must include intensified surveillance of the mother and fetuses. Our protocol includes (1) modified bed rest at home initiated at 16 weeks' gestation; (2) frequent prenatal visits with cervical assessment for evidence of effacement or dilatation and measurement of cervical length by ultrasound (routine cerclage is not recommended, but is offered to patients with clinical documentation or historical evidence of cervical incompetence); (3) contraction monitoring for evidence of increased uterine activity or signs of preterm labor beginning at 20 weeks' gestation; (4) serial ultrasound studies for evaluation of fetal growth; (5) early initiation of weekly nonstress tests at 26 to 28 weeks' gestation; (6) hospitalization for any evidence of preterm labor or other obstetric/medical complications; (7) tocolytic agents and betamethasone restricted to patients with documented preterm labor; and (8) elective cesarean delivery recommended in all cases either at onset of labor near term or at 36 completed weeks' gestation following documentation of lung maturity.

The Intrapartum Period

A number of factors must be considered when evaluating a laboring patient with twins or reviewing series

857

that present delivery outcomes in women with multiple gestations. These variables include the gestational age and estimated weights of fetuses, their positions relative to each other, the availability of real-time ultrasound on the labor floor and in the delivery room, and the capability of monitoring each twin independently during the entire intrapartum period. Older series may not be applicable to current practice because our ability to monitor both twins closely during labor and delivery has increased considerably in recent years.

All combinations of intrapartum twin presentations can be classified into three groups: twin A vertex, twin B vertex; twin A vertex, twin B nonvertex; and twin A nonvertex, twin B either vertex or nonvertex. In a series of 362 twin deliveries presented by Chervenak et al., [261] these presentations were found in 42.5, 38.4, and 19.1 percent of cases, respectively. These data were similar to the findings of other investigators. [19], [30] In the series by Chervenak et al., [261] 81.2 percent of the vertex-vertex twin gestations were delivered vaginally. These investigators, and several others cited in their article, believe that when both twins are in vertex presentation, a cesarean delivery should only be performed for the same indications applied to singletons. This recommendation holds true for any gestational age and implies that both twins can be monitored during labor. Currently, cesarean delivery seems to be the method of choice when the presenting twin is in a nonvertex position, as there are no studies documenting the safety of vaginal delivery for this group. External cephalic version of the presenting twin would be difficult, if not impossible, in these patients. Furthermore, if the second twin is in a vertex presentation and faces its sibling, the potential for locking exists. Khunda [262] states that frequency of locking is approximately 1 per 1,000 twin deliveries, with an associated fetal mortality of 31 percent. This condition occurs most commonly in

breech-vertex presentations when the fetal chins overlie each other. It is usually not recognized until the body of the presenting twin is out of the vagina and the aftercoming head cannot be delivered. Eventually it becomes clear that entry of the first twin's head into the pelvis is being obstructed by that of the second twin. Sevitz and Merrell^[263] published a case in which a vaginal delivery was accomplished and one twin survived after intravenous administration of a -mimetic agent to a woman whose twins had locked during delivery. The more devastating consequences of this disorder, however, have been aptly described by Nissen.^[264] Finally, it is possible that the second twin could complicate the delivery of the first twin in more subtle ways, such as by deflexing its head. It may eventually be shown that in some circumstances fears regarding a vaginal delivery when the leading twin presents in a nonvertex position are unwarranted, but this has not yet been convincingly demonstrated.

The management of that subset of women whose twins are in a vertex-breech or vertex-transverse lie is particularly controversial. Chervenak et al.^[261] cite 11 references in which depressed Apgar scores and increased perinatal mortality rates associated with vaginal breech delivery of the second twin have led some of the investigators to recommend cesarean delivery whenever twin B is in a nonvertex lie. Conflicting data have been reported, however. Acker et al.^[265] found no perinatal deaths when 74 nonvertex first or second twins weighing more than 1,499 g were delivered by cesarean section or when 76 nonvertex second twins with similar birth weights were delivered vaginally. Furthermore, no statistically significant difference was found in low 5-minute Apgar scores when these two groups were compared.

Chervenak and colleagues^[266] presented the intrapartum management of 93 vertex-breech and 42 vertex-transverse twin sets. Seventy-eight percent of the vertex-breech group and 53 percent of the vertex-transverse group were delivered vaginally. Seventy-six second twins were delivered vaginally by breech extraction, 16 of whom had birth weights of less than 1,500 g. Within that group there were six neonatal deaths, four intraventricular hemorrhages, and a 67 percent occurrence of depressed 5-minute Apgar scores. It should be noted, however, that there were also seven neonatal deaths and four intraventricular hemorrhages in the firstborn fetuses of the same pregnancies, all of whom were delivered in vertex presentation. At birth weights above 1,500 g, there were no neonatal deaths or documented intraventricular hemorrhages and only three cases (5 percent) of 5-minute Apgar scores of less than 7 in the group of second twins delivered vaginally by breech extraction. Chervenak et al.^[266] state that their data do not prove vaginal breech delivery of the low-birth-weight second twin to be more damaging than cesarean delivery. Nevertheless, because of the documented ill effects of vaginal delivery on low-birth-weight singleton breech infants^[267],^[268] and the absence of evidence that being a second twin gives these infants an advantage relative to their singleton counterparts, vaginal breech delivery was not advised for second twins weighing less than 1,500 g. On the other hand, if a second twin weighs between 1,500 and 3,500 g and the criteria for vaginal delivery of a singleton breech are met, this series suggests that vaginal breech delivery is an acceptable option.

The same group has also reported their experience with 25 external cephalic versions performed on 14 transverse and 11 breech malpositioned second twins.^[269] Version-to-vertex presentation was successful in 71 and 73 percent of cases, respectively. Among the 25 attempted cases, only 2 neonates had 5-minute Apgar scores below 7. However, in a study reported by Gocke et al.,^[270] the success rate for external cephalic

version of the second twin was only 46 percent. Their study analyzed 136 sets of vertex-nonvertex twins with birth weights above 1,500 g in whom delivery of the second twin was managed by primary cesarean delivery, external version, or primary breech extraction. A primary attempt at delivery of the second twin by external version was performed on 41 twins, 55 underwent attempted breech extraction, and 40 patients had a primary cesarean delivery. No differences were noted in the incidence of neonatal mortality or morbidity among the three modes of delivery. External version was associated not only with a higher failure rate than breech extraction, but also a higher rate of fetal distress, cord prolapse, and compound presentation. The authors, therefore, suggest that primary breech extraction of the second nonvertex twin weighing more than 1,500 g is a reasonable alternative to either cesarean delivery or external version. Analyzing their own extensive experience along with a review of the published literature, Chervenak et al.^[261] have made the following recommendations for patients presenting with twins in vertex-nonvertex presentation. During the intrapartum period, a sonographic estimation of fetal weight (EFW) for twin B should be determined. With current methods,^[271] there is a 10 percent SD in the sonographic EFW so that 95 percent of the time estimates are accurate to within ± 20 percent. Therefore, using a cutoff for EFW of 2,000 g is unlikely to result in the birth of a neonate weighing less than 1,500 g. On the basis of the arguments cited above, the investigators believe that a birth weight in excess of 1,500 g is sufficient for a vaginal breech delivery, but a lesser weight is not. Regardless of the estimated weight, they suggest that an attempt be made to convert the second twin to a vertex presentation by performing an external version after the first twin has been delivered. If this proves successful, a vaginal delivery can be anticipated. If the attempted version is unsuccessful and the EFW is between 2,000 and 3,500 g, a breech extraction can be performed unless the other criteria for a singleton vaginal breech delivery are not satisfied. Recent reports support these recommendations and have documented the efficacy and safety of either external cephalic version^[272] or total breech extraction^[273],^[274] for the delivery of second nonvertex twins weighing more than 1,500 g. However, if the EFW of the second twin is less than 2,000 g, or the criteria for a singleton vaginal breech delivery are not met, a cesarean delivery should be performed following a failed external version. Evrard and Gold^[275] discuss the reluctance of some obstetricians to ever consider a combined vaginal-abdominal approach to delivering twins but point out that there are some situations in which it is appropriate. Other workers have made reference to this form of delivery in a small number of patients in their twin series.^[261],^[276]

In commenting on their series of triplets, quadruplets, and quintuplets, Loucopoulos and Jewelewicz^[20] state that "the mode of delivery does not seem to play any particular role insofar as outcome is concerned." Several studies prior to 1990 suggested low neonatal morbidity and mortality rates with cesarean section delivery of patients with triplet pregnancies, and therefore recommended cesarean delivery in all these patients.^[19],^[277]^[278]^[279]^[280]^[281] More recent studies, however, suggest that in selected cases vaginal delivery of triplets can be accomplished without increased neonatal or maternal morbidity and mortality. Furthermore, successful vaginal delivery in these patients would decrease maternal hospital stay and postoperative morbidity.^[282]^[283]^[284]^[285] Loucopoulos and Jewelewicz^[20] suggest that "continuous fetal surveillance, speed, and atraumatic delivery are the hallmarks of successful intrapartum management. In experienced hands, vaginal delivery should be attempted unless there is a medical indication for cesarean section." They caution, however, that general anesthesia should be used if one is contemplating vaginal delivery, since the absence of adequate uterine relaxation could make an internal version or extraction impossible and thereby increase the risk of neonatal injury. It is fair to point out that great skill with external versions and/or breech deliveries might be required in order to achieve the atraumatic but speedy delivery called for by these authors. In our opinion, only an experienced obstetrician with demonstrated expertise in these maneuvers should even consider attempting the vaginal delivery of a patient who is known to have three or more viable fetuses. We currently feel that elective cesarean delivery is the safest mode for these pregnancies.

TIME INTERVAL BETWEEN DELIVERIES

Another variable that many investigators have considered important in the outcome of twin pregnancies is the time interval between their deliveries. After delivery of the first twin, uterine inertia may develop, the second twin's cord can prolapse, and partial separation of its placenta may render the second twin hypoxic. In addition, the cervix can clamp down, making rapid delivery of the second twin extremely difficult if fetal distress develops. Many reports have suggested that the interval between deliveries should ideally be within 15 minutes and certainly not more than 30 minutes.^[6],^[13],^[30],^[285],^[286] Most of the data in support of this view, however, were obtained before the advent of intrapartum fetal monitoring.

There are obviously situations in which expeditious

delivery of the second twin is desirable shortly after the birth of the first, but this is not always the case. Several extraordinary examples attest to this fact. Mashiach et al.^[287] reported a case of a woman with a triplet pregnancy in a uterus didelphys, with fetuses A and B in the right uterine horn and fetus C in the left horn. A missed abortion of fetus A was noted at 22 weeks. At 27 weeks the right horn began to contract and a macerated fetus A was delivered vaginally, but the passage of fetus B was obstructed by the vertex of fetus C. A cesarean section was then performed on the right uterine horn and a 1,080-g infant was delivered who died in 2 weeks.

Since the left horn was not contracting, it was left intact. At 37 weeks, 72 days after the first two deliveries, an elective cesarean delivery was performed, and a 2,490-g healthy infant was delivered who went home with the mother on the seventh postpartum day. These workers cite several other examples of significant delays in the delivery of twins who were located in separate uterine horns.

Woolfson et al.^[288] reported the case of a woman with a single normally shaped uterus who delivered a 570-g first twin vaginally as a breech at 25 weeks. This infant died of respiratory distress in 5 days. The first twin's placenta was retained within the uterus, and the cervical os closed to less than 3 cm after delivery. The cord was cut at the level of the cervix, and prophylactic antibiotics were administered. The patient was followed with serial maternal clotting profiles and ultrasound examinations of the remaining fetus. At 32 weeks, after 53 days in the hospital following delivery of the first twin, labor resumed and spontaneous rupture of the membranes occurred. A cesarean delivery was performed and a 1,600-g infant with Apgar scores of 7 and 9 was delivered. The placentas weighed 310 and 110 g, and the patient's postoperative course was uneventful. These authors cite four other reports in which intervals varying from 14 to 84 days were reported in twin deliveries wherein tocolytics, cervical cerclage, or simple observation were the mainstays of management.

Another such case reported by Feichtinger et al.^[289] achieved 12 additional weeks and delivery of a healthy second twin, following delivery and death of the first twin at 21 weeks' gestation. This patient presented with preterm labor and ruptured membranes at 21 weeks. A cerclage suture that had been prophylactically placed at 12 weeks gestation was removed to allow delivery of a nonviable twin A. There was no evidence of placental separation, the sac of twin B was intact, and its heart rate monitoring was normal. A Shirodkar type of cerclage was then placed, and the patient was treated with tocolytics, intravenous antibiotics, and vaginal antiseptic suppositories. Her subsequent antepartum course after discharge from the hospital at 24 weeks was apparently unremarkable, until readmission for preterm labor and uneventful delivery at 33 weeks' gestation. The infant weighed 1,750 g and had an uncomplicated neonatal course.

The total number of reported cases in which delayed delivery of the retained twin, triplets, or quadruplets has been attempted are limited. Four publications report the authors' experience and a review of the literature on this subject.^[290]^[291]^[292]^[293] These reports suggest general agreement on a management protocol for these patients, which should include high ligation of the umbilical cord of the delivered twin with an absorbable suture, prophylactic use of tocolytics, bed rest, ongoing monitoring of the patient for evidence of infection and/or coagulation disorders, and serial monitoring for growth and well-being of the viable fetus(es). In the management of these pregnancies, three areas that still remain controversial are the routine use of cervical cerclage, prophylactic antibiotics, and corticosteroids for enhancement of fetal lung maturity of the viable fetus(es).

It must be recognized that most of the reported cases represent spectacular successes. This type of management, however, should not be considered "standard of care." If an individual case is considered for such a treatment protocol, the potential risks, which may be considerable, along with the benefits must be discussed in detail and a fully informed consent obtained from the patient and her partner.

Rayburn et al.^[276] reported the outcome of 115 second twins delivered vaginally at or beyond 34 weeks' gestation after the vertex delivery of their siblings. The second twin was visually monitored ultrasonically on some occasions, and continuous monitoring of the fetal heart was performed in all cases. Oxytocin was used if uterine contractions subsided within 10 minutes after delivery of the first twin. In this series, 70 second twins delivered within 15 minutes of the first twin, 28 within 16 and 30 minutes, and 17 more than 30 minutes later. The longest interdelivery interval was 134 minutes. All these infants survived, and none of them had traumatic deliveries. All 17 of the neonates delivering beyond 30 minutes had 5-minute Apgar scores of 8 and 10. In those cases with delivery intervals in excess of 15 minutes, the birth weight differential was not in excess of ± 200 g when first and second twins were compared. In the series reported by Chervenak et al.,^[269] the fetal heart of the second twin was monitored with ultrasound visualization throughout the period between twin deliveries, and no difference in the occurrence of low 5-minute Apgar scores was noted in relationship to the length of the interdelivery interval.

It therefore seems apparent that while some second twins may require rapid delivery, others can be safely followed with fetal heart rate surveillance and remain

undelivered for substantial periods of time. This less hurried approach when twin B is not in distress may reduce the incidence of both maternal and fetal trauma associated with difficult deliveries performed to meet arbitrary deadlines.

ULTRASOUND AND THE INTRAPARTUM MANAGEMENT OF MULTIPLE GESTATIONS

Ultrasound can also be useful during labor and delivery. On admission to the delivery floor, the position of each twin can be quickly and accurately assessed and viability of both fetuses confirmed by direct visualization of their hearts. Knowledge of the presentation of each twin permits the establishment of a management protocol regarding the anticipated route of delivery. If a vaginal delivery is to be attempted, the weights of both twins can be rapidly estimated. This information is particularly important for the second twin because if it is thought to weigh less than 1,500 g or more than 3,500 g, a vaginal breech delivery might not be attempted. It is also possible to rule out extension of the head when a fetus is in breech presentation by using the method described by Berkowitz and Hobbins.^[294] Ballas et al.^[295] cited an incidence of more than 70 percent for spinal cord transection when 11 breeches with extended heads were delivered vaginally compared with no cord injuries when nine infants with deflexed heads were delivered by cesarean section. Although these data were derived from singleton breeches, there is no reason to believe that they could not apply to twins as well.

Both fetuses must be monitored electronically throughout labor in order to ensure their well-being. When membranes are already ruptured, a scalp electrode can easily be attached to the presenting part of twin A, and the second twin can be monitored with an external Doppler transducer. In practice, however, it is sometimes difficult to find the optimal spot from which to monitor the second twin. By using real-time ultrasound, the heart of twin B can be precisely located and the Doppler transducer placed accordingly. If movement of the second twin results in loss of a readable tracing, the transducer can be repositioned after real-time ultrasound has revealed the new position of twin B's heart. When a patient with twins or triplets is taken to the delivery room, the real-time scanner should accompany her. After delivery of the first infant, real-time examination immediately and precisely establishes the position of the second fetus. Visualization of the fetal heart allows the second fetus to be monitored for evidence of bradycardia until one fetal pole settles into the pelvis, membranes are ruptured, and a scalp electrode is applied. While visual monitoring of the heart does not provide subtle information such as a loss of baseline variability, it does permit early detection of significant deviations from the normal fetal heart rate range.

In addition to monitoring heart rate, visualization of the second twin permits both external and internal manipulations to be performed in a more controlled fashion. Externally, it is often possible to guide the vertex over the inlet by directing pressure from the ultrasound transducer over the fetal head while pushing the buttocks toward the fundus with the other hand.^[294] If this is unsuccessful, an internal version can be made less difficult by visualizing the operator's hand within the uterus and directing it toward the fetal feet. This technique can reduce the confusion often experienced when a small fetal part is blindly caught, and it is unclear whether it belongs to an upper or a lower extremity.

CONCLUSION

The patient carrying more than one fetus presents a formidable challenge to the obstetrician. The high perinatal morbidity and mortality rates traditionally associated with multiple gestations are due to many factors, some of which can still not be altered. The extraordinary advances in technology during the past 25 years, however, have given us new insights into some problems peculiar to multifetal pregnancies as well as some tools with which to detect those problems. Early diagnosis of multiple gestations and follow-up with serial studies hold the potential for administering specialized regimens to selected patients, and this should have a beneficial impact on the outcome of those pregnancies.

Key Points

Perinatal/neonatal morbidity and mortality are significantly higher in multiple gestations than singleton pregnancies.

Any patient with a multiple gestation should be clinically managed as a high-risk pregnancy.

The incidence of congenital structural malformations is two to three times higher in fetuses of multiple gestations when compared with those of singleton gestations.

861

Ultrasound evaluation is the single most important diagnostic test in multiple gestations.

All patients with multiple gestations should have a thorough first- and second-trimester ultrasound examination to assess for chorionicity, amnionicity, individual fetal growth, and congenital malformations.

Twin-to-twin transfusion syndrome is a serious potential complication in monozygotic twins, with a high fetal mortality rate.

Prophylactic cerclage, tocolytics, or hospitalization for bed rest do not have any proven advantage in the management of multiple gestations.

In twin pregnancies with discordant growth, fetal lung maturity studies obtained from amniotic fluid of the larger twin will usually also represent similar or greater lung maturity of the smaller twin.

The presentation of each fetus must be sonographically verified as soon as a patient with twin pregnancy presents in labor.

As a general rule, mode of delivery should be vaginal when both twins are vertex, individualized for vertex-nonvertex twins, and cesarean section when the first twin is nonvertex. For triplets or more, the safest mode of delivery is by cesarean section.

Chapter 25 - Intrauterine Growth Restriction

Ira Bernstein
Steven G. Gabbe
Kathryn L. Reed

The identification of pregnancies at risk for preventable perinatal morbidity and mortality is a primary goal of the obstetric care provider. Intrauterine growth restriction (IUGR) is the second leading contributor to the perinatal mortality rate.^[1] The perinatal mortality rate for these infants is 6 to 10 times greater than that for a normally grown population, 120 per 1,000 for all cases of growth restriction and 60 to 80 per 1,000 if anomalous infants are excluded. As many as 40 percent of all stillborns are growth restricted.^[6] This includes 53 percent of preterm stillbirths and 26 percent of term stillbirths. The incidence of intrapartum asphyxia in cases complicated by IUGR has been reported to be 50 percent.^[2] A portion of these perinatal complications are preventable. If the growth-restricted fetus is appropriately identified and managed, the perinatal mortality can be lowered. This chapter presents the varied etiologies of the growth restriction syndromes, recent advances in the detection and management of this problem, and the available information on the long-term prognosis for infants who have suffered from impaired intrauterine growth.

NOMENCLATURE

A variety of terms have been used to identify the fetus who is small relative to its peers. They include "premature," "low birth weight," "small for gestational age," "fetal growth retarded," "small for dates," and "intrauterine growth restricted." All represent the small fetus and have intentional distinctions based on their origins, found primarily in the pediatric literature.

The evolution of terms used to classify the small newborn is illustrative of the difficulty in identifying the appropriate descriptive term for the growth-restricted fetus. The recognition and identification of the small neonate has its modern origin in 1919. Ylppo^[3] suggested that all children with birth weights under 2,500 g be labeled "premature," while recognizing that many small children were the products of normal length gestations. This label persisted until 1961, when the WHO Expert Committee on Maternal and Child Health acknowledged that many babies defined as premature were not born prematurely and reclassified birth weight below 2,500 g as "low birth weight."^[4] As early as 1946, McBurney^[5] reported cases of "undernourished full-term infants," and this phenomenon was further highlighted in 1963 by Gruenwald,^[6] who noted the important differences between the neonate with low birth weight secondary to prematurity, the infant born too soon, and the infant who was small compared with other newborns of the same gestational age. Lubchenco et al.,^[7] Usher and McLean,^[8] and others throughout the 1960s laid the groundwork for the classification of the growth-deficient infant through population studies that established the relationship between gestational age and weight. In 1974, at the WHO Scientific Meeting in Geneva, the concepts of "light" and "heavy" for dates emerged.^[9] These concepts correlate most closely with the current classification of the growth-restricted neonate. However, the definition used to define "light for dates" (either by percentile rank or standard deviations [SD]) was not established. A commonly used subclassification has developed that reserves the obstetric label of IUGR for the fetus who suffers morbidity and/or mortality associated with the failure to reach growth potential (Fig. 25-1) and the pediatric term "small for gestational age" as the more general term for the small fetus for whom no pathology is identified. For the purposes of this chapter, we have chosen the terms "fetal" or "intrauterine growth restriction" and apply the label

Figure 25-1 A growth-restricted infant exhibiting subcutaneous wasting.

in the prenatal period based on estimates of fetal size alone. We believe that this term appropriately characterizes the syndrome and eliminates the negative cognitive associations of the term "retardation."

DEFINITION

Neonatal growth restriction is recognized as a syndrome encompassing small size as well as specific metabolic abnormalities including hypoglycemia, hypothermia, and polycythemia. In contrast, IUGR is currently characterized as a syndrome marked by failure to reach growth potential. Additional prenatal diagnostic criteria that support the diagnosis of fetal growth restriction exist but are generally not required for the diagnosis to be applied. Small size is therefore the hallmark of the syndrome, and varying criteria have been used to identify the growth-restricted fetus.

Whereas failure to reach growth potential is the abnormality recognized in this disorder, individual growth capacity is not routinely established, and as a result, fetal size is most often compared with appropriate population-based "growth curves." On occasion, individual growth projections may be available, and this allows for a more direct examination of a failure to achieve growth potential.

Ultrasound criteria have emerged as the diagnostic standard used in the identification of fetal growth restriction. Wilcocks et al.^[10] in 1964 first demonstrated the correlation between ultrasound measurement of the fetal head and birth weight. Campbell and Dewhurst^[11] published the first sonographic descriptions of fetal growth restriction with their analysis of the changes in biparietal diameter over time. Two patterns of altered head growth were described. In "late flattening," which represents approximately two thirds of all cases of IUGR, the biparietal diameter (BPD) increases normally until late pregnancy and then lags behind. In the "low-profile" or symmetric type, impaired head growth occurs much earlier in gestation. These abnormal growth patterns were later labeled types 1 (late flattening) and 2 (low profile), and these concepts would become generalized to describe asymmetric and symmetric growth deficiencies, respectively.

As an individual parameter, abdominal circumference (AC) has demonstrated the greatest sensitivity in the identification of the small child. The use of AC, a directly measurable fetal parameter, in combination with head circumference has been widely adopted for the identification of growth restriction by many clinicians.

The most common assessment of fetal size in the United States is the estimation of fetal weight. This was first described by Campbell and Wilkin^[12] using a combination of BPD and abdominal circumference. Since that report, numerous investigators have identified distinct fetal parameters identifiable by ultrasound that are useful in the estimation of fetal size.^{[13] [14] [15]} All of the techniques incorporate an index of abdominal size as a variable contributing to the estimation of fetal weight. These techniques generally have 95 percent confidence limits that deviate approximately 15 percent around the actual value. Numerous population-specific formulas have been derived.^[16]

An absolute threshold used for the definition of growth restriction can be applied to any of the parameters evaluated (BPD, AC, or estimated fetal weight [EFW]). These criteria have been statistically defined rather than outcome based and use either a threshold percentile ranking (nonnormative data) or a number of standard deviations below the mean (normative data) for the definition to be fulfilled. Birth weight below the population 10th percentile, corrected for gestational age, has been the most widely used criterion for defining growth restriction at birth, and this has been generalized

to imply a sonographically estimated fetal weight below the 10th percentile for appropriate population-based cross-sectional growth charts.

Although ultrasound estimation of fetal size is independently capable of fulfilling the diagnostic criteria for growth restriction, the identification of small fetal size serves as a screen for the identification of the fetus at risk. It would be logical, therefore, for the major aim of identifying growth restriction sonographically to be sensitivity in the identification of a group of fetuses at increased risk for perinatal morbidity and mortality. Using the birth weight 10th percentile cutoff, approximately 70 percent of the infants thus identified as growth restricted are normally or constitutionally small, so-called light for gestational age or small for gestational age (SGA).^[17] These neonates are *not* at increased risk for poor outcome, but represent one end of the spectrum of normal neonatal size. This group, however, does include infants who are truly growth restricted and who are at risk for increased perinatal morbidity and mortality. Usher and McLean^[8] have pointed out that, when restricting the cutoff weight for IUGR to 2 SD below the mean, only infants below the 3rd percentile are considered growth restricted. The exact thresholds are a matter of debate. Using the 3rd percentile overlooks an increased number of growth-restricted infants, whereas the 10th percentile cutoff includes normal infants who will be monitored unnecessarily. Others have suggested a cutoff of the 5th percentile based on the distribution of short-term morbidity in their population. More recently, Seeds and Peng have demonstrated increased mortality for birth weights through the 15th percentile with an odds ratio of 1.9 for mortality in newborns with birth weights between the 10th and 15th percentiles.^[18]

The biologic significance of any definition of IUGR can only be measured by discovering which parameters most accurately predict infants at risk for both short- and long-term impairment. The broad prognostic significance of the 3rd, 5th, 10th, or 15th percentiles still remains to be clinically validated. It is this information that will allow us to uniformly apply appropriate population-specific growth curves. Only then will we be able to determine how effectively we have detected and treated IUGR.

ETIOLOGY

When considering the definition and detection of IUGR, it is important to review the etiologies of IUGR and possible therapies. Etiologies for fetal growth restriction can be crudely separated into fetoplacental and maternal in origin ([see the box "Fetoplacental Etiologies of Fetal Growth Retardation"](#)) and (["Risk Factors for Fetal Growth Restriction"](#)). The fetoplacental origins of growth restriction include those etiologies that have been traditionally ascribed to the fetus, including the chromosomal abnormalities, the genetic syndromes, and the infectious etiologies, as well as those secondary to placental abnormalities.

Fetoplacental Etiologies of Fetal Growth Retardation
Chromosomal abnormalities
Trisomies (13, 18, 21)
Trisomy 9 mosaicism
Trisomy 4p
4p-, 5p-, 11p-, 13q- syndromes
Partial trisomy 10q
Genetic syndromes
Cretinism (hypothyroidism)
Russell-Silver
Bloom's
Lowe's
De Lange's
Progeria
Leprechaunism
Congenital malformations
Infectious diseases
Cytomegalovirus
Toxoplasmosis
Rubella
Placental pathology
Previa
Abruptio
Circumvallate
Mosaicism
Infarctions
Twins

Fetoplacental Origins

Intrauterine infection, though long recognized as a cause of growth restriction, accounts for less than 10 percent of all cases. Herpes, cytomegalovirus, rubella, and toxoplasmosis are well documented, and other intrauterine infections are strongly suspected ([see Chapter 40](#)). The infectious process produces early disruption of fetal growth during the stage of cell hyperplasia and is, therefore, associated with a poor prognosis for normal development. For the agents associated with IUGR, prevention of the infection is the most important therapy.

Risk Factors for Fetal Growth Restriction: Indications for Ultrasound

History of fetal growth restriction

Hypertension

Diabetes mellitus

Elevated MSAFP/hCG

Antiphospholipid syndrome

Chronic medical illnesses

Low maternal prepregnancy weight (<90% IBW)

Poor maternal weight gain

Twin gestation

Substance abuse (tobacco, alcohol, drugs)

Preterm labor

Abnormalities of placentation

Vaginal bleeding

Maternal anemia (Hgb < 10)

Maternal hypoxia (cyanotic cardiac or pulmonary disease, altitude)

Maternal hemoglobinopathies

Drug ingestion (hydantoin, coumarin)

Chromosomal abnormalities, congenital malformations, and genetic syndromes have been associated with less than 10 percent of cases of IUGR. Abnormalities in cell replication and reduced cell number produce a pattern of impaired growth that is early in onset and symmetric. Neonatal prognosis in these cases is determined by the specific abnormality identified. Growth restriction has been observed in 53 percent of cases of trisomy 13, and 64 percent of cases of trisomy 18.^[19] This growth abnormality may manifest as early as the first trimester.^[20] Congenital anomalies such as renal agenesis represent a related situation.

Placental abnormalities can be a cause of fetal growth restriction. An absolute or relative decrease in placental mass affects the quantity of substrate the fetus receives and has been recognized ultrasonographically to antedate fetal growth restriction. Thus, a circumvallate placenta, partial placental abruption, placenta accreta, placental infarction, or hemangioma may result in growth restriction. An elevated maternal serum -fetoprotein (MSAFP) or human chorionic gonadotropin (hCG) level in the second trimester has been associated with an increased risk for IUGR and may result from abnormal placentation.^[21]^[22]^[23]^[24] Davis has suggested that elevated MSAFP precedes an increased risk of preterm birth, but not growth restriction.^[25] However, the strong association of preterm birth with fetal growth restriction discussed in detail later in this chapter suggests that when live birth criteria are used to evaluate newborn size, a stability in birth weight percentile in preterm neonates reflects an increased frequency of fetal growth restriction. Intrinsic placental pathology has been identified in some cases of growth restriction, including the presence of a single umbilical artery or the presence of placental mosaicism, either of which may act to impair normal fetoplacental exchange mechanisms.^[26] Placental location has also been linked to growth restriction. Placenta previa without bleeding has been suggested as a risk factor, because the low implantation site may not be optimal for nutrient transfer.^[27]

Twin gestation is often associated with IUGR (see Chapter 24). In 1966, Gruenwald^[28] observed that the growth curve of twins deviated from that of singletons with a progressive fall of growth after 32 weeks. This finding implies relative placental insufficiency as opposed to intrinsic fetal compromise and suggests that the longer the twin pregnancy continues, the greater the delay in intrauterine growth, with "catch-up" growth observed after birth. Thus, twins represent a group of fetuses at high risk for IUGR, as confirmed by an incidence of 17.5 percent in one study.^[29] The appropriate growth standard to apply to twin fetuses would appear to be the same as that for singletons. Two trials demonstrate that the morbidity and mortality of fetuses from twin gestations are equivalent, or elevated when the twins are monochorionic, when compared with birth weight and gestational age-matched singletons.^[30],^[31]

Maternal Origins

Decreased uteroplacental blood flow with its associated reduction in transfer of nutrients to the fetus is responsible for the majority of clinically recognized cases of IUGR. Maternal vascular disease, whether chronic hypertension, preeclampsia, or diabetes with vasculopathy, has been associated with impaired fetal growth. In preeclampsia, failure of trophoblastic influenced modification of maternal spiral arterioles by 20 to 22 weeks' gestation and intimal thickening accompanied by fibrinoid degeneration of the media of these arterioles result in luminal narrowing and, therefore, decreased blood flow through the placental bed.^[32] Such cases are generally marked by asymmetric IUGR with maintenance of normal fetal head growth and reduction in the size of the fetal liver, heart, thymus, spleen, pancreas, and adrenal glands. Ward et al.^[33] have demonstrated that mutations in the angiotensinogen gene contribute to the development of both preeclampsia and the associated incidence of fetal growth restriction. Thus, a portion of this compromised maternal vascular expansion may be explained by specific genetic deficiencies. Decreased placental blood flow from postural maternal hypotension and maternal hyperviscosity with sludging has also

been reported to cause IUGR. Some patients with, or at risk for, pregnancy-associated hypertension have either a reduction in the expansion of blood volume in pregnancy, or have a baseline reduction in circulating volume.^[34]^[35]^[36] This contracted circulating blood volume has been correlated with IUGR.^[37] A reduction in circulating volume or maternal oxygenation in women living at high altitude or those with cyanotic heart disease or parenchymal lung disease may be responsible for the IUGR observed with these conditions. Those hemoglobinopathies and anemias that impair maternal and fetal oxygenation have also been linked to limited fetal growth.

Poor maternal weight gain has long been recognized as a risk factor for growth restriction. Controversy still exists about the contribution maternal malnutrition can make to IUGR. Studies of the offspring of women pregnant during the siege of Leningrad in 1942 and the Dutch famine in 1945 indicate little effect on fetal growth by such dietary restriction.^[38] In Holland, despite a maternal intake of 600 to 900 calories daily for 6 months, the average birth weight fell only 240 g in women with good prepregnancy nutritional status. However, investigation of Guatemalan Indian tribes has indicated that protein malnutrition before 26 weeks can result in symmetric

growth restriction.^[39] Protein restriction after 26 weeks did not limit fetal growth. The degree of malnourishment observed in Guatemala or during the Dutch famine would not ordinarily be found in the United States. Nevertheless, maternal prepregnancy weight and weight gain in pregnancy are two of the most important variables contributing to birth weight.

Pregnant women may be subject to poor nutrition through limited gastrointestinal absorption imposed by Crohn's disease or ulcerative colitis. These conditions have not been generally associated with increased numbers of growth-restricted infants. Massively obese women who have undergone ileojejeunal bypass are reported to have smaller infants than average, but they usually fall above the 10th percentile in birth weight.

Glucose is a critical fetal nutrient, and if its supply is reduced growth restriction may result. Using cord blood sampling, Economides and Nicolaides^[40] observed significantly lower maternal and fetal glucose levels in cases of growth restriction and speculated that the major cause of fetal hypoglycemia in these cases was reduced glucose supply from the mother caused by impaired placental perfusion. Khouzami et al.^[41] documented a significant association between maternal hypoglycemia on a 3-hour oral glucose tolerance test (GTT) and subsequent birth of non-low-birth-weight but growth-restricted babies. Sokol et al.^[42] and Langer et al.^[43] have confirmed that a flat maternal response to glucose loading is associated with an increased risk for fetal growth restriction. Langer et al.^[43] demonstrated that a "flat" GTT was associated with a 20-fold increase in IUGR in normotensive patients. This relationship is further strengthened by the data of Caruso et al., who have demonstrated heightened maternal insulin sensitivity in association with otherwise unexplained fetal growth restriction.^[44]

Maternal drug ingestion may result in IUGR by a direct effect on fetal growth as well as through inadequate dietary intake. Smoking produces a symmetrically smaller fetus through reduced uterine blood flow and impaired fetal oxygenation and is a major cause of growth restriction in developed countries. The consumption of alcohol and the use of coumarin or hydantoin derivatives are now well known to produce particular dysmorphic features in association with impaired fetal growth. Mills et al.^[45] have demonstrated a significant increase in the risk of IUGR with the consumption of one to two drinks daily, in the absence of fetal alcohol syndrome. Maternal use of cocaine has been associated with not only IUGR but also reduced head circumference growth.^[46]

In 1971, Lobi et al.^[47] reported that advanced maternal age was a factor in the etiology of IUGR. Berkowitz et al.^[48] found no evidence that the first births of women between 30 and 34 years or those over 35 years were at increased risk for growth restriction. In summary, if one controls for underlying medical complications, maternal age is not related to restricted fetal growth.

A history of poor pregnancy outcome is clearly correlated with the subsequent delivery of a growth-restricted infant. Galbraith et al.^[49] and Tejani^[50] have shown that prior birth of an IUGR infant is the obstetric factor most often associated with the subsequent birth of a growth-restricted infant. These study populations did include women with underlying medical problems. Tejani and Mann^[51] in a retrospective study of 83 multigravidas who had delivered IUGR infants noted that the perinatal wastage from their 200 prior pregnancies was 41 percent. This striking figure, which includes spontaneous abortions as well as neonatal and intrauterine deaths, points to the significance of poor obstetric history as a risk factor for IUGR. Women whose first pregnancy results in a growth-restricted infant have a one in four risk of delivering a second infant below the 10th percentile. After two pregnancies complicated by IUGR, there is a fourfold increase in the risk of a subsequent growth-restricted infant.^[52] When all indices of risk have been applied, the one third of the population considered at highest risk accounts for two thirds of the infants identified as growth restricted. Two thirds of pregnancies, although not judged to be "at risk" for IUGR, yield one third of neonates below the 10th percentile.^[49] Most of these babies are constitutionally small.

In summary, a framework does exist for considering

the causes of growth restriction. Is the fetus abnormal? Is the delivery system disrupted? Is the maternal supply line compromised? These questions categorize the source of the problem without explaining the mechanism by which the growth process is disturbed. Even when one is aware of these clinical associations, the sum of the many factors affecting the growth of an individual fetus is unpredictable.

DIAGNOSIS

Significant improvements have been made in detecting and characterizing the growth-restricted fetus. These improvements have served as the basis for plans designed to reduce the associated perinatal morbidity and mortality. In the past, clinical parameters such as maternal weight gain and measurement of fundal height were used to reflect fetal growth. Belizan et al.^[53] observed that curvilinear fundal height measurements in centimeters from the symphysis pubis could be closely correlated with gestational age: a lag of 4 cm or more suggests growth restriction. Persson et al.^[54] reported a sensitivity of only 27 percent and a positive predictive value of 18 percent using carefully performed fundal height measurements to detect IUGR. Additional studies have confirmed the lack of sensitivity of fundal height measurements for detecting fetal growth restriction. The presence of risk factors should therefore prompt ultrasound estimation of fetal size independent of maternal weight gain or fundal height growth.

Fetal Measurements

The use of fetal weight has been the most common method for characterizing fetal size and thereby growth abnormalities. This requires that an accurate sonographic estimate of fetal weight can be performed to detect and follow patients suspected of having a growth-restricted infant.^[55] Using a multifactorial equation and a measurement of abdominal size, a weight can be predicted and related to BPD. Formulas that incorporate the femur length (FL) may increase the accuracy of in utero weight estimation for the fetus with IUGR.

A significant limitation of using estimated fetal weight to measure fetal size is that it cannot be measured directly, but must be calculated from a combination of directly measured parameters. This results in an increased error in the estimate. In addition, the lack of directly measured normative data creates difficulty in establishing normal growth curves. Commonly, cross-sectional birth weight data have been used to characterize ultrasound-estimated fetal weight. These live birth-weight criteria, however, do not appropriately describe sonographic estimated fetal weights, as there is a significant association of preterm birth with fetal growth restriction.^[56] Thus, the weights of preterm infants are not normally distributed as they are at term. This association has been highlighted by several investigators who have identified the discrepancy between birth-weight-defined growth curves and sonographically estimated fetal weight-defined growth curves in preterm gestation.^{[57] [58] [59]} Ultrasound-generated estimated fetal weight growth curves consistently demonstrate higher fetal weights over the range of preterm gestation than do birth-weight-generated growth curves. This discrepancy results from the fact that ultrasound examinations represent a larger breadth of the entire population at any gestational age. Preterm birth weight reflects only those individuals who have delivered under abnormal circumstances. It is therefore most appropriate to compare estimated fetal weights by ultrasound with ultrasound-derived growth curves in order to characterize preterm estimated fetal weight appropriately. The utility of this approach has been confirmed in preterm gestation by Lackman et al., who demonstrated that the use of fetal growth curves, rather than live birth curves, was associated with an improved ability to identify perinatal mortality risk.^[60]

The use of the individualized growth model has been supported by several investigators.^{[61] [62]} The obvious advantage is the lack of dependency on population-based normative data and the ability to detect a true personal growth restriction. This can be done even when the estimated fetal weight is greater than the 10th percentile for the population. The disadvantages of these models are that they require baseline ultrasound morphometric data in the second trimester as well as an additional later scan to establish growth potential for an individual morphometric parameter. A third scan is then necessary to identify that a growth abnormality exists. This volume of information is frequently not available, limiting the practical application of this type of individual growth model. An alternative approach using individualized growth modeling is to account for the variables that contribute the majority of the variance to newborn size. These include early pregnancy weight, maternal height, ethnic group, parity, and sex.^[63] Using these variables and fetal growth patterns, the estimated size of a fetus of a given mother can be projected at term and estimated at any specific point in gestation. Deviations from this projected growth pattern can then be recognized. Overall, the diagnostic advantages of these individualized growth models has been questioned when compared with the sequential comparison of the percentile ranking of individual or composite growth parameters to population-based growth curves.^[64]

Fetal growth as opposed to fetal size is a dynamic process and requires more than a single evaluation for its estimation. The absence of fetal growth over a sustained

Figure 25-2 Growth chart in a case of asymmetric IUGR. Although head circumference is preserved, AC growth falls off early in the third trimester. For this reason, the H/A ratio shown in the lower right corner of the graph becomes elevated. IUGR, intrauterine growth restriction. (From Chudleigh P, Pearce JM: *Obstetric Ultrasound*. Edinburgh, Churchill Livingstone, 1986, with permission.)

period is a concern. The routine clinical evaluation of fetal growth is based on fundal height enlargement during the course of pregnancy. In pregnancies at risk or in those in whom fetal size is already estimated to be below the 10th percentile, serial ultrasound estimations of fetal size are performed. The appropriate observation interval for the evaluation of fetal growth has been based on two assumptions: (1) growth is continuous rather than sporadic and (2) the identification of growth is limited by the technical capability of the ultrasound equipment used to measure the fetus.^[3] The recommended interval between evaluations is 3 weeks, as shorter intervals increase the likelihood of a false-positive diagnosis.^{[65] [66]} Recent data have demonstrated that early childhood growth, up to 21 months of age, is characterized by sporadic growth pulses that punctuate prolonged periods of growth stasis.^[67] Whereas the fetal growth rate of the third trimester is greater than the early childhood growth rate, it may be that fetal growth is also saltatory and that the detection of growth is limited by the physiologic interval of growth pulses rather than by the technical limitations of the measuring tool.^[68]

In an attempt to increase detection of the fetus with asymmetric growth restriction, head circumference (HC)/AC ratios can be assessed (Fig. 25-2) and (Fig. 25-3).^[69] In the normally growing fetus, the HC/AC ratio exceeds 1.0 before 32 weeks' gestation, is approximately 1.0 at 32 to 34 weeks' gestation, and falls below 1.0 after 34 weeks' gestation. In fetuses affected by asymmetric growth restriction, the HC remains larger than that of the body (Fig. 25-2). The HC/AC ratio is then elevated. In symmetric IUGR, both the HC and the AC are reduced, and the HC/AC ratio remains normal (Fig. 25-3). Using the HC/AC ratio, 85 percent of growth-restricted fetuses are detected, with a reduction in false-negative diagnoses. Thus, a single set of measurements, even when determined in the latter part of pregnancy, can be very helpful in evaluating the status of intrauterine growth.

In some cases, measurement of the HC may be difficult as a result of fetal position. One can then compare the FL, which is relatively spared in asymmetric IUGR, to the AC.^[70] The FL/AC is 22 at all gestational ages from 21 weeks to term and so can be applied without knowledge of the number of weeks gestation. An FL/AC ratio

greater than 23.5 suggests IUGR.

In summary, the ability to determine appropriate fetal growth using fundal height measurements in a normal

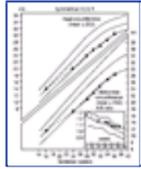

Figure 25-3 Growth chart in a case of symmetric IUGR. Note the early onset of both HC and AC growth restriction. For this reason, the H/A ratio shown in the lower right corner remains normal. 876

population is limited. Fundal height measurements lack both sensitivity and specificity in the identification of the small fetus. It is therefore reasonable to use a better tool (ultrasound) whenever clinical circumstances point to an increased risk for a growth-restricted fetus. A number of clinical conditions that increase the risk for a small child were listed earlier. In the absence of routine clinical indications, ultrasound screening of these high-risk pregnancies should be performed at 16 to 18 weeks for dating (if not otherwise established) and again at 32 to 34 weeks.

Oligohydramnios

Decreased amniotic fluid volume has been associated clinically with IUGR and may be the earliest sign detected on ultrasonography, preceding an elevation in HC/AC ratio and lagging fetal growth (Fig. 25-4). Decreased perfusion of the fetal kidneys and reduced urine production explain this observation.^[72] In an early study, Manning et al.^[73] reported that a vertical pocket of amniotic fluid measuring 1 cm or more reflected an adequate fluid volume. Of fetuses with fluid pockets less than 1 cm, 96 percent were actually growth restricted. Only 5 of 91 cases with an adequate amount of amniotic fluid exhibited IUGR. The patient with an uncertain gestational age who presents late in pregnancy poses a difficult diagnostic dilemma because interpretation of BPD and HC/AC ratios must be related to accurate gestational age. Under these conditions, measuring an amniotic fluid pocket, or an FL/AC ratio, may be helpful, as these do not rely on knowledge of the gestational age. Manning and his colleagues^[74] later broadened their criteria. A 2-cm vertical pocket was considered normal, 1 to 2 cm marginal, and less than 1 cm decreased. Using this definition, they observed a 6 percent incidence of IUGR with a pocket 2 cm or larger, 20 percent with a pocket 1 to 2 cm, and 39 percent with a pocket less than 1 cm. One may also use the amniotic fluid index to quantitate amniotic fluid volume (see Chapter 10), although this technique requires a knowledge of gestational age. The overall clinical impression of reduced amniotic fluid on ultrasonography may be most important. The volume of amniotic fluid also has prognostic significance for the course of labor. Groome et al.^[75] demonstrated that oligohydramnios associated with fetal oliguria is associated with a higher rate of intrapartum complications that may be attributed to reduced placental reserve.

Maternal Doppler Velocimetry

Doppler velocimetry of the maternal uterine artery has been examined to establish its usefulness in the prediction of pregnancies destined to produce a growth-restricted newborn. Schulman^[76] found that women with hypertensive disorders who had an elevated uterine artery systolic/diastolic (S/D) ratio (>2.6) and/or diastolic notching were more likely to have pregnancies complicated by IUGR and intrauterine fetal death. He noted that the changes in uterine artery flow patterns might precede those observed in the umbilical artery and antedate fetal growth restriction. Jacobson et al.^[77] observed that an elevated uteroplacental artery resistance index (RI) predicted fetal growth restriction with a sensitivity of 70.6 percent and had a positive predictive value of 33.3 percent in women at high risk for either preeclampsia or growth restriction. In low-risk patients, the examination of second-trimester maternal uterine artery waveforms has produced sensitivities and positive predictive values for fetal growth restriction as high as 72 percent and 35 percent, respectively; values slightly better than routine clinical indicators of fetal growth.^[78] Valensise and Romanini^[83] have demonstrated that the combination of abnormal second-trimester maternal uterine artery Doppler velocimetry and maternal glucose tolerance testing demonstrating a "flat" response results in a positive predictive value of 94 percent and a sensitivity of 54 percent for the detection of fetal growth restriction.

In summary, the overall value of second-trimester maternal uterine artery Doppler waveforms in screening of pregnancies at risk for growth restriction is unclear. At present, there are no data suggesting that sensitivity is improved beyond that achieved with standard clinical assessment. The availability of second-trimester stratification of risk for fetal growth restriction has not yet demonstrated an impact on perinatal morbidity or mortality.

Fetal Body Composition

The ponderal index was first described by Rohrer^[84] in 1921 as an index of corpulence. This index of neonatal size (weight/length^[3]) that is normally distributed accurately described the nutritional state of the neonate. When compared with birth weight percentile, the ponderal index demonstrates an improved ability to predict neonatal asphyxia, acidosis, hypoglycemia, and hypothermia.^[85] The ponderal index also correlates with direct measures of neonatal fat as estimated by skinfold thickness.^[86] Attempts to translate the ponderal index directly to the fetus have been hampered by the difficulty in accurately assessing fetal length. Attempts to modify the ponderal index for fetal sonographic estimation have been made. Yagel et al.^[87] demonstrated that the addition of a fetal ponderal index improved the prediction of perinatal morbidity in fetuses already suspected of having IUGR. Alternative methods for the characterization of fetal growth by physiologic compartments have recently been attempted. Several studies have examined fetal subcutaneous fat content using

877

Figure 25-4 A and E, Amniotic fluid index (AFI) performed at 35 weeks on a patient whose fundal height measured 30 cm. Findings consistent with asymmetric growth restriction were observed, including estimated fetal weight of 1,500 g, HC/AC ratio of 1.15, and AFI of 5.0 cm, as illustrated. At 35 weeks, the 50th percentile for the AFI is 14.0 cm; the 5th percentile is 7.9 cm. Note that one amniotic fluid pocket greater than 2.0 cm was found.

ultrasound examination. Subcutaneous fat deposition has been examined in the face, abdomen, arm, and thigh.^[88] Reduction in facial fat stores has been strongly associated with being SGA. This reduction in fat content is consistent with observations made in the growth-restricted neonate and may prove to be a sensitive indicator of the small fetus at increased risk for perinatal complications. The optimal method of in utero assessment for fetal fat has not yet been determined.

Biochemical Markers

Biochemical markers have been used to assist in the identification of the small fetus who is at increased risk for the morbidity and mortality associated with fetal growth restriction. The most widely examined include fetal erythropoietin and amino acid concentrations.

Erythropoietin production in the fetus, as in the adult, is stimulated by the presence of anemia or hypoxia.^[93] Numerous studies have demonstrated the

878

ability of the fetus to respond to hypoxic conditions with the production of erythropoietin. This increase in erythropoietin may or may not lead to increased red cell production, depending on erythropoietic reserve. ^[93], ^[95] Erythropoietin, identified in the cord blood of growth-restricted fetuses by cordocentesis, amniotic fluid, or cord blood at delivery, may prove to be of benefit in the identification of the child at risk for long-term morbidity. ^[95] ^[96] ^[97] ^[98] Ruth et al. ^[99] identified an association between cord blood erythropoietin levels and developmental outcome (including cerebral palsy and death) at 2 years in nonpreeclamptic patients with evidence of acute asphyxia at birth. Neonates from pregnancies complicated by preeclampsia had elevated cord erythropoietin levels regardless of outcome. ^[99]

Altered amino acid concentrations, particularly the relationship between the branched chain amino acids such as valine and the gluconeogenic amino acids like glycine, have been identified in the growth-restricted fetus and newborn. These changes reflect a specific fetal response that is independent of maternal amino acid levels. The observed increase in the glycine/valine ratio appears to result from a reduction in phosphoenolpyruvate carboxykinase activity, a rate-limiting enzyme for gluconeogenesis. ^[100] Studies have demonstrated that cord blood samples from growth-restricted neonates demonstrate an increased glycine/valine ratio within the first few hours of life. ^[101] This profile of amino acids parallels the aminogram observed in children who suffer from protein calorie malnutrition. ^[102] In the growth-restricted neonate, the glycine/valine ratio of umbilical cord blood has been correlated with specific neonatal risk, including hypoglycemia and death. ^[103] Amino acid data from umbilical venous plasma obtained by percutaneous umbilical blood sampling and amniotic fluid confirms that the elevation in glycine/valine ratio precedes parturition in the growth-restricted fetus. ^[104] ^[105] ^[106] ^[107] Fetal cord blood glycine/valine ratios have been shown to be inversely proportional to fetal arterial oxygen content. ^[108] No relationship with short-term or long-term morbidity has been established. Elevated amniotic fluid glycine/valine ratios in growth-restricted fetuses have not been found to predict neonatal hypoglycemia or cord blood gas abnormalities. ^[109]

MANAGEMENT

In developing a plan for the management of suspected growth restriction, it is important to remember the major etiologic groups. Most infants thought to be growth restricted are constitutionally small and require no intervention. Approximately 15 percent exhibit symmetric growth restriction attributable to an early fetal insult for which there is no effective therapy. Here, an accurate diagnosis is essential. Finally, approximately 15 percent have growth restriction or extrinsic growth failure because of placental disease or reduced uteroplacental blood flow. In such cases, antepartum fetal monitoring and carefully timed delivery may be critical.

Once growth restriction is suspected, a well-organized approach to management should be undertaken. The clinician should evaluate and treat problems that may be contributing to growth restriction. Therapy of growth restriction is often nonspecific but should be directed at the underlying cause of poor fetal growth if one can be determined. When a maternal medical problem such as inflammatory bowel disease is contributing to poor growth, specific therapy should be instituted. Alleviation of hypoxia, therapy of high blood pressure and anemia, and hyperalimentation are three examples.

When placental infarction was implicated as the underlying etiology, Moe^[109] reported subcutaneous heparin therapy to have a favorable influence on pregnancy outcome. Certainly, mothers should be counseled to stop smoking and ingesting alcohol. Nonspecific therapies include bed rest in the left lateral decubitus position to increase placental blood flow. Although an inadequate diet has not been clearly established as a cause of growth restriction in this country, dietary supplementation may be helpful in those with poor weight gain or low prepregnancy weight.

Antepartum Evaluation

Fetal Growth

Serial evaluations of fetal growth should be instituted as soon as the diagnosis of growth restriction is confirmed or for patients in whom the suspicion for growth restriction is high. Ultrasound examinations should be scheduled every 3 to 4 weeks and should include determinations of the BPD, HC/AC, fetal weight, and amniotic fluid volume (Table 25-1). Arrested head growth is of great concern, especially in light of the most recent data available on ultimate developmental potential for the growth-restricted infant. Clear documentation of arrested head growth over a 4-week period is alarming, and the feasibility and safety of delivery should be reviewed.^[119]

Ultrasound should be used not only to document abnormal growth but also to detect lethal congenital malformations such as renal agenesis (see Chapter 10). In cases of severe symmetric growth restriction, amniocentesis, placental biopsy, or cordocentesis should be considered to rule out a chromosomal abnormality such as trisomy 13, 18, or 21 (Table 25-2).^[19] Trisomy 18 may present with the unusual combination of growth restriction and polyhydramnios. If the diagnosis of a lethal anomaly can be made with certainty, an unnecessary

TABLE 25-1 -- UTILIZATION OF ULTRASONOGRAPHY IN THE DIAGNOSIS AND EVALUATION OF IUGR

Parameter	Results	Diagnosis	Plan
BPD	Appropriate for dates (within 2 weeks of dates)	No IUGR	Repeat only if indicated by clinical parameters (e.g., lagging fundal growth)
EFW	Above 10th percentile		
HC/AC ratio	In normal range		
Amniotic fluid volume	Normal		
BPD	Appropriate for dates (within 2 weeks of dates)	Probable asymmetric IUGR	Repeat ultrasound examination every 3 weeks if not delivered
EFW	Below 10th percentile		Start antepartum surveillance and continue until delivery
HC/AC ratio	Above 95th percentile		
Amniotic fluid volume	Low		
BPD	2 weeks or more; smaller than expected for menstrual dates	Probable symmetric IUGR	Repeat ultrasound examination every 3 weeks if not delivered
EFW	Below 10th percentile		Start antepartum surveillance and continue until delivery
HC/AC ratio	In normal range		If IUGR present before 20 weeks, scan for anomalies and consider fetal karyotype
Amniotic fluid volume	Normal or low		

Modified from Grannum PAT: Ultrasonic measurements for diagnosis. In Gross TM, Sokol RJ (eds): Intrauterine Growth Retardation. Chicago, Year Book Medical Publishers, 1989, p 123.

cesarean delivery for fetal distress may be prevented.

Fetal Well-Being

Fetal well-being should also be assessed regularly once the diagnosis of growth restriction is entertained. These infants have an increased incidence of intrauterine demise, presumably from cord compression as well as placental insufficiency. Monitoring these infants decreases the stillbirth rate by detecting the compromised fetus and allowing timely intervention. Experience with the nonstress test (NST) in cases of growth restriction has confirmed that a reactive NST correlates highly with

a fetus that is not in immediate danger of intrauterine demise. Twice-weekly nonstress testing is an appropriate interval. ^[111] Visser and associates^[112] performed antepartum fetal heart rate monitoring immediately before cordocentesis in 58 growth-restricted and 29 appropriately grown fetuses. In the appropriately grown fetuses, blood P_{O2} and pH values were within the normal range for gestation in 27 cases, demonstrating a reactive heart rate pattern and in 2 in which the tracing was nonreactive. In contrast, abnormal antepartum heart rate patterns were found in 15 of the 19 growth-restricted fetuses with hypoxemia, acidemia, or both. The best heart rate marker for fetal hypoxemia was a pattern characterized by repetitive decelerations. In that group, only two fetuses demonstrated normal P_{O2} and pH values. In none of the cases with a reactive heart rate pattern was the growth-restricted fetus acidemic. However, many growth-restricted fetuses with a normal heart rate pattern were found to have fetal P_{O2} values in the lower range of normal. Overall, antepartum fetal heart rate patterns in both normal and growth-restricted fetuses were found to correlate well with fetal oxygenation. The appearance of spontaneous decelerations during the NST may reflect oligohydramnios and cord compression and has been associated with a high perinatal mortality rate. ^[113] The addition of a measure of amniotic fluid volume to the NST has been called a "modified biophysical profile." When compared with a weekly contraction stress test, the twice-weekly modified biophysical profile results in similar perinatal outcome. ^[114] An assessment of amniotic fluid volume at least weekly is advised in cases of suspected IUGR.

TABLE 25-2 -- CHROMOSOMAL ABNORMALITIES AND IUGR

Ultrasound Findings Present			Abnormal Karyotype
IUGR	Anomaly	Hydramnios	
X			12/180 (7%)

From Eydoux P, Choiset A, LePorrier N, et al: *Chromosomal prenatal diagnosis: study of 936 cases of intrauterine abnormalities after ultrasound assessment. Prenat Diagn* 9:255, 1989, with permission.

Nonreactive NST results are often falsely positive and should be further evaluated before any management decision is made. Contraction stress testing (CST) is one option for additional testing. A negative CST result, even when the CST is performed early in the third trimester, is an indication of adequate placental respiratory reserve. ^[115] Conversely, positive CST results occur in 30 percent of the pregnancies complicated by proven growth restriction. In a study by Lin et al., ^[116] 30 percent of growth-restricted infants had nonreactive NST results and 40 percent had positive CST results. Ninety-two percent of IUGR infants with a nonreactive positive pattern exhibited perinatal morbidity. However, a 25 to 50 percent false-positive rate has been associated with the CST by some investigators. ^[115] Therefore, information from antepartum fetal heart rate testing must always be reviewed in concert with the gestational age of the fetus, as well as other indices of fetal well-being and fetal growth.

The fetal biophysical profile score developed by Manning et al. ^[117] can provide appropriate follow-up to nonreassuring fetal heart rate testing or can be used as an alternative method for primary antenatal surveillance. Several studies have demonstrated good correlation between these test results and the level of fetal acidemia as determined by percutaneous umbilical blood sampling in the growth-restricted fetus without anomalies. ^[118], ^[119] Vintzileos et al. ^[120] have demonstrated that the components of the biophysical score are affected at different levels of hypoxemia and acidemia, the earliest manifestations of abnormal fetal biophysical activity being the loss of reactivity in the NST along with the absence of fetal breathing. This is followed by decreased fetal tone and movement in association with more advanced acidemia, hypoxemia, and hypercapnia. As a backup test for nonreassuring fetal heart rate testing the biophysical profile leads to lower rates of intervention when compared with the CST, with no impact on perinatal outcome. ^[121]

Maternal monitoring of fetal activity has been used extensively in Great Britain, Scandinavia, and Israel for the assessment of pregnancies complicated by IUGR. In a study of 50 cases, Matthews^[122] clearly showed the predictive value of fetal activity charting for growth-restricted fetuses subsequently demonstrating distress in labor. The techniques available for monitoring fetal movement are reviewed [in Chapter 12](#).

Doppler flow studies of the fetal circulation have been used to identify and manage the fetus with suspected growth restriction. These studies have also contributed to our understanding of the pathophysiology of IUGR. Doppler studies of fetal internal carotid and intracerebral arterial blood flow have shown a decrease in pulsatility index in these vessels in fetuses with IUGR. ^[123], ^[124] The mechanism would be consistent with an increase in blood flow that results from vasodilation in response to hypoxia. Renal and aortic blood flow velocity waveforms show evidence of increased pulsatility indices, consistent with increases in resistance. ^[125], ^[126] These findings and others have confirmed some of the basic fetal responses to growth restriction, including the preservation of brain growth and oligohydramnios observed in asymmetric IUGR.

The major focus of Doppler studies for the assessment of fetal health has been the umbilical circulation. The association between an increase in Doppler blood flow indices in the umbilical artery and increased resistance in the placental circulation has been demonstrated by many investigators. Trudinger embolized the umbilical arterial circulation in fetal lambs and found an increase in the umbilical arterial S/D velocity ratio along with an increase in arterial resistance. ^[127] In a similar model, Morrow and Ritchie demonstrated progression from normal to increased S/D ratios and the eventual development of reversed end-diastolic velocities, even in the absence of hypoxia. ^[128] Studies by Giles et al. ^[129] demonstrated that the small arterial vessel count in the tertiary stem villi of the placenta is significantly lower in patients with high umbilical artery S/D ratios than in those with normal S/D ratios. Rochelson et al. ^[130] also confirmed a significant reduction in the small muscular artery count and the small muscular artery/villus ratio in the placentas of trisomic fetuses. This study suggests that growth restriction in the fetus with a chromosomal abnormality may be attributable not only to poor intrinsic growth potential but also to abnormalities in placental morphology and fetoplacental blood flow. Based on these observations, it is suggested that the increased resistance to flow indicated by a high S/D ratio is associated with a failure to develop, or an obliteration, of the small muscular arteries in the tertiary stem villi.

Randomized prospective trials have been performed to examine the impact of Doppler velocimetry on perinatal outcome. Divon and Ferber summarized three meta-analyses on the association of the use of umbilical artery Doppler studies and perinatal outcome. ^[131] In these studies, the use of umbilical artery Doppler was associated with a decrease in perinatal mortality, antenatal admissions, inductions of labor, and cesarean deliveries for fetal distress in labor in women considered at high risk. ^[132] ^[133] ^[134] No improvement in outcome was demonstrated with the use of Doppler in screening normal pregnancies. ^[135]

Absent or reversed end-diastolic velocity in the umbilical artery has repeatedly been associated with poor perinatal outcome ([Fig. 25-5](#)). Farine summarized 31 reports of 904 fetuses with absent or reversed end-diastolic flow velocities in the umbilical artery. ^[136] Eighty percent of the fetuses were growth-restricted. The perinatal mortality was 36 percent. The time between the discovery of the absence of end-diastolic

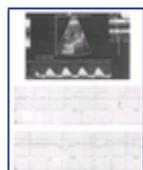

Figure 25-5 A 30-year-old G1P0 at 28 3/7 weeks' gestation who was found to have an estimated fetal weight below the 10th percentile for population-based norms. Doppler flow studies (A) demonstrated reversed end-diastolic flow in the umbilical artery. The patient was taken to labor and delivery, where she was placed on face mask oxygen and betamethasone was administered. The fetal heart rate tracing (E) was considered reassuring. Within 24 hours, the fetal heart rate tracing deteriorated (C) and the patient was taken for primary cesarean delivery. A viable male infant weighing 480 g was delivered and received Apgar scores of 3 and 8.

blood flow in the umbilical artery and an indication for delivery, such as abnormal fetal heart rate testing, averaged 6 to 8 days and ranged from 0 to 49 days.

Fetuses with absent end-diastolic umbilical flow velocity should undergo intensive antenatal surveillance at a level greater than that usually provided for the small fetus. Reversed end-diastolic flow in the umbilical artery reflects severe fetal compromise and is an ominous finding. Fetuses with this finding should be monitored immediately, and delivery should be considered.

In several studies, the umbilical venous circulation of fetuses with abnormal Doppler umbilical arterial velocities has been examined. Indik reported a 54 percent mortality in fetuses with absent end-diastolic velocities in the umbilical artery and umbilical venous pulsations compared with a 10 percent mortality in fetuses with similar arterial velocities and normal (monophasic) venous velocities.^[137] Arduini studied fetuses from the time of onset of absent end-diastolic velocities in the umbilical artery until the onset of abnormal heart rate testing or delivery. He found that gestational age at onset, maternal hypertension, and the development of pulsations in the umbilical venous velocities were significantly correlated with the interval of time between diagnosis and delivery.^[139] Hecher noted that fetuses with abnormal arterial velocities who also developed abnormal venous velocities (inferior vena cava, hepatic, and ductus venosus) had a higher morbidity than fetuses without abnormal venous flow.^[139]

In summary, Doppler velocimetry of fetal vessels has improved our understanding of the pathophysiology of fetal growth restriction. Weekly evaluation of umbilical artery Doppler velocimetry has been used in combination with the modified biophysical profile in fetuses exhibiting poor growth. A small fetus with normal umbilical artery Doppler studies is probably constitutionally small and is at low risk for morbidity. However, a small fetus with abnormal umbilical artery waveforms is at greater risk for neonatal morbidity and mortality.^[69],^[140] Fetuses with development of pulsatile umbilical venous velocities have even higher increases in neonatal morbidity and mortality. In controlled trials, the use of fetal Doppler waveform analysis has been associated with improved perinatal outcome.

As previously noted, cordocentesis may be indicated to rapidly karyotype a severely growth-restricted fetus. Evaluation of fetal acid-base status in the growth-restricted fetus appears to offer limited benefit. Nicolini et al.^[141] examined 58 growth-restricted fetuses, using cordocentesis for acid-base evaluation in addition to karyotyping. They found significant differences in pH, P_{CO_2} , P_{O_2} , and base equivalents in fetuses who had no evidence of end-diastolic flow by umbilical artery Doppler velocimetry. However, they observed no relationship between acid-base determination and perinatal outcome. Pardi et al.^[142] examined umbilical blood acid-base status in 56 growth-restricted fetuses and demonstrated an association between acid-base status and the results of cardiocardiographic and umbilical artery Doppler waveform analysis. If both fetal heart rate and Doppler studies were normal, neither hypoxemia nor acidemia was noted. When both tests were abnormal, 64 percent of the growth-restricted fetuses demonstrated abnormal acid-base analysis. Unfortunately, the prognostic significance of these abnormalities is uncertain. In summary, there would appear to be no direct fetal benefit from the use of percutaneous umbilical blood sampling in the setting of fetal growth restriction.

Therapy

Several studies have examined the potential benefits of maternal hyperoxygenation in the treatment of the compromised growth-restricted fetus. Nicolaidis et al.^[143] administered 55 percent oxygen by face mask to mothers whose pregnancies were complicated by severe growth restriction, oligohydramnios, and decreased blood flow in the fetal descending aorta. Ten minutes of maternal hyperoxygenation raised the fetal P_{O_2} , to normal or near normal in five of six cases. Therapy was provided for an average duration of approximately 5 weeks in the five survivors. No improvement in fetal growth velocity was noted. Ribbert et al.^[144] provided maternal oxygen therapy (2.5 L/min nasal prong) to four growth-restricted infants at 27 to 28 weeks. Pregnancy was prolonged an average of 9 days beyond the first recognition of fetal heart rate decelerations. Neonates who were exposed to maternal hyperoxygenation had improved blood gas measurements but more hypoglycemia, thrombocytopenia, and disseminated intravascular coagulation compared with concordant gestational age and fetal heart rate-matched growth-restricted controls not exposed to oxygen. The ability to improve fetal blood gas values with maternal oxygen therapy has also been confirmed in the growth-restricted fetus by Battaglia et al.^[145]

Maternal hyperoxygenation may be of value for the safe, short-term prolongation of pregnancy. Such therapy may be of benefit to allow the administration of corticosteroids to reduce the risk of neonatal respiratory distress syndrome and intraventricular hemorrhage in anticipation of a preterm delivery. In addition, maternal hyperoxygenation may be of benefit in prolonging pregnancy when the growth-restricted fetus is too immature to survive. Although maternal hyperoxygenation may reduce fetal hypoxia, overall neonatal outcome may not be improved with prolonged therapy, since the deleterious effects of continued intrauterine substrate deprivation may extend beyond the benefits of improved fetal oxygen tension.

In 1987, Wallenburg and Rotmans^[146] significantly reduced

the incidence of fetal growth restriction in women with a history of recurrent IUGR using low-dose aspirin and dipyridamole beginning at 16 weeks' gestation. Women receiving therapy had a rate of fetal growth restriction of 13 percent compared with 61 percent in an untreated control group. No treated woman had a child with severe growth restriction (birth weight <2.3 percentile) compared with 27 percent in the untreated group. Recently, a meta-analysis of the efficacy of low-dose aspirin (50 to 100 mg/day) has demonstrated a significant reduction in the frequency of IUGR when low-dose aspirin is used.^[147] There is a dose-dependent relationship in that higher doses (100 to 150 mg/day) were significantly more effective in preventing IUGR than were lower doses (50 to 80 mg/day). The authors concluded that low dose aspirin should not be used routinely in pregnant women. We agree and restrict its usage, at the higher dose level, to women who have previously experienced early-onset IUGR associated with significant preterm delivery (<32 weeks).

Timing of Delivery

Proper timing of delivery is often the critical management issue when dealing with the growth-restricted fetus. Frigoletto^[148] has emphasized, "The majority of fetal deaths occur after the 36th week of gestation and before labor which leads to the conclusion that many deaths could be prevented by accurate recognition of growth restriction and appropriately timed and conducted intervention." The crux of management is to balance the hazards of prematurity with the threat of intrauterine demise. Careful consideration should be given to the reliability of the information on which the gestational age of the fetus has been established, the fetal growth curve, and the results of antepartum fetal monitoring.

Amniocentesis may be an important adjunct to this decision-making process. The lecithin/sphingomyelin (L/S) ratio may also provide information that allows more accurate dating of the pregnancy. A surprisingly low L/S ratio would suggest an earlier gestational age rather than fetal growth restriction. In cases of symmetric growth restriction, a late amniocentesis may also be used to obtain amniotic fluid for a fetal karyotype.

To review, if growth restriction is suspected or anticipated, appropriate fetal testing and daily maternal assessment of fetal activity should be instituted. Ultrasound examinations to assess fetal growth should be scheduled every 3 to 4 weeks. As long as studies show continued fetal head growth and test results remain reassuring, no intervention is required. If the patient fails a primary surveillance tool such as the NST or fetal Doppler surveillance, follow-up evaluation may be appropriate. If the CST result is positive, or the fetal biophysical profile score is either 6 with oligohydramnios or 4 or less or reversed end-diastolic flow is observed, delivery should be considered. An assessment of fetal lung maturity should be made if possible. In the face of a mature L/S ratio and ominous antepartum test results, delivery should be effected. If the patient has an immature L/S ratio and abnormal test findings, then consideration can be given to steroid administration with continuous heart rate monitoring and oxygen supplementation until delivery or until antepartum test results improve. If amniotic fluid cannot be obtained for an L/S ratio as a result of oligohydramnios and the clinical picture supports the diagnosis of severe IUGR, early delivery should be considered.

Because a large proportion of growth-restricted infants suffer intrapartum asphyxia, intrapartum management demands continuous fetal heart rate monitoring. Cord blood sampling has demonstrated that these fetuses may exhibit increased lactic acid levels, polycythemia, hypoglycemia, and acidosis before labor.^[149] During labor, a tracing without late decelerations is predictive of a good outcome in cases complicated by IUGR. However, with late decelerations, the incidence of asphyxia in growth-restricted infants is far greater than in normally grown infants. Therefore, earlier intervention may be indicated.^[150] As many growth-restricted fetuses require preterm delivery, an unfavorable cervix is not uncommon. The presence of IUGR has been considered a relative contraindication to the use of prostaglandin for cervical preparation by some authors.^[151] An unfavorable cervix may also preclude internal fetal heart rate monitoring. In the face of an inadequate external tracing,

cesarean delivery may be necessary.

NEONATAL OUTCOME

Immediate Morbidity

The association of selected neonatal morbidity with fetal growth restriction is a complex one (see the box "Early Neonatal Morbidities in IUGR"). Initial reports suggested the possibility of a protective effect of IUGR with reduced occurrence of respiratory distress syndrome (RDS) and intraventricular hemorrhage (IVH).^[152] In contrast, Piper and Langer^[153] found no difference in indices of fetal lung maturity comparing gestational age-matched SGA and appropriate-for-gestational-age (AGA) fetuses. Similarly, Thompson et al.^[154] found no difference in the frequency of ventilatory support when growth-restricted and AGA infants were matched for gestational age and mode of delivery. Most recently, several large trials suggest that RDS is significantly more likely to occur in growth-restricted neonates.^[155],^[156] Bernstein has also demonstrated a significant increase in

884

the risk for necrotizing enterocolitis and no difference in the rates of intraventricular hemorrhage when growth-restricted newborns are evaluated. Dashe noted a significant increase in RDS in infants with asymmetric IUGR when compared with neonates with symmetric IUGR (9 percent vs. 4 percent).^[157] Mortality rates are uniformly higher when IUGR is present. These data should put to rest the notion that fetal growth restriction is associated with any reduction in newborn illness.

Early Neonatal Morbidities in IUGR
Birth asphyxia
Meconium aspiration
Hypoglycemia
Hypocalcemia
Hypothermia
Polycythemia, hyperviscosity, hyperbilirubinemia
Thrombocytopenia
Pulmonary hemorrhage
Malformations
Sepsis
Respiratory distress syndrome
Necrotizing enterocolitis

The impact of prenatal glucocorticoid administration on illness in the growth-restricted newborn has recently been examined. Elimian et al. studied 1,148 newborns with birth weights less than 1,750 g and demonstrated no benefits to neonatal outcome when perinatal glucocorticoids were used.^[158] Bernstein et al., in a study of 19,759 newborns between 500 and 1,500 g, controlled for a different set of confounding variables, and demonstrated a significant reduction in neonatal RDS, IVH, and death when prenatal glucocorticoids were administered. These benefits were not qualitatively different from those observed in appropriately sized newborns.^[159] The potential benefits of prenatal glucocorticoid administration on neonatal morbidity and mortality in the growth-restricted newborn would appear to be an area worthy of prospective evaluation.

Additional neonatal morbidity must be anticipated when the growth-restricted fetus is delivered. These infants suffer more frequently from meconium aspiration than do appropriately grown infants. Gasping in utero in response to asphyxia appears to contribute to this problem. Meconium aspiration is rarely seen before 34 weeks' gestation and is, therefore, largely a problem of the mature growth-restricted infant. At delivery, careful suctioning of the nasopharynx and oropharynx with the DeLee catheter decreases the incidence of this complication.^[160] Further clearing of the airway can be accomplished at delivery by direct laryngoscopy and aspiration by an experienced pediatrician. Because immediate attention to the many neonatal problems experienced by these infants is essential, appropriate pediatric support should be present in the delivery room when an infant suspected of being growth restricted is to be delivered.

Hypoglycemia is a frequent problem in growth-restricted infants, a result of both inadequate glycogen reserves secondary to intrauterine malnutrition and a gluconeogenic pathway that is less responsive to hypoglycemia than that of the normally grown infant.^[161] Hypoglycemia should be anticipated in all growth-restricted infants and frequent blood glucose monitoring instituted. Hypocalcemia, another well-recognized problem in growth-restricted babies, may be caused by relative hypoparathyroidism, a result of acidosis associated with intrauterine asphyxia.^[162] Hyperphosphatemia secondary to tissue breakdown may also contribute. Frequent calcium monitoring is essential, as symptoms are nonspecific and similar to those associated with hypoglycemia.

Polycythemia is observed three to four times more frequently in the growth-restricted infant than in weight-matched controls. Polycythemia results from hypoxia, which leads to increased production of red blood cells, and from transfer of blood volume from the placental circulation to the fetal circulation in the face of intrauterine asphyxia.^[163] Thus, these infants produce more red blood cells that are shunted to them if hypoxia occurs during labor. Polycythemia leads to increased red blood cell breakdown, accounting in part for the high incidence of hyperbilirubinemia in these infants. Polycythemia is a criterion for, but does not necessarily lead to, hyperviscosity, which can result in capillary bed sludging and thrombosis. Multiple organ systems can be affected, leading to pulmonary hypertension, cerebral

infarction, and necrotizing enterocolitis.

Hyponatremia resulting from impaired renal function is also frequently reported in growth-restricted infants. The renal complications associated with IUGR may be attributed to asphyxia, which can produce central nervous system injury leading to inappropriate antidiuretic hormone (ADH) secretion. ^[160]

Hypothermia is another common problem for the growth-restricted infant and results from decreased body fat stores secondary to intrauterine malnourishment. ^[160] Hypothermia, if unrecognized and untreated, can contribute to the metabolic deterioration of an already unstable growth-restricted infant.

Long-Term Morbidity

The past two decades have seen tremendous advances in the overall management of the low-birth-weight infant. Obstetricians

885

are more aware of the syndrome of IUGR, and improved techniques for the detection of impaired intrauterine growth and the assessment of well-being are now available. Technology required for the neonatal care of these infants advances each year. Have improvements in obstetric and pediatric care favorably affected the outcome of the growth-restricted infant? The perinatal mortality rate for those infants who receive optimal intrapartum and neonatal management is decreased when compared with that for age-matched controls who did not have intensive care. ^[162]

The ultimate growth potential for growth-restricted infants appears to be good. The degree of catch-up growth observed in several longitudinal studies suggests that these infants can be expected to have normal growth curves and normal albeit slightly reduced size as adults. In an 8-year follow-up of children weighing less than 1,500 g at birth by Kitchen et al., ^[163] 75 percent of growth-restricted infants achieved a height and weight above the 10th percentile. Of infants whose birth weight fell below the 3rd percentile, 60 percent had reached the 25th percentile for weight at 8 years. In Kitchen and associates' study, ^[163] however, 50 percent of the children with small head circumferences still had head circumferences below the 10th percentile at the 8-year follow-up visit in spite of their growth in height and weight. Hediger observed that growth-restricted infants experienced a period of catch-up growth in early infancy but remained near the 25th percentile through age 47 months. ^[164] Kumar et al. ^[165] noted that in infants whose birth weights were less than 1,250 g, at 1 year 46 percent of the growth-restricted infants remained less than the 3rd percentile for weight and 38 percent remained less than the 3rd percentile for height. In general, those infants suffering growth restriction near the time of delivery do tend to catch up. However, those neonates with earlier onset and more longstanding growth restriction in utero continue to lag behind.

The issue of long-term neurologic sequelae remains unresolved. In 1972, Fitzhardinge and Steven, ^[166] evaluating a group of 96 growth-restricted infants, noted that 50 percent of males and 36 percent of females had poor school performance and, overall, 25 percent had minimal cerebral dysfunction. Major neurologic deficits were much less frequent. Other studies have shown low birth weight and short gestation to be risk factors for cerebral palsy. However, the vast majority of children with cerebral palsy are not growth restricted.

The positive effect of intrapartum surveillance for the growth-restricted fetus is reflected in the data of Low et al. ^[167] In a study of 88 growth-restricted infants, they reported no severe neurologic sequelae. They did detect a lag in mental development that was significant in the growth-restricted babies when compared with appropriately grown controls, especially in the group with birth weights less than 2,300 g. This study correlates well with the data of Lipper et al. ^[167] on low-birth-weight babies. They observed that growth-restricted infants with a head circumference below the 10th percentile have two to three times the number of serious neurologic sequelae of their normocephalic counterparts. Strauss and Dietz found that term infants with IUGR and a head circumference less than 2 SD below the mean had significantly poorer performance on intelligence and visual motor development testing at age 7 when compared with their control siblings. ^[168] Walther, ^[169] in an examination of 7-year-olds who suffered no perinatal complications despite IUGR and who were matched for social class with a control group, showed an increase in teacher-identified hyperactivity, poor concentration, and clumsiness. In a study of school performance in 8-year-olds matched for socioeconomic status, Robertson et al. ^[170] demonstrated a tendency toward hyperactivity in preterm growth-restricted children compared with control groups. Low et al. ^[171] have shown that in 9- to 11-year-olds only fetal growth restriction and socioeconomic status contributed independently to the presence of learning deficits. Intrapartum fetal asphyxia, assessed by umbilical artery base deficit, was not associated with learning deficits in this group of children.

The pattern that emerges from evaluation of these data emphasizes that neurologic outcome depends on the degree of growth restriction, especially the impact on head growth, its time of onset, the gestational age of the infant at birth, and the postnatal environment. An early intrauterine insult, between 10 and 17 weeks' gestation, could limit neuronal cellular multiplication and would obviously have a profound effect on neurologic function. ^[172] In the third trimester, brain development is characterized by glial multiplication, dendritic arborization, establishment of synaptic connections, and myelination, all of which continue during the first 2 years of life. Recovery after a period of impaired growth in the third trimester is, therefore, more likely to occur. Thus, the preterm appropriately grown infant has more normal neurologic development and fewer severe neurologic deficits than its preterm growth-restricted counterpart. Developmental milestones and neurologic development of mature infants with IUGR and mature infants of normal birth weight are similar. Presumably, this also reflects heightened physician awareness of the growth-restricted infant that allows detection, appropriate antepartum management, intrapartum therapy, and early pediatric intervention. The premature growth-restricted infant suffers from increased susceptibility to intrauterine asphyxia and all of the neonatal complications of the premature, as well as those of the infant with IUGR. If growth restriction is associated with lagging head growth before 26 weeks, even mature infants have significant developmental delay at 4 years of age. ^[173]

886

There has been significant interest in the hypothesis that diseases commonly associated with adulthood may have their origins during fetal life, the "Barker Hypothesis." Dr. David Barker, an epidemiologist from Southampton, England, first proposed that intrauterine conditions could program the development of the cardiovascular system later in life. ^[174] He and his colleagues took advantage of meticulous birth records maintained in England and Wales. Those areas in which infant mortality was highest in 1901 to 1910 correlated with areas in which there was also an increased risk for coronary artery disease in men ages 35 to 74 during the 1960s and 1970s. ^[175] Barker realized that the infant mortality was highest in low-birth-weight infants and proposed that low-birth-weight survivors might be at greater risk for coronary artery disease. Examining birth records that included not only the infant's birth weight but its birth length, abdominal and head circumference measurements, and placental weight, these investigators found that infants with a birth weight of less than 5.5 lb had a threefold increase in death attributable to coronary artery disease later in life. ^[175] The risks for stroke and hypertension were also greater. The infants at greatest risk were those who not only were low birth weight but had a smaller head circumference, were shorter, and had an increased placenta/birth weight ratio.

Epidemiologic data support a link between IUGR, low birth weight and an increased risk of developing cardiovascular disease, abdominal obesity, type 2 diabetes mellitus, and hyperlipidemia. ^[176] ^[177] ^[178] ^[179] Proposed mechanisms for this association include congenital pancreatic deficiency, which manifests in later life as insulin resistance, ^[180] ^[181] as well as alterations in sympathetic nervous activity ^[182] or adrenocortical function. ^[183] ^[184] ^[185]

In summary, there is increasing evidence to support the observed epidemiologic association between low birth weight, fetal growth restriction, and adult diseases.

SUMMARY

Overall, increased awareness of the IUGR syndrome and an improved ability to observe intrauterine growth and evaluate fetal well-being in utero have improved along with our understanding of this disease. Continued assessment of the underlying physiology, the efficacy of therapy, and the relationship of fetal status to specific short- and long-term developmental outcome are necessary if overall morbidity and mortality are to be decreased.

Key Points

Fetal growth restriction is a major cause of perinatal morbidity and mortality. Intrauterine growth restriction is currently defined by fetal size alone. Characterization of fetal size should be performed using growth curves that are population specific and appropriate. The definition of fetal growth restriction has not been based on correlations with short- and long-term morbidity. Preterm delivery is associated with an increased incidence of fetal growth restriction. Fundal height measurements have low sensitivity in the identification of fetal growth restriction. Mortality resulting from fetal growth restriction can be reduced with appropriate antenatal surveillance strategies, which may include early delivery. Low-dose aspirin therapy can prevent recurrent IUGR. The use of fetal umbilical Doppler flow studies in the management of the growth-restricted fetus reduces perinatal morbidity and mortality. Fetal growth restriction is associated with high rates of intrapartum asphyxia. Intrauterine growth restriction can result in both short-term and lifelong morbidities.

Chapter 26 - Alloimmunization in Pregnancy

Marc Jackson
D. Ware Branch

This chapter reviews the causes and management of alloimmunization in pregnancy. Topics included are Rh alloimmunization, sensitization caused by other erythrocyte antigens, and platelet alloimmunization. Rh alloimmunization is emphasized because it remains a leading cause of perinatal death from hemolytic disease. Also, to a great degree, the principles of pathophysiology and management discussed under Rh alloimmunization apply to the other causes of alloimmunization. With regard to Rh alloimmunization, the following are discussed: the genetics and biochemistry of the Rh antigen, the causes of Rh alloimmunization, the use of Rh-immune globulin, and the assessment and management of the Rh-alloimmunized pregnancy. Throughout this chapter, the traditional term *sensitization* is used interchangeably with *alloimmunization*.

HISTORY OF ERYTHROBLASTOSIS FETALIS

In 1932, Diamond et al.^[1] observed that erythroblastosis fetalis was associated with fetal edema, neonatal hyper-bilirubinemia, and neonatal anemia. Later, Darrow^[2] proposed that these related conditions were caused by the passage of maternal antibodies across the placenta and that it was the antibodies that caused the destruction of the fetal erythrocytes. In 1939, Levine and Stetson^[3] observed the presence of atypical agglutinins in the serum of a woman who had just delivered a hydropic stillborn infant; these agglutinins were found to be active against her husband's erythrocytes even though he was of the same ABO blood group. Levine and Stetson suggested that an immunizing property in the blood or tissues of the fetus had been inherited from the father and passed into the maternal circulation, causing her to develop the agglutinin. This was the first suggestion that erythroblastosis fetalis was an alloimmune disorder, and within 3 years the role of alloimmunization in the pathogenesis of erythroblastosis was established.^[4]

Although many erythrocyte antigens have subsequently been described, only a few are clinically important causes of maternal alloimmunization leading to hemolysis of fetal and neonatal cells. Fortunately, the number of cases of fetal and neonatal hemolytic disease resulting from Rh antigen incompatibility has greatly decreased because of the widespread use of Rh-immunoglobulin prophylaxis. This has led to an increase in the importance of the "minor antigens" of the erythrocyte membrane as a cause of alloimmunization.

GENETICS AND BIOCHEMISTRY OF THE Rh ANTIGEN

Nomenclature

In 1940, Landsteiner and Wiener^[5] announced that they had produced rabbit immune sera to rhesus monkey erythrocytes that, even after adsorption, agglutinated the majority (85 percent) of human erythrocytes; they designated this newly discovered property of serum the *Rh factor*. Agglutinated cells were called *Rh-positive*. It is now recognized that the "Rh factor" is an antibody directed against an erythrocyte surface antigen of the rhesus blood group system.

Since its discovery, the development of an adequate nomenclature for the Rh blood group system has been hampered by its high degree of polymorphism. Five major antigens can be identified with known typing sera, and there are many variant antigens. Unfortunately,

894

three different systems of nomenclature have been suggested since the discovery of the Rh antigen. Two of these, the Fisher-Race system and the Wiener system, were established during the 1940s and are the ones most frequently used in the literature. The HLA-like system of Rosenfield and colleagues^[6] was proposed in 1962.

In obstetrics, the Fisher-Race nomenclature is best known. Although this system has some limitations in terms of our current understanding of genetics and in its classification of the numerous variant antigens, it is well suited to understanding the inheritance of the Rh antigen and the clinical management of Rh alloimmunization.^[7]

The Fisher-Race nomenclature assumes the presence of three genetic loci, each with two major alleles. The antigens produced by these alleles were originally identified by specific antisera and have been lettered C, c, D, E, and e. No antiserum specific for a "d" antigen has been found, and use of the letter "d" indicates the absence of a discernible allelic product. Anti-C, anti-c, anti-D, anti-E, and anti-e designate specific antibodies directed against the respective antigens.

An Rh gene complex is described by the three appropriate letters; thus eight gene complexes could exist (listed in decreasing order of frequency in the white population): CDe, cde, cDE, cDe, Cde, cdE, CDE, and CdE. Genotypes are indicated as pairs of gene complexes, such as CDe/cde. Certain genotypes, and thus certain phenotypes, are more prevalent than others. The genotypes CDe/cde and CDe/CDe are the most common, with approximately 55 percent of all whites having the CcDe or CDe phenotype (Table 26-1).^[8] The genotype CdE has actually never been demonstrated.^[7] Although the alleles are always written in the order C(c), D, E(e), the actual order for the genes on chromosome 1 coding for the antigens is D, C(c), E(e).

According to the Fisher-Race concept, the Rh antigen complex is the final expression of a group of at least five possible antigens (C, D, E, c, e). The vast majority of Rh alloimmunization causing transfusion reactions or serious hemolytic disease of the fetus and newborn is the result of incompatibility with respect to the D antigen. For this reason, common convention holds that *Rh-positive* indicates the presence of the D antigen and *Rh-negative* indicates the absence of D antigen on erythrocytes.

Working at the same time as Fisher and Race, Wiener^[9] developed a system of nomenclature based on the assumption of only one genetic locus. In the Wiener system, the eight genotypes are designated (in decreasing order of frequency in the white population) R^1 , r , R^2 , R^0 , r , r , R^z , and r^v (Table 26-1).

In the 1970s, Rosenfield and co-workers^[6],^[10] suggested that none of the previously described models could explain the vast quantitative differences observed in the

TABLE 26-1 -- FREQUENCY OF Rh PHENOTYPES AND GENOTYPES AMONG WHITES

Phenotype	Population Frequency (%)	Frequency Within	
		Genotype	(%)
CcDe	35	CDe/cde (R^1/r)	94
		CDe/cDe (R^1/R^0)	6
		cDe/Cde (R^0/r)	<1
CDe	20	CDe/CDe (R^1/R^1)	95
		CDe/Cde (R^1/r)	5
ce	16	cde/cde (r/r)	100
		CcDEe	13
		CDe/cDE (R^1/R^2)	189
		CDe/cdE (R^1/r)	7
CcDEe	13	cDE/Cde (R^2/r)	2
		CDE/cde (R^z/r)	1
		CDE/cDe (R^z/R^0)	<1
cDEe	10	cDE/cde (R^2/r)	93
		cDE/cDe (R^2/R^0)	6
		cDe/cdE (R^0/r)	1
cDE	3	cDE/CDE (R^2/R^2)	86
		cDE/cdE (R^2/r)	14
cDe	2	cDe/cde (R^0/r)	97
		cDe/cDe (R^0/R^0)	3

expression of Rh antigens. Furthermore, they pointed out that genetic concepts such as the operon model of gene function with nonlinked regulator genes were poorly accommodated by the simple mendelian model of Fisher and Race. Rosenfield therefore proposed an updated system of nomenclature that numbered the antigens, designated Rh1 through Rh48.

Unique Rh antibodies have been used to identify more than 30 antigenic variants in the Rh blood group system. Two of the most common (albeit infrequent in absolute terms) are the C^w antigen and the D^u antigen, which is now referred to as *weak D*. The latter is a heterogeneous group of clinically important D antigen variants most often found in blacks. The erythrocytes of most weak D positive individuals appear to have a quantitative decrease in expression of the normal D antigen, although some weak D variants are significantly different, antigenically speaking, from D. Thus, it appears that there are at least two cellular expressions responsible for the weak D phenotype, including a reduction in the number of D antigen sites with all epitopes represented, and expression of only some of the various D antigen epitopes with some epitopes missing. Weak D positive erythrocytes can bind anti-D typing sera, but in some cases only by sensitive indirect antiglobulin methods. At least some weak D positive patients are capable of producing anti-D, presumably by sensitization to missing D epitopes. This could result in a weak D positive mother becoming sensitized to her D positive fetus, but such an occurrence is exceedingly rare.

895

Genetic Expression

The genetic locus for the Rh antigen complex is on the short arm of chromosome 1.^[11],^[12] Within the Rh locus are two distinct structural genes adjacent to one another, RhCcEe and RhD. These two genes likely share a single genetic ancestor, as they are identical in more than 95 percent of their coding sequences.^[13] The first gene codes for the C/c and E/e antigens, and the second gene codes for the D antigen.

Expression of the D antigen occurs if one (heterozygous) or both (homozygous) chromosome 1 contains a normal RhD gene sequence. Patients who are D-negative lack the normal RhD gene sequence on both their chromosomes. Therefore, they cannot transcribe this region, which is responsible for producing the D antigen.

The expression of the Rh antigen on the erythrocyte membrane is genetically based, not only in terms of the structure of the antigen but also in terms of the number of specific Rh-antigen sites (e.g., D, E, C, c, or e). Several genetic factors have been shown to alter the number of specific Rh-antigen sites; these include the gene dose, the relative position of the alleles, and the presence or absence of regulator genes.

There is a relatively constant number of Rh antigen sites available on the erythrocyte surface, totaling about 100,000 sites per cell; these sites appear to be approximately evenly divided between C(c), D, and E(e) antigens.^[14],^[15]

Gene dosage has an effect on the number of specific Rh antigen sites that express antigen; individuals who are homozygous for a particular genotype have more antigen sites than individuals who are heterozygous.^[16] For example, the erythrocytes of individuals who are homozygous for the c allele have twice as many c antigen sites expressed as are found on the erythrocytes of heterozygotes. Similar observations have been made with regard to the other alleles (E, e, and C).^[16],^[17]

An effect of allelic interaction on Rh antigen sites has been described: erythrocytes of genotype CDe/cde express less D antigen than do the erythrocytes of genotype cDE/cde.^[18] Thus, the presence of the C antigen seems to affect the expression of the D antigen. Similarly, individuals of genotype CDe/cDE express less C antigen than individuals of genotype CDe/cde.^[9] In addition, genes other than those coding for the Rh antigen may affect the final antigenic expression; two independently segregating regulator genes have been described.^[10]

Biochemistry and Immunology

The Rh antigens on human erythrocytes are polypeptides embedded in the lipid phase of the erythrocyte membrane, distributed throughout the membrane in a nonrandom fashion. D antigen sites are spaced in a lattice-like pattern across the red cell membrane, at a mean distance of 92 nm in RhD heterozygotes and 64 nm in homozygotes.^[19],^[20] The Rh polypeptides are polymorphic, with the molecular weight of the D antigen being approximately 31,900 daltons and the C(c) and E(e) polypeptides having a molecular weight of about 33,100 daltons.^[21] The final tertiary structure and antigenic expression of the protein are dependent on its association with lipids in the membrane, and in this context it may be thought of as a proteinlipid complex, or proteolipid.^[22],^[23] It appears that most of the Rh polypeptide lies within the phospholipid bilayer of the erythrocyte membrane, spanning the membrane 13 times, with short segments extending outside the red cell and extruding into the cytoplasm.^[24],^[25]

The D antigen appears very early in embryonic life and has been demonstrated on the red blood cells of a 38-day-old fetus.^[26] The antigen is also expressed early in the erythroid cell series; with ¹²⁵I-labeled anti-D, pronormoblasts have been shown to contain D antigen.^[27]

Ten different D antigen epitopes have been identified or deduced using human monoclonal anti-D antibodies, and as many as 30 may exist.^[28],^[29] One hypothesis suggests that these different epitopes are part of the same proteinlipid complex, but are more or less expressed according to the depth that the polypeptide portion is embedded in the red cell membrane lipid bilayer.^[30] It is possible that some of the immunologic variation in the Rh blood group system (and fetal hemolytic disease) is explained by the variable expression of the D antigen epitopes and the specificity of the antibodies formed against them.

The precise function of the Rh antigens is unknown, although they probably have a role in maintaining red cell membrane integrity. Rh_{null} erythrocytes, which lack all of the Rh antigens, manifest several membrane defects. The Rh antigens may interact with a membrane adenosine triphosphatase,^[23] possibly functioning as part of a proton or cation pump that controls volume or electrolyte flux across the erythrocyte membrane. Supporting this hypothesis, Rh_{null} erythrocytes have increased osmotic fragility and abnormal shapes.^[31] It has also been proposed that Rh antigens regulate the asymmetric distribution of different phospholipids through the red cell membrane as a component of the enzyme phosphatidyl flippase.^[32],^[33]

CAUSES OF Rh ALLOIMMUNIZATION

For Rh alloimmunization to occur in a pregnancy, at least three circumstances must exist:

896

1. The fetus must have Rh-positive erythrocytes, and the mother must have Rh-negative erythrocytes.
2. A sufficient number of fetal erythrocytes must gain access to the maternal circulation.
3. The mother must have the immunogenic capacity to produce antibody directed against the D antigen.

Incidence of Rh-Incompatible Pregnancy

About 15 percent of whites of European extraction are Rh-negative; only 5 to 8 percent of American blacks and 1 to 2 percent of Asians and Native Americans are Rh-negative. In the white population, an Rh-negative woman has about an 85 percent chance of mating with an Rh-positive man. About 60 percent of Rh-positive men are heterozygous and 40 percent are homozygous at the D locus. Given that one half of conceptions due to heterozygous men will be Rh-positive, the overall chance of an Rh-positive man producing an Rh-positive fetus is about 70 percent. Thus, without knowing the father's blood type, an Rh-negative woman has about a 60 percent chance of bearing an Rh-positive fetus (0.85×0.70). Among whites, the net result is that about 10 percent of pregnancies are Rh incompatible (0.15×0.60). However, because sufficient fetomaternal hemorrhage and a subsequent maternal antibody response do not occur in every case, less than 20 percent of incompatible pregnancies eventuate in maternal sensitization. Thus, in the era before Rh-immune globulin prophylaxis, about 1 percent of pregnant women had anti-D antibody.

Fetomaternal Hemorrhage

Although transplacental passage of fetal erythrocytes was proposed to be the cause of maternal alloimmunization in the 1940s,^[4] it was not until the mid-1950s that fetal erythrocytes were first demonstrated in the maternal circulation.^[34] Since then, numerous studies have confirmed that fetal red cells gain access to the maternal circulation during pregnancy and the immediate postpartum period. Fetomaternal hemorrhage in a volume sufficient to cause alloimmunization is most common at delivery, occurring in about 15 to 50 percent of births.^{[34] [35] [36] [37]} In more than half of these intrapartum fetomaternal bleeds, the amount of fetal blood entering the maternal circulation is 0.1 ml or less.^{[37] , [38]} However, in 0.2 to 1 percent of cases, the estimated volume of fetomaternal hemorrhage is 30 ml or more.^{[35] , [36] , [40]} Clinical factors such as cesarean delivery, multiple gestation, bleeding placenta previa or abruption, manual removal of the placenta, and intrauterine manipulation may increase the chance of substantial hemorrhage. However, the majority of excessive fetomaternal hemorrhages occur in patients without risk factors who have an uncomplicated vaginal delivery.^{[40] , [41]}

The amount of fetomaternal hemorrhage necessary to cause alloimmunization varies from patient to patient, probably due to the immunogenic capacity of the Rh-positive erythrocytes and the immune responsiveness of the mother. As little as 0.1 ml of Rh-positive red blood cells has been shown to sensitize some Rh-negative volunteers, and about 3 percent of women found to have 0.1 ml of fetal erythrocytes in their circulation after an Rh-incompatible delivery develop anti-D antibodies within 6 to 12 months.^[37]

Overall, about 16 percent of Rh-negative women will become alloimmunized by their first Rh-incompatible (ABO-compatible) pregnancy if not treated with Rh-immune globulin.^[38] Half of these women respond with the production of sufficient anti-D antibody to be detectable within the first 6 months after delivery; in the remainder, anti-D is not detected until early in the next incompatible pregnancy. In this latter group, sensitization likely occurred during the first pregnancy, but the primary immune response was too slight for detectable antibody levels to develop. Though not all Rh-negative women bearing Rh-positive infants will become sensitized, the risk of sensitization approaches 50 percent after several incompatible pregnancies.

Even without labor or obvious disruption of the choriodecidual junction, antepartum fetomaternal hemorrhage occurs in sufficient volume to result in alloimmunization in a small percentage of cases. In one large series, fetomaternal hemorrhage was detected in the first trimester in 7 percent of patients, in 16 percent of patients during the second trimester, and in 29 percent of the third-trimester determinations.^[34] The result of this antepartum fetomaternal hemorrhage is an overall rate of Rh sensitization of about 1 to 2 percent before delivery.^[42] However, antepartum sensitization rarely occurs before the third trimester.

Fetomaternal hemorrhage leading to alloimmunization has also been described with abortion and tubal pregnancy.^{[43] [44] [45] [46]} As mentioned above, fetal Rh antigens are present at least by the 38th day after conception and, assuming that as little as 0.1 ml of fetal blood can cause alloimmunization, a fetomaternal hemorrhage leading to sensitization could occur by the seventh week after the last menses.^[47] In one case, a significant number of fetal red blood cells was demonstrated in the maternal circulation after an elective termination of pregnancy at 6 weeks after the last menses.^[48]

Estimates of the incidence and the amount of fetomaternal hemorrhage after spontaneous abortion have varied, but review of the literature suggests that between 5 and 25 percent of spontaneous abortions result in detectable fetomaternal hemorrhage.^[36] For the unsensitized Rh-negative woman, a spontaneous first-trimester abortion carries a 3 to 4 percent risk of alloimmunization.^[49] Induced

897

abortions are also likely to produce detectable fetomaternal hemorrhage (in 7 to 27 percent of cases); the overall risk of sensitization is about 5 percent.^[46] In the second trimester, pregnancy termination by either saline injection or hysterotomy is associated with significant fetomaternal hemorrhage.^{[45] , [46]}

Threatened abortion in the first trimester may also increase the risk of sensitization. Fetomaternal hemorrhage can be demonstrated in 11 to 45 percent of such patients,^{[50] , [51]} and a case of apparent sensitization following threatened first-trimester miscarriage has been reported.^[52]

As discussed below, all Rh-negative unsensitized women should receive 50 g of Rh-immune globulin within 72 hours of induced or spontaneous first-trimester abortion. Patients in the second trimester, 13 weeks or more, are routinely given a full dose, 300 g.

Ectopic pregnancy can result in alloimmunization in a susceptible woman.^[43] The risk of significant fetomaternal hemorrhage may be greater in cases of ruptured tubal pregnancy, presumably because of the absorption of fetal erythrocytes into the maternal circulation across the peritoneum.^[53]

Amniocentesis in the second and third trimesters is associated with fetomaternal hemorrhage in 15 to 25 percent of cases, even when ultrasound is used to identify placental location.^[54], ^[55] Alloimmunization occurring after amniocentesis has been reported.^[56]

Maternal Immunologic Response

At least two characteristics affect whether alloimmunization will occur in a susceptible Rh-negative woman. First, as many as 30 percent of Rh-negative individuals appear to be immunologic "nonresponders" who will not become sensitized, even when challenged with large volumes of Rh-positive blood.^[57], ^[58] Second, ABO incompatibility exerts a protective effect against the development of Rh sensitization.^[59] Levine and Stetson^[3] are credited with first recognizing the association between ABO incompatibility and a lower than expected incidence of Rh sensitization, and fetomaternal ABO incompatibility is now well accepted as being partially protective.^[59], ^[60]

Two mechanisms explaining the protective effect of ABO incompatibility have been proposed. The first suggests that the ABO-incompatible fetal cells are more rapidly cleared from the maternal circulation so that trapping of the antigen in the spleen, where sensitization can be initiated, does not occur. Although the incidence of fetomaternal hemorrhage is no different in ABO-incompatible pregnancies, the number of fetal cells in the maternal circulation is less than in ABO-compatible pregnancies, suggesting an increased clearance rate.^[35], ^[36] A second mechanism for the protective effect of ABO incompatibility proposes that maternal anti-A or anti-B antibodies damage or alter the fetal Rh antigen so that it is no longer immunogenic.^[60]

Whatever the mechanism, ABO incompatibility diminishes the risk of alloimmunization to about 1.5 to 2 percent after the delivery of an Rh-positive fetus.^[61] This effect is most pronounced in matings in which the mother is type O and the father is type A, type B, or type AB.^[62]

THE USE OF Rh-IMMUNE GLOBULIN

The principle that a passively administered antibody will prevent active immunization by its specific antigen is termed *antibody-mediated immune suppression* (AMIS) and was well known to immunologists for decades before being applied to the prevention of Rh disease. During the early 1960s, Freda et al. [66] in the United States and Clarke et al. [64] in Great Britain simultaneously undertook to evaluate AMIS in humans. Both groups achieved a high degree of protection from alloimmunization by administering anti-D immune globulin (Rh-immune globulin) to Rh-negative male volunteers who had been infused with Rh-positive red cells. [63] , [64] In 1963, Pollack et al. [65] established that 300 g of Rh-immune globulin would reliably prevent alloimmunization in male volunteers who had received 10 ml of Rh-positive cells. By extrapolation of the data, Pollack et al. showed that 20 g of Rh-immune globulin per milliliter of fetal erythrocytes or 10 g/ml of whole fetal blood was required to prevent alloimmunization. Thus, the rule was established that 10 g Rh-immune globulin should be given for every 1 ml of fetal blood in the maternal circulation.

The early trials using AMIS to prevent alloimmunization in Rh-negative women delivering Rh-positive infants were excitingly successful. [66] [67] [68] The administration of Rh-immune globulin within 72 hours of delivery reduced alloimmunization to less than 1.5 percent in the Rh-negative women who were followed through a subsequent incompatible pregnancy. This represented a 7- to 10-fold decrease in alloimmunization compared with untreated controls. Although 300 g or more of Rh-immune globulin was used, it has subsequently been shown that a dose of 100 to 150 g is probably adequate for routine use. [68] , [69] Nonetheless, the standard approved dose for Rh prophylaxis in the United States remains 300 g.

The 72-hour time limit set for the postpartum administration of Rh-immune globulin is an artifact of the design of the early male prisoner volunteer studies. Prison officials would only allow the investigators to visit the volunteers at 3-day intervals [70] thus, the use of Rh-immune globulin at intervals of more than 3 days

after a challenge with Rh-positive cells was never extensively evaluated. However, to be effective, Rh-immune globulin must be given before the primary immune response is established. The time required to mount a primary immune response doubtlessly varies from case to case, and it is prudent to administer Rh-immune globulin to appropriate mothers as soon as possible after delivery. If for some reason the neonatal Rh status is unknown by the third day after delivery, it is preferable to administer Rh-immune globulin to an Rh-negative mother rather than to continue to await the neonatal results. Finally, if an Rh-negative mother who is a candidate for Rh-immune prophylaxis is mistakenly not treated within the recommended 72 hours following delivery, she may be given Rh-immune globulin up to 14 to 28 days after delivery in an effort to avoid sensitization. [71]

Antepartum Prophylaxis

Early trials showed that 1 to 2 percent of susceptible women became sensitized in spite of postpartum Rh-immune prophylaxis. The majority of these "prophylaxis failures" resulted from antepartum fetomaternal hemorrhage. In an effort to address this problem, Bowman and colleagues [72] in Canada conducted an antepartum Rh prophylaxis trial in which 300 g of Rh-immune globulin was given at 28 and 34 weeks' gestation. Antenatal sensitization was reduced from 1.8 to 0.1 percent. Subsequently, it was shown that 300 g of Rh-immune globulin given only at 28 weeks' gestation is nearly as effective. [73] Reviewing several large studies, the 1979 McMaster University Conference on the prevention of Rh disease confirmed that the antepartum administration of Rh-immune globulin could reduce the risk of antepartum alloimmunization by more than half. [42] In more than 18,000 control cases, the incidence of antepartum sensitization was 1.05 percent, whereas in the 10,000 treated cases it was only 0.17 percent.

Despite these results, antepartum Rh prophylaxis remains somewhat controversial. From a safety perspective, there is a risk of infection (although exceedingly small) to the donors who provide plasma for human anti-D immunoglobulin, which is produced by immunization and antibody boosting by injecting incompatible Rh-positive red cells into Rh-negative volunteers. Also, Hensleigh [74] has argued that the safety of Rh-immune globulin prophylaxis to the recipient mother and fetus has not been convincingly demonstrated. However, decades of experience with Rh-immune globulin have not produced any suspicion of detrimental effects, and a systematic evaluation of a large cohort of women receiving Rh-immune globulin failed to detect any untoward side effects. [75]

The cost-effectiveness of antepartum prophylaxis has also been addressed. Setting aside the ethical issues of withholding Rh-immune globulin prophylaxis because of financial concerns, it nonetheless appears that routine antepartum prophylaxis is much less expensive than managing later sensitized pregnancies. [71] , [76] Baskett and Parsons [77] calculated that the cost per case of Rh alloimmunization prevented was less than half of the cost per case treated, with 80 percent of treatment costs being accounted for by neonatal intensive care.

More recently, monoclonal antibody techniques have been used to produce human anti-D. [78] This technology has the potential to produce a standardized antibody in essentially unlimited supply. Human donor risk will be eliminated, and production costs seem certain to decrease, improving the cost/benefit ratio even further. Initial in vitro testing of monoclonal anti-D has been favorable, [79] and preliminary human trials to determine effectiveness in blocking endogenous anti-D production are underway. [80] At this point, though, it is uncertain whether monoclonal anti-D will be as effective as human-derived polyclonal Rh-immune globulin, and routine clinical use of monoclonal anti-D is likely years away.

Mechanism of Action

The precise mechanism of AMIS is not clearly understood. There are three theories: (1) antigen deviation, (2) antigen blocking-competitive inhibition, and (3) central inhibition. The hypothesis that AMIS works by deviation of the antigen away from the immunologic apparatus that is responsible for the formation of antibody was first suggested by Race and Sanger. [7] Support for this theory came from the observation of an increased clearance of ⁵¹Cr-labeled Rh-positive red cells in Rh-negative volunteers who were treated with Rh-immune globulin. This increase in clearance was presumed to be caused by intravascular hemolysis that resulted in the destruction or alteration of the Rh antigen so that it did not incite the production of anti-D antibody. However, it is now known that IgG anti-D does not cause intravascular hemolysis of Rh-positive cells; instead, the intact, antibody-coated cells are removed from the circulation by the spleen or lymph nodes, [81] the very site of antibody formation.

Antigen deviation could also occur by the phagocytosis of the antibody-coated Rh-positive cells; this could, and presumably does, occur in the spleen and lymph nodes. However, macrophage ingestion and processing of antigen are essential for immunization to occur, and passive immunization that is directed against red cell antigens has been shown to be specific. [82] Also, if antigen deviation through phagocytosis was the primary mechanism of AMIS, it seems likely that all red cell

antigens would be destroyed. For these reasons, antigen deviation is probably not the mechanism of AMIS.

Antigen blocking by anti-D antibody is also not the probable mechanism for AMIS: antibody preparations that lack the Fc portion have been shown to bind avidly to antigen, yet they do not suppress the immune response.^[83] In addition, with the usual doses of anti-D used to effect immune suppression, less than 20 percent of the Rh antigen is bound.^[82]

The most likely mechanism for AMIS is that of central inhibition, as proposed by Gorman and elaborated upon by Pollack.^[82] In this hypothesis, fetal erythrocytes coated with exogenously administered anti-D are filtered out of the circulation by the spleen and lymph nodes. The increase in the local concentrations of anti-D bound to the D antigen appears to "suppress" the primary immune response by interrupting the commitment of B cells to IgG-producing plasma cell clones. Exactly how this suppression is effected is poorly understood, but the binding of antibody-antigen complexes (anti-D-D antigen complexes) by immune effector cells results in the release of cytokines that inhibit the proliferation of B cells specific for the antigen. The process appears to be dependent on the presence of the Fc receptor on IgG, as Fab fragments do not inhibit AMIS.

MANAGEMENT OF THE UNSENSITIZED Rh-NEGATIVE PREGNANT WOMAN

At the first prenatal visit of each pregnancy, every patient should have her ABO blood group, Rh type, and antibody screen checked (Fig. 26-1). It is essential that these determinations are made in each subsequent pregnancy, as previous maternal antibody screening is not an adequate assessment.

If the patient is Rh-negative, weak D-negative, and has no demonstrable antibody, she is a candidate for 300 g Rh-immune globulin as prophylaxis at 28 weeks' gestation and again immediately after birth. It is the recommendation of the American Association of Blood Banks that a second antibody screen be obtained before administration of Rh-immune globulin at the beginning of the third trimester, [84] to ensure that the patient is not already sensitized and producing anti-D, but this second screen is probably clinically unnecessary. [85] Similarly, a repeat antepartum antibody screen at 35 to 36 weeks' gestation is unnecessary. Routine screening of Rh-positive patients for irregular antibodies at the beginning of the third trimester is not warranted. [86]

When the Rh-negative, unsensitized patient is admitted

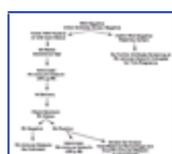

Figure 26-1 Flow diagram outlining the management of Rh-negative, non-immunized pregnancies.

for delivery, an antibody screen is routinely done. If the antibody screen is negative and the newborn is Rh-positive or weak D-positive, the patient should again be given Rh-immune globulin.

Because up to 1 percent of deliveries result in a fetomaternal hemorrhage of greater than 30 ml (the largest volume of fetal blood adequately covered by a standard 300 g dose of Rh-immune globulin), Rh-negative patients with an Rh-positive or weak D-positive newborn should be screened for "excessive" fetomaternal hemorrhage immediately postpartum. [84] An erythrocyte rosette test has been shown to be a simple and sensitive method for detecting excessive fetomaternal bleeding, [44] and most laboratories use one of the commercially available versions of the erythrocyte rosette test as a screening test. For patients with a positive screen, Kleihauer-Betke testing can be used to quantitate the volume of fetal red cells in the maternal circulation. In this way, the appropriate dose of Rh-immune globulin can be calculated. If the volume of hemorrhage is estimated to be greater than 30 ml whole blood, a dose of Rh-immune globulin calculated at 10 g/ml of whole fetal blood should be administered.

Management of the weak D-positive patient is sometimes confusing. A weak D-positive mother who delivers an Rh-positive infant is not at significant risk of Rh sensitization, probably because the weak D antigen is actually an incompletely expressed D antigen. Thus, weak D-positive mothers are clinically treated as if they were Rh-positive, and they do not require Rh-immune globulin. However, occasionally a woman previously typed as Rh-negative is unexpectedly found to be weak D-positive during pregnancy or after delivery. In this situation, the clinician should be suspicious that the patient's "new" weak D-positive status is actually due to a large number of Rh-positive fetal cells in the maternal circulation. Appropriate diagnostic studies should be performed, and if fetomaternal hemorrhage is found, the mother should be treated with Rh-immune globulin.

Because of the risk of significant fetomaternal hemorrhage with abortion or ectopic pregnancy, Rh-immune globulin prophylaxis is indicated if the patient is Rh-negative and unsensitized. If the pregnancy loss occurs at 12 weeks' gestation or less, a 50-g dose of Rh-immune globulin is adequate to cover the entire fetal blood volume [87] (Table 26-2). If the gestational age is unknown or beyond 12 weeks, a full 300 g dose of Rh-immune globulin is indicated.

Management of the Rh-negative patient with threatened miscarriage in the first trimester is controversial, and there is no clear consensus or evidence-based recommendation on use of Rh-immune globulin. [88] Even though fetal-maternal hemorrhage can occur with threatened abortion before 12 weeks, [51] documented sensitization is extremely uncommon. In the United

TABLE 26-2 -- RECOMMENDED DOSES OF Rh-IMMUNE GLOBULIN

Indication	Dose (g) of Rh-Immune Globulin
First-trimester spontaneous or induced abortion	50
First-trimester chorionic villus sampling	50
Ectopic pregnancy	
Prior to 12 weeks' gestation	50
After 12 weeks' gestation	300
Amniocentesis, second-trimester chorionic villus sampling, or other intrauterine procedures	300
Abdominal trauma or fetal death in the second or third trimester	300
Fetomaternal hemorrhage	10 per estimated ml of whole fetal blood

From American College of Obstetricians and Gynecologists: *Prevention of RhD alloimmunization*. ACOG Practice Bulletin 4. Washington, DC, American College of Obstetricians and Gynecologists, 1999.

Kingdom, current recommendations are that Rh-immune globulin is unnecessary with threatened miscarriage before 12 weeks, although anti-D can be considered for patients with heavy or repeated bleeding late in the first trimester. [88]

An Rh-negative, unsensitized patient who has antepartum bleeding or suffers an unexplained second- or third-trimester fetal death should receive 300 g Rh-immune globulin and be evaluated for the possibility of massive fetomaternal hemorrhage. If fetal cells are found in the maternal circulation, Rh-immune globulin is indicated at

a dose of 10 g per estimated milliliter of whole fetal blood ([Table 26-2](#)) .

Antenatal Rh-immune globulin is indicated at the time of chorionic villus sampling or amniocentesis in an Rh-negative, unsensitized patient. For first-trimester procedures, 50 g of Rh-immune globulin is protective. However, for second- or third-trimester procedures, a full 300-g dose is indicated even if the procedure is not associated with detectable hemorrhage ([Table 26-2](#)) . When amniocentesis is performed within 72 hours of delivery, such as for the determination of fetal pulmonary maturity, Rh-immune globulin may be withheld and administered immediately postpartum if the infant is found to be Rh-positive or D^u positive; if delivery is to be delayed for more than 72 hours, Rh-immune globulin should be given.

Since Rh-immune globulin became available in the United States in the late 1960s, the incidence of Rh alloimmunization has been drastically reduced. Antepartum sensitizations have markedly declined with the now widespread practice of antepartum prophylaxis; however, postpartum prophylaxis failures still represent

a significant problem.^[89] The routine use of postpartum screening programs to detect "excessive" fetomaternal hemorrhage will likely avoid the majority of these postpartum sensitizations.

Failure to administer Rh-immune globulin when it is indicated also remains a problem.^[89] In one study, nearly one fourth of the cases of new sensitization were due to this inexcusable oversight.^[90] It is imperative that the physician be responsible for determining the Rh type in every patient who undergoes abortion, chorionic villus sampling, amniocentesis, blood transfusion, or pregnancy.

THE Rh-ALLOIMMUNIZED PREGNANCY: ASSESSMENT OF THE FETUS

Any patient with an anti-D antibody titer of greater than 1:4 should be considered Rh sensitized and her pregnancies managed accordingly. The eventual goal of management is to minimize fetal and neonatal morbidity and mortality. Patients (fetuses) can be roughly categorized as (1) those who are unlikely to require intrauterine intervention and who can be delivered when they achieve pulmonary maturity and (2) those who will likely have moderate to severe hemolytic disease and require intrauterine transfusion and early delivery. An accurate assignment of gestational age using menstrual dates and early ultrasound is crucial in management of the Rh-alloimmunized pregnancy, as the timing of amniocentesis, umbilical cord blood sampling, in utero treatment, and delivery will depend on it.

Determination of the Fetal Antigen Status

When first confronted with an Rh-immunized pregnancy, the possibility that the fetus might be Rh-negative and therefore not need expensive and potentially hazardous procedures should be considered. If the woman might have become sensitized during a pregnancy fathered by another partner or by a mismatched blood transfusion, determining the paternal Rh antigen status is reasonable, since the father of the current pregnancy might be Rh-negative. If he is Rh-negative (and it is certain that he is the father of the fetus), further assessment and intervention are unnecessary. If the father is Rh-positive, the blood bank laboratory can reliably estimate the probability that he is heterozygous for the D antigen by using Rh antisera to determine his most likely genotype (Table 26-1). Alternatively, DNA analysis can be used to determine his zygosity with a high degree of certainty.^[91] Of course, if the man has fathered Rh-negative children, he is a known heterozygote.

If the father is homozygous for the D antigen, all his children will be Rh-positive; if he is heterozygous, there is a 50 percent likelihood that each pregnancy will have an Rh-negative fetus who is at no risk of anemia and does not require further assessment or treatment.

In the past, cordocentesis with analysis of fetal red blood cells was required to determine fetal antigen status. Some authors advocated routine umbilical cord blood sampling for fetal Rh antigen status at 18 to 20 weeks' gestation in all Rh-immunized pregnancies with a heterozygous father.^[92] However, this approach never gained widespread acceptance, at least in part because of the increased risks of fetal loss and fetomaternal hemorrhage associated with cordocentesis.^[93]

More recently, advances in molecular genetics have made it possible to determine fetal Rh status without direct analysis of fetal red blood cells. The Rh locus on chromosome 1p34p36 has been cloned,^[94] and polymerase chain reaction (PCR) now allows determination of fetal Rh status from the uncultured amniocytes in 2 ml of amniotic fluid or as little as 5 mg of chorionic villi.^[95],^[96]

Several PCR techniques using different primers have been developed.^[95],^[97]^[98]^[99] Initial reports of fetal Rh genotyping used a single primer set to identify the RhD locus, with a second primer specific for the CcEe locus used as a control.^[95],^[96] Using a single set of primers, error rates of 0.3 to 2.5 percent were reported.^[97],^[100],^[101] In an effort to reduce error, PCR was performed using two independent sets of primers specific for different regions of the RhD gene. Simsek et al.,^[97] using blood, and Spence et al.,^[102] using amniotic fluid and chorionic villi, both reported complete concordance between two-primer PCR results and serologic testing.

Because of the possibility of severe fetal anemia and death, it is most important that an Rh-positive fetus not be misidentified as Rh-negative. Van den Veyver et al.^[103] pointed out that such a misdiagnosis can occur when an Rh-positive father carries a gene rearrangement near the RhD locus which would prevent binding of the primer and yield a negative result with PCR. They recommended that paternal blood be analyzed simultaneously with amniotic fluid, using the same primers and PCR technique.

Although DNA testing for fetal Rh status has proven to be highly accurate, errors do not happen in clinical practice. Although estimates vary, misdiagnosis is thought to occur in about 1 percent of cases.

At most centers in the United States, DNA analysis of fetal cells is routinely included in the Rh assessment protocol. If an Rh-sensitized patient (with a partner who is heterozygous or whose status is unknown) is having a chorionic villus sampling or second-trimester amniocentesis for another, unrelated indication, fetal

RhD typing is performed at that time. In other cases, fetal Rh typing is performed at the time of the first amniocentesis for amniotic fluid bilirubin analysis. When PCR results indicate an Rh-negative fetus, patients are offered surveillance with fetal kick counts and serial ultrasounds, after a full discussion and explanation of the small likelihood of a misdiagnosis.

Because of the added risk and expense, chorionic villus sampling or early amniocentesis are not warranted solely for Rh typing, except for patients with severe Rh sensitization who would consider termination of an Rh-positive pregnancy. In the future, it seems likely that fetal Rh status may be routinely available from analysis of maternal blood. Favorable early experience with prenatal diagnosis of fetal antigen status has been reported using maternal blood,^[104] fetal DNA extracted from maternal plasma,^[105] and fetal mRNA in maternal blood.^[106] Preimplantation genetic diagnosis of RhD type on single blastomeres has also been described.^[99]

Antibody Titer

In the first sensitized pregnancy, the level of the anti-D antibody titer determines the need for amniocentesis. A number of authors have noted that severe erythroblastosis or perinatal death does not occur when the antibody levels remain below a certain "critical titer."^[60],^[107],^[108] This titer varies between laboratories but is usually 1:16 or 1:32. For instance, Freda^[109] found no perinatal deaths caused by hemolytic disease when the anti-D titer within 1 week of delivery was 1:16 or less. Queenan^[69] reported no intrauterine deaths with a maternal anti-D titer of 1:16 or less and only one fetal death with an anti-D titer of 1:32. Gottvall et al.^[109] found that no newborns in their series needed exchange transfusion if the maternal anti-D titer was 1:32 or less within 2 weeks of delivery.

Unfortunately, the reliability and method of antibody titration vary greatly between laboratories. As the number of sensitized pregnancies diminishes, the familiarity of laboratory personnel with titration techniques also decreases. Because of this potential difficulty, an anti-D titer of 1:8 or greater is considered at many centers to be an indication for amniocentesis to manage the sensitized pregnancy (Fig. 26-2). If the initial anti-D titer is less than 1:8, and if the patient does not have a history of a previously affected infant, the pregnancy may be followed with anti-D titers every 2 to 4 weeks and serial ultrasound assessment of the fetus.

Measurement of serial antibody titers has not been commonly used in Rh-sensitized pregnancies other than for determining the need for amniocentesis in first sensitized pregnancies. However, when anti-D levels are above the critical titer, a substantial proportion of fetuses are not significantly anemic. A number of investigators have sought to determine whether serial antibody titers might reduce the need for amniocentesis. MacGregor et al.^[110] reported a small series of patients in which amniocentesis results were poorly predictive of fetal anemia. However, a three-fold rise in anti-D titer identified all five fetuses with anemia, while none of

those with an anti-D rise of two-fold or less were anemic.

In Europe, anti-D is generally measured with an AutoAnalyzer (using one of several reference standards) and reported as a concentration, rather than as a dilutional titer. A number of authors have suggested that anti-D concentrations have better predictive value than titers. ^[109], ^[111] Nicolaidis and Rodeck^[112] showed a close association between anti-D concentration and degree of fetal anemia at cord blood sampling, and no fetuses had moderate or severe anemia if the maternal anti-D concentration was less than 15 IU/ml. Similar findings were reported by Economides et al. ^[113]

Gottvall et al. ^[109] measured anti-D titers and concentrations in 93 Rh-sensitized pregnancies. They found that anti-D titers less than 1:32 or greater than 1:1,000 were strong predictors of mild and severe disease, respectively. In the group with intermediate titer levels,

Figure 26-2 Flow diagram outlining the management of a first Rh-sensitized pregnancy.

903

however, anti-D concentration was a superior predictor, as 72 percent of patients with levels above their cutoff had moderate or severe disease, while 78 percent of patients below that cutoff had mild disease. They concluded that measurement of serial anti-D concentrations may decrease the need for amniocentesis in patients with Rh disease.

Even though anti-D concentrations were more predictive of anemia in the middle range of titers, Gottvall et al. ^[109] failed to identify 20 percent of fetuses with moderate to severe anemia by following anti-D concentrations, and 28 percent of patients above the cutoff did not have significant neonatal anemia. Bowell et al. ^[114] reported similar results, finding that less than a quarter of patients with concentrations above their cutoff had newborn hemoglobin levels less than 10 g/dl.

Currently, maternal serum anti-D titers are not particularly useful in the management of most Rh-alloimmunized pregnancies, except for using the "critical titer" to establish the need for amniocentesis in the first sensitized pregnancy. Indeed, titers may remain stable throughout gestation in as many as 80 percent of severely affected pregnancies. ^[104] Variability between maternal antibody levels and severity of fetal disease is explained by the fact that antibody concentration is only one factor influencing the degree of anemia. Other factors, which vary between individuals, include antibody subclass and degree of glycosylation, placental transfer of antibody, antigen expression on fetal erythrocytes, functional maturity of the fetal reticuloendothelial system, and the presence of HLA-related antibodies that inhibit fetal erythrocyte destruction. ^[30], ^[111]

Obstetric History

A well-documented obstetric history can be an important management guide for the Rh-alloimmunized patient. Fetal hemolytic disease tends to be either as severe, or more severe, in subsequent pregnancies. A history of previous intrauterine or neonatal death from hemolytic disease carries a particularly grave prognosis. ^[107], ^[115] As a general rule of thumb, if a mother has had a hydropic fetus, the chance that the next Rh-incompatible fetus will become hydropic (if left untreated) is more than 80 percent. Only occasionally will an Rh-incompatible fetus be less severely affected than its previous sibling.

In general, hemolysis and hydrops develop at about the same time or somewhat earlier in subsequent pregnancies; this can be used as a rough guide for timing initial fetal studies and transfusions. However, the history is not particularly helpful if the previous pregnancy was the first sensitized pregnancy, since relatively few fetuses develop hydrops in a first sensitized pregnancy.

Amniotic Fluid Analysis

Assessment of amniotic fluid in Rh immunization is based on the original observations of Bevis ^[116] that spectrophotometric determinations of amniotic fluid bilirubin correlated with the severity of fetal hemolysis. The bilirubin in amniotic fluid is a by-product of fetal hemolysis that reaches the amniotic fluid primarily by excretion into fetal pulmonary and tracheal secretions and diffusion across the fetal membranes and the umbilical cord. Using a semilogarithmic plot, the curve of optical density of normal amniotic fluid is approximately linear between wavelengths of 525 and 375 nm. Bilirubin causes a shift in the spectrophotometric density with a peak at a wavelength of 450 nm. The amount of shift in optical density from linearity at 450 nm (the OD_{450}) is used to estimate the degree of fetal red cell hemolysis (Fig. 26-3).

Liley^[117] provided a framework for the management of Rh-immunized pregnancies on the basis of OD_{450} values in the third trimester. Retrospectively, he correlated amniotic fluid OD_{450} values with newborn outcome by dividing a semilogarithmic graph of gestational age versus OD_{450} into three zones. Unaffected fetuses and those with mild anemia had OD_{450} values in zone I (the lowest zone), whereas severely affected

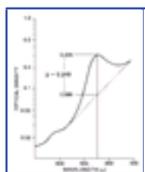

Figure 26-3 Graph of spectrophotometric analysis of amniotic fluid taken from an Rh-sensitized pregnancy with fetal hydrops. The solid line is the plot of the optical density of the bilirubin-containing fluid across the wavelengths on the x-axis. The interrupted line represents the curve expected from amniotic fluid without increased bilirubin. The difference between the optical density of the solid line and the interrupted line at 450 nm is the OD_{450} value.

904

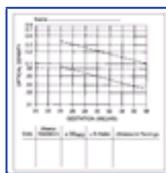

Figure 26-4 Liley graph with linear extrapolation of boundaries to 24 weeks' gestation.

fetuses had OD_{450} values in zone III (the highest zone). Fetuses with zone II values (the middle zone) had disease ranging from mild to severe, indicated primarily by the trend of the amniotic fluid bilirubin determinations. There is a normal tendency for amniotic fluid bilirubin to decrease as pregnancy advances; thus, the boundaries of the zones slope downward as gestational age increases (Fig. 26-4).

Management prior to this time consisted primarily of early induced delivery, but Liley's method identified pregnancies that could be safely allowed to continue without great risk of hydrops and stillbirth. In this way, iatrogenic prematurity was avoided in many cases, with a reduction in perinatal mortality from 22 percent to 9 percent over a 5-year period. ^[117]

It became clear with further study that a single measurement of OD_{450} was poorly predictive of fetal condition unless it was very high or very low. ^[11] Also, because of the wide range of severity of disease in the middle zone, Liley emphasized the need for repeating the amniotic fluid analyses to establish the OD_{450} trend. Queenan ^[119] subsequently analyzed serial amniotic fluid OD_{450} values in patients delivering unaffected (Rh-negative), mildly affected (cord hemoglobin > 14 g/dl), severely affected (cord blood hemoglobin < 10 g/dl), and stillborn infants. There was a clear downward trend in the OD_{450} values in unaffected and mildly affected infants, and

values from the severely affected fetuses showed a mixed pattern of higher values. The amniotic fluid OD₄₅₀ values from infants who died in utero from erythroblastosis showed upward trends except in a single case that was complicated by polyhydramnios. Thus, a horizontal or rising trend is ominous and indicates the need for intervention either by intrauterine transfusion or delivery. Clinical management now includes serial amniocenteses to determine the trend of OD₄₅₀ values over time.^[119], ^[120]

The usefulness of the late second- and early third-trimester amniotic fluid OD₄₅₀ determinations for the management of Rh-immunized pregnancies has been confirmed by decades of experience in many centers. However, several practical caveats deserve emphasis. First, a single OD₄₅₀ value is often insufficient for management purposes; the OD₄₅₀ trend, as established by serial amniocenteses, provides more reliable information about the fetal status. Second, amniotic fluid bilirubin levels are an indirect measure of fetal anemia, and relying solely on the OD₄₅₀ values occasionally leads to the false impression that a mildly or moderately involved fetus is severely anemic or vice versa. Finally, the fairly common practice of extrapolating Liley's original graph for use prior to 27 weeks' gestation is controversial.

Data for OD₄₅₀ analysis were originally obtained from third-trimester pregnancies, and several investigators have arbitrarily extrapolated the Liley graph backward and interpreted the results as for third-trimester fetuses.^[121] Nicolaides and colleagues^[122] questioned this approach. They obtained amniotic fluid and umbilical cord blood samples from 59 fetuses with Rh immunization between 18 and 25 weeks' gestation and correlated OD₄₅₀ values with fetal hemoglobin. Whereas, the OD₄₅₀ roughly correlated with the degree of fetal anemia, the OD₄₅₀ values were widely scattered and did not accurately predict the hematocrit in an individual fetus. Also, two thirds of severely affected fetuses (hemoglobin < 6 g/dl) had OD₄₅₀ values in the middle or lower zone, incorrectly suggesting only mild to moderate anemia. The authors concluded that second-trimester amniotic fluid bilirubin analysis is unreliable and that umbilical cord blood sampling is the only accurate method of assessing fetal anemia.^[122] These results were widely accepted, and standard recommendations for second-trimester fetal assessment were modified to include fetal blood sampling instead of amniocentesis.^[123]

However, some authors disagreed with these conclusions. Spinnato and co-workers^[124] suggested that the OD₄₅₀ results of Nicolaides et al.^[122] were misleading because no correction for amniotic fluid contamination was utilized. They showed that chloroform extraction of amniotic fluid in Rh-immunized pregnancies (to recover bilirubin and remove contaminants such as blood and meconium) resulted in a decrease in OD₄₅₀ values in 90 percent of samples by a mean of 20 percent and allowed accurate clinical categorization of each patient tested. Nicolaides' group also included hydropic fetuses

905

in their analysis, relied more on single OD₄₅₀ values than on trends, and did not address the risk/benefit ratio for routine umbilical cord blood sampling. Spinnato et al.^[124] concluded that second-trimester chloroform-extracted amniotic fluid bilirubin analysis permits accurate fetal assessment and avoids umbilical cord blood sampling in all but about 15 percent of patients.

Others have found amniotic fluid bilirubin analysis before 28 weeks to be valuable as well. Ananth and Queenan^[125] studied OD₄₅₀ values and trends in 32 Rh-sensitized pregnancies between 16 and 20 weeks' gestation. They found that OD₄₅₀ values greater than or trending above 0.15 predicted severe alloimmunization, whereas OD₄₅₀ values below 0.09 indicated mild or absent disease. They concluded that umbilical blood sampling is necessary only in second-trimester pregnancies with OD₄₅₀ values greater than 0.15; fetuses with OD₄₅₀ values below 0.15 can be managed with serial amniocenteses to determine whether the trend indicates severe disease.

In a subsequent analysis of amniotic fluid bilirubin levels obtained between 14 and 40 weeks' gestation, Queenan et al.^[126] plotted 520 OD₄₅₀ values from unaffected fetuses and 163 OD₄₅₀ values from Rh-immunized pregnancies, using a nonlogarithmic graph. In unaffected pregnancies, normal amniotic fluid OD₄₅₀ values trended upward between 14 and 22 weeks, leveled off until 26 weeks, then declined steadily until term. Using the mean and standard deviation of values across the gestational age range, these authors proposed a new graphic framework for assessment of OD₄₅₀ values in Rh-sensitized pregnancies, with four zones instead of Liley's three. Queenan et al. then proposed a management scheme based on their review of data, with timing of repeat amniocentesis or cordocentesis based on the OD₄₅₀ results.

To evaluate the accuracy of Queenan's chart, Spinnato et al.^[127] compared OD₄₅₀ results using both Queenan's graph and a Liley curve extrapolated linearly back to 20 weeks. They plotted 231 OD₄₅₀ values from 73 alloimmunized patients using both methods and found that Queenan's graph was twice as likely to overestimate risk both before and after 28 weeks, and placed patients' highest OD₄₅₀ value in the upper zone three times as often. Queenan's standards were more accurate for only two patients, both at 21 to 22 weeks' gestation. Using the extended Liley curve for clinical management, only 16 percent of patients required cordocentesis or transfusion, and no fetuses developed hydrops. Spinnato et al.^[127] concluded that a linearly extended Liley curve is safe and accurate for second- and third-trimester assessment, and that Queenan's chart overestimates risk of fetal anemia.

Others have reported similar findings. Scott and Chan^[128] superimposed Queenan's graph and the Liley curve, and showed that Queenan's cutoff levels are lower than those of Liley, especially before 32 weeks. Although they concluded that Queenan's chart is a suitable alternative to the Liley curve, Scott and Chan found that 11 of 13 OD₄₅₀ values from fetuses with moderate anemia fell in Queenan's intrauterine death risk zone, and only 2 of 18 values from unaffected fetuses were in the lowest zone.^[128]

Recognizing that this issue is not completely settled, we currently use a standard semilogarithmic Liley curve for amniotic fluid assessment, extrapolated linearly back to 24 weeks' gestational age (Fig. 26-4). As mentioned above, we emphasize trends rather than single OD₄₅₀ values, especially before the third trimester, taking history and gestational age into consideration in clinical management.

Fetal Blood Analysis

Direct fetal vascular access with fetoscopy and ultrasound-guided umbilical vein puncture was developed in the 1980s, thus enabling accurate assessment of the degree of fetal anemia and fetal intravascular transfusion.^[129] ^[130] ^[131] At that time, fetal blood sampling was also the only method to reliably determine fetal antigen status when the zygosity of the father was unknown or uncertain. As a result, fetal blood sampling was considered by many to be the first step in the assessment of the fetus at risk for severe hemolytic disease.

MacKenzie and colleagues^[132] confirmed the utility of fetal blood sampling in the management of Rh-alloimmunized pregnancies. In 51 consecutive sensitized pregnancies, 11 fetuses were found by blood sampling to be Rh-negative and thus required no further evaluation. Of the continuing pregnancies, the fetal hematocrit and the amniotic fluid OD₄₅₀ values were in agreement in 79 percent of instances. However, the amniotic fluid OD₄₅₀ value underestimated the degree of fetal anemia in 11 percent of comparisons and overestimated the degree of fetal anemia in 10 percent.

Adoption of routine umbilical cord blood sampling has not been universal because of concern for potential fetal and maternal morbidity. The procedure is successful in greater than 95 percent of cases, but attributable fetal loss rates between 0.5 and 2 percent per procedure have been reported by experienced investigators.^[133] ^[134] ^[135] In approximately 5 percent of patients, other morbidity occurs; complications such as acute refractory fetal distress, umbilical cord hematoma, amnionitis with maternal adult respiratory distress syndrome, and placental abruption have been described.^[136] ^[137] ^[138]

Additionally, there appears to be a significant risk of fetomaternal bleeding with umbilical cord blood sampling, with the potential for worsened maternal sensitization and fetal involvement.^[139] ^[140] ^[141] Although most studies of this issue have described patients undergoing cordocentesis with intravascular transfusion rather than

906

umbilical blood sampling alone, it appears that significant fetomaternal hemorrhage occurs in 25 to 50 percent of procedures.

Traversing an anterior placenta with the sampling needle is generally thought to increase the likelihood of fetomaternal hemorrhage. In the series of Nicolini et al.,^[93] 65 percent of patients with an anterior placenta had significant increases in maternal serum -fetoprotein (used as a marker for fetomaternal bleeding) compared with 17 percent of patients with a posterior placenta. However, Bowman et al.^[141] found little effect of placental location on the incidence of fetomaternal hemorrhage. Using Kleihauer-Betke testing for the presence of fetal cells in the maternal circulation, they identified transplacental hemorrhage greater than 0.05 ml in 61 percent of those with an anterior placenta and 48 percent with a posterior placenta. Similarly, they found a significant increase in maternal antibody levels in approximately one half of the patients, regardless of placental location. Also, they reported that 56 percent of patients having a cordocentesis without transfusion had significant transplacental hemorrhage.

Although concern for worsened maternal sensitization as a consequence of fetal blood sampling has been raised, there are no longitudinal data available with which to determine whether cordocentesis with fetomaternal bleeding and increased antibody titers worsen the prognosis for subsequent pregnancies.

Currently, the need for cordocentesis to determine fetal antigen status has been obviated by the availability of DNA analysis of amniotic fluid. Thus, the role of umbilical cord blood sampling in the management of alloimmunization is limited to assessment of those fetuses already known to be antigen-positive and who are suspected of having moderate to severe anemia. Because of the technical difficulty and increased hazard (both immediate and remote) associated with the procedure, umbilical cord blood sampling should be used with caution and performed only by properly trained personnel.

Ultrasound and Doppler Studies

Ultrasonographic examination of the fetus has become an extremely important adjunct in the management of the Rh-sensitized pregnancy, primarily as a guide to amniocentesis, fetal blood sampling, and intrauterine transfusion. Ultrasound has also been studied in an effort to identify sonographic findings that might predict the severity of erythroblastosis fetalis and reduce the need for invasive assessments. Polyhydramnios, placental thickness greater than 4 cm, pericardial effusion, dilation of the cardiac chambers, chronic enlargement of the spleen and liver, visualization of both sides of the fetal bowel wall, and dilation of the umbilical vein have all been proposed as indicators of significant prehydropic fetal anemia.^{[142] [143] [144] [145] [146] [147] [148] [149] [150] [151]}

In an effort to determine which, if any, ultrasound parameters are most predictive, Chitkara et al.^[149] reviewed the ultrasound findings just prior to umbilical cord blood sampling on 35 occasions between 21 and 33.5 weeks' gestation in 15 severely sensitized pregnancies. The relationship between fetal hematocrit and the sonographic findings of polyhydramnios, increased placental thickness, increased umbilical vein diameter, and hydrops was studied. All fetuses with hydrops had a hematocrit less than 15 percent, but two of eight fetuses with a hematocrit below 15 percent had a normal sonogram and another had only moderate polyhydramnios. Of 19 fetuses with a hematocrit between 16 and 29 percent, more than half had a normal sonogram, 42 percent had mild to moderate polyhydramnios, and 17 percent had placental thickening. Polyhydramnios was the first and only sonographic sign before fetal anemia (hematocrit <26 percent) in 6 of 10 patients studied serially. Although polyhydramnios may be an early indication of significant hemolysis and fetal anemia, the absence of this sonographic finding did not preclude significant anemia; half of fetuses with normal ultrasound examinations had hematocrits below 30 percent. Although these results indicate that ultrasound is insensitive for detection of fetal anemia, it is important to note that there was no normal control group for comparison, and many of these sonograms were performed when fetuses had already undergone at least one transfusion.

Nicolaides et al.^[147] measured fetal head circumference, abdominal circumference, head/abdomen ratio, estimated intraperitoneal volume, placental thickness, and extrahepatic and intrahepatic umbilical vein diameters in 50 patients prior to umbilical cord blood sampling for severe Rh disease. No fetus had been transfused, and the measurements were compared with those from 410 healthy women with normal singleton pregnancies. The presence of hydrops predicted a fetal hemoglobin less than 5 g/dl in all 12 cases so affected. In the absence of hydropic changes on ultrasound, none of the other ultrasonographic parameters differentiated mild from severe anemia. Half of the fetuses with a hemoglobin less than 5 g/dl had no sonographic abnormality, and no consistent pattern was apparent in those with abnormal ultrasound findings. Of the fetuses with a hemoglobin level of 5 to 10 g/dl, two thirds had a normal ultrasound examination.

Taken together, these data suggest that sonographic findings other than hydrops are not sufficiently reliable in distinguishing mild from severe hemolytic disease, even in experienced hands, and the role of ultrasound in the monitoring of fetuses with severe Rh immunization is still limited to the establishment of gestational

age; monitoring for hydropic changes; and guidance for amniocentesis, umbilical cord blood sampling, and transfusion.

Doppler flow velocity waveforms have also been extensively investigated as noninvasive predictors of fetal anemia^{[152] [153] [154] [155] [156] [157] [158] [159] [160] [161]} and acidosis.^{[162] [163]} Fetal cardiac output and blood velocities in the umbilical artery, umbilical vein, fetal descending aorta, fetal ductus venosus, fetal splenic artery, and fetal middle cerebral artery have all been studied in alloimmunized pregnancies.

Nicolaides et al.^[154] compared fetal aorta Doppler blood velocities in 68 severely immunized fetuses and 218 normal controls. In nonhydropic fetuses, an aortic mean velocity above the normal range suggested fetal anemia, and a normal mean velocity made significant anemia unlikely. However, the authors concluded that because of the large overlap in values between anemic and nonanemic fetuses, Doppler measurements of the aortic blood flow cannot accurately predict the degree of fetal anemia.

In a similar study, Copel et al.^[155] retrospectively found that a calculation based on the peak velocity in the descending aorta was predictive of a fetal hematocrit above or below 25 percent with a high degree of sensitivity. However, their formula and its modifications were not useful in predicting the hematocrit after fetal transfusion. Most importantly, this group was unable to predict the degree of fetal anemia in a prospective evaluation of their method.^[156]

Legarth and colleagues^[159] compared Doppler blood flow velocities to umbilical vein hematocrit during 49 fetal blood sampling or transfusion procedures. Using the S/D ratio, the pulsatility index, and the resistance index, they found no correlation between umbilical artery Doppler indices and fetal hematocrit at the time of blood sampling, and the blood flow velocity indices did not predict fetal hematocrit.

Most recently, Mari and colleagues^[160] measured the peak systolic velocity of the middle cerebral artery in 111 fetuses undergoing cordocentesis for red cell alloimmunization. They found that all fetuses with moderate or severe anemia had peak velocity greater than 1.5 times the median of values derived from normal controls, with the same cutoff having a false-positive rate of 12 percent. Although the study population was relatively large, patients were sensitized to a number of different antigens, and Mari et al. used definitions of anemia not commonly employed in clinical management. Although encouraging, these data await confirmation by others and comparison with standard screening techniques.

In general, fetal blood flow velocity waveforms have not been predictive of acid-base status in Rh-alloimmunized pregnancies. Similarly, although many studies have found statistically significant differences in blood flow indices between groups of anemic and nonanemic fetuses, the wide range and overlap of values in both groups of patients have limited the clinical utility of Doppler technology.

Ultrasound and Doppler ultrasound technology continue to advance rapidly. It seems likely that these noninvasive tools may one day be used to reliably determine the degree of fetal anemia and, thus, to direct fetal management. However, at present, neither ultrasound nor Doppler blood flow analysis can be recommended in lieu of amniotic fluid OD₄₅₀ determinations or fetal blood sampling for determining the need for intrauterine transfusion or delivery in Rh-immunized pregnancies.

Determining the Need for Intrauterine Transfusion

About one half of susceptible infants of Rh-immunized pregnancies do not require intrauterine transfusion or extensive extrauterine therapy. Such fetuses are considered to have mild to moderate hemolytic disease. In general, mild to moderate fetal hemolysis is expected when (1) the involved pregnancy is the first sensitized pregnancy or (2) previously delivered Rh-positive infants have been mildly to moderately affected (mild to moderate anemia without hydrops). In such cases, we perform ultrasound examinations of the fetus every 2 to 4 weeks from 20 weeks' gestation until delivery. If the fetus shows no signs of hydrops, we use amniotic fluid OD₄₅₀ determinations for the initial management, performing the first amniocentesis at 24 to 28 weeks' gestation. The timing of repeat amniocenteses and determination of the need for intrauterine transfusion or delivery are based on the OD₄₅₀ values and trend (Fig. 26-5). If the values fall within the low zone or the

lower half of the middle zone on the Liley graph, amniocentesis is repeated every 2 to 4 weeks, depending on the OD₄₅₀ trend. Severe anemia requiring intrauterine transfusion is suspected when the OD₄₅₀ values rise into the upper quarter of the middle zone or into zone III, especially before 30 weeks' gestation. Depending on the clinical situation, a single OD₄₅₀ value in zone III also may be taken as an indication of severe anemia. If at any time the fetus has evidence of hydrops by ultrasound, one can assume a fetal hematocrit less than about 15 percent, [146], [147] and fetal blood sampling and transfusion should be arranged immediately.

The need for cordocentesis in the management of nonhydropic fetuses with OD₄₅₀ values indicative of severe anemia (and requiring intrauterine transfusion) is controversial. As discussed below, there is no proven advantage to cordocentesis and intravascular transfusion in nonhydropic fetuses, and experienced practitioners

Figure 26-5 Flow diagram outlining the management of an Rh-sensitized pregnancy. The timing of the first amniocentesis is based on the history, maternal titer, and gestational age. At the first amniocentesis, fluid should be sent for determination of fetal antigen status, and if negative, a noninvasive surveillance protocol is continued. In incompatible pregnancies, all patients monitor fetal movements on a daily basis after 26 to 28 weeks and have nonstress tests one to two times weekly and ultrasound exams every 1 to 2 weeks, in addition to assessment of amniotic fluid bilirubin or umbilical cord hematocrit.

have described excellent perinatal outcomes using amniotic fluid OD₄₅₀ values with intraperitoneal transfusions. [164] [165] [166] However, because of the morbidity associated with fetal transfusion regardless of route, it seems appropriate to obtain umbilical cord blood when practical to confirm anemia prior to transfusion. The optimum management in any individual case will be determined by the clinical presentation and the experience and expertise of the physicians involved.

When the obstetric history suggests that the fetus is at risk for moderate to severe hemolysis and hydrops, we are more likely to begin the search for fetal anemia earlier in the pregnancy. In this situation, we usually follow the trend of OD₄₅₀ values, using an extrapolation of the Liley curve, with the understanding that interpretation of OD₄₅₀ values before 24 weeks is difficult. Between 18 and 24 weeks, we stress OD₄₅₀ trends over single values and typically use Queenan's horizontal zones, [125] with OD₄₅₀ values below 0.09 suggesting an unaffected or mildly affected infant and OD₄₅₀ values above 0.15 suggesting fetal anemia. In some cases, especially those with a history of severe second-trimester disease or previous severe disease with misleading OD₄₅₀ values, cordocentesis to determine the fetal hematocrit is a reasonable first step. Again, the optimum management in an individual case will be determined by history, clinical findings, and the experience and expertise of the management team.

At any gestational age, the presence of fetal hydrops should be taken as evidence of severe fetal anemia, and cordocentesis with immediate intravascular transfusion is indicated.

INTRAUTERINE TRANSFUSION IN THE Rh-ALLOIMMUNIZED PREGNANCY

When Liley^[167] reported the first successful intrauterine transfusion in 1963, a new therapy was created that provided obstetricians with a much-needed alternative to preterm delivery in severe erythroblastosis fetalis. The

administration of erythrocytes to the anemic fetus accomplishes two goals: (1) it corrects fetal anemia and consequently improves fetal oxygenation, and (2) it reduces extramedullary hematopoietic demand, leading to a fall in portal venous pressure and improved hepatic function.

Originally, intrauterine transfusions were done by the intraperitoneal route, and this approach was the mainstay of transfusion therapy until the mid-1980s. In 1981, Rodeck et al.^[129] reported the successful intravenous transfusion of two erythroblastotic fetuses using a fetoscopic technique. Although successful, ^[130] the fetoscopic approach is complicated and introduction of the transfusion needle by ultrasound guidance (without the fetoscope) has become the standard technique. ^[168] ^[169] ^[170] ^[171] ^[172] ^[173] ^[174] ^[175] ^[176] The umbilical vein is the most commonly used vessel, usually at its insertion into the placenta.

Intrauterine Intraperitoneal Transfusion

Placement of erythrocytes in the fetal peritoneal cavity reverses fetal anemia by gradual uptake of the transfused red cells into the fetal circulatory system via subdiaphragmatic lymphatics. Perinatal survival following intraperitoneal transfusion is related to gestational age at delivery and the severity of fetal disease, particularly with regard to whether hydrops develops. When transfusions were performed with radiographic guidance, overall neonatal survival was approximately 60 percent, survival of nonhydropic infants was near 70 percent, and less than 40 percent of those developing hydrops survived. ^[38] The routine use of ultrasound for transfusion and monitoring, improvements in transfusion technique, and advances in neonatal care have led to more favorable outcomes (Table 26-3).

Prior to intraperitoneal transfusion, an intravenous line is placed in the mother, and she is often sedated with an intravenous narcotic or short-acting benzodiazepine. Many practitioners also administer an antiemetic and a prophylactic antibiotic. Using real-time ultrasound, fetal size, position, and condition; placental location; and amniotic fluid volume are determined. Intraperitoneal access is best accomplished with the fetus on its side or back, and some authors have suggested external manipulation of the fetus for positioning. ^[121] ^[177] Peritoneal access is ideally accomplished through the lateral or anterolateral abdominal wall, with the fetal bladder and pelvic bones serving as landmarks. Care should be taken to avoid the umbilical cord and its insertion into the fetal abdomen.

After a site for needle insertion is chosen on the maternal abdomen, the area is prepared and draped in sterile fashion, and a local anesthetic is injected. Using a sterile technique, an 18- or 20-gauge needle is directed under continuous real-time ultrasound guidance into the fetal peritoneum, ideally just cephalad and lateral to the fetal bladder. When it appears that the needle tip has entered the fetal peritoneal cavity, saline or a small air bubble is introduced through the needle to verify its location (Fig. 26-6). Although we prefer to infuse the blood through the needle, Bowman^[120] suggests using an epidural catheter passed through a 16-gauge Tuohy needle for the actual transfusion. When the catheter is clearly seen in the fetal peritoneal cavity, the needle is then withdrawn from the maternal abdomen, leaving the catheter threaded for transfusion.

After confirmation that the needle tip or catheter is in the fetal peritoneal cavity, the transfusion is performed at a rate no faster than 5 to 10 ml/min. With real-time ultrasound, the flow of red cells into the peritoneum can usually be visualized. Type O-negative, leukocyte-poor, packed erythrocytes cross-matched with
