the maternal serum are used; the desired hematocrit for the packed cells is 75 to 85 percent. The transfusion is carried out manually with a 20- or 30-ml syringe

connected to the transfusion line with a three-way stopcock.

The volume of blood in milliliters for intraperitoneal transfusion is calculated by subtracting 20 from the gestational age in weeks and then multiplying by 10. Thus, a 28-week fetus would receive 80 ml of blood. This simple formula is intended to provide a reasonable amount of blood to the fetus without creating undue intraperitoneal pressure. When fetal ascites is present, some of this fluid should be gently aspirated before transfusion. Bowman^[139] has suggested that no more than twice the volume of the proposed transfusion should be removed, with a maximum being 150 ml. The rate of absorption of the transfused blood from the peritoneal cavity into the bloodstream is said to be about 12 percent per day in the nonhydropic fetus. In our experience, little or none of the transfused blood is detectable by ultrasonographic examination 3 to 5 days after transfusion in cases in which the fetus was not hydropic. If the fetus is hydropic, red cell uptake is variable and unpredictable; in some cases it is adequate,^[138] but in others absorption is quite poor.

It is important that the fetal heart rate be monitored periodically during the transfusion in case fetal bradycardia occurs. Bradycardia early in the procedure presages fetal death.^[129] Late in the procedure, a fall in the fetal heart rate may indicate compression of the vena cava by increased intraperitoneal pressure. Measurement of fetal heart rate during the transfusion can easily be done with ultrasound.

Bowman^[129] developed a formula for estimating the residual donor hemoglobin in the fetus following transfusion. With a goal of keeping the hemoglobin in the fetus above 10 g/dl, the first and second transfusions are performed about 10 days apart. The timing of subsequent transfusions can then be calculated using the donor hemoglobin and estimated fetal weight, and assuming that 55 percent of the transfusion hemoglobin enters the fetal circulation after intraperitoneal instillation and that the daily red cell loss is about 1/120th of the total. According to Bowman's formula, the basic intraperitoneal transfusion schedule puts the second transfusion about 10 days after the first, and repeat transfusions every 4 weeks thereafter.

The routine use of ultrasound for needle guidance has dramatically reduced the procedure-related morbidity and mortality associated with intraperitoneal transfusion. Confirmation of appropriate needle placement is usually straightforward, but inadvertent transfusion into the bowel, liver, abdominal wall, and retroperitoneum may occur. Infection, premature rupture of the membranes, refractory preterm labor, and fetal distress necessitating immediate delivery continue to be hazards. Bowman and Manning^[164] reported 5 traumatic deaths in 53 transfusions (9.4 percent) during the 2 years prior to instituting ultrasound guidance; there were no deaths in the 64 transfusions after ultrasound was introduced. In a similar analysis, Scott et al.^[165] observed a reduction in traumatic death rate from 8.0 percent to 2.3 percent per transfusion. Most recently, Harman et al.^[175] have reported a traumatic death rate of 7.6 percent per procedure; nearly three fourths of the fetal and neonatal deaths in this series were due to trauma or complications of prematurity and not to Rh disease. Thus, while intraperitoneal transfusion has evolved into a relatively safe procedure, it is not without risk for fetal loss.

Intrauterine Intravascular Transfusion

First described by Rodeck et al.^[129] with fetoscopy, intravascular fetal transfusion has been widely adopted in modified form using ultrasound to guide placement of a needle into the umbilical vein. Direct access to the fetal circulation for transfusion offers several advantages over the intraperitoneal approach: (1) the initial fetal

911

hematocrit can be measured, allowing a more precise calculation of the volume of blood required for transfusion; (2) in some cases, the fetus will have a higher hematocrit than expected and transfusion can be delayed; and (3) a post-transfusion hematocrit can be used to determine whether the transfusion was adequate and when the next one should be scheduled. Also, transfusion into the fetal vascular system ensures complete uptake of the intended red blood cell mass with a more rapid correction of fetal anemia. This is especially important for hydropic fetuses who often do not adequately absorb intraperitoneally transfused erythrocytes. Potential disadvantages of intravascular fetal transfusion include the rare possibility of volume overload in the compromised fetus, procedure-related complications, and the risk of increasing the severity of maternal sensitization due to fetomaternal hemorrhage.

Despite the recent popularity of intravascular over intraperitoneal transfusion, perinatal survival in pregnancies managed with intravascular transfusion is convincingly improved only for hydropic fetuses. Reported overall survival rates range from 76 to 94 percent (Table 26-3). The perinatal survival of nonhydropic fetuses exceeds 90 percent, and approximately 75 percent of hydropic fetuses survive with intravascular transfusion.

Preparation of the patient is the same as for fetal intraperitoneal transfusion, and the approach to the umbilical cord is defined with real-time ultrasound. A 20- or 22-gauge needle is used, and the progress of the needle tip is guided with continuous ultrasound. When the placenta is anterior, we prefer to use the transplacental approach into the umbilical vein (Fig. 26-7). Otherwise, we attempt to enter the vessel by traversing the amniotic sac and puncturing the cord near its insertion into the placenta. If the fetus is particularly active (in spite of sedation administered to the mother) or if the needle passes near the fetal extremities, the fetus can be paralyzed immediately upon entry into the vein by injecting pancuronium bromide, 0.1 to 0.3 mg/kg of estimated fetal weight.^{[178], [179]} As with intraperitoneal transfusion, O-negative, leukocyte-poor, packed erythrocytes cross-matched with the maternal serum are used.

When vascular access is attained, a small amount of blood is withdrawn into one to three heparinized 1-ml syringes and the initial fetal hematocrit immediately determined. With adequate visualization using ultrasound, there is usually little doubt about the proper placement of the needle tip in the fetal circulation. Comparison of the red cell indices to those of a maternal sample can help confirm that the blood sample is of fetal origin; in addition to the expected difference in hematocrit, fetal red cells have a higher mean corpuscular volume than

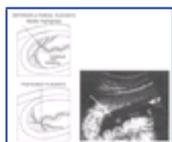

Figure 26-7 Needle placement for intravascular fetal transfusion.

912

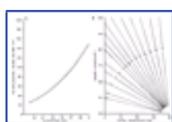

Figure 26-8 Graphs used to rapidly determine the volume of blood to be transfused intravascularly to achieve a posttransfusion hematocrit of 40 to 45 percent. First, the estimated fetoplacental blood volume (EFBV) is determined using the gestational age and *A*. Second, the pretransfusion fetal hematocrit and the donor blood hematocrit are used in conjunction with *B* to derive the multiplying factor. This factor is then multiplied by the EFBV to determine the amount of blood to be transfused. For example, at 26 weeks' gestation, the EFBV is found on the abscissa of *A* to be 85 ml. If the pretransfusion hematocrit is 20 percent and the donor blood hematocrit is 80 percent, the multiplying factor derived from *B* is 0.5. Multiplying this number by the EFBV (0.5 x 85 ml) shows that about 42 ml should be transfused. (Adapted from Nicolaidis KH, Clewell WH, Mibashan RS, et al: Fetal haemoglobin measurement in the assessment of red cell isoimmunization. *Lancet* 1:1073, 1988.)

adult erythrocytes. One sample should be used to determine the fetal antigen status if it is still uncertain.

Several different methods of estimating the volume of blood needed for transfusion have been reported.^{[181] [182] [183] [184]} A posttransfusion hematocrit of around 40 percent is generally the target of these formulae, although some have suggested that transfusion of larger volumes to a hematocrit of 45 to 55 percent is superior.^[185]

We calculate the volume of blood to be transfused according to the method described by Nicolaidis et al.,^[189] with a posttransfusion hematocrit of 40 to 45 percent as the usual goal. The initial fetal hematocrit, the hematocrit of the donor blood, and the gestational age are used in conjunction with the graphs shown in Figure 26-8 to determine the amount of blood to be infused. When the infusion is started, streaming or turbulence can be seen within the vessel, confirming that the needle tip is still within the vein. We infuse the blood at a rate of about 10 ml/min. At the end of the transfusion and before withdrawing the needle, a minute or so of circulation time is

allowed; then a post-transfusion sample is drawn for measurement of the final hematocrit.

Following intravascular transfusion, the decline in the donor hematocrit is most dependent on the life span of the donor erythrocytes, the rate of fetal growth (and increased vascular volume), and the ratio of fetal to donor erythrocytes (since the fetal erythrocytes are subject to continued hemolysis). The latter is most influential between the first and second intravascular transfusions, when the ratio of fetal cells to donor cells is greatest. MacGregor and colleagues [186] have used the following equations to predict the fetal hematocrit after transfusion: Predicted Hct after first transfusion = $[(Hct_f - Hct_i) \times (EFW1/EFW2) \times (120 \text{ days elapsed})] \div 120$ Predicted Hct after subsequent transfusions = $[Hct_f \times (EFW1/EFW2) \times (120 \text{ days elapsed})] \div 120$

913

where Hct_f is the post-transfusion hematocrit, Hct_i is the initial (pretransfusion) hematocrit. EFW1 is the estimated fetal weight at the index transfusion, and EFW2 is the estimated fetal weight at the subsequent transfusion. Using different methods, other authors have predicted similar hematocrit changes. [187]

On average, the decline in the fetal hematocrit following the first transfusion is about 1.5 percent per day; following subsequent transfusions, the decline in fetal hematocrit is about 1.0 to 1.2 percent per day. Using intravascular transfusions for the management of severe fetal hemolysis, repeat transfusions are scheduled to keep the fetal hematocrit above 20 to 25 percent.

Although most authors recommend simple transfusion, some perform intravascular exchange transfusions, feeling that exchange transfusion may allow a longer interval between intravascular transfusions by replacing a greater volume of the fetal cells with donor cells. [171] Also, exchange transfusion is preferred in some centers because of the fear that the increase in blood volume with simple transfusion might compromise fetal cardiac capacity. [171], [174] These fears are probably unfounded, as it seems that even a hydropic fetus can tolerate a bolus infusion of red cells without further compromise. [188]

Morbidity and mortality related to the technique of vascular access and transfusion are similar to those with intraperitoneal transfusion. [136], [172], [174], [176] Fetal bradycardia is the most common problem, occurring in 8 to 12 percent of cases, although it is usually transient and only rarely requires immediate delivery. Postprocedure infection and premature rupture of the membranes have also been reported. The reported fetal death rate ranges between 0.6 percent [175] and 4.7 percent [136] per procedure, with hydropic fetuses being at greatest risk. Overall, it appears that intravascular transfusion in experienced hands seems to have a procedure-related complication rate of around 10 to 15 percent and a perinatal mortality rate of between 1 and 5 percent.

Using intravascular transfusions alone probably increases the total number of procedures required for each pregnancy because the volume of blood transfused at each procedure is smaller than that given via the intraperitoneal route. Also, up to 80 percent of blood transfused into the peritoneal cavity of nonhydropic fetuses appears in the fetal circulation, [189] a figure considerably higher than originally thought. Finally, as mentioned above, concern has been raised that intravascular procedures may increase maternal sensitization and iatrogenically worsen the disease. [93], [139], [141] It appears that umbilical cord blood sampling and intravascular transfusion can be associated with significant fetomaternal bleeding and a heightened maternal immune response, but actual clinical data from subsequent pregnancies are not available. Additionally, comparative data from intraperitoneal procedures are not available, and it is not certain whether increases in -fetoprotein and anti-D are greater following intravascular transfusion than following intraperitoneal transfusion.

Intraperitoneal versus Intravascular Transfusion

For the hydropic fetus, analysis of the collective experience of the last 15 years definitely shows an improved survival rate using intravascular transfusion when compared with treatment with intraperitoneal transfusion. However, the difference in outcome between the two techniques is much less clear in nonhydropic fetuses. In the absence of hydrops, survival rates of 80 to 100 percent have been documented for both methods, with near-identical rates of survival when the large published series are combined (Table 26-3). Unfortunately, a prospective, randomized clinical trial designed to determine the superior technique for the nonhydropic fetus has not been performed.

In an attempt to compare the two methods, Harman et al. [175] analyzed results from patients who underwent intravascular and intraperitoneal transfusions for severe fetal anemia. Forty-four patients undergoing 173 intravascular transfusions were compared retrospectively to 44 fetuses treated with 104 intraperitoneal transfusions in the same institution and matched for severity of disease, placental location, and gestational age. The authors concluded that intravascular transfusion was superior, based on a higher survival rate, a greater gestational age at delivery, and significant reductions in low Apgar scores, cesarean delivery rate, the need for and number of neonatal exchange transfusions, and intensive care nursery admissions and duration of stay. Additionally, the intraperitoneal group had a higher procedure-related mortality (7.7 percent vs. 0.6 percent per transfusion) and a greater overall rate of maternal complication (12.5 percent vs. 3 percent). However, the survival of nonhydropic fetuses was not significantly different between the two treatment groups, and the morbidity data were not analyzed separately for hydropic and nonhydropic fetuses. Acknowledging that the difference in survival for nonhydropic fetuses was statistically unconvincing, the authors nonetheless argued that the lower procedure-related loss rate with intravascular treatment was clinically significant and that intraperitoneal transfusion should be reserved for those situations where intravascular transfusion is impossible due to position of the fetus and cord.

Combined Intravascular Intraperitoneal Transfusion

In an effort to reduce the number of transfusions necessary during treatment of a severely involved pregnancy, Nicolini et al. [190] have combined intravascular and intraperitoneal

914

transfusions. After intravascular transfusion to a fetal hematocrit of approximately 40 percent, additional blood calculated to raise the intravascular hematocrit to 60 percent was then transfused intraperitoneally. Using the estimated decline in fetal hematocrit and clinical parameters to decide upon the timing of the next transfusion, the authors performed only 3.2 procedures per patient, and the mean fall in hematocrit was slightly less than 1 percent per day. Comparison of 32 patients who had combined procedures to another 17 who received only intravascular transfusions revealed a slightly increased mean interval between transfusions (24.2 vs. 21.6 days) and a higher fetal hematocrit at the time of the subsequent procedure (27.0 vs. 23.2 percent). Although these differences achieved statistical significance, their clinical importance is unclear. While some authors have advocated routinely combining intravascular and intraperitoneal transfusion, [191] it is unknown whether the addition of intraperitoneal erythrocytes can reduce the number of transfusions per pregnancy or improve the outcomes achieved with intravascular transfusion alone. Because the increased morbidity associated with intraperitoneal transfusion likely offsets any benefits of the combined procedure, we do not routinely perform combined intravascular and intraperitoneal transfusions.

Other Therapies

A number of noninvasive alternatives to intrauterine transfusion have been investigated for the treatment of fetal hemolysis. Most of these alternative therapies have been aimed at modifying the maternal immune response so as to decrease the severity of erythroblastosis. Two of these, promethazine and oral ingestion of Rh-positive erythrocytes, are of historical interest only and were never proven to be of benefit. [192], [193], [194], [195]

Plasmapheresis to reduce the level of maternal anti-D has been used in the treatment of severe Rh alloimmunization. Although the removal of several liters of plasma per week will result in a transient reduction in the anti-D titer during or immediately after treatment, a chronic, significant reduction in antibody titer is difficult, if not impossible, to achieve by this technique. [196], [197], [198] Some studies have suggested a benefit from plasmapheresis, but these results are difficult to interpret because of the concurrent use of other treatments and the lack of controls. [199], [200] Furthermore, all studies of plasmapheresis in which several or more liters of plasma were removed weekly demonstrated an increase in anti-D titers or concentration soon after plasmapheresis was stopped. This "rebound" phenomenon has been attributed to the removal of the negative feedback influence on further anti-D production by high circulating titers of anti-D antibody. [201] Repeated, "small-volume" plasmapheresis may avoid antibody rebound. [201] The potential usefulness of plasmapheresis must be tempered by its potential for serious consequences for the mother and fetus, including sepsis. [197], [198] Lacking a clearly documented benefit, plasmapheresis is not currently used at most centers in the treatment of severe Rh sensitization.

Plasmapheresis in combination with immunosuppression to prevent antibody rebound has also been used to treat severe Rh alloimmunization. Odendaal et al. [202] reported their experience with nine patients, seven of whom had a previous pregnancy loss or neonatal death directly or indirectly due to alloimmunization. Using plasmapheresis three to seven times a week and immunosuppression with azathioprine and prednisone, eight patients delivered liveborns between 28 and 33 weeks' gestation, with the single fetal death being associated with a placental abruption. Again, because of the potential for morbidity with plasmapheresis and immunosuppression, and because benefit has not yet been demonstrated in adequate numbers of patients, such therapy is not commonly used.

The successful use of high-dose intravenous immunoglobulin (IVIg) in platelet alloimmunization has led to its use in the treatment of severe Rh alloimmunization. [203] [204] [205] [206] [207] [208] [209] The mechanism of action is uncertain, but is thought to be via blockade of Fc-mediated antibody placental transport (limiting the transplacental passage of anti-D to the fetus), by blockade of Fc receptors in the fetal reticuloendothelial system (inhibiting the removal and destruction of anti-D-coated erythrocytes in the fetal spleen and liver), or by feedback inhibition of maternal anti-D production. It is most likely that the effect of IVIg is at the maternal or placental level, since anecdotal evidence suggests that administration of IgG directly to the fetus is not reliably effective in either Rh disease [210] or platelet alloimmunization. [211] , [212] Also, placental transport of exogenous IgG may be limited before 32 weeks' gestation. [213]

Unfortunately, data regarding IVIg use are mostly case reports and small case series using very different doses and schedules, and no sizable randomized trials are available. For instance, Marguiles et al. [204] administered IVIg to 24 Rh-sensitized women at a dose of 400 mg/kg for 5 consecutive days, every 2 weeks. All patients had either OD₄₅₀ results suggesting severe anemia, or a severely affected fetus in a previous pregnancy. None of the treated fetuses developed hydrops or required transfusion in utero or as neonates. Porter et al. [205] reported a patient with severe Rh disease whose clinical course was improved by weekly administration of IVIg, given at 1,000 mg/kg.

Deka et al. [206] treated six patients with severe Rh sensitization who had previous pregnancies complicated by hydrops at 28 to 34 weeks, four with stillbirths. Beginning at 14 to 18 weeks, they infused 100 mg/kg

IVIg every 3 to 4 weeks until fetal transfusion or delivery was necessary. Four patients delivered after 34 weeks without fetal treatment, and although the others required intrauterine transfusion, both delivered after 32 weeks.

Other groups have used IVIg but with less success. Voto et al. [207] reported a higher survival rate in selected Rh-sensitized patients who received IVIg, but found no improvement in the number of intrauterine transfusions necessary, the incidence of severe fetal anemia, or neonatal morbidity. Similar unimpressive findings have been reported elsewhere, [208] and a publication bias favoring positive outcomes is likely.

The success of IVIg therapy in ameliorating some cases of severe Rh disease presents exciting possibilities. Currently, use of IVIg should be reserved for the most severe cases that are refractory to traditional treatment. Further study and experience with more patients will be necessary before IVIg therapy has a place in the routine management of severe Rh immunization.

Timing of Delivery

During the early 1960s, liberalized use of preterm delivery markedly reduced the incidence of perinatal death in Rh-sensitized pregnancies, primarily by decreasing the incidence of intrauterine death. [114] , [214] However, severely affected fetuses continued to die in utero or from complications of prematurity. Fortunately, refinements in the technique of intrauterine transfusion have made possible the prolongation of pregnancy until a gestational age compatible with neonatal survival is reached. Also, the analysis of the phospholipid content of amniotic fluid to determine fetal pulmonary maturity has greatly clarified neonatal risk in relation to the timing of delivery. Finally, the tremendous improvements in neonatal care over the past three decades have led to excellent survival rates, with acceptable morbidity rates, for even the very preterm infant.

If the history and antenatal studies indicate only mild fetal hemolysis, we undertake delivery by induction of labor at 37 to 38 weeks' gestation, unless fetal pulmonary maturity is documented earlier by amniocentesis. In these cases, fetal pulmonary maturation does not seem to be either delayed or accelerated by disease, and amniotic fluid studies accurately reflect fetal maturity. [215] , [216] If the cervix is not ripe, we typically use intracervical prostaglandin gel prior to oxytocin induction.

With severely sensitized pregnancies, the risks of continued cord blood sampling and transfusions must be weighed against the expected neonatal morbidity and mortality associated with early delivery. Because the overall neonatal survival rate in most neonatal intensive care nurseries is greater than 95 percent after 32 weeks, procedures have generally been timed so that the last transfusion is performed at around 30 to 32 weeks' gestation, with patients then delivered at 32 to 34 weeks after maternal steroid administration to enhance fetal pulmonary maturity.

A number of authors, in the interest of limiting neonatal morbidity, now recommend intrauterine transfusion up to 36 weeks' gestation when intravascular transfusion is feasible. [217] Delivery can then be accomplished between 37 and 38 weeks. Because the procedure-related death rate likely decreases with advancing gestational age, others have proposed performing transfusion as late as 37 weeks in selected cases, in order to decrease neonatal morbidity and cost. [218]

Rather than subject the fetus to the risk of repeated intrauterine transfusions, we generally time the last procedure so that delivery can be carried out at about 34 to 36 weeks. Overall neonatal survival approaches 100 percent at this gestational age and long-term morbidity from prematurity is exceedingly low. Regardless of the usual institutional practices, individual case circumstances need to be carefully weighed when making the decision as to when the fetus should be delivered.

SENSITIZATION CAUSED BY MINOR ANTIGENS

In addition to the D antigen, hundreds of other distinct antigens exist on the red blood cell surface. Known as "minor," "atypical," or "irregular" antigens, they have different frequencies in different ethnic populations. For instance, about 30 percent of blacks are positive for the Duffy antigen, whereas less than 5 percent of whites are Duffy positive.

In the past, minor antigens were a relatively infrequent cause of maternal sensitization and fetal or neonatal hemolytic disease. Because of the reduction in Rh disease brought about by Rh-immune globulin prophylaxis, minor antigen sensitization has become relatively more frequent in pregnancy. In fact, antibodies to minor antigens are much more common in the general population than antibodies to the D antigen.^[90]

The large majority of cases of minor antigen sensitization are caused by incompatible blood transfusion. Although some authors have argued for adoption of routine screening of Kell status, most blood banks do not routinely assess donorrecipient compatibility for antigens other than ABO and RhD. Overall, antibodies to minor antigens occur in about 1.5 to 2.5 percent of obstetric patients.^[219],^[220] Fortunately, some of the most common atypical antibodies, such as anti-Le^a, anti-Le^b, and anti-I, do not cause fetal or neonatal hemolysis. Le^a

916

and Le^b, the Lewis antigens are not true erythrocyte antigens, but are secreted by other tissues and then adsorbed onto the red cell surface.^[221] Fetal erythrocytes acquire very little antigen in utero and thus react only weakly to anti-Lewis.

However, antibodies to a number of the minor antigens can result in fetal anemia and hydrops. Of the potentially serious antibodies, anti-E, anti-Kell, anti-c, anti-c + E, and anti-Fy^a (Duffy) are the most common.^[90] A complete listing of the irregular antigens and antibodies as compiled by Weinstein^[222] is shown in [Table 26-4](#), with the potential severity of fetal involvement and proposed management listed.

As with RhD, the genes coding for a number of the minor antigens have been identified and DNA-based diagnosis is commercially available.^[223]^[224]^[225]^[226]^[227]^[228] The C, c, E, and e genes have been identified together on chromosome 1, Duffy is elsewhere on chromosome 1, Kell is on the long arm of chromosome 7, and Kidd (Jk^a) is found on chromosome 18. Using PCR techniques to amplify fetal DNA, fetal antigen status can be reliably determined from fetal cells in uncultured amniotic fluid. At the time of the first amniocentesis, an additional 5 ml of amniotic fluid should be withdrawn and sent for fetal genotyping, if available.

In general, management of the pregnant patient with antibody to one of the significant minor antigens has been much the same as for RhD immunization. Pregnancies are followed using previous history as a guide, paternal antigen and zygosity testing to determine risk, frequent measurement of maternal antibody levels until a critical titer is reached, then serial amniocenteses with assessment of fetal antigen status and amniotic fluid bilirubin levels, and transfusion or delivery based on the OD₄₅₀ values and trends.^[120],^[229] However, few centers have a large number of pregnancies affected by minor antigen sensitization; thus, establishment of a critical maternal titer is difficult, and it is uncertain whether amniotic fluid bilirubin studies are as reliable as with RhD alloimmunization.

Several of the minor antigens deserve special mention. The M antigen is part of the MNSs blood group system and is one of the commonly encountered minor antigens, since approximately 20 to 25 percent of the population is M negative. Improvements in antibody screening techniques have improved the sensitivity of detection of anti-M, and the frequency of identification of maternal anti-M is apparently increasing. De Young-Owens et al.^[229] reported on 115 pregnancies complicated by M alloimmunization over more than 25 years. Of the 70 incompatible fetuses, none had severe fetal or neonatal anemia, and only 9 (13 percent) required phototherapy. Also, 104 of the 115 pregnancies (90 percent) had an initial anti-M titer of 1:4 or less, and only one of these patients had a titer rise to greater than 1:32. The authors concluded that there is limited benefit to following serial anti-M titers, and if there is no previous history of an affected fetus and the initial titer is 1:4 or less, no further assessment of anti-M titers is necessary.

However, there are a number of case reports of severe fetal and neonatal hemolytic disease due to M sensitization.^[230],^[231] It has been suggested that although most anti-M is an IgM antibody with no implications for the fetus, some sensitized women produce a potent anti-M IgG which can cross the placenta and result in fetal anemia and hydrops.

Despite the favorable experience of De Young-Owens et al.,^[229] we assess paternal M antigen status and perform serial anti-M titers in sensitized pregnancies without a history of an affected fetus. If the titer rises unexpectedly, amniocentesis is performed for amniotic fluid bilirubin studies and determination of fetal M status. Because anti-M does not seem to be as aggressive or as serious as most of the other antigens, our threshold for amniocentesis is generally higher than for the other serious antigens, although we consider each case on an individual basis.

The Kell antigen also requires additional discussion. Pregnancy with Kell sensitization can result in severe fetal anemia, hydrops, and fetal death. In common usage, "Kell" refers to the K or K1 antigen of the Kell blood group system. Only about 9 percent of whites are positive for the Kell antigen; the population frequency of kk (Kell negative) is 91.1 percent, Kk (heterozygous positive) 8.7 percent, and KK (homozygous positive) 0.2 percent.^[7] About 0.2 percent of pregnant women are positive for anti-Kell and, as mentioned above, most cases of immunization are the result of Kell-incompatible transfusion.

A number of investigators have suggested that the fetal anemia associated with Kell sensitization is qualitatively different from that of Rh disease and requires a different management protocol.^[232],^[233] Specifically, maternal titers and amniotic fluid OD₄₅₀ values may not be as predictive of the degree of fetal anemia as with RhD sensitization. For example, Berkowitz et al.^[232] reported a case of fetal hydrops and death due to Kell sensitization despite amniotic fluid OD₄₅₀ values trending downward in the lower third of the Liley mid-zone. Similarly, Parilla et al.^[233] reported a Kell-positive fetus that developed hydrops despite declining values in zone II of the modified Liley curve. Copel et al.^[234] reported a case of fetal hydrops with a maternal anti-Kell titer of 1:4; in another patient, the anti-Kell titer spontaneously rose from 1:32 to 1:2,048 even though the fetus was Kell negative.

It has been proposed that the mechanism of anemia in Kell sensitization is different than with RhD disease. Although hemolysis is important and Kell antibody can activate the complement cascade to attach C3 to red cell membranes,^[235] it also appears that suppression of

fetal erythropoiesis plays a role in the development of fetal anemia due to anti-Kell. [\[239\]](#) [\[240\]](#) [\[241\]](#)

Vaughn et al. [\[239\]](#) compared amniotic fluid bilirubin concentrations and nucleated red blood cell and reticulocyte counts in fetuses with Kell and RhD alloimmunization. Kell-sensitized pregnancies had lower levels of all three parameters and no relation between fetal hematocrit and reticulocytosis, in contrast to Rh-sensitized pregnancies. Similar findings were reported by Weiner et al., [\[240\]](#) who also showed that fetal erythropoietin levels in both groups rose significantly as hematocrit declined. Weiner and colleagues speculated that the anemia of Kell sensitization is associated with greater hemolysis of nonhemoglobinized or incompletely hemoglobinized erythroid precursors.

To test the effect of Kell sensitization on fetal erythropoiesis, Vaughn et al. [\[241\]](#) compared the growth in vitro of immature Kell-positive and Kell-negative red cells in the presence of anti-Kell IgG antibody. They found that anti-Kell antibody inhibited Kell-positive erythroid progenitor cell growth in a dose-dependent fashion, with the more immature progenitor cells being affected the most. There was no inhibition of Kell-negative cells, and anti-D did not impair the growth of immature RhD-positive erythrocytes.

Caine and Mueller-Heubach [\[235\]](#) described their clinical experience with 127 Kell-sensitized pregnancies. Thirteen (10 percent) had an affected Kell-positive fetus, and five (38 percent of those affected) had severe disease. Only 3 percent of pregnancies with a maternal titer of less than or equal to 1:16 had a Kell-positive fetus compared with 29 percent of those with a titer greater than 1:16. No patient with a titer less than or equal to 1:16 had a fetal death, and all patients with a poor perinatal outcome had a titer greater than or equal to 1:128 at delivery. Importantly, no patient with a poor outcome had an amniotic fluid OD₄₅₀ value in the highest Liley zone, suggesting that serious hemolytic disease develops at lower OD₄₅₀ values than with Rh sensitization.

Leggat and co-workers [\[236\]](#) described 194 pregnancies over 25 years in which anti-Kell was the only antibody identified. Of the 178 unaffected babies, 106 (60 percent) had maternal titers greater than or equal to 1:16. There were 16 affected infants (9 percent of the total), 10 with mild disease and 6 with moderate or severe anemia. Of the six mothers who delivered affected infants, four had titers greater than or equal to 1:16, while two had titers less than or equal to 1:8. Amniotic fluid analysis was also performed in pregnancies that resulted in 16 unaffected and five affected newborns; fetuses with disease of moderate or greater severity had OD₄₅₀ values trending upward or in the upper part of the Liley midzone, but four unaffected fetuses had OD₄₅₀ values that would be associated with moderate to severe hemolysis in Rh disease. The authors concluded that neither maternal antibody titer or amniotic fluid analysis was a satisfactory predictor of fetal status.

Bowman and colleagues [\[242\]](#) on the other hand, found that amniotic fluid OD₄₅₀ measurements were accurate in predicting fetal status in 16 of 18 Kell-negative pregnancies. In 10 of 12 Kell-positive fetuses, OD₄₅₀ values appropriately predicted disease severity, although the OD₄₅₀ level of one fetus with a hydropic death was in the lower half of zone II, and those of another fetus with only moderate disease reached the line between zones II and III.

McKenna et al. [\[243\]](#) reported their experience with 21 pregnancies affected with Kell alloimmunization. Eight (38 percent) were severely affected, and all of these had maternal anti-Kell titers of 1:32 or greater. Using a Liley curve extrapolated back to 20 weeks, the authors also showed that OD₄₅₀ values which remained in zone I excluded severe disease. Similar to others' experience (and to that with Rh disease), values in zone III nearly always indicated severe involvement, whereas values in zone II were difficult to characterize, being a mix of severe, mild, and unaffected fetuses.

Because of concern for misleading amniotic fluid results, several authors suggested a management scheme for Kell-sensitized pregnancies that includes umbilical cord blood sampling at 20 weeks' gestation when the father is either Kell positive or of uncertain status. [\[237\]](#), [\[244\]](#) With this protocol, more than half of the fetuses will be found to be Kell negative, and no further testing will be necessary; rarely, a fetus will be found to be significantly anemic and can be promptly transfused. However, management after 20 weeks' gestation of the approximately 80 percent of Kell-positive fetuses destined to have mild or moderate disease is not addressed by this cord sampling protocol. Also, the more recent advances in diagnosis of antigen status from amniotic fluid obviate the need for cordocentesis for determining fetal blood type.

Recognizing that amniotic fluid bilirubin studies may be misleading in some pregnancies and that more liberal use of umbilical cord blood sampling is appropriate, we agree with Bowman et al., [\[242\]](#) and McKenna et al. [\[243\]](#) that serial OD₄₅₀ measurements are still of value. When the father is known to be Kell negative, the fetus will also be Kell negative, and no surveillance or testing is necessary. When the father is Kell positive or of uncertain status and there is no history of severe fetal involvement, we follow maternal anti-Kell titers, track fetal movements, and perform serial ultrasounds as long as the maternal titer remains below 1:8. For patients whose titers rise above 1:8 or who have a history of fetal involvement, we perform serial amniocenteses every 1 to 4 weeks unless the fetus is known to be Kell negative, beginning at 20 to 28 weeks depending on history, maternal titer, and previous

OD₄₅₀ value. At the first amniocentesis, we also determine fetal Kell antigen status by DNA testing. As with RhD disease, we use a modified Liley curve extrapolated back to 24 weeks ([Fig. 26-4](#)); before 24 weeks' gestation, we typically use Queenan's boundaries [\[125\]](#) with an emphasis on OD₄₅₀ trends. If OD₄₅₀ levels rise into or above the middle of zone II, we recommend umbilical cord blood sampling for hematocrit, with blood ready for transfusion if necessary. Between amniocenteses and/or fetal blood samplings, we perform nonstress tests and frequent ultrasounds, watching for any signs of developing hydrops.

PLATELET ALLOIMMUNIZATION

Like erythrocytes, platelets contain specific surface antigens, and maternal sensitization to platelet antigens can occur when there is an incompatibility between fetus and mother. In a situation analogous to Rh disease, alloimmune thrombocytopenia is the result of maternal sensitization to incompatible fetal platelets with transfer of antiplatelet antibody to the fetus and subsequent sequestration of platelets in the reticuloendothelial system. ^[245] In affected cases, the maternal platelet count is normal, and fetal/neonatal thrombocytopenia ranges from mild to profound.

Five major biallelic systems of platelet-specific antigens have been well described. Formerly known as PI^{A1}/PI^{A2}, Ko^b/Ko^a, Bak^a/Bak^b (Lek^a/Lek^b), Pen^a/Pen^b (Yuk^b/Yuk^a), and Br^b/Br^a, a new and simplified system of nomenclature for the human platelet antigens has been proposed (Table 26-5). ^[246] The major platelet antigen families are now numbered in chronologic order of discovery (HPA-1 through HPA-5), and the older naming system is gradually being replaced. Platelets also express HLA class I antigens but not those of class II. ^[247], ^[248]

TABLE 26-5 -- PLATELET-SPECIFIC ALLOANTIGENS

Old Nomenclature	New Nomenclature	Gene Frequency
PI ^{A1}	HPA-1a	0.85
PI ^{A2}	HPA-1b	0.15
Ko ^b	HPA-2a	0.93
Ko ^a	HPA-2b	0.07
Bak ^a (Lek ^a)	HPA-3a	0.61
Bak ^b (Lek ^b)	HPA-3b	0.39
Pen ^a (Yuk ^b)	HPA-4a	0.99
Pen ^b (Yuk ^a)	HPA-4b	0.01
Br ^b	HPA-5a	0.89
Br ^a	HPA-5b	0.11

Sensitization to the HPA-1a (PI^{A1}) antigen is the etiology in about three fourths of cases of neonatal alloimmune thrombocytopenia. Approximately 2 percent of whites, 0.4 percent of blacks, and less than 0.1 percent of Asians are negative for HPA-1a. Sensitization to HPA-5b (Br^a) and HPA-3a (Bak^a) account for most of the remainder of cases of neonatal alloimmune thrombocytopenia; about 15 percent of whites are negative for HPA-3a, and less than 1 percent of whites are negative for HPA-5b. ^[247], ^[248] Although HLA antigens are less immunogenic on platelets than on other cells, anti-HLA antibodies can rarely cause neonatal alloimmune thrombocytopenia. ^[249]

Neonatal alloimmune thrombocytopenia occurs in about 1 in 1,000 to 1 in 2,000 births and is probably the most common reason for severe thrombocytopenia in the newborn. ^[245], ^[250], ^[252] Even though fetalmaternal incompatibility to platelet antigens is relatively common, only a small fraction of gravidas become sensitized. For instance, around 2 percent of all pregnancies are complicated by HPA-1a incompatibility, and as many as 60 percent of pregnancies are mismatched for HPA-3a. The reasons for the infrequent occurrence of alloimmunization are not completely clear, but in addition to platelet antigen incompatibility, maternal HLA class II type appears to influence susceptibility to platelet alloimmunization; HLA-DRw52 is associated with HPA-1a alloimmunization, and HLA-DRw6 is associated with sensitization to HPA-5b. ^[253]

The clinical severity of neonatal alloimmune thrombocytopenia varies widely. Approximately 90 percent of affected newborns have diffuse petechiae, and 9 to 12 percent suffer intracranial bleeding, with a neonatal mortality of 5 to 13 percent. ^[247], ^[250] About 45 percent of cases of central nervous system hemorrhage are thought to occur before birth, often resulting in porencephalic cysts that can be identified with ultrasound. ^[254] Fetal thrombocytopenia appears to be most common in the third trimester, but has been detected as early as 20 weeks' gestation. ^[134], ^[255]

Unlike Rh alloimmunization, maternal titers of antibody to the platelet antigen are not predictive of clinical outcome, antiplatelet IgG production can occur in the first pregnancy, and firstborn children are often affected. Primiparas account for between 20 and 60 percent of identified cases, ^[247], ^[256] and mothers at risk are usually identified only after the birth of an affected newborn.

Although routine testing of pregnant women for HPA status has been proposed, ^[257] there are several reasons why all pregnant women are not screened for antigen status or the presence of antiplatelet antibodies. First, perhaps one fourth of cases of alloimmune neonatal thrombocytopenia are not due to the most commonly involved antigen. Second, the maternal immune response seems to be influenced by other factors such

as HLA type, and only a minority of infants of mothers negative for the platelet antigen will develop significant thrombocytopenia. Finally, adequate analyses of risk/benefit ratio and cost effectiveness have not been performed.

Recognizing the possibility of ascertainment bias, the incidence of recurrent fetal/neonatal thrombocytopenia following delivery of an affected newborn is thought to be 90 to 95 percent, generally of equal or greater severity. ^[247], ^[248] Bussel and colleagues ^[258] described the natural history of alloimmune thrombocytopenia in 107 untreated fetuses; nearly all cases were identified because of thrombocytopenia in an older sibling. With cordocentesis at a mean gestational age of 25 weeks, 42 percent had a platelet count less than the newborn count of their older sibling, 70 percent had a platelet count less than 50,000 cells/l, and 50 percent had platelet counts less than 20,000 cells/l. Seven fetuses had an initial platelet count greater than 80,000/l and were not treated; follow-up sampling showed decreases in platelet count of at least 10,000 cells/l per week in these fetuses.

Bussel et al. ^[259] found no correlation between the platelet count at cordocentesis and the degree of thrombocytopenia in the previously affected sibling. However,

patients with HPA-1a incompatibility had lower cord blood platelet counts than those sensitized to other antigens, and a past history of antenatal intracranial hemorrhage predicted a more severe thrombocytopenia.

The management of patients at risk for neonatal alloimmune thrombocytopenia is directed at preventing hemorrhage in the fetus and neonate. Before the availability of umbilical cord blood sampling, the management strategy for these pregnancies was to avoid fetal trauma with bed rest during the pregnancy and cesarean delivery before labor.^[259], ^[260] However, since approximately half of fetuses who suffer intracranial bleeding do so before labor, avoidance of labor and vaginal delivery only partially reduces the associated morbidity and mortality. As mentioned, maternal platelet counts are normal, and maternal antibody levels are not predictive of fetal platelet count. Umbilical cord blood sampling and direct measurement of fetal platelet count is currently the only method to accurately assess disease severity.

Several strategies have been proposed for the management of pregnancies at risk for alloimmune thrombocytopenia. One group has suggested that the diagnosis of fetal thrombocytopenia be made by cordocentesis at 20 to 22 weeks' gestation, and patients with an affected fetus should be advised to rest carefully and avoid abdominal trauma.^[261], ^[262] At 37 weeks' gestation, umbilical cord blood sampling can be repeated, and if the fetal platelet count is normal, labor can be induced; if the platelet count is less than 50,000 cells/l, maternal platelets are transfused into the fetal circulation using the following formula, allowing safe induction of labor and vaginal delivery:

where V is volume of platelet concentrate to be transfused, EFBV is estimated fetal blood volume, and FPC is fetal platelet count.^[262] This approach, with a single fetal platelet transfusion immediately before delivery, does not address the possibility of spontaneous hemorrhage in utero, but may be the most reasonable management plan for fetuses considered to be at low risk for antepartum bleeding.

In an effort to prevent antepartum intracranial bleeding, Nicolini et al.^[263] and Murphy et al.^[264] reported the use of serial platelet transfusions throughout the third trimester. Both patients described had previous infants with HPA-1a alloimmune thrombocytopenia leading to severe antepartum intracranial hemorrhage with neurologic sequelae. Fetal thrombocytopenia was documented with cordocentesis, and weekly platelet transfusions were begun at 26 to 29 weeks. Platelets transfused in utero have a short life span (even HPA-1a-negative platelets), and counts dropped from posttransfusion levels of over 150,000 cells/l to less than 50,000 cells/l at the next weekly transfusion. The pregnancies were carried to 32 and 35 weeks, respectively, and delivered by cesarean section. Neonatal platelet counts were greater than 44,000 cells/l, and neither infant suffered intracranial bleeding. Because of the potentially high fetal morbidity and mortality associated with frequent cordocentesis in alloimmune thrombocytopenia^[265] and because of the difficulty and risks of repeated maternal platelet pheresis, this management scheme has not been widely adopted. Fetal intracranial hemorrhage is rare before the third trimester, and it has been suggested that the weekly intrauterine platelet transfusion might be limited to the third trimester, with delivery as soon as pulmonary maturity is documented.^[266], ^[267]

The most widely used management for fetal thrombocytopenia involves the maternal administration of high-dose IgG.^[258], ^[268] This treatment is based on the well-established observation that most cases of neonatal alloimmune thrombocytopenia are effectively treated by giving the neonate IVIG.^[270] ^[271] ^[272] The mechanism of action in pregnancy is uncertain but may involve Fc-receptor blockade in the fetal reticuloendothelial system and inhibition of uptake of IgG-coated platelets by reticuloendothelial cells, or Fc-receptor saturation in the placenta, inhibiting the transplacental transfer of specific antiplatelet antibody. A maternal or placental mechanism of effect seems more likely, since maternally administered IgG does not appear to cross the placenta effectively prior to 32 weeks' gestation.^[219] Reports of umbilical cord infusion of IgG failing to improve fetal

platelet count, and a lack of correlation between fetal IgG levels and response to treatment also suggest that any beneficial effect of maternal immunoglobulin infusion is likely attributable to maternal or placental factors.^[211], ^[212] Finally, immunoglobulin has been shown in vitro to block transport of antiHPA-1a in a human placental perfusion model.^[273]

Expanding on an earlier report,^[255] Lynch and co-workers^[268] administered IVIG (maternal) and serially measured fetal platelet counts in 18 women who had previously delivered an infant with severe alloimmune thrombocytopenia. After confirming thrombocytopenia at 20 to 22 weeks' gestation or at referral, weekly infusions of IVIG (1.0 g/kg body weight) were initiated. Umbilical cord blood sampling was repeated 4 to 6 weeks later to assess the effect of the therapy and then again at term to determine the mode of delivery. Nine of the 18 patients also received corticosteroids. The median platelet count rose from 32,000 cells/l before treatment to 60,000 cells/l at birth. Only three infants had a fetal platelet count less than 30,000 cells/l at term, and there were no cases of intracranial hemorrhage (compared with 7 of the 18 previous, untreated siblings). In this series, steroid treatment did not appear to have a beneficial effect on fetal platelet count.

Bussel and colleagues^[269] then studied the effect of maternal IVIG and steroids in 54 pregnancies complicated by alloimmune thrombocytopenia; 52 cases were due to HPA-1a alloimmunization, and all fetuses had platelet counts less than 100,000 cells/l at first cordocentesis. Forty-seven patients had a second cordocentesis after weekly IVIG (1.0 g/kg), either with or without additional dexamethasone (1.5 mg/day). Seventy-four percent of these patients demonstrated a favorable response to treatment, defined as either (1) an increased platelet count, with a level of at least 20,000 cells/l; or (2) a decrease of no more than 10,000 cells/l while maintaining a count greater than 40,000 platelets/l. Addition of steroids did not influence the response.

Nine patients who failed initial treatment (and another with late presentation who was not previously treated) were then given "salvage" therapy with prednisone (60 mg/day) added to their IVIG regimen.^[269] Five patients had a favorable response, increasing their platelet count to a mean of 77,600 cells/l at birth, and all newborns had a platelet count greater than 30,000 cells/l. Thus, Bussel and colleagues found that around 75% of patients with alloimmune thrombocytopenia responded adequately to weekly maternal IVIG, and half of the nonresponders improved with addition of high-dose prednisone. There were no cases of intracranial hemorrhage in their series.

Similar results have been reported by others. Kaplan et al.^[274] had 67 percent of patients respond with either an improvement or plateau in fetal platelet counts with use of maternal IVIG; only about a third of patients treated with prednisone alone showed a favorable effect. Silver et al.^[212] reported that six of eight patients treated with IVIG had an increase in fetal platelet count, with five of the six having a neonatal platelet count greater than 50,000 cells/l.

Although these results are encouraging, fetal platelet count is not always increased with maternal high-dose immunoglobulin infusion, even with a documented increase in fetal immunoglobulin levels.^[212], ^[262], ^[275] ^[276] ^[277] Also, IVIG is quite expensive (>\$1,000 per weekly infusion), occasional shortages in supply have occurred, and although the infectious risk of blood product infusion is low, sporadic outbreaks of acute hepatitis C associated with use of IVIG have been reported.^[278]

Determination of platelet antigen genotypes using PCR has been described,^[279], ^[280] and confirmation of paternal zygosity is straightforward. In cases of alloimmunization where the father is homozygous for the antigen and paternity is certain, the fetus will always be heterozygous and at significant risk for thrombocytopenia. On the other hand, if the father is heterozygous, there is a 50 percent likelihood that the fetus will not inherit the platelet incompatibility. About 25 percent of whites are heterozygous HPA-1a/HPA-1b, around 50 percent are heterozygous HPA-3a/HPA-3b, and 20 percent are heterozygous HPA-5a/HPA-5b. Thus, a significant proportion of the fetuses of alloimmunized women will not be at risk for thrombocytopenia.

As with Rh disease, determination of fetal antigen status (and risk of thrombocytopenia) in sensitized pregnancies is routinely available from uncultured amniocytes, and diagnosis of fetal platelet antigen status is possible without umbilical cord blood sampling.^[281], ^[282]

In the management of patients at risk for alloimmune thrombocytopenia, we first determine paternal genotype. If the father is heterozygous for the particular antigen, we recommend amniocentesis at 16 to 20 weeks to assess fetal antigen status. If the fetus is antigen-negative, there is no significant risk of thrombocytopenia or intracranial hemorrhage and no fetal blood sampling is performed.

If the fetus is antigen-positive, we offer cordocentesis at 22 to 26 weeks to determine fetal platelet count. If the platelet count is normal, or if the patient declines cordocentesis and treatment, we advocate modified bed rest with avoidance of abdominal trauma. In cases where the fetal platelet count is less than about 100,000 cells/l, weekly infusions of IgG are initiated.

In agreement with the protocol of Bussel et al.^[269] we then recommend a second cordocentesis about 6 weeks later, regardless of initial platelet count. If an untreated patient manifests thrombocytopenia at the second sampling, weekly infusions of IgG are begun. If a treated patient demonstrates a favorable response, IVIG is

continued. On the other hand, if a treated patient has a

further decline in platelet count or if their count is unacceptably low, we add daily prednisone to their IgG regimen.

If vaginal delivery is anticipated, a third cordocentesis is performed at about 37 weeks. If the platelet count is greater than 50,000 cells/l, labor is induced. If the platelet count is less than 50,000 cells/l, platelet transfusion into the umbilical vein, with documentation of an adequate posttransfusion platelet count, is followed by induction of labor. If cesarean delivery is planned, this final cordocentesis is omitted from the management scheme.

Patients thought to be at relatively lower risk for intracranial hemorrhage may begin their assessment somewhat later than outlined above. Conversely, patients with a previous severely thrombocytopenic fetus and significant antepartum morbidity are generally offered surveillance at an earlier gestational age, but the risks of repeated umbilical blood sampling and serial platelet transfusions do not seem to be warranted except in extreme cases. If the fetus remains severely thrombocytopenic (<50,000 platelets/l) in spite of attempts to raise the platelet count, cesarean delivery is preferred.

The risks of umbilical cord blood sampling have been described, with reported fetal death rates of around 0.5 to 2 percent.^[133]^[134]^[135]^[136]^[137]^[138] The fetus with thrombocytopenia is perhaps at greatest risk from cordocentesis, because of the possibility of uncontrolled bleeding at the puncture site. Paidas et al.^[265] described five fetuses who died following cordocentesis for alloimmune thrombocytopenia. The group had a mean platelet count of only 5,000 cells/l, and all five had levels less than 20,000 platelets/l. Four of the five had a previous sibling with antenatal intracranial hemorrhage, a significantly greater proportion than in a comparison group without fetal loss.

To reduce the risk of exsanguination, concentrated maternal (antigen-negative) platelets, obtained by pheresis a day or two prior to cordocentesis, should be infused after sampling and before needle removal. The volume to be infused can be calculated using the formula above, aiming for a target of at least 50,000 cells/l, and is generally in the range of 3 to 10 ml, depending on gestational age and concentration of the infusate. Despite use of maternal platelets, postprocedure hemorrhage is still a risk; one patient in the series of Silver et al. bled after an apparently uneventful cordocentesis with prophylactic platelet infusion.^[212] Because of the risk of emergent delivery after cordocentesis, we generally administer corticosteroids for enhancement of fetal pulmonary maturity prior to the procedure.

In all cases of documented fetal/neonatal alloimmune thrombocytopenia, maternal platelets should be available for transfusion after delivery, regardless of the treatment protocol used or the antepartum fetal platelet count.

Key Points

To reduce the incidence of Rh sensitization, Rh-immune globulin should be given to Rh-negative unsensitized women at 28 weeks' gestational age and again after delivery if the newborn is Rh-positive. Rh-immune globulin is also indicated for these patients in cases of miscarriage; ectopic pregnancy; chorionic villus sampling, amniocentesis, or other intrauterine procedures; abdominal trauma or fetal death in the second or third trimester; or fetomaternal hemorrhage.

The gene coding for the D antigen has been identified, and prenatal determination of fetal Rh status is routinely available from uncultured amniocytes obtained at amniocentesis.

Measurement of amniotic fluid bilirubin remains the standard for assessment of pregnancies at risk for significant fetal anemia. Neither ultrasound alone nor Doppler studies are adequately sensitive to identify anemic fetuses.

The timing of the first amniocentesis is based on history, maternal anti-D titers, gestational age, and ultrasound findings. The timing of subsequent amniocenteses is based on the OD₄₅₀ values and trends.

Analysis of amniotic fluid bilirubin before 26 weeks is controversial. Although most data suggest that OD₄₅₀ values and trends are accurate before the third trimester, more liberal use of cordocentesis may be appropriate.

Fetal transfusion can be performed using either the intraperitoneal or intravascular route. For hydropic fetuses, intravascular transfusion is clearly superior. For nonhydropic fetuses, perinatal survival rates are similar with either method. Despite this, the intravascular route is generally preferred because of its directness and precision in correcting anemia, and because of the greater morbidity of intraperitoneal transfusion.

With the reduction in Rh disease brought about by widespread use of Rh-immune globulin prophylaxis,

sensitization to the minor or atypical antigens has become relatively more common. A number of these minor antigens can cause several fetal anemia.

Management of pregnancies complicated by sensitization to one of the serious minor antigens (such as Kell) is based on the experience with Rh disease, and determination of fetal antigen status from uncultured amniocytes is available for the most common antigens. However, amniotic fluid bilirubin analysis may not be as accurate an indicator of fetal anemia with Kell sensitization as with Rh disease, and a more frequent use of cordocentesis is probably appropriate.

Platelets also carry distinct antigens and, in a process similar to Rh sensitization, platelet alloimmunization can occur. Unlike Rh disease, firstborn fetuses can be affected, and maternal antibody titers do not predict fetal platelet count.

The optimal management scheme for pregnancies affected with platelet alloimmunization is unclear. A protocol has been proposed that involves (1) cordocentesis at 22 to 26 weeks for documentation of thrombocytopenia, (2) weekly maternal administration of IVIG, (3) a second cordocentesis later to assess response, and (4) addition of prednisone to the regimen for patients who fail initial treatment. A third cordocentesis is then performed at term to determine platelet count before delivery, unless cesarean section is planned.

Chapter 27 - Prolonged Pregnancy

Michael Y. Divon

In 1902, Ballantyne questioned the ability of the placenta to support the fetus that "has stayed too long in intrauterine surroundings." ^[1] Ballantyne further stated that the postmature infant "has remained so long in utero that his difficulty is to be born with safety to himself and his mother." For the better part of the 20th century most authors recognized that prolonged pregnancy was associated with an increased risk for fetal macrosomia and its related morbidity, but felt that the risk of adverse perinatal outcome was small relative to the risks related to induction of labor in the presence of an unfavorable uterine cervix. In 1954, Clifford recognized that prolonged pregnancy could result in fetal growth restriction when he described the "postmaturity with placental dysfunction syndrome." ^[2] Clifford suggested that these neonates appeared malnourished due to recent weight loss with loose, peeling skin and meconium staining. Birth asphyxia, meconium aspiration, and perinatal death were reported in severe cases.

It was only in the 1970s that it became apparent that perinatal mortality was significantly increased in prolonged pregnancies, and that fetal surveillance combined with selective use of induction of labor might result in improved perinatal outcome.

Gabbe: Obstetrics - Normal and Problem Pregnancies, 4th ed. , Copyright © 2002 Churchill Livingstone, Inc.

DEFINITION

Different terms are used loosely to describe pregnancies whose duration has exceeded the upper limit of a normal term gestation. The lack of consensus regarding definitions of terms such as "postmaturity," "postdates," "postterm" or "prolonged pregnancy," combined with the absence of a precise definition of the upper limit of a normal term gestation, result in a wide range of pregnancies reported as "prolonged pregnancy."

The definition of the upper limit of a normal pregnancy is somewhat arbitrary and certainly imprecise. The standard definition of a prolonged pregnancy is 42 completed weeks of gestation (i.e., 294 days after the first day of the last menstrual period [LMP] or more). This definition is endorsed by the American College of Obstetricians and Gynecologists (ACOG), The World Health Organization (WHO), and the International Federation of Gynecology and Obstetrics (FIGO).^[3]^[4]^[5] It is based on data derived prior to the widespread use of fetal surveillance modalities and the use of ultrasound for pregnancy dating. In view of more recent perinatal mortality data that were derived from accurately dated pregnancies, it would be reasonable to conclude that prolonged pregnancy should be defined as a gestational age at birth of greater than or equal to 41 weeks of gestation (see section Perinatal Morbidity and Mortality, below).

The incidence of prolonged pregnancy varies depending on the criteria used to define gestational age at birth. It is estimated that 4 to 19 percent of pregnancies reach or exceed 42 weeks' gestation and 2 to 7 percent complete 43 weeks of gestation. Ventura and colleagues estimated that approximately 520,000 of the 4 million neonates born in the United States during 1993 were born at 41 weeks' gestation, whereas approximately 360,000 were born at or beyond 42 weeks' gestation.^[6]

ETIOLOGY

Labor is a poorly defined biologic process involving fetal, placental, and maternal signals. ^[7], ^[8] Recent data

932

suggest that human parturition is determined by placental release of corticotropin-releasing hormone (CRH) and that women who have low levels of this hormone are more likely to deliver beyond their due date. ^[9] While the details of these physiologic processes await further definition, it is clear that the most common cause of prolonged gestation is an error in determining the patient's due date. Using the LMP for the determination of gestational age is fraught with inaccuracy. Patients' failure to recall accurately the date of the first day of their LMP combined with the varying duration of the luteal and follicular phases of the menstrual cycle may result in an overestimation of gestational age. When prolongation of pregnancy is adequately documented, its cause is often undetermined and the most likely etiology is biologic variability of the duration of pregnancy.

Clinical Features Associated with Prolonged Pregnancy

1. Incorrect dates
2. Biologic variability
3. Maternal factors: previous prolonged pregnancy, primiparity
4. Fetal factors: congenital anomalies (e.g., adrenal hypoplasia, anencephaly)
5. Placental factors: sulfatase deficiency

Various fetal and placental abnormalities may predispose to prolongation of pregnancy. The increase in the incidence of fetal anomalies among women who deliver beyond their due date is generally explained by abnormalities of the fetal hypothalamic-pituitary-adrenal axis. ^[8] Indeed, major central nervous system (CNS) abnormalities (such as anencephaly) have long been associated with loss of the normal mechanisms that initiate labor at term. The role of the fetal adrenal gland in the initiation of labor was highlighted by Naeye, who documented marked adrenal hypoplasia in 10 of 19 postterm fetuses with lethal congenital anomalies. ^[10]

Additional evidence regarding the complexity of the mechanisms involved with initiation of labor is provided by the X-linked recessive deficiency of placental sulfatase, which leads to abnormally low estrogen production in affected male fetuses with a subsequent prolongation of pregnancy and difficulties in both cervical ripening and labor induction. ^[11]

The role of primary prostaglandins (such as PGE₂ and PGF₂) as uterine stimulants is well established. Nonsteroidal anti-inflammatory drugs inhibit the synthesis of these prostaglandins and, therefore, their use is thought to possibly prolong gestation. Nonetheless, the extent to which the chronic use of these drugs (such as aspirin) results in actual prolongation of pregnancy is unknown.

Various maternal conditions have been suggested as risk factors for the development of prolonged pregnancy. A recent regression analysis performed on a large data set evaluated maternal age, parity, and marital status as well as maternal health before and during pregnancy. Primiparity was identified as the only maternal variable, which had a small but significant association with prolonged pregnancies of greater than or equal to 294 days (relative risk [RR] of 1.06 and 95 percent confidence interval [CI], 1.05 to 1.07). ^[12] Interestingly, maternal age of 35 years or older and the use of medicines during pregnancy were associated with a small but significant protective effect (odds ratios [OR] of 0.93 and 0.93, respectively), probably suggesting that older women and those on chronic medications were induced prior to 42 weeks' gestation. Zweidling suggested that women who have previously delivered beyond term have a 50 percent chance of experiencing a subsequent prolonged pregnancy. ^[13] Thus, history of a previous delivery beyond term is a strong predictor of a subsequent late delivery.

The significance of overestimation of the duration of gestation with the use of the LMP should not be overlooked. Congenital anomalies such as anencephaly are easily diagnosed by ultrasound and their presence mandates management options that may not be related to the gestational age at the time of delivery. The contributions attributable to primiparity or to the presence of a male fetus are so minimal that they are unlikely to result in any clinically useful information. In contrast, the fact that 50 percent of women who previously had a prolonged pregnancy would have a similar occurrence with their subsequent pregnancy could be used in counseling the patient and outlining potential management schemes long before the patient reaches her estimated due date.

DIAGNOSIS

The term "prolonged pregnancy" represents a diagnosis that is based on the best available estimation of the duration of gestation at the time of delivery. Optimal diagnosis of gestational age at the time of delivery is hindered by inaccuracy in pregnancy dating. Recently, it has become apparent that clinical methods for estimation of gestational age are inferior to sonographic measurements obtained early in pregnancy.^[14] Several studies have demonstrated that the use of more accurate estimates of gestational age based on early ultrasound or known conception dates results in a significantly

lower frequency of prolonged pregnancies. Boyd et al. showed that the incidence of patients whose pregnancy exceeded 293 days was 7.5 percent by menstrual dating and fell to 2.6 percent when dates were based on early sonographic examination. This incidence fell to 1.1 percent when the diagnosis was limited to patients whose gestational age exceeded 293 days by both menstrual dates and sonographic dates.^[15] A similar conclusion was reached by Gardosi et al., who evaluated 24,675 spontaneous, singleton, nonanomalous deliveries and showed a drop in the postterm (>294 days) pregnancy rate from 7.5 percent when these pregnancies were dated by LMP to 1.5 percent when ultrasound dating was used.^[14] These authors also found that 71.5 percent of routine labor inductions at 42 weeks' gestation were actually not indicated because they were performed before the patients reached 42 weeks by scan dates. Recently, Nguyen et al. evaluated 14,805 spontaneous deliveries with a reliable LMP and showed that ultrasound dating reduced the proportion of deliveries beyond 294 days of gestation by 39 percent (from 7.9 percent to 5.2 percent).^[16] Furthermore, when scan and LMP dates were compared to known dates in patients who had undergone assisted reproduction, it was shown that the 95 percent CI for scan dates was ± 8.3 days. In contrast, the 95 percent CI of menstrual dating was -9 to +27 days.^[17],^[18] These results suggest that the LMP is more likely to overestimate, rather than underestimate, the gestational age at delivery.

The error in gestational dating by the LMP is mainly due to poor recall by the patient. It is, however, important to recognize that even when the LMP is recalled with certainty, it is not a good predictor of ovulation and that physiologic variations in the duration of the follicular phase result in an error that favors an overestimation of the true gestational age. In fact, similar considerations have led to the conclusion that even when both early ultrasound and a reliable LMP are available, gestational dating should be based solely on the ultrasound measurements.^[19]

Since the true date of conception is seldom known, there is a possibility that any adjustment of gestational age may increase the risk of adverse perinatal outcome by failing to identify pregnancies that are actually beyond term but are misclassified as being at term. Therefore, Tunon et al. have evaluated fetal outcome in pregnancies defined as postterm according to the LMP but whose scan dates indicated that they were less than 295 days at the time of delivery.^[20] A total of 11,510 singleton pregnancies with reliable LMP were studied. Apgar score of less than 7 at 5 minutes and admission to the neonatal intensive care unit (NICU) were used as outcome variables. The authors concluded that there was no increase in perinatal morbidity when scan dates were used as the sole predictor of gestational age at delivery.

PERINATAL MORTALITY AND MORBIDITY

Recent studies that have used very large computerized databases of well-dated pregnancies provide new insights into the true incidence and nature of adverse perinatal outcome in prolonged pregnancy. Divon et al. evaluated fetal and neonatal mortality rates in 181,524 accurately dated term and prolonged pregnancies. ^[21] A significant increase in fetal mortality was detected from 41 weeks' gestation onward (OR of 1.5, 1.8, and 2.9 at 41, 42, and 43 weeks, respectively). The odds ratios for neonatal mortality did not demonstrate a significant gestational age dependency. Fetal growth restriction (i.e., birthweight of <2 SD below the mean for gestational age) was associated with significantly higher odds ratios for both fetal and neonatal mortality rates at every gestational age examined with odds ratios ranging from 7.1 to 10.0 for fetal death and from 3.4 to 9.4 for neonatal death. Thus, this study documented a small but significant increase in fetal mortality in accurately dated pregnancies that extend beyond 41 weeks' gestation and demonstrated that fetal growth restriction is independently associated with a large increase in perinatal mortality in these pregnancies. These results were confirmed by other investigators. ^[22], ^[23] Clausson et al. studied perinatal mortality rates among 458,744 term appropriate-for-gestational-age (AGA) infants, 10,312 term small-for-gestational-age (SGA) infants, 39,415 postterm (294 days) AGA infants and 1,558 postterm SGA infants. ^[23] Odds ratios for perinatal death in the postterm AGA infant were not significantly different when compared to AGA term deliveries. In contrast, SGA fetuses had an OR of 10.5 (95 percent CI, 6.9 to 16.0) and 5.0 (95 percent CI, 3.0 to 8.2) for stillbirth and neonatal death, respectively. The stillbirth rate did not change significantly when fetuses with congenital malformations were excluded. However, an 80 percent drop in neonatal deaths occurred when malformed neonates were excluded from the analysis. Further support for the concept that the "small and old" fetus suffers from increased perinatal mortality was provided by Campbell et al., who performed a multivariate analysis of factors associated with perinatal death among 65,796 singleton postterm (294 days) births. ^[12] Three variables were identified as independent predictors of perinatal mortality: (1) SGA status (i.e., birthweight <10th percentile for gestational age) had a RR of 5.7 and 95 percent CI, 4.4 to 7.4; (2) maternal age equal or greater than 35 years had a RR of 1.88 and 95 percent CI, 1.2 to 2.9; (3) interestingly, LGA status (i.e., birthweight 90th percentile for gestational age) was associated with a modest protective effect for

perinatal death (RR of 0.51 with 95 percent CI, 0.26 to 1.0). The independent impact of an increasing gestational age on these mortality rates was minimal.

An interesting concept was recently proposed by Hilder et al., who argued that the risk of stillbirth should be expressed by fetal losses per 1,000 ongoing pregnancies rather than by the traditional mortality rates, which reflect the number of stillbirths per 1,000 live births. ^[24] Using this methodology, the authors demonstrated an eightfold increase in perinatal mortality from 37 weeks' to 43 weeks' gestation (0.7 per 1,000 ongoing pregnancies at 37 weeks to 5.8 per 1,000 ongoing pregnancies at 43 weeks).

Several recent studies evaluated the association of perinatal morbidity with prolonged pregnancy. Campbell et al. compared 65,796 Norwegian pregnancies at greater than or equal to 42 weeks with 379,445 term births (37 to 41 weeks) and concluded that prolongation of pregnancy was associated with a significant increase in adverse outcome (Table 27-1). ^[12] Fetal compromise was more common in the SGA fetuses, whereas shoulder dystocia, labor dysfunction, obstetric trauma, and maternal hemorrhage were more common in the LGA fetus.

Clausson et al. evaluated a large Swedish database of term and postterm (defined as 294 days) singleton, normally formed neonates, and showed that prolonged pregnancies were associated with an increased frequency of neonatal convulsions, meconium aspiration syndrome, and Apgar scores of less than 4 at 5 minutes (Table 27-2). ^[23] Again, morbidity in postterm SGA infants was higher than in postterm AGA infants.

Tunon et al. compared NICU admission rates among 10,048 term pregnancies and 246 prolonged pregnancies (296 days by both scan and LMP dates). ^[20] Prolonged pregnancy was associated with a significant increase in NICU admissions (OR of 2.05, 95 percent CI, 1.35 to 3.12).

TABLE 27-1 -- COMPLICATION RATES IN TERM AND POSTTERM BIRTHS

Complication	Prevalence (%)		Relative Risk (95% CI) Postterm vs. Term
	In Term Births	In Postterm Births	
Fetal distress	5.0	8.4	1.68 (1.621.72)
Shoulder dystocia	0.5	0.7	1.31 (1.211.42)
Labor dysfunction	9.4	11.9	1.26 (1.231.29)
Obstetric trauma	2.6	3.3	1.25 (1.201.31)
Hemorrhage	9.1	10.0	1.09 (1.061.12)

LONG-TERM OUTCOME

Small study populations and the lack of appropriate controls hinder evaluation of long-term developmental outcome in children born after a prolonged gestation. Additional difficulties are introduced by inconsistent definitions of prolonged pregnancy, inaccuracy in pregnancy dating, and the fact that these studies do not differentiate between the apparently normal newborn and those suffering from perinatal asphyxia, severe growth restriction, or meconium aspiration. An uncontrolled study of 106 infants revealed a relatively large frequency of abnormal neurologic signs, sleep disorders, and inadequate social competence during the first year of life.^[25] In contrast, Ting et al. suggested that there are no physical or mental deficiencies in surviving dysmature infants.^[26] These results were confirmed by a prospective study of 129 well-dated children born after a prolonged pregnancy and 184 controls. This report did not demonstrate any significant differences in either intelligence scores or physical milestones at 1 and 2 years of age.^[27] Thus, until large-scale prospective studies are available, it is reasonable to conclude that in the absence of perinatal asphyxia, growth restriction, or meconium aspiration, prolonged pregnancy is associated with normal, long-term neonatal developmental outcome.

ABERRANT FETAL GROWTH

In 1954, Clifford pointed out that prolongation of pregnancy is associated with placental dysfunction and

935

neonatal dysmaturity.^[2] Typically, the affected neonates would appear malnourished with wasting of subcutaneous tissue, meconium staining, and peeling of skin. More recently, Campbell et al. identified birthweight less than or equal to the 10th percentile for gestational age as the risk factor with the largest effect on perinatal mortality (RR of 5.68; 95 percent CI, 4.37 to 7.38) in patients at greater than or equal to 42 weeks' gestation.^[12] These authors also showed that macrosomia was associated with a protective effect. The relative risk for perinatal death in the presence of fetal macrosomia was only 0.51 (95 percent CI, 0.26 to 1.00). However, macrosomia was associated with a higher incidence of labor dysfunction, obstetric trauma, shoulder dystocia, and maternal hemorrhage.

The incidence of fetal macrosomia increases with advancing gestational age.^[28] For example, a gradual increase in both birthweight and head circumference was documented by McLean et al., who studied 7,000 pregnancies between 39 and 43 weeks' gestation.^[29] Similarly, Nahum et al. showed that fetal growth is a linear function of gestational age between 37 and 42 weeks' gestation with a daily fetal weight gain of 12.7 ± 1.4 g (mean \pm SD).^[30] Thus, it should come as no surprise that Pollack et al. who evaluated 519 singleton pregnancies at greater than or equal to 41 weeks' gestation, detected a 23 percent incidence of infants whose birthweight was greater than 4,000 g and a 4 percent incidence of birthweights greater than 4,500 g.^[31] Chervenak et al. have shown that prolonged pregnancy is not only associated with an increased incidence of macrosomia, but that this increase also results in doubling the cesarean delivery rate for protraction or descent disorders.^[32]

The accurate and timely prediction of macrosomia may well influence delivery management decisions. However, one should note that the accurate estimation of fetal weight must be viewed in its broad clinical context of fetopelvic disproportion. Thus, the crucial factor is the relationship of the fetal size to the maternal pelvis rather than the common clinical preoccupation with macrosomia alone. Focusing on either one of these factors in isolation represents a conceptual error.^[33] For example, despite an increase in the relative risk of birth trauma in infants weighing more than 4,000 g, most are delivered vaginally without complications. Likewise, a birth weight of less than 4,000 g does not preclude the possibility of shoulder dystocia. In fact, most infants with brachial plexus injury weigh less than 4,000 g at birth.

Traditionally, obstetricians have predicted fetal weight by abdominal palpation or symphysial-fundal height measurement. When ultrasound was first utilized to estimate fetal weight, there was widespread expectation that it would provide a more useful tool than the traditional clinical methods. Chervenak et al. evaluated 317 patients at greater than or equal to 41 weeks' gestation and reported that a sonographic estimate of fetal weight (EFW) of greater than 4,000 g had a sensitivity, specificity, positive predictive value, and negative predictive value of 61, 91, 70, and 87 percent, respectively, in the diagnosis of a birthweight greater than 4,000 g.^[34]

In a subsequent study of 519 pregnancies of greater than or equal to 41 weeks' gestation, Pollack et al. reported that sonographic estimates of fetal weight that were obtained within 1 week of delivery in pregnancies of greater than or equal to 41 weeks were associated with a mean absolute error of 7.7 percent and a wide range of actual birth weights.^[35] For example, the 95 percent CI of an EFW of 4,000 g ranged from 3,142 g to 4,665 g, and the 95 percent CI for an EFW of 4,500 g ranged from 3,465 g to 4,993 g. The positive predictive value of an EFW greater than or equal to 4,000 g in the prediction of a birth weight greater than or equal to 4,000 g was only 64 percent and, therefore, the authors concluded that routine sonographic screening for macrosomia in prolonged pregnancies is associated with relatively low accuracy.

In an attempt to improve the accuracy of sonographic estimates of fetal weight, O'Reilly-Green and Divon used receiver operating characteristic curve analysis to identify optimal cut-off values of EFW in the prediction of macrosomia in prolonged pregnancies.^[34] At the inflection point cut-off level of 3,711 g, sensitivity, specificity, and positive and negative predictive values for predicting birthweight of greater than or equal to 4,000 g were 85, 72, 49, and 94 percent, respectively. At the inflection point cut-off level of 4,192 g for predicting birthweight of greater than or equal to 4,500 g, these values were 83, 92, 30, and 99 percent. The authors concluded that cut-off values derived from their analysis resulted in reasonable sensitivities but disappointingly low positive predictive values.

The practical implications of the low predictive value of ultrasonography have been recently highlighted by Rouse et al.^[35],^[36] These authors have shown that in non-diabetic pregnancies, the level of intervention and the economic costs of prophylactic cesarean delivery for fetal macrosomia diagnosed by means of ultrasonography would be excessive. The inaccuracy of sonographic estimates of fetal weight combined with the rarity of permanent brachial plexus injury led these authors to conclude that "a prophylactic cesarean policy with either a 4,000 g or 4,500 g macrosomia threshold would require more than 1,000 cesarean deliveries and millions of dollars to avert a single permanent brachial plexus injury." Even more striking is their suggestion that a policy of prophylactic cesarean would result in one maternal death for every 3.2 brachial plexus injuries that would be prevented.

Despite many years of research and debate, the management of suspected fetal macrosomia is still controversial. The

936

increased incidence of maternal and fetal morbidity associated with macrosomia has prompted some authors to recommend a proactive approach including either a cesarean delivery for cases of "established" macrosomia or a prophylactic induction of labor for "impending" macrosomia. It would seem reasonable that as fetal weight continues to increase with advancing gestational age, delivery of those pregnancies with a potential for macrosomia might prevent some cases of shoulder dystocia and a subsequent brachial plexus injury. However, this intervention could be achieved only by increasing the rate of inductions of labor or by an increased use of cesarean deliveries, both of which would subject the patient to added morbidity or even unnecessary mortality. Furthermore, preliminary evidence suggesting that such interventions would be beneficial is lacking.

Leaphart et al. evaluated the practice of labor induction when fetal macrosomia is suspected.^[37] Similar to many other studies, they showed that induction of labor resulted in doubling of their baseline cesarean section rate (from 17 percent to 36 percent), a more frequent use of regional analgesia (from 53 percent to 83 percent), and no difference in the incidence of shoulder dystocia relative to matched controls who were managed by awaiting spontaneous onset of labor. The authors concluded that induction of labor following a prenatal diagnosis of macrosomia results in unnecessary cesarean deliveries and emphasized that their data support a plan of expectant management when fetal macrosomia is suspected. In a prospective randomized study of 273 patients with suspected macrosomia at term, Gonen et al. could not demonstrate that induction of labor resulted in reduced neonatal morbidity.^[38] The authors concluded that "ultrasonic estimation of fetal weight between 4,000 g and 4,500 g should not be considered an indication for induction of labor."

Some authors have gone as far as suggesting that the availability of a sonographic EFW indicating macrosomia is in and of itself responsible for an increased cesarean delivery rate and have questioned the logic of obtaining these EFWs if their availability does not improve perinatal outcome.^[39] Although the recommendation for proactive management of the macrosomic fetus is well intentioned, evidence-based research does not support the practice of either induction of

labor or a cesarean delivery for fetal macrosomia in the absence of other indications for these interventions. A more reasonable policy for management of macrosomia would entail a conservative approach awaiting the onset of spontaneous labor in the absence of a favorable uterine cervix, adequate intrapartum management such as assessment of the adequacy of the maternal pelvis, assessment of the progress of labor and careful use of oxytocin, avoidance of vaginal operative deliveries, and avoidance of excessive traction on the impacted shoulder in favor of the maneuvers described for the management of shoulder dystocia ([see Chapter 16](#)).

FETAL SURVEILLANCE

Fetal surveillance may be used in an attempt to observe the prolonged pregnancy safely while awaiting the onset of labor or spontaneous ripening of the cervix prior to elective induction. The pitfalls of the use of antenatal testing in this setting are twofold. On the one hand, false-positive tests commonly lead to unnecessary interventions that are potentially hazardous to the gravida. On the other hand, to date, no program of fetal testing has been shown to completely eliminate the risk of stillbirth. Current research on the use of fetal testing has focused on the refinement of testing protocols and the application of new technology to address these issues.

The optimal gestational age for the initiation of fetal testing has not been established. Data presented earlier in this chapter indicate that perinatal mortality is significantly increased as early as 41 weeks' gestation. Additional support for this concept was provided by Guidetti et al., who reported an increased incidence of perinatal morbidity at greater than or equal to 41 weeks' gestation and by Jazayeri et al., who demonstrated elevated plasma erythropoietin levels, indicating altered fetal oxygenation, in patients at greater than or equal to 41 weeks.^[40],^[41] Thus, it would seem prudent to initiate fetal testing at 41 weeks of gestation.

Extensive experience with biophysical profile testing in high-risk populations indicates a perinatal mortality rate of 0.73 per 1,000 tested pregnancies within 1 week of a normal test, provided that the amniotic fluid volume is normal.^[42] Twice-weekly testing with the biophysical profile in a series of 293 patients followed beyond 42 weeks of gestation has been reported. No stillbirths were observed in this small series.^[43]

The primary disadvantages of biophysical profile scoring are the time required to perform the test and the need for an experienced sonographer. Recently, investigators have examined the efficacy of using the nonstress test as a primary testing modality with the addition of a sonographic assessment of amniotic fluid volume. Measurement of the amniotic fluid index (AFI) requires minimal sonographic experience,^[44] and vibroacoustic stimulation may be used to shorten the duration of the nonstress test.^[45] Results of the use of such a protocol in the antepartum management of 5,973 high-risk pregnancies have been described by Clark et al.^[46] Amniotic fluid volume assessment was performed by measurement of the AFI, with induction of labor reserved for an AFI of 5 cm or less. Twice-weekly testing

was performed in a subset of 279 prolonged pregnancies. No stillbirths were recorded.

More recently, Miller et al. reported the use of a similar protocol in 15,482 high-risk pregnancies for which 54,617 tests were performed.^[47] The false-negative rate of this test was 0.8 per 1,000 women tested a rate that favorably compares with those reported for the contraction stress test or the complete biophysical profile.^[42],^[48] Of note, 6,390 patients were assessed in this study for prolonged pregnancy. These patients were first evaluated in the 41st week of gestation and twice-weekly testing was initiated after 42 weeks of gestation. Five stillbirths were reported in this subpopulation. An analysis of all false-positive tests showed that the routine use of nonstress testing combined with the AFI resulted in a 60 percent false-positive rate in the prediction of intrapartum fetal compromise compared with a 40 percent false-positive rate using the complete biophysical profile. This increase in false-positive tests was felt to be partly a result of poor specificity of the AFI in predicting fetal compromise.

Oligohydramnios

The formation of amniotic fluid is a complex and poorly understood process. Many authors have demonstrated that amniotic fluid volume decreases as gestational age advances beyond 32 or 34 weeks' gestation. Marks and Divon evaluated the AFI in 511 well-dated prolonged pregnancies.^[49] Gestational age at the time of the study ranged from 41 weeks to 43 weeks and 6 days. AFI measurements ranged from 1.7 to 24.6 cm with a mean and standard deviation of 12.4 cm \pm 4.2 cm at 41 weeks. Oligohydramnios (AFI <5.0 cm) was detected in 11.5 percent of the study population. Longitudinal data were available from 121 patients. These patients demonstrated a mean decrease in AFI of 25 percent per week. Thus, the authors concluded that the majority of pregnancies at greater than or equal to 41 weeks' gestation have a normal volume of amniotic fluid.

Numerous hypotheses have been offered to explain the pathophysiology of oligohydramnios. Oligohydramnios, when defined as an AFI less than or equal to 5.0 cm, has an incidence of 8.5 to 15.5 percent. In the absence of ruptured membranes or fetal urinary tract abnormalities, diminishing levels of amniotic fluid volume may be related to poor placental function.^[50] Nicolaides et al. hypothesized that fetal hypoxemia may result in redistribution of blood flow with decreased renal perfusion and diminished urine production, which in turn may cause oligohydramnios.^[51] A vicious cycle could develop with oligohydramnios causing cord compression, resulting in further hypoxemia, oligohydramnios, and fetal heart rate (FHR) abnormalities. Under these circumstances, fetal hypoxemia may induce relaxation of the rectal sphincters and hence meconium staining resulting in meconium aspiration syndrome. In fact, meconium-stained amniotic fluid is found in up to 50 percent of pregnancies at 42 weeks' gestation upon rupture of the membranes. Trimmer et al. detected diminished urine production in pregnancies of 42 weeks or more with oligohydramnios and suggested that decreased fetal urine production was the result of preexisting oligohydramnios, which limited fetal swallowing of amniotic fluid rather than a decrease in renal perfusion.^[52] Bar-Hava et al. used pulsed wave Doppler to evaluate resistance index values in the fetal middle cerebral artery, renal, and umbilical arteries in 57 pregnancies at greater than or equal to 41 weeks' gestation.^[53] Oligohydramnios (AFI <5 cm) was detected in 15 patients. The various resistance index values and the ratios among them were not significantly different in patients with or without oligohydramnios. Interestingly, the mean birthweight in patients with oligohydramnios was significantly lower than the mean birthweight in patients with a normal AFI (3,297 \pm 438 g vs. 3,742 \pm 448 g, respectively). The author concluded that oligohydramnios in these patients is not associated with a noticeable redistribution of blood flow and suggested that the cause of oligohydramnios is probably unrelated to renal perfusion.

The fact that oligohydramnios was found more often in the smaller fetuses is intriguing. It suggests that the appearance of oligohydramnios is a pathologic rather than a physiologic process. It may indicate that the pathophysiology of oligohydramnios in prolonged pregnancy is similar to that involved with the formation of oligohydramnios in the growth-restricted fetus, and overall, it is consistent with the concept that it is the small and "older" fetus who is more prone to complications arising from asphyxia. Other causes of oligohydramnios include spontaneous rupture of membranes, genitourinary anomalies, and an abnormal karyotype. It is important to rule out these other causes of oligohydramnios before attributing reduced amniotic fluid levels to fetal hypoxemia.

Regardless of the exact cause of oligohydramnios, its presence has been used by Leveno et al. to explain the increased incidence of abnormal antepartum and intrapartum FHR abnormalities seen in prolonged pregnancies.^[54] These authors suggested that prolonged FHR decelerations representing cord compression preceded 75 percent of cesarean deliveries for fetal jeopardy. The association between a reduced AFI and variable decelerations is well documented.^[55],^[56] As suggested by Gabbe et al. and Lee and Hon, variable FHR decelerations detected in patients with oligohydramnios are probably related to increased umbilical cord compression.^[55],^[57] This concept is further supported by reports of intrapartum amnioinfusion in mothers with oligohydramnios. This procedure was shown to reduce the incidence

of variable FHR decelerations, meconium staining below the vocal cords, and operative delivery for fetal distress.^[58],^[59] A similar mechanism is probably functional in the antepartum period. Both Phelan et al. and Divon et al. found that the frequency of nonstress tests demonstrating FHR decelerations or bradycardia increased as the ultrasonographic estimates of the amniotic fluid declined.^[60]^[61]^[62]^[63]

Quantifying amniotic fluid volume presents significant problems. Various sonographic semiquantitative estimates such as the 1-cm pocket, the 2-cm pocket, or the 3-cm pocket have been proposed as definitions of oligohydramnios.^[64]^[65]^[66] The use of an AFI of less than or equal to 5.0 cm to define oligohydramnios was first suggested by Phelan et al. in 1987, as an arbitrary cut-off value based on retrospective studies. Nevertheless, it has since gained popular appeal.^[60],^[62] A recent meta-analysis evaluated the risk of cesarean delivery for fetal distress, 5-minute Apgar score of less than 7, and umbilical artery pH less than 7.00 in patients with antepartum or intrapartum AFI or less than 5.0 cm.^[67] Eighteen reports describing 10,551 patients at various gestational ages were included in the analysis. The overall incidence of oligohydramnios was 15.2 percent. The authors concluded that an AFI of less than or equal to 5.0 cm is associated with an increased risk of cesarean delivery for fetal distress (RR of 2.2; 95 percent CI, 1.5 to 3.4) and an Apgar score of less than 7 at 5 minutes (RR of 5.2; 95 percent CI, 2.4 to 11.3). However, no association was demonstrated between oligohydramnios and severe fetal acidosis.

The presence of sonographically diagnosed oligohydramnios is often used as an indication for delivery of pregnancies that reach term gestation or extend beyond term. One should realize, however, that up to 50 percent of patients who are diagnosed as having oligohydramnios by ultrasound will have a normal volume of amniotic fluid upon artificial rupture of the membranes.^[68] In addition, there are no large-scale, prospective, randomized studies documenting the benefits of delivery once oligohydramnios has been detected. In the absence of such studies, it would seem prudent to deliver patients at or beyond 41 weeks' gestation who demonstrate oligohydramnios primarily because of the large body of data that documents an association between diminished amniotic fluid volume and adverse perinatal outcome.

Doppler Ultrasound

Umbilical artery Doppler velocimetry has not been able to improve the positive predictive value of fetal testing in prolonged pregnancy.^[69]^[70]^[71] Recently, Doppler ultrasound has been applied to investigations of the fetal circulation in an attempt to identify perturbations that might be associated with adverse outcomes. Bar-Hava et al. analyzed renal artery and middle cerebral blood velocity waveforms in 57 pregnancies prolonged beyond 287 days' gestation.^[53] Findings in pregnancies complicated by oligohydramnios were compared with those found in pregnancies with normal amniotic fluid volume. It was expected that, with hypoxia, impedance in the cerebral circulation might decrease as impedance increased in the renal circulation. However, no differences were seen. These results were confirmed in a larger, prospective investigation undertaken by Zimmermann et al.^[72] In this cross-sectional, prospective study, 153 pregnancies were examined beyond 287 days of gestation and 36 percent were followed beyond 42 weeks of gestation. The resistance indices of umbilical artery and middle cerebral artery waveforms were studied every 2 days until delivery. All velocities fell within the known 95 percent CIs for normal term fetuses. Doppler measurements were unable to predict adverse fetal outcomes, such as abnormal fetal heart rate tracings, thick meconium, the need for urgent operative delivery, acidemia at delivery, or neonatal encephalopathy.

Weiner et al. used Doppler ultrasound to study fetal cardiac function in prolonged pregnancy. The velocity time integral of blood flow across each valve was multiplied by the fetal heart rate to obtain a measure of fetal ventricular function.^[73] Results were compared with measurements obtained from a control group of patients studied between 38 and 41 weeks of gestation. No differences were seen between controls and prolonged pregnancies with an AFI of 6 cm or greater. Prolonged pregnancies with abnormal amniotic fluid volumes had statistically significant differences in fetal left cardiac function. The authors concluded that an abnormality of cardiac function may be present prior to or coincident with the development of oligohydramnios.

MANAGEMENT

In spite of many years of research, the optimal management of the prolonged pregnancy is still controversial. These pregnancies have traditionally been considered to be at elevated risk for adverse perinatal outcome. Thus, it is generally accepted that these patients should undergo some form of fetal testing. Although most authors agree that induction of labor is indicated in women with an "inducible" uterine cervix, there is lack of agreement as to the management of the patient whose cervix is deemed "unfavorable." Antenatal testing may be used in an attempt to observe the prolonged pregnancy safely while awaiting the spontaneous onset of labor or for ripening of the cervix prior to

939

labor induction. Other opinions argue in favor of induction of labor regardless of the cervical status.

Fibronectin

Approximately 50 percent of patients who are undelivered by 41 weeks' gestation will present in spontaneous labor within 7 days, and over 90 percent will do so by 44 weeks.^[79] Attempts to evaluate the role of fetal fibronectin in cervical secretions as a predictor of the onset of spontaneous labor have been inconclusive. Goffeng et al. studied 80 women at 42 weeks' gestation and found that the presence of fetal fibronectin was not significantly correlated with either the Bishop score or the time interval between cervical sampling and delivery.^[79] In contrast, Mouw et al. concluded that the sensitivity and specificity of fetal fibronectin concentration of at least 50 ng/ml in the prediction of spontaneous onset of labor within 3 days of examination were 71 and 64 percent, respectively.^[76] With a sensitivity of only 71 percent and a relatively low specificity, it is unlikely that this test would have any practical clinical application in the management of the prolonged pregnancy.

Sweeping the Membranes

Membrane sweeping or stripping is an age-old method of inducing labor that is still in common use. This intervention results in a local increase in prostaglandin production and is believed to hasten the onset of labor. A meta-analysis of the use of sweeping of the membranes to induce labor or to prevent prolonged pregnancy has recently been published.^[77] The analysis showed that sweeping of the membranes in term pregnancies shortens the duration of pregnancy by a mean of 4 days. Consequently, it decreases the frequency of patients reaching 41 or 42 weeks' gestation. Eight women need to be treated at term in order to avoid one pregnancy continuing beyond 41 weeks, and 25 women need to be treated to avoid one pregnancy continuing beyond 42 weeks' gestation. The intervention had no significant impact on mode of delivery or the incidence of maternal or neonatal infections. Vaginal bleeding, painful uterine contractions not leading to delivery, and discomfort during vaginal examination were significantly more common in women allocated to sweeping of the membranes.

Induction of Labor

A major concern in the management of the prolonged pregnancy is the balance between the likelihood of a successful induction of labor and the risks of expectant management. The October 1997 ACOG Practice Patterns states that there is insufficient information to determine whether either labor induction or expectant management result in the best outcome in women with a prolonged pregnancy and a favorable cervix.^[3] This publication does state that "according to current obstetric practice, labor is induced in most of these women." Accordingly, most practitioners feel that if the likelihood of a successful vaginal delivery is sufficiently high, there is no reason to expose the patient to the added risks associated with prolongation of pregnancy. Thus, in the absence of randomized controlled trials, induction of labor in women with prolonged pregnancy and a favorable cervix is a reasonable approach.

The management of the patient who presents with an unfavorable cervix is much more controversial. It consists of either expectant management (i.e., antenatal surveillance until there are signs of fetal jeopardy, or until the patient presents in either spontaneous labor or with a favorable cervix) or induction of labor any time after 41 weeks' gestation.

Magann et al. showed that daily membrane stripping or daily placement of prostaglandin gel (0.15 mg of PGE₂) beginning at 41 weeks resulted in fewer inductions at 42 weeks.^[79] Other attempts at outpatient management have been inconclusive. Lien et al. randomized patients to either PGE₂ gel or placebo gel at the time of scheduled nonstress testing and showed that there was no decrease in the induction rate or cesarean delivery rate in patients with prolonged pregnancy who received intracervical PGE₂ gel.^[79] In contrast, Ohel et al. randomized patients at 40 to 41 weeks into either outpatient administration of 3 mg of vaginal PGE₂ or expectant management, and observed that the average number of days to delivery was significantly lower in the induction group (1.6 vs. 5.2 days), with no difference in the cesarean section rates between groups.^[80]

Several other investigators have evaluated the use of PGE₂ gel for inducing labor in patients with a prolonged pregnancy and an unfavorable cervix. Shaw et al. studied PGE₂ gel in a double-blind, placebo-controlled trial and showed that it was associated with an improvement in cervical ripeness, shorter duration of labor, reduced need for high-dose oxytocin, and a lower rate of cesarean deliveries.^[81] A study by Papageorgiou et al.^[82] confirmed these findings, as PGE₂ gel was associated with a higher success rate and a lower cesarean delivery rate when compared to oxytocin. In contrast, a large and well-designed multicenter, randomized, controlled trial of expectant management versus induction of labor reported no reduction in the induction-delivery interval or in the cesarean delivery rate in the PGE₂ group relative to placebo.^[83]

Other medical and mechanical methods for induction of labor have been described such as misoprostol, relaxin, balloon catheters, nipple stimulation, and hygroscopic tents.^[84] Unfortunately, the ideal mode of induction of labor has yet to be determined. Oxytocin in combination with amniotomy remains the method of

940

choice for inducing labor in women with a favorable cervix. The use of cervical ripening agents in patients with an unfavorable cervix certainly results in a significant increase in cervical dilation and effacement. However, the use of these agents is still associated with a high cesarean delivery rate subsequent to a failed induction of labor. Relative to women who present in spontaneous labor, the cesarean delivery rate is approximately doubled when induction of labor is attempted in nulliparous women at term.^[85]

Induction of Labor versus Expectant Management

Although most authors agree that induction of labor is indicated in women with an "inducible" uterine cervix, there is lack of agreement as to the management of the patient whose cervix is deemed "unfavorable." Induction of labor in all women at 42 weeks' gestation is one option. Another option is serial fetal surveillance to assess well-being in women with an unfavorable cervix. These surveillance programs have focused on the detection of fetal hypoxia associated with uteroplacental insufficiency. To this end, fetal heart rate monitoring, biophysical profile, and ultrasonographic assessment of amniotic fluid volume have been utilized. Delivery is undertaken when signs of fetal or maternal compromise are detected. In a recent study, Hanna et al. randomized 3,407 women with uncomplicated pregnancies of 41 or more weeks' gestation to two management protocols: induction of labor or serial fetal monitoring.^[86] They concluded that the rates of perinatal morbidity and mortality were the same with the two approaches; however, the cesarean section rate was lower in the induction group. In contrast, Almstrom et al., who also randomized patients into active and conservative management protocols, concluded that serial fetal monitoring resulted in a lower cesarean section rate.^[87] A recent meta-analysis of 11 prospective studies demonstrated that induction of labor resulted in a slightly lower cesarean section rate compared with expectant management.^[88] The randomized controlled trial ($n = 440$) conducted by the National Institute of Child Health and Human Development Network of Maternal-Fetal Medicine Units reported no fetal or maternal advantages to elective induction of labor at 41 weeks of gestation relative to serial fetal monitoring and indicated that either management approach was acceptable.^[83] Adverse fetal outcome was defined by the presence of neonatal seizures, intracranial hemorrhage, need for mechanical ventilation, or nerve injury. The incidence of adverse fetal outcome was 1.5 percent in the induction group and 1 percent in the expectant management group. The cesarean delivery rate was 18 percent in the expectant group, 23 percent in the PGE₂ gel group, and 18 percent in the placebo gel group. The authors concluded that there is good evidence that no approach is superior, thus suggesting that either induction of labor or serial monitoring would be equally reasonable.

SUMMARY AND RECOMMENDATION

Management of the prolonged pregnancy is primarily determined by the interplay of three factors: certainty of gestational dating, the risks associated with expectant management, and the likelihood of spontaneous vaginal delivery following an induction of labor.

Key Points

Whenever possible, gestational age should be established by a first- or an early second-trimester ultrasound examination.

Sweeping of the membranes at term decreases slightly the number of pregnancies reaching either 41 or 42 weeks' gestation.

Consider induction of labor at or beyond 41 weeks' gestation in patients with a favorable cervix.

Initiate semiweekly fetal testing (nonstress test and AFI) at 41 weeks' gestation.

Conservative management (i.e., semiweekly fetal testing) or active management (i.e., induction of labor) are equally reasonable options for patients with an unfavorable cervix.

Perinatal morbidity and mortality are significantly increased when gestational age at birth is 41 weeks or more.

Section 6 - Pregnancy and Coexisting Disease

945

Chapter 28 - Hypertension

Baha M. Sibai

Hypertensive disorders are the most common medical complications of pregnancy, with a reported incidence between 5 and 10 percent. ^[1] The incidence varies among different hospitals, regions, and countries. In addition, these disorders are a major cause of maternal and perinatal mortality and morbidity worldwide. ^[2] The term *hypertension in pregnancy* is usually used to describe a wide spectrum of patients who may have only mild elevations in blood pressure or severe hypertension with various organ dysfunctions. The manifestations in these patients may be clinically similar (e.g., hypertension, proteinuria); however, they may result from different underlying causes such as chronic hypertension, renal disease, or pure preeclampsia. The three most common forms of hypertension are acute gestational hypertension, preeclampsia, and chronic essential hypertension.

The terminology used to classify the hypertensive disorders of pregnancy has been confusing and inconsistent, making comparison of studies difficult and often impossible. For many years, the hypertensive disorders of gestation were labeled *toxemia of pregnancy*. This term was used because it was felt that this wide variety of disorders had as a common etiologic agent a circulating toxin. We now know this to be untrue.

DEFINITIONS

Hypertension may be present before pregnancy, or it may be diagnosed for the first time during pregnancy. In addition, in some women hypertension may become evident only intrapartum or postpartum. For clinical purposes, women with hypertension may be classified into one of three categories (Table 28-1) (Table Not Available).^[2]

Gestational Hypertension

Gestational hypertension is the development of an elevated blood pressure during pregnancy or in the first 24 hours postpartum without other signs or symptoms of preeclampsia or preexisting hypertension. The blood pressure must return to normal within 6 weeks after delivery. Hypertension is defined as a blood pressure greater than or equal to 140 mm Hg systolic or 90 mm Hg diastolic. The hypertension should be present on at least two occasions, at least 4 hours apart, but within a maximum of a 1-week period.^[3] Some women with gestational hypertension may have undiagnosed chronic hypertension, whereas others will subsequently progress to develop the clinical syndrome of preeclampsia.^[4] In general, the rate of progression to preeclampsia will depend on gestational age at time of diagnosis, with higher rates if onset of hypertension is before 35 weeks' gestation.^[4]

Preeclampsia and Eclampsia

The so-called classic triad of preeclampsia includes hypertension, proteinuria, and edema. However, there is now universal agreement that edema should not be considered as part of the diagnosis of preeclampsia.^[5] ^[6] ^[7] Indeed, edema is neither sufficient nor necessary to confirm the diagnosis of preeclampsia, since edema is a common finding in normal pregnancy and approximately one third of eclamptic women never demonstrate the presence of edema.^[8] At present, preeclampsia is primarily defined as gestational hypertension plus proteinuria. Proteinuria is defined as a concentration of 0.1 g/L or more in at least two random urine specimens collected 4 hours or more apart or 0.3 g in a 24-hour period. In the absence of proteinuria, the syndrome of preeclampsia should be considered when gestational hypertension

TABLE 28-1 -- HYPERTENSIVE DISORDERS OF PREGNANCY

(Not Available)

is present in association with persistent cerebral symptoms, epigastric or right upper quadrant pain plus nausea or vomiting, fetal growth restriction, or with abnormal laboratory tests such as thrombocytopenia and abnormal liver enzymes.^[9] ^[9] In mild preeclampsia, the diastolic blood pressure remains below 110 mm Hg and the systolic blood pressure remains below 160 mm Hg (see the box "Criteria for Severe Preeclampsia"). Eclampsia is the occurrence of seizures not attributable to other causes.

Chronic Hypertension

Chronic hypertension is defined as hypertension present before the pregnancy or that diagnosed before the 20th week of gestation. Hypertension that persists for more than 42 days postpartum is also classified as chronic hypertension.

Chronic Hypertension with Superimposed Preeclampsia

Women with chronic hypertension may develop superimposed preeclampsia, which increases morbidity for both the mother and fetus. The diagnosis of superimposed preeclampsia is based on one or more of the following findings. In women with hypertension and no proteinuria prior to 20 weeks' gestation, development of new-onset proteinuria is defined as the urinary excretion of 0.5 g protein or greater in a 24-hour specimen. In women with hypertension and proteinuria before 20 weeks, the diagnosis requires severe exacerbation in hypertension plus development of symptoms and/or thrombocytopenia and abnormal liver enzymes.^[10]

Criteria for Severe Preeclampsia

1. Blood pressure of 160 mm Hg systolic or 110 mm Hg diastolic, recorded on at least two occasions at least 6 hours apart with patient at bed rest
2. Proteinuria of 5 g in 24 hours
3. Oliguria (400 ml in 24 hours)
4. Cerebral visual disturbances
5. Epigastric pain, nausea, and vomiting
6. Pulmonary edema
7. Impaired liver function of unclear etiology
8. Thrombocytopenia

Gestational Hypertension

Gestational hypertension is the most frequent cause of hypertension during pregnancy. The incidence ranges between 6 and 18 percent in nulliparous women^[3] ^[11] ^[12] ^[13] and between 6 and 8 percent in multiparous women.^[12] The incidence is markedly increased in patients with twin pregnancies.^[12] ^[13] In general, the majority of cases of gestational hypertension develop at or beyond 37 weeks' gestation, and thus the overall pregnancy outcome is usually similar or superior to that seen in

women with normotensive pregnancies.^[3], ^[12], ^[13] Both gestational age at delivery and birth weight in these pregnancies are significantly higher than that in normotensive pregnancies.^[3], ^[11], ^[12] However, women with gestational hypertension have higher rates of induction of labor for maternal reasons and higher rates of cesarean delivery as compared to women with normotensive gestation.^[3], ^[13]

Management

Women with gestational hypertension are at risk for progression to either severe hypertension, preeclampsia, or eclampsia.^[4] The risks are increased with lower gestational age at time of diagnosis. Therefore, these patients require close observation of maternal and fetal conditions. Maternal evaluations require weekly prenatal visits, education about reporting preeclamptic symptoms,

evaluation of complete blood count, platelet count, and liver enzymes.^[14] Fetal evaluation includes ultrasound examination of fluid and estimated fetal weight at time of diagnosis and weekly nonstress testing.^[15] Restriction of neither dietary salt nor activity has been proven beneficial in the management of these patients.^[16] Additionally, the results of several randomized trials reveal that control of maternal blood pressure with antihypertensive drugs does not improve pregnancy outcome in women with gestational hypertension.^[2], ^[16], ^[17]

In the absence of progression to severe hypertension and/or preeclampsia, women with gestational hypertension can continue pregnancy until term. During labor and immediately postpartum, they do not require any prophylaxis against seizures, since the rate of eclampsia in these women is less than 1 in 500.^[18]

PREECLAMPSIA

Preeclampsia is a form of hypertension that is unique to human pregnancy. Very rarely, it has been reported in subhuman primates.^[19] Incidence ranges between 3 and 7 percent in nulliparas^[3],^[11]^[12]^[13] and between 0.8 and 5.0 percent in multiparas.^[12],^[20] The incidence is significantly increased in patients with twin pregnancies, where both the rates and severity are higher than singleton pregnancies^[12],^[13] (see the box "Risk Factors for Preeclampsia").

The etiology of preeclampsia is unknown. Many theories have been suggested, but most of them have not withstood the test of time. Some of the theories that are still under consideration are listed [in the box "Theories Associated with the Etiology of Preeclampsia."](#)

Risk Factors for Preeclampsia

- Nulliparity
- Family history of preeclampsia
- Obesity
- Multifetal gestation
- Preeclampsia in previous pregnancy
- Poor outcome in previous pregnancy
 - Intrauterine growth retardation, abruptio, fetal death
- Preexisting medical/genetic conditions
 - Chronic hypertension
 - Renal disease
 - Type 1 (insulin-dependent) diabetes mellitus
 - Thrombophilias
 - Antiphospholipid antibody syndrome
 - Protein C, S, antithrombin deficiency
- Factor V Leiden

Theories Associated with the Etiology of Preeclampsia

- Abnormal trophoblast invasion
- Coagulation abnormalities
- Vascular endothelial damage
- Cardiovascular maladaptation
- Immunologic phenomena
- Genetic predisposition
- Dietary deficiencies or excesses

Pathophysiology

During normal pregnancy, impressive physiologic changes occur in the uteroplacental vasculature in general, and in the cardiovascular system in particular. These changes are most likely induced by the interaction of the fetal (parental) allograft with maternal tissue. The development of mutual immunologic tolerance in the first trimester is thought to lead to important morphologic and biochemical changes in the systemic and uteroplacental maternal circulation.

Uterine Vascular Changes

The human placenta receives its blood supply from numerous uteroplacental arteries that are developed by the action of migratory interstitial and endovascular trophoblast into the walls of the spiral arterioles. This transforms the uteroplacental arterial bed into a low-resistance, low-pressure, high-flow system. The conversion of the spiral arterioles of the nonpregnant uterus into the uteroplacental arteries has been termed *physiologic changes* by Brosens.^[22] In a normal pregnancy, these trophoblast-induced vascular changes extend all the way from the intervillous space to the origin of the spiral arterioles from the radial arteries in the inner one third of the myometrium. It is suggested that these vascular changes are effected in two stages: "the conversion of the decidual segments of the spiral arterioles by a wave of endovascular trophoblast migration in the first trimester and the myometrial segments by a subsequent wave in the second trimester."^[22] This process was reportedly associated with extensive fibrinoid formation and degeneration of the muscular layer in the arterial wall. These vascular changes result in the conversion of approximately 100 to 150 spiral arterioles into distended, tortuous, and funnel-shaped vessels that communicate through multiple openings into the intervillous space.

948

In contrast, pregnancies complicated by preeclampsia and/or by fetal growth restriction demonstrate inadequate maternal vascular response to placentation. In these pregnancies, the above vascular changes are usually found only in the decidual segments of the uteroplacental arteries. Hence, the myometrial segments of the spiral arterioles are left with their musculoelastic architecture, thereby rendering them responsive to hormonal influences.^[23] Additionally, the number of well-developed arterioles is smaller than that found in normotensive pregnancies. The authors postulated that this defective vascular response to placentation is due to inhibition of the second wave of endovascular trophoblast migration that normally occurs from about 16 weeks' gestation onward. These pathologic changes may have the effect of curtailing the increased blood supply required by the fetoplacental unit in the later stages of pregnancy, and they may be responsible for the decreased uteroplacental blood flow seen in most cases of preeclampsia. These conclusions were recently supported by Frusca and associates.^[24] These authors studied placental bed biopsies obtained during cesarean delivery from normal pregnancies ($n = 14$), preeclamptic pregnancies ($n = 24$), and chronic hypertensive pregnancies only ($n = 5$). Biopsies from the preeclamptic group demonstrated abnormal vascular changes in every case, with 18 having acute atherosclerotic changes. On the other hand, 13 of the 14 biopsies from normotensive pregnancies had normal vascular physiologic changes, while the biopsies from the hypertensive patients showed all three types of physiologic changes. In addition, they found that the mean birth weight was significantly lower in the group with atherosclerosis than it was in the other group without such findings. However, it is important to note that these vascular changes are not a consistent finding in spiral arterioles of hypertensive pregnancies and were demonstrated in a significant proportion of normotensive pregnancies complicated by fetal growth restriction.^[23] Furthermore, a recent investigation by Meekins and associates^[26] found that endovascular trophoblast invasion was not an all-or-none phenomenon in normal and preeclamptic pregnancies. They also observed that morphologic features in one spiral artery may not be representative of all vessels in a placental bed.

Using electron microscopy, Shanklin and Sibai^[27] studied the ultrastructural changes in placental bed and uterine boundary vessels in 33 preeclamptic and 12 normotensive pregnancies. They found extensive ultrastructural endothelial injury in both placental site and nonplacental site in all the specimens from preeclamptic women, but not in the normotensive women. The injury appeared to affect the endothelial mitochondria, which suggests a possible metabolic link in the pathophysiology. The endothelial injury ranged from swelling to complete erosion, and the swelling was associated

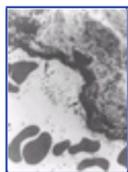

Figure 28-1 Compacted heavy fibrin deposition (arrows) and loose lamina fibrin replacing extensively eroded endothelium, nonplacental site region, uterine boundary zone, preeclampsia. (Original electron microscopic magnification, X 2,500). (From Shanklin DR, Sibai BM: *Ultrastructural aspects of preeclampsia. I. Placental bed and uterine boundary vessels. Am J Obstet Gynecol* 161:735, 1989, with permission.)

with enlargement of endothelial nuclei resulting in reduction of the lumen. In some cases, the erosion was complete with associated deposition of heavy fibrin (Fig. 28-1). In addition, there was no correlation between the type or degree of endothelial damage and the level of maternal hypertension.

Hemostatic Changes

Preeclampsia is associated with vasospasm, activation of the coagulation system, and abnormal hemostasis. There is good evidence from several studies that preeclampsia is accompanied by endothelial injury, increased platelet activation with platelet consumption in the microvasculature, and excessive clotting activity.^[28] Saleh et al.^[28] evaluated the hemostatic system before and 24 to 48 hours after delivery in 26 control pregnancies, 15 with mild preeclampsia and 18 with severe preeclampsia. They found that preeclampsia was associated with

949

high fibronectin, low antithrombin III, and low α_2 -antiplasmin levels, reflecting endothelial injury (high fibronectin), clotting (low antithrombin III), and fibrinolysis (low α_2 -antiplasmin). In addition, they noted that, after delivery, fibronectin levels decreased in the preeclamptic group, while α_2 -antiplasmin levels increased in all groups. They concluded that "vascular endothelial injury plays a central role in the hemostatic changes associated with preeclampsia." In a subsequent report,^[29] the authors evaluated hemostasis in various hypertensive disorders of pregnancies. They found elevated fibronectin, low antithrombin III, and reduced α_2 -antiplasmin in patients with pure preeclampsia as well as chronic hypertension with superimposed preeclampsia. In addition, they observed that fibronectin levels had better correlation with preeclampsia than either antithrombin III or α_2 -antiplasmin. They suggested that fibronectin might be useful for diagnosing superimposed preeclampsia in women with chronic hypertension.

In recent reports, elevated fibronectin values were identified in some patients prior to the development of preeclampsia.^[30] Taylor and colleagues^[30] measured cellular fibronectin levels in plasma of women who ultimately had preeclampsia, hypertension only, or normotensive pregnancies. They found elevated cellular fibronectin levels during the second and third trimesters only in women destined to develop preeclampsia. Halligan et al. reported that increased fibronectin levels are evident as early as 9 weeks' gestation in women who ultimately develop preeclampsia.^[31] Platelet consumption is a late finding in preeclampsia, but increased platelet turnover may be an early marker of preeclampsia. A mean platelet volume greater than or equal to 11 fL at 28 weeks' gestation was found to be associated with subsequent preeclampsia by some authors.^[32]

The enzyme thrombin converts fibrinogen to fibrin and is inactivated by antithrombin III, resulting in generation of thrombin-antithrombin III complexes. An increased level of these complexes suggests enhancement of thrombin generation. DeBoer et al.^[33] investigated plasma levels of the coagulation inhibitors antithrombin III, protein C, protein S, and thrombin-antithrombin III complexes. They observed reduced protein C levels, but normal protein S levels, in preeclampsia compared with normotensive pregnancies. In addition, they observed an increased thrombin-antithrombin III complex level in the preeclamptic group. The level of these complexes correlated with platelet count and antithrombin III levels. Thus, they suggested that enhanced thrombin generation in preeclampsia may result from increased platelet activation and consumption. Gilabert et al.^[34] evaluated protein C, protein S, and antithrombin III in normal pregnancy and severe preeclamptic states. They found reduced protein C and antithrombin III levels, but normal protein S in severe preeclampsia.

Changes In Prostanoids

Several investigators have described the various prostaglandins and their metabolites throughout pregnancy. They have measured the concentrations of these substances in plasma, serum, amniotic fluid, placental tissues, urine, or cord blood. The data have been inconsistent, reflecting differences in methodology.

During pregnancy, prostanoid production increases in both maternal and fetoplacental tissues.^[35] Prostacyclin is produced by the vascular endothelium as well as in the renal cortex. It is a potent vasodilator and inhibitor of platelet aggregation. Thromboxane A_2 (TXA₂) is produced by the platelets and trophoblasts. It is a potent vasoconstrictor and platelet aggregator. Hence, these eicosanoids have opposite effects and play a major role in regulating vascular tone and vascular blood flow

(Fig. 28-2) .

Changes in prostaglandin production and/or catabolism in uteroplacental and umbilical tissues have been reportedly associated with the development of preeclampsia, although the reports have been inconsistent.^{[36] [37] [38]} These discrepancies may reflect some of the inherent problems in the measurement of prostaglandins and the diagnosis of preeclampsia. An imbalance in prostanoid production or catabolism has been suggested as responsible for the pathophysiologic changes in preeclampsia.^[35] However, the role of prostaglandins in the etiology of preeclampsia remains unclear.^[38]

Recently, Mills and associates^[39] investigated the excretion of urinary metabolites of prostaglandin I₂ (PGI₂) and TXA₂ as measured prospectively before 22 weeks', between 26 and 29 weeks', and at 36 weeks' gestation among 134 women who ultimately developed preeclampsia and 134 matched women who remained normotensive. The authors found that reduced PGI₂ production, but no increase in TXA₂ production, occurs as early as 13 to 16 weeks in women who ultimately developed preeclampsia. In addition, the ratio of TXA₂ metabolite to PGI₂ metabolite was 24 percent higher throughout pregnancy in preeclamptic women.^[39]

Changes in Endothelium-Derived Factors

Recent data indicate that endothelium-derived substances such as endothelium-derived relaxing factor (EDRF) and endothelin may play a central role in the pathophysiology of preeclampsia.^[39] After its discovery, EDRF was found to be nitric oxide, an extremely potent vasodilator. In contrast, endothelin is an extremely potent vasoconstrictor. Pinto and associates^[40] reported a significant reduction in EDRF release from the endothelium of human umbilical blood vessels collected from patients with pregnancy-induced hypertension (PIH). In addition, Fickling et al.^[41] found higher concentrations of an endogenous inhibitor of nitric oxide

950

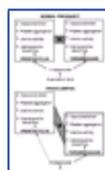

Figure 28-2 Comparison of the balance in the biologic actions of prostacyclin and thromboxane in normal pregnancy with the imbalance of increased thromboxane and decreased prostacyclin in preeclamptic pregnancy. The heavy type and box for thromboxane suggest an exacerbation of its actions in preeclampsia, whereas the lighter type and box for prostacyclin suggest a diminution of its actions. (From Walsh SW: *Preeclampsia: an imbalance in placenta prostacyclin and thromboxane production*. *Am J Obstet Gynecol* 152:335, 1985, with permission.)

synthesis in eight third-trimester patients with preeclampsia than in nine patients with PIH and 10 women with normotensive pregnancies. Recently, numerous studies described the role of nitric oxide metabolism in the pathogenesis of preeclampsia. These findings were the subject of two reviews by Seligman et al.^[42] and Baylis et al.^[43] There are several reports describing plasma levels of endothelin in patients with preeclampsia. While the majority of these studies report elevated levels in preeclamptic pregnancies compared with normotensive pregnancies,^{[44] [45] [46]} a recent study did not find higher levels of endothelin in patients with preeclampsia.^[47] These data suggest that levels are increased only in women with severe disease.^[37]

Lipid Peroxide, Free Radicals, and Antioxidants

Evidence is accumulating that lipid peroxides and free radicals may be important in the pathogenesis of preeclampsia.^{[48] [49] [50] [51]} Superoxide ions may be cytotoxic to the cell by changing the characteristics of cellular membrane and producing membrane lipid peroxidation. Elevated plasma concentrations of free radical oxidation products precede the development of preeclampsia.^[52] Uotila et al.^[53] demonstrated that lipid peroxidation was significantly higher in 56 women with hypertension in pregnancy than in control subjects. Lipid peroxidation products had a high correlation with the level of hypertension but failed to show a significant relation to perinatal outcome. In contrast, high levels of plasma and platelet glutathione peroxidase, an antioxidant, were found to have an association with fetal growth restriction and asphyxia. In addition, several studies reported lower serum antioxidant activity in patients with preeclampsia than in normotensive pregnancies.^{[53] [54] [55] [56] [57] [58] [59]}

Placental Peptide Hormones, Cytokines

Several investigators have studied changes in placental peptide or cytokines in maternal plasma in women with preeclampsia. These studies were the subject of two recent reviews.^{[21] , [60]}

Genetic Factors in Preeclampsia

Because a family history of preeclampsia increases the risk of preeclampsia, numerous investigations during the past decade have evaluated a possible link between preeclampsia and specific genetic mutations or thrombophilia.^{[61] [62] [63] [64] [65] [66] [67] [68] [69]} Some of the genetic mutations studied include a molecular variant of angiotensinogen (T₂₃₅), factor V Leiden mutation, which causes resistance to activated protein C, and mutations in methyltetrahydro-drofolate reductase, and the prothrombin gene, the presence of anticardiolipin antibodies, and inherited deficiencies in antithrombin III, protein S, and protein C. Unfortunately, the findings of these studies have been highly inconsistent.^{[61] [62] [63] [64] [65] [66] [67] [68] [69]}

Diagnosis

Preeclampsia is a clinical syndrome that embraces a wide spectrum of signs and symptoms that have been clinically observed to develop alone or in combination. Elevated blood pressure is the traditional hallmark for

951

diagnosis of the disease. However, recent evidence suggests that in some patients the disease may manifest itself in the form of either a capillary leak (edema, proteinuria) or a spectrum of abnormal hemostasis with multiple organ dysfunction. These latter patients usually present with clinical manifestations that are not typical of preeclampsia (i.e., hypertension is absent).

The diagnosis of preeclampsia and the severity of the disease process are generally based on maternal blood pressure measurements as ascertained by a variety of medical personnel who regularly measure blood pressure in prenatal clinics, local physicians' offices, and in hospital units. There are many factors that may influence measurement of the blood pressure with a sphygmomanometer, including the accuracy of the equipment used, size of the cuff, duration of the rest period before recording, the posture of the patient, and the Korotkoff phase used (phase IV or phase V) for diastolic blood pressure measurement. Reports on effects of these factors on measurements of blood pressure have been summarized by Steer.^[70] In these reports, the authors recommend that all blood pressure values be recorded with the woman in a sitting position for ambulatory patients or in a semireclining position for hospitalized patients. The right arm should be used consistently, with the arm being in a roughly horizontal position at heart level. For diastolic blood pressure measurements, both phases (muffling sound and disappearance sound) should be recorded. This is very important, since the level measured at phase IV is about 5 to 10 mm Hg higher than that measured at phase V.^[71] Lopez et al.^[71] compared Korotkoff phases IV and V in a cohort of 1,194 nulliparous pregnant women who were followed prospectively from the 20th week of pregnancy until delivery. Blood pressure measurements were obtained with random-zero sphygmomanometers and were recorded in supine, lateral, and seated positions. Lopez et al.^[71] found that the prevalence of hypertension (diastolic blood pressure [BP] 90 mm Hg or higher on 6 occasions 6 hours apart) when phase IV was used was double the prevalence when phase V was used. However, phase IV had a better sensitivity in the prediction of complications associated with hypertension (proteinuria, hyperuricemia, and intrauterine growth restriction), but a lower specificity. In addition, the authors found that phase V was easy to obtain during pregnancy. Blank et al.^[72] compared diastolic blood pressure values using Korotkoff phases IV and V in 58 pregnant women (42 hypertensive and 16 normotensive) at various stages of pregnancy. They concluded that phase V is a more accurate, reliable, and less variable measurement of diastolic blood pressure in pregnancy than muffling (phase IV). The literature in this area was recently reviewed by Johanning and Barron.^[73]

A rise in blood pressure has been used by several authors as a criterion for the diagnosis of hypertension in pregnancy. This definition is usually unreliable, since a

gradual increase in blood pressure from second to third trimester is seen in most normotensive pregnancies. MacGillivray et al.^[74] reported that 73 percent of primigravid patients with normotensive pregnancies demonstrate a rise in diastolic blood pressure of more than 15 mm Hg at some stage during the course of their pregnancies. In a study of 16,211 singleton pregnancies, Redman and Jeffries^[75] analyzed different cutoffs for diastolic blood pressure used in the diagnosis of preeclampsia. They found that an elevation in diastolic blood pressure of at least 25 mm Hg and a reading of at least 90 mm Hg were the best criteria. Similar findings were recently reported by Perry and Beevers.^[76]

Villar and Sibai^[77] prospectively studied blood pressure changes during the course of pregnancy in 700 young primigravidas. One hundred thirty-seven patients (19.6 percent) had preeclampsia. The pregnancy outcome according to blood pressure findings is summarized in Table 28-2. The sensitivity and positive predictive values for preeclampsia of a threshold increase in diastolic blood pressure of at least 15 mm Hg on two occasions were 39 and 32 percent, respectively. The respective values for a threshold increase in systolic pressures were 22 and 33 percent. Two recent studies, one from Australia and another from the United States, investigated pregnancy outcome in women with a rise in diastolic blood pressure of more than 15 mm Hg but an absolute diastolic level below 90 mm Hg as compared with gravidas who remained normotensive.^[78],^[79] The Australian report^[78] included women with elevated blood pressures without proteinuria, whereas the American investigation^[79] included women with an increased diastolic pressure 15 mm Hg or more plus proteinuria (300 mg/24 h). Both found that overall pregnancy outcomes were similar among women who remained

TABLE 28-2 -- PREGNANCY OUTCOME ACCORDING TO THRESHOLD INCREASE IN SYSTOLIC OR DIASTOLIC PRESSURES ON TWO OCCASIONS DURING THE THIRD TRIMESTER

Blood Pressure Criteria	Normotensive No. (%)	Preeclampsia No. (%)
Increase in diastolic 15 mm Hg	113 (68)	53 (32)
Increase in systolic 30 mm Hg	60 (67)	30 (33)
Threshold increase in both	32 (58)	23 (42)

Adapted from Villar MA, Sibai BM: Clinical significance of elevated mean arterial blood in second trimester and threshold increase in systolic or diastolic pressure during third trimester. Am J Obstet Gynecol 60:419, 1989.

normotensive and those who demonstrated a rise in diastolic pressure of 15 mm Hg or higher but did not reach 90 mm Hg.^[78],^[79] The use of an increase in blood pressure as a diagnostic criterion is dependent on at least two observations during the course of pregnancy that will be influenced by at least three factors: gestational age at time of first observation, frequency of blood pressure measurements, and the two observations to be selected. Thus, these criteria are inadequate to diagnose preeclampsia as such. However, they may be useful if used in association with the presence of proteinuria, or other associated symptoms of preeclampsia such as a persistent headache, visual symptoms, or epigastric pain. It should be emphasized that the presence of these symptoms is more important than the absolute level of blood pressure in establishing the diagnosis of preeclampsia. Indeed, there is more to preeclampsia than the presence of hypertension.^[80]

The diagnosis of preeclampsia requires the presence of an elevated blood pressure with proteinuria. Poor perinatal outcome is usually seen in patients who have hypertension plus proteinuria.^[3],^[81] The presence of proteinuria is usually determined by the use of either dipstick or protein/creatinine ratio in random urine samples. The concentration of urinary protein is highly variable.^[82] It is influenced by several factors, including contamination, urine-specific gravity, pH, exercise, and posture.^[83] In addition, urinary protein/creatinine excretion is highly variable in patients with preeclampsia.^[84],^[85] Moreover, recent studies found that urinary dipstick determinations correlate poorly with the amount of proteinuria found in 24-hour urine determinations.^[86]^[87]^[88]^[89] Therefore, the definitive test for diagnosing proteinuria should be quantitative measurement of total protein excretion over a 24-hour period. The diagnosis of severe preeclampsia requires that proteinuria of more than 5 g/24 h be documented. Using urine dipstick measurements (3+) is not adequate (Table 28-3).^[87]

Prediction of Preeclampsia

A review of the world literature reveals that more than 100 clinical, biophysical, and biochemical tests have been recommended to predict or identify the patient at risk for the future development of the disease^[60],^[90],^[91] (see the box "Clinical Tests Used to Predict Preeclampsia"). The results of the pooled data for the various tests and the lack of agreement between serial tests suggest that none of these clinical tests is sufficiently reliable for use as a screening test in clinical practice.^[90],^[91] We do not use any of them for screening purposes.

Clinical Tests Used to Predict Preeclampsia
Average mean arterial pressure (MAP) in the second trimester 8590 mm Hg
MAP at 20 weeks 90 mm Hg
Rollover test at 2832 weeks
Isometric exercise test
Angiotensin infusion test at 2630 weeks
Doppler velocimetry of uterine and umbilical vessels at 1826 weeks

There are reports describing the predictive value of a variety of substances measured in maternal plasma, serum, or urine, including cations, hormones, prostaglandins, metabolites, various parameters of coagulation and hemostasis, and uric acid.^[60],^[90],^[91] These studies differ in their methodologies and have included a heterogeneous group of patients with all forms of hypertension, parity, and gestational ages at time of sampling. Comparison and evaluation is, therefore, limited, which explains the wide scatter of results and lack of agreement among these findings.

Prevention of Preeclampsia

There are numerous reports and clinical trials describing the use of various methods to prevent or reduce the incidence of preeclampsia. Since the etiology of the disease is unknown, these methods were used in an attempt to correct theoretical abnormalities in preeclampsia. Some of the methods used are summarized in the box "Methods Used to Prevent Preeclampsia."^[92] No efficacy of high-protein or low-salt diets has ever been documented.

TABLE 28-3 -- VALUE OF DIPSTICK PROTEIN IN PREDICTING 24-HOUR URINARY PROTEIN EXCRETION

Urinary Dipstick	Protein Excretion (mg/24 h)	Sensitivity (%)	Specificity (%)	Positive Predictive Value (%)	Negative Predictive Value (%)
1+	300	67	74	92	34
3+	500	75	81	36	96

Methods Used to Prevent Preeclampsia

High-protein and low-salt diet
 Nutritional supplementation (protein)
 Calcium
 Magnesium
 Zinc
 Fish and evening primrose oil
 Antihypertensive drugs including diuretics
 Antithrombotic agents
 Low-dose aspirin
 Dipyridamole
 Heparin
 Vitamins E and C

Calcium Supplementation

The relationship between dietary calcium intake and hypertension has been the subject of several experimental and observational studies.^[93] Several authors reported reduced urinary excretion of calcium at the time of preeclampsia, as well as several weeks prior to the onset of PIH or preeclampsia.^{[94] [95] [96]}

Epidemiologic studies have documented an inverse association between calcium intake and maternal blood pressure and the incidences of preeclampsia and eclampsia. These findings were recently reviewed by Belizan and associates.^[97] The BP-lowering effect of calcium was thought to be mediated by alterations in plasma renin activity and parathyroid hormone. In addition, calcium supplementation during pregnancy was shown to reduce vascular sensitivity to angiotensin II.^[98]

There are nine clinical studies comparing the use of calcium versus no treatment or a placebo in pregnancy.^{[98] [99] [100] [101] [102] [103] [104] [105] [106] [107]} These trials differ in the populations studied (low-risk or high-risk for hypertensive disorders of pregnancy), study design (randomization, double-blind, or use of a placebo), gestational age at enrollment (20 to 32 weeks' gestation), sample size in each group (range, 22 to 588), dose of elemental calcium used (156 to 2,000 mg/day), and the definition of hypertensive disorders of pregnancy used.

Eight of the studies were randomized and placebo-controlled.^{[94] [95] [96] [97] [98] [99] [100] [101] [102] [103] [104] [105] [106]} The dose of elemental calcium used was 600 to 2,000 mg/day. Five of these trials studied healthy pregnant women (low risk), and the other three studied pregnant women who had either a positive rollover test or both a positive rollover test and increased sensitivity to angiotensin II infusion.^[98] Results of the nine studies are summarized in Table 28-4.

The largest of these trials is the National Institute of Child Health and Human Development (NICHD) trial in healthy nulliparous women reported by Levine and associates.^[104] This trial revealed no beneficial effects from calcium supplementation on the rates of preeclampsia and preterm delivery. In contrast, a recent Australian multicenter trial in nulliparous women revealed beneficial effects.^[106] In summary, calcium supplementation may be beneficial in a select group of women considered at extremely high risk for preeclampsia.

Magnesium Supplementation

Serum magnesium levels are usually lower in pregnancy and rapidly return to prepregnancy concentrations after delivery. The relationship between dietary magnesium deficiency and hypertension has been the subject of several experimental and observational studies.^[108] Dietary magnesium deficiency during pregnancy has been implicated in the pathogenesis of preeclampsia, fetal growth restriction, and preterm delivery.^{[109] [110]} In patients with

Positive rollover test or angiotensin II.

preeclampsia, magnesium levels were reported to be lower or similar to those in normotensive pregnancies. Since parenteral magnesium sulfate is the drug of choice in the treatment of preeclampsia, some authors have suggested an etiologic relationship between magnesium deficiency and preeclampsia. ^[109], ^[110]

In a retrospective study, Conradt et al. ^[110] compared pregnancy outcomes in 4,023 low-risk pregnancies with those in 882 high-risk pregnancies. The high-risk group was treated with -sympathomimetic agents in combination with various doses of magnesium aspartate hydrochloride. Preeclampsia was not observed in the high-risk treated group, while the incidence was 2 percent in the control group. In addition, the incidence of fetal growth restriction was significantly reduced in the treated group. The authors concluded that routine supplementation with magnesium during pregnancy prevents preeclampsia and fetal growth restriction.

Spatling and Spatling ^[111] reported a double-blind study involving 568 women who were randomized to receive either 14 mmol magnesium aspartate hydrochloride (*n* = 278) or aspartic acid as a placebo (*n* = 290). The supplementation was given daily starting at or before 16 weeks' gestation and was continued throughout pregnancy. The rates of preeclampsia were similar in the two groups; however, the magnesium-supplemented group had a lower incidence of both preterm delivery and the number of newborns admitted to the intensive care unit.

Sibai et al. ^[108] studied 400 young primigravidas who were enrolled at 13 to 24 weeks' gestation to receive either 365 mg of elemental magnesium as magnesium aspartate hydrochloride or an aspartic acid placebo. The magnesium-supplemented group had significantly higher serum magnesium levels. However, there were no significant differences between the two groups regarding the rates of preeclampsia, fetal growth restriction, or preterm delivery. In addition, magnesium supplementation did not influence systolic or diastolic blood pressure during the course of pregnancy.

Zinc Supplementation

Dietary zinc deficiency has been associated with poor pregnancy outcome. In addition, reduced plasma zinc levels as well as lowered placental zinc levels have been reported in pregnancies complicated by preeclampsia. ^[112] Hunt et al. ^[113] studied the effects of zinc supplementation on the outcomes of pregnancy in 213 low-income Mexican women. The patients were randomly allocated in a double-blind fashion to receive either a placebo or capsules containing 20 mg zinc per day. The incidence of pregnancy-induced hypertension was significantly reduced in the zinc-supplemented group (2 vs. 16 percent). There were no other differences in pregnancy outcome between the two groups.

Mohamed and associates ^[114] studied pregnancy outcome in 494 women who were enrolled in a zinc supplementation trial; 246 patients were given 20 mg zinc daily, while 248 received a placebo. They found no differences between the two groups regarding weight gain, blood pressure, or the incidence of preeclampsia (4.6 percent in the zinc group vs. 1.3 percent in the control group). In addition, they found no differences regarding neonatal birth weight, fetal growth restriction, or the incidence of preterm delivery.

At the present time, there are inadequate data to prove a strong association between the prevention of preeclampsia and any nutritional supplementation. For this reason, routine supplementation with these nutrients is not recommended.

Antithrombic Agents

Preeclampsia is associated with vasospasm and activation of the coagulation-hemostasis systems. Enhanced platelet activation plays a central role in the above process with resultant abnormality in the thromboxane/prostacyclin balance. Hence, several authors have used pharmacologic manipulation to alter the above ratio in an attempt to prevent or ameliorate the course of preeclampsia.

Aspirin inhibits the synthesis of prostaglandins by irreversibly acetylating and inactivating cyclooxygenase. In vitro, platelet cyclooxygenase is more sensitive to inhibition by low doses of aspirin (<80 mg) than vascular endothelial cyclooxygenase. Therefore, treatment with low-dose aspirin could alter the balance between prostacyclin and thromboxane. ^[115] This biochemical selectivity of low-dose aspirin appears to be related to its unusual kinetics that result in presystemic acetylation of platelets exposed to higher concentrations of aspirin in the portal circulation. Sibai et al. ^[116] found that effective inhibition of thromboxane generation by platelets, 98 percent decrease from baseline, can be achieved after 1 week of therapy with 80 mg of daily aspirin during pregnancy. In addition, they observed that a 60-mg dose resulted in a 60 percent decrease in platelet thromboxane generation after 1 week and a 97 percent decrease after 2 weeks of therapy.

Several studies have described the effects of low-dose aspirin (60 to 81 mg/day) on angiotensin II sensitivity during pregnancy. ^[117] These data suggest that enhanced vascular responsiveness to angiotensin II infusions may be mediated by an imbalance in thromboxane/PGL₂ production that may be corrected in some women by the use of low-dose aspirin. In addition, several prospective studies suggest that the administration of aspirin in women at high risk for preeclampsia might

No treatment.

reduce the incidence of hypertensive disorders of pregnancy, fetal growth restriction, and preterm delivery. These studies included a limited number of patients who were identified to be at high risk for preeclampsia on the basis of a poor obstetric history, chronic hypertension, positive rollover test, increased sensitivity to angiotensin II infusions, or abnormal Doppler studies of the uterine vessels. In general, these studies ^[117] suggested that low-dose aspirin was highly effective in the prevention of preeclampsia and fetal growth restriction in women considered at risk for these complications.

Recently, several multicenter, randomized, prospective trials have been reported from centers around the world. Some of these studies were conducted in healthy nulliparous women, ^[91] whereas others included patients with a variety of obstetric and medical complications. ^[9], ^[118], ^[119], ^[120], ^[121], ^[122], ^[123], ^[124] In general, about 75 percent of all preeclampsia occurs in nulliparous women. Therefore, prevention of preeclampsia in these women has major clinical implications. There are four randomized, placebo-controlled trials describing the use of 60 mg/day of aspirin in healthy nulliparous women (Table 28-5). The results reveal no reduction in the rates of preeclampsia with low-dose aspirin. In addition, four trials included women at risk for preeclampsia, but none revealed a reduction in rates of preeclampsia. The largest of these trials was conducted by the NICHD Maternal-Fetal Network Units in women with pregestational diabetes, chronic hypertension, previous preeclampsia-eclampsia, and multifetal gestation. Reduction of preeclampsia was not achieved in any of the groups studied (Table 28-6). ^[123]

In summary, the use of low-dose aspirin in healthy nulliparous women does not improve pregnancy outcome even when the rate of preeclampsia is reduced. The role of low-dose aspirin in women at high risk for preeclampsia particularly those with previous severe preeclampsia before 28 weeks and those with marked abnormalities

in uterine Doppler studies at both 18 to 20 weeks' and 24 weeks' gestation remains controversial. ^[125] ^[126] ^[127]

Fish Oil

Researchers have evaluated the effects of N-3 fatty acid supplementation during pregnancy on the rates of preeclampsia in high-risk women. ^[92] Overall, no reduction in the rate of preeclampsia was observed with N-3 fatty acid supplementation in a recent randomized trial. ^[128]

One recent study has suggested a beneficial effect from pharmacologic doses of vitamins E and C in women identified at-risk for preeclampsia by means of abnormal uterine Doppler flow velocimetry. ^[59] However,

* No difference for any of the groups.

the study had limited sample size and must be confirmed in other populations.

Finally, it is important to emphasize that most of the positive trials found a benefit in the prevention of a "definition of preeclampsia," but not in pregnancy outcome.

Laboratory Abnormalities in Preeclampsia

Women with preeclampsia may exhibit a symptom complex ranging from minimal blood pressure elevation to derangements of multiple organ systems. The renal, hematologic, and hepatic systems are most likely to be involved.

Renal Function

Renal plasma flow and glomerular filtration rate (GFR) increase during normal pregnancy. These changes are responsible for a fall in serum creatinine, urea, and uric acid concentrations. In preeclampsia, vasospasm and glomerular capillary endothelial swelling (glomerular endotheliosis) lead to an average reduction in GFR of 25 percent below the rate for normal pregnancy. ^[129] Serum creatinine is rarely elevated in preeclampsia, but uric acid is commonly increased. ^[130] In a study of 200 women with mild preeclampsia remote from term, Sibai et al. ^[130] found the mean serum creatinine to be 0.80 mg/dl, mean uric acid 6.1 mg/dl, and mean creatinine clearance 112 ml/min. In a subsequent study of 95 women with severe preeclampsia, Sibai and associates ^[131] reported a mean serum creatinine of 0.91 mg/dl, a mean uric acid of 6.6 mg/dl, and a mean creatinine clearance of 100 ml/min.

The clinical significance of elevated uric acid levels in preeclampsia/eclampsia has been confusing. In a study of 332 women with preexisting hypertension, plasma urate levels were found to be a better indicator of fetal prognosis than blood pressure. Uric acid levels above 5 mg/dl were associated with poor perinatal outcome. ^[132] However, in a comparison of 69 eclamptic women who had uric acid levels of less than 6.0 mg/dl with those who had values above 10.0 mg/dl, Pritchard and Stone ^[133] found no significant difference between the two groups in blood pressure, perinatal outcome, or the incidence of hypertension in subsequent pregnancies.

Hepatic Function

The liver is not primarily involved in preeclampsia, and hepatic involvement is observed in only 10 percent of women with severe preeclampsia. ^[134] Fibrinogen deposition has been found along the walls of hepatic sinusoids in preeclamptic patients with no laboratory or histologic evidence of liver involvement. ^[135] When liver dysfunction does occur in preeclampsia, mild elevation of serum transaminase is most common. ^[136] Bilirubin is rarely increased in preeclampsia but, when elevated, the indirect fraction predominates. Elevated liver enzymes are part of the syndrome of hemolysis, elevated liver enzymes, and low platelets (HELLP), a variant of severe preeclampsia.

Hematologic Changes

Many studies have evaluated the hematologic abnormalities in women with preeclampsia. ^[137] ^[138] Plasma fibrinopeptide-A, D-dimer levels, and circulating thrombin-antithrombin complexes are higher in women with preeclampsia than in normotensive gravidas. In contrast, plasma antithrombin III activity is decreased. These findings indicate enhanced thrombin generation. ^[137] ^[138]

Plasma fibrinogen rises progressively during normal pregnancy. When a group of 50 severe preeclamptic women were compared with 50 normotensive women matched by gestational age, no differences in mean plasma fibrinogen levels were found between the two groups. ^[139] In general, plasma fibrinogen levels are rarely reduced in women with preeclampsia in the absence of abruptio placentae.

Thrombocytopenia is the most common hematologic abnormality in women with preeclampsia. Its incidence will depend on the severity of the disease process, definition, and the presence or absence of abruptio placentae. A platelet count of less than 150,000/mm³ was reported in 32 to 50 percent of women with severe preeclampsia. ^[139] ^[140] In a study of 1,414 women with hypertension during pregnancy, Burrows and Kelton ^[141] found a platelet count of less than 150,000/mm³ in 15 percent.

Leduc and associates ^[140] studied the coagulation profile (platelet count, fibrinogen, prothrombin time, and partial thromboplastin time) in 100 consecutive women with severe preeclampsia. A platelet count less than 150,000/mm³ was found in 50 percent and a count of less than 100,000/mm³ in 36 percent of the women. Thirteen women had a fibrinogen level of less than 300 mg/dl, and two had prolonged prothrombin and partial thromboplastin times, as well as thrombocytopenia on admission. They found the admission platelet count to be an excellent predictor of subsequent thrombocytopenia, and concluded that fibrinogen levels, prothrombin time, and partial thromboplastin time should be obtained only in women with a platelet count of less than 100,000/mm³. A recent study by Barron et al. reported similar results in over 800 women with hypertension in pregnancy. ^[142]

The HELLP Syndrome

Recent reports have described the HELLP syndrome in severe preeclampsia. There is considerable debate regarding the definition, diagnosis, incidence, etiology, and management of this syndrome.^[143] Patients with such findings were previously described by many investigators. Goodlin^[144] labeled this syndrome "EPH gestosis type B"; he claimed that this clinical presentation had been reported in the obstetric literature a century earlier. Weinstein^[134] considered it a unique variant of preeclampsia and coined the term "HELLP syndrome" for this entity, while MacKenna and colleagues^[145] considered it to be misdiagnosed preeclampsia.

A review of the literature highlights the differences regarding the degree of abnormal laboratory findings and the criteria used to diagnose HELLP syndrome. Thrombocytopenia, a platelet count less than 100,000/mm³, has been the most consistent finding among the various reports. However, some investigators have included only those values determined before delivery, while others have reported platelet counts obtained both antepartum and postpartum. In addition, there are considerable differences regarding what constitutes an abnormal level of serum glutamic-oxaloacetic transaminase (SGOT) or bilirubin. Several reports have not even included these data.^[146] Barton and associates^[147] performed liver biopsies in patients with preeclampsia and HELLP syndrome. Periportal necrosis and hemorrhage were the most common histopathologic findings. In addition, they found that the extent of the laboratory abnormalities in HELLP syndrome including the platelet count and liver enzymes did not correlate with hepatic histopathologic findings.

Based on a retrospective review of 302 cases of HELLP syndrome, Martin et al.^[148] devised the following classification based on platelet count nadir. Class I HELLP syndrome was defined as a platelet nadir below 50,000/mm³, class 2 platelet nadirs between 50,000 and 100,000/mm³, and class 3 a platelet nadir between 100,000 and 150,000/mm³. These classes have been used to predict the rapidity of recovery postpartum, maternal-perinatal outcome, and the need for plasmapheresis.^[149] Miles et al.^[150] reported a strong association between the presence of HELLP syndrome and eclampsia. In that study, the HELLP syndrome was present in 30 percent of patients with postpartum eclampsia and in 28 percent of patients having eclampsia prior to delivery.

Hemolysis, defined as the presence of microangiopathic hemolytic anemia, is the hallmark of the HELLP syndrome. The role of disseminated intravascular coagulation (DIC) in preeclampsia is controversial. Most authors do not regard HELLP syndrome to be a variant of DIC, since coagulation parameters such as prothrombin time, partial thromboplastin time, and serum fibrinogen are normal. However, the diagnosis of DIC in clinical practice is difficult. When sensitive determinants of this condition are used such as antithrombin III, fibrinopeptide-A, fibrin monomer, D-dimer, α_2 -antiplasmin, plasminogen, prekallikrein, and fibronectin, many patients have laboratory values consistent with DIC.^[151],^[152] Unfortunately, these tests are time consuming and not suitable for routine monitoring. Consequently, less sensitive parameters are often used in clinical practice. Sibai et al.^[143] defined DIC as the presence of thrombocytopenia, low fibrinogen levels (plasma fibrinogen <300 mg/dl), and fibrin split products above 40 mg/ml. These authors observed DIC in 38 percent of the 112 patients with HELLP syndrome. In a subsequent report, Sibai et al.^[153] noted the presence of DIC in 21 percent of 442 patients with HELLP syndrome. They also found that the majority of cases occurred in women who had antecedent abruptio placentae or peripartum hemorrhage and in all four women who had subcapsular liver hematomas. In the absence of these complications, the frequency of DIC was only 5 percent.^[153] Aarnoudse et al.^[154] diagnosed DIC in HELLP syndrome by light microscopic and immunofluorescence findings in tissue biopsies and laboratory findings of thrombocytopenia, elevated fibrinogen degradation products, reduced antithrombin III levels, and fragmented red blood cells.

In view of the above diagnostic problems, Sibai^[146] recommended that uniform and standardized laboratory values be used to diagnose this syndrome. He suggested that low-density lipoprotein and bilirubin values be included in the diagnosis of hemolysis. In addition, the degree of abnormality of liver enzymes should be defined as a certain number of standard deviations from the normal value for each hospital population. Furthermore, the rate of change in either liver enzymes or platelet count may be as important as the absolute value in establishing the diagnosis. Our laboratory criteria to establish the diagnosis are presented [in the box "Criteria to Establish the Diagnosis of HELLP Syndrome."](#)

The reported incidence of HELLP syndrome in preeclampsia has ranged from 2 to 12 percent,^[146] reflecting the differences in diagnostic criteria used. The syndrome appears to be most common in Caucasian patients. The incidence of HELLP syndrome is also higher in preeclamptic patients who have been managed conservatively.

The patient is usually seen remote from term complaining of epigastric or right upper quadrant pain (65 percent), some will have nausea or vomiting (50 percent), and others will have nonspecific viral syndrome-like symptoms. The majority of patients (90 percent) will give a history of malaise for the past few days

before presentation; some may present with hematuria or gastrointestinal bleeding. Hypertension and proteinuria may be absent or slightly abnormal.^[153]^[154]^[155] Physical examination will demonstrate right upper quadrant tenderness and significant weight gain with edema.

Criteria to Establish the Diagnosis of HELLP Syndrome	
Hemolysis	
Abnormal peripheral blood smear	
Increased bilirubin <1.2 mg/dl	
Increased lactic dehydrogenase >600 IU/L	
Elevated liver enzymes	
Increased SGOT 72 IU/L	
Increased lactic dehydrogenase >600 IU/L	
Thrombocytopenia	
Platelet count <100,000/mm ³	

It is important to remember that severe hypertension is not a constant or even a frequent finding in HELLP syndrome. Although 66 percent of the 112 patients studied by Sibai and associates^[143] had a diastolic blood pressure of at least 110 mm Hg, 14.5 percent had a diastolic blood pressure of less than 90 mm Hg. Aarnoudse and colleagues^[154] described six women presenting with severe epigastric pain in the third trimester who had significantly elevated liver enzymes, low platelets, and evidence of hemolysis. None of these patients had a blood pressure higher than 140/90 mm Hg proteinuria. As a result, they are often misdiagnosed as having various medical and surgical disorders ([see the box "Medical and Surgical Disorders Confused with the HELLP Syndrome"](#)). Occasionally the presence of this syndrome is associated with hypoglycemia leading to coma, severe hyponatremia, and cortical blindness. A rare but interesting complication of HELLP syndrome is transient nephrogenic diabetes insipidus. Unlike central diabetes insipidus, which occurs due to the diminished or absent secretion of arginine vasopressin by the hypothalamus, transient nephrogenic diabetes insipidus is characterized by a resistance to arginine vasopressin mediated by excessive vasopressinase. It is postulated that elevated circulating vasopressinase may result from impaired hepatic metabolism of the enzyme.

Medical and Surgical Disorders Confused with the HELLP Syndrome

Acute fatty liver of pregnancy
Appendicitis
Diabetes mellitus
Gallbladder disease
Gastroenteritis
Glomerulonephritis
Hemolytic uremic syndrome
Hepatic encephalopathy
Hyperemesis gravidarum
Idiopathic thrombocytopenia
Kidney stones
Peptic ulcer
Pyelonephritis
Systemic lupus erythematosus
Thrombotic thrombocytopenic purpura
Viral hepatitis

It is important to emphasize that these patients may have a variety of unusual signs and symptoms, none of which are diagnostic of severe preeclampsia. Pregnant women with probable preeclampsia presenting with atypical symptoms should have a complete blood count, a platelet count, and liver enzyme determinations irrespective of maternal blood pressure.^[146]

Management of preeclamptic patients presenting with the HELLP syndrome is highly controversial.^[146] Consequently, there are several therapeutic modalities described in the literature to treat or reverse the HELLP, syndrome. Most of these modalities are similar to those used in the management of severe preeclampsia remote from term (see the box "Therapeutic Modalities Used to Treat or Reverse HELLP Syndrome").^[146]

Therapeutic Modalities Used to Treat or Reverse HELLP Syndrome

Plasma volume expansion
 Bed rest
 Crystalloids
 Albumin 5 to 25 percent
Antithrombotic agents
 Low-dose aspirin
 Dipyridamole
 Heparin
 Antithrombin III
 Prostacyclin infusions
Immunosuppressive agents
 Steroids
Miscellaneous
 Fresh frozen plasma infusions
 Exchange plasmapheresis
 Dialysis

From Sibai BM: The HELLP Syndrome (hemolysis, elevated liver enzymes, and low platelets): much ado about nothing? Am J Obstet Gynecol 162:311, 1990, with permission.

Goodlin^[159] described five patients with features of HELLP syndrome who were treated conservatively with bed rest in an attempt to increase plasma volume. Three women also received intravenous infusions of 5 or 25 percent albumin. Goodlin felt that the efforts at plasma volume expansion were in part beneficial as measured by a fall in hemoglobin concentration, a rise in platelet count, and resolution of some of the symptoms of "severe toxemia." Thiagarajah et al. ^[157] treated five patients with prednisone or betamethasone and observed an improvement in platelet count and liver enzymes.

Heyborne^[158] reported five cases where temporary reversal of the HELLP syndrome was achieved using low-dose aspirin (81 mg/day) and corticosteroids. The average prolongation of pregnancy was 4 weeks; however, three pregnancies beginning at 25 weeks or earlier were prolonged for an average of 5.5 weeks. No long-term maternal morbidity occurred, although one patient developed DIC and eclampsia. Critics of this study note that three patients had platelet counts above 100,000 mm³ at initial diagnosis, and hemolysis was not documented in three patients.

Clark and associates^[159] reported three cases in which temporary reversal of the HELLP syndrome was achieved using bed rest and corticosteroids. Pregnancy was prolonged 4 to 10 days, and all patients had a live birth. It is important to note that two of the patients had a platelet count of more than 100,000/mm³, and one had normal liver enzymes.

Van Assche and Spitz^[160] treated a patient who developed preeclampsia and HELLP syndrome at 32 weeks' gestation with bed rest, albumin infusion, and dazoxiben, a thromboxane synthetase inhibitor. All maternal laboratory values returned to normal after 4 days of treatment with dazoxiben. The patient had a cesarean delivery 1 week later, delivering a small-for-gestational-age infant. The authors suggested that dazoxiben might have beneficial effects in the management of such patients.

Two reports by Magann and associates from the University of Mississippi ^[161], ^[162] suggested that the use of corticosteroids either antepartum or postpartum results in transient improvement in laboratory values and urine output in some patients diagnosed with HELLP syndrome. It is important to note that in the antepartum group delivery was delayed by an average of only 41 hours and the study was not placebo controlled. ^[161] Recently, authors from the same institution expanded on their experience with the use of high-dose dexamethasone in the management of women with HELLP syndrome. They observed improved outcomes, shorter hospital stays, and fewer blood transfusions. ^[163] A transient beneficial effect on hematologic findings with steroids was also reported by Tompkins and Thiagarajah. ^[164] However, these recommendations require testing in a randomized trial and their use should be considered experimental.

Recently, investigators from the Netherlands reported that expectant management is possible in women with HELLP syndrome below 34 weeks' gestation. ^[165], ^[166] Visser and Wallenburg reported the use of plasma volume expansion in 128 women with HELLP syndrome before 34 weeks' gestation. They noted complete reversal of HELLP in 43 percent of their patients. Pregnancy was prolonged a median of 10 days (range, 0 to 62). Overall perinatal mortality was 14.1 percent, and no maternal complications occurred. ^[165] Similar management was reported to improve outcome in women with preterm HELLP by Van Pampus et al. ^[169]

Confounding variables make it difficult to evaluate any treatment modality proposed for this syndrome. Occasionally, some patients without true HELLP syndrome may demonstrate antepartum reversal of hematologic abnormalities following bed rest, the use of steroids, or plasma volume expansion. However, the majority of these patients will experience deterioration in either maternal or fetal condition within 1 to 10 days after conservative management. It is doubtful that such limited pregnancy prolongation will result in improved perinatal outcome, and maternal and fetal risks are substantial.

There is general agreement that pregnancies complicated by preeclampsia and the HELLP syndrome are associated with poor maternal and perinatal outcomes. ^[4], ^[16], ^[153] The reported perinatal mortality has ranged from 7.7 to 60 percent and maternal mortality from 0 to 24 percent. Maternal morbidity is common. Most of these patients have required transfusions of blood and blood products and are at increased risk for the development of acute renal failure, pulmonary edema, ascites, pleural effusions, and hepatic rupture. ^[151], ^[153], ^[164], ^[167], ^[168], ^[169], ^[170] Moreover, these pregnancies are associated with high incidences of abruptio placentae and DIC (Table 28-7). ^[170]

The HELLP syndrome may develop antepartum or postpartum. Analysis of 442 cases studied by Sibai and associates ^[153] revealed that 309 (70 percent) had evidence of the syndrome antepartum, and 133 (30 percent) developed the manifestations postpartum. There were four maternal deaths, and morbidity was frequent (Table 28-8).

In the postpartum period, the time of onset of the manifestations may range from a few hours to 7 days, the majority developing within 48 hours postpartum. Eighty percent of the postpartum patients had preeclampsia prior to delivery, whereas 20 percent had no evidence of either preeclampsia either antepartum or intrapartum. It is the author's experience that patients in this group are at increased risk for the development of pulmonary edema and acute renal failure (Table 28-9). The differential diagnosis should include exacerbation

TABLE 28-7 -- MATERNAL COMPLICATIONS IN 316 PREGNANCIES WITH HELLP SYNDROME, PARTIAL HELLP SYNDROME, OR SEVERE PREECLAMPSIA WITH NORMAL LABORATORY VALUES

of systemic lupus erythematosus, thrombotic thrombocytopenic purpura, and hemolytic uremic syndrome.

Patients with the HELLP syndrome who are remote from term should be referred to a tertiary care center, and their initial management should be the same as that for any patient with severe preeclampsia. The first priority is to assess and stabilize maternal condition, particularly coagulation abnormalities. The next step is to

evaluate fetal well-being using the nonstress test and biophysical profile. Then, a decision must be made as to whether immediate delivery is indicated. Amniocentesis may be performed in patients at less than 34 weeks' gestation. In the absence of laboratory evidence of DIC and fetal lung maturity, the patient may be given two doses of steroids to accelerate fetal lung maturity and then delivered 24 hours after the last dose. During this time, both maternal and fetal conditions should be monitored closely. This syndrome is not an indication for immediate cesarean delivery. It is the author's opinion that such an approach might prove detrimental for both mother and fetus. Patients presenting with well-established labor should be allowed to deliver vaginally as indicated. In addition, labor may be initiated with oxytocin in those with a favorable cervix.

Patients with delayed resolution of HELLP syndrome including persistent severe thrombocytopenia represent a management dilemma. Exchange plasmapheresis with fresh frozen plasma has been advocated as a treatment by some authors.^{[149], [171]} Since the majority of these patients will have spontaneous resolution of their disease, however, early initiation of plasmapheresis may be an unnecessary intervention. Schwartz^[171] suggested that serial studies indicating a progressive elevation of bilirubin or creatinine associated with hemolysis and thrombocytopenia be considered an indication for plasmapheresis. Martin et al.^[149] reported the use of plasma exchange with fresh frozen plasma in seven women in the postpartum period with HELLP syndrome that persisted for more than 72 hours following delivery. All patients had persistent thrombocytopenia, rising lactic dehydrogenase, and evidence of multiorgan dysfunction. Sustained increases in mean platelet count and decreases in LDH concentrations were associated with plasma exchange. The authors recommended that a trial of plasma exchange with fresh frozen plasma be considered in HELLP syndrome that persists past 72 hours postpartum and in which there is evidence of a life-threatening microangiopathy. Potential adverse effects of this technique are numerous. Ultimately, the question remains how many patients would spontaneously improve without benefit of plasmapheresis. It is the author's experience that plasmapheresis is not needed in the management of such patients.^{[153], [170]}

Subcapsular Hematoma of the Liver in HELLP Syndrome

Because it occurs so rarely, the diagnosis of a subcapsular hematoma of the liver in pregnancy is often overlooked. Indeed, in four recent cases managed at our institution, our initial clinical impression was placental abruption with DIC in three cases and a complication

TABLE 28-8 -- SERIOUS MATERNAL COMPLICATIONS IN 442 PATIENTS WITH HELLP SYNDROME

of a postpartum tubal ligation in the fourth patient.^[153] The differential diagnosis of an unruptured subcapsular hematoma of the liver in pregnancy should include acute cholecystitis with sepsis, acute fatty liver of pregnancy, ruptured uterus, placental abruption with DIC, and thrombotic thrombocytopenia purpura (TTP). Most patients present in the third or late second trimester of pregnancy, although cases have been reported in the immediate postpartum period. In addition to the signs and symptoms of preeclampsia, physical findings consistent with peritoneal irritation and hepatomegaly may be present. Profound hypovolemic shock with hypotension in a previously hypertensive patient is a hall-mark of rupture of the hematoma.

Laboratory evaluation is often consistent with DIC, including low platelet count, low fibrinogen, and prolonged prothrombin and partial thromboplastin times. As a result of hemolysis, total bilirubin and serum lactate dehydrogenase are markedly elevated. Other liver function tests such as aspartate and alanine aminotransferase are also significantly elevated.^{[153], [172]}

Rupture of a subcapsular hematoma of the liver is a life-threatening complication of HELLP syndrome. In most instances, rupture involves the right lobe and is preceded by the development of a parenchymal hematoma. The condition usually presents with severe epigastric pain that may persist for several hours prior to circulatory collapse. Patients frequently present with shoulder pain, shock, or evidence of massive ascites, respiratory difficulty, or pleural effusions, and often with a dead fetus. An ultrasound or computed axial tomographic (CAT) scan of the liver should be performed to rule out subcapsular hematoma and detect the presence of intraperitoneal bleeding.^[172] Paracentesis can confirm intraperitoneal hemorrhage suspected by radiographic imaging.

The presence of a ruptured subcapsular liver hematoma resulting in shock is a surgical emergency requiring acute multidisciplinary treatment. Resuscitation should consist of massive transfusions of blood, correction of the coagulopathy with fresh frozen plasma and platelets, and immediate laparotomy. Options at laparotomy

include packing and drainage, the preferred approach, surgical ligation of the hemorrhaging hepatic segments, embolization of the hepatic artery to the involved liver segment, and loosely suturing omentum or surgical mesh to the liver to improve integrity. Even with appropriate treatment, maternal and fetal mortality is over 50 percent. Mortality is most commonly associated with exsanguination and coagulopathy. Initial survivors are at increased risk for developing adult respiratory distress syndrome, pulmonary edema, and acute renal failure in the postoperative period. ^[153], ^[168]

Surgical repair has been recommended for hepatic hemorrhage without liver rupture. More recent experience suggests, however, that this complication can be managed conservatively in patients who remain hemodynamically stable. ^[172] ^[173] ^[174] Management should include close monitoring of hemodynamics and coagulation status. Serial assessment of the subcapsular hematoma with ultrasound or computed tomographic (CT) scan is necessary with immediate intervention for rupture or worsening maternal status. It is important with conservative management to avoid exogenous sources of trauma to the liver such as abdominal palpation, convulsions, or emesis and to use care in transportation of the patient. Indeed, any sudden increase in intra-abdominal pressure could potentially lead to rupture of the subcapsular hematoma. ^[175]

Smith et al. ^[176] reviewed their management of seven cases of spontaneous rupture of the liver occurring during pregnancy. Of the four survivors, the mean gestational age was 32.8 weeks and the mean duration of hospitalization was 16 days. All the survivors were managed with packing and drainage of the liver, whereas the three patients treated with hepatic lobectomy

died. The authors also extracted 28 cases from the literature reported since 1976. In 35 cases, there was an 82 percent overall survival for the 27 patients managed by packing and drainage, whereas only 25 percent of eight gravidas undergoing hepatic lobectomy survived. The authors emphasized that hepatic hemorrhage with persistent hypotension unresponsive to transfusion of blood products may be managed surgically with laparotomy, evaluation of the hematoma, packing the damaged liver, and draining the operative site. In certain cases where the patient is stable enough to undergo angiography, transcatheter embolotherapy is a reasonable alternative to surgery. ^[177]

At the University of Tennessee, Memphis, we have managed four patients with HELLP syndrome complicated by ruptured subcapsular hematoma in 14 years. Three cases required transfusion of 22 to 40 units of packed red blood cells and multiple units of platelets and fresh frozen plasma. Two of these three cases were complicated by pulmonary edema and acute renal failure, but all survived without any residual deficiency. The fourth case was a patient who presented in profound shock and with DIC. This patient subsequently died secondary to a ruptured pulmonary emphysematous bleb during management of adult respiratory distress syndrome. ^[153]

Any algorithm for the management of a subcapsular hematoma of the liver in pregnancy must emphasize the potential need for large amounts of blood products and the need for aggressive intervention if rupture of the hematoma is suspected. Our algorithm, employed at the University of Tennessee, Memphis, is presented in [Figure 28-3](#). Our experience is in agreement with the recent observations of Smith et al. ^[176] in that a stable patient with an unruptured subcapsular hematoma may be managed conservatively. Constant monitoring must continue during this management, however, as patients can rapidly become unstable following rupture of the hematoma.

Survival depends on rapid diagnosis and medical and surgical stabilization. The coagulopathy must be aggressively reversed, as failure to do so is associated with an increased incidence of renal failure. In addition, these patients should be managed in an intensive care unit with close hemodynamic monitoring to avoid pulmonary edema, respiratory compromise, or both.

Postpartum follow-up for patients with subcapsular hematoma of the liver should include serial computed tomography or ultrasound until the defect resolves. ^[172]

Hemodynamic Changes in Preeclampsia

The cardiovascular hemodynamics of preeclampsia have been investigated over the years by many authors using various techniques for measurements of blood pressure, cardiac output, pulmonary capillary wedge pressure (PCWP), and central venous pressure (CVP). ^[178]

The true hemodynamic findings in patients with preeclampsia are controversial. A review of the English literature demonstrates considerable disagreement regarding one or more of the hemodynamic parameters studied. This lack of agreement has been attributed to differences in the definition of preeclampsia, variable severity and duration of the disease process, presence of underlying cardiac or renal disease, the techniques used to measure cardiac output and blood pressure, and the therapeutic interventions applied before obtaining the various measurements. In addition, the dynamic minute-to-minute fluctuation of the various cardiovascular parameters studied makes it difficult to standardize the conditions under which these observations are made, limiting the value of a single measurement.

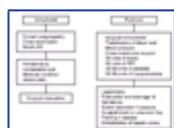

Figure 28-3 An algorithm for the management of a subcapsular hematoma at the University of Tennessee, Memphis.

Invasive techniques have been used by many authors to study the hemodynamic findings in untreated women with severe preeclampsia. ^[179] ^[180] ^[181] ^[182] ^[183] The reported cardiac index ranged from a low of 2.8 to a high of 4.8 L/min/m², and the reported PCWP from a low of 3.3 to a high of 12 mm Hg. The findings suggest that cardiac index and PCWP are either low or normal in severe preeclampsia. The reported CVP values also ranged from 2 to 6 mm Hg.

[Table 28-10](#) compares the invasive hemodynamic findings in treated patients with severe preeclampsia. ^[181], ^[184], ^[185] The data for the various parameters are similar among the three studies. The findings demonstrate that treated patients with preeclampsia have normal to high cardiac index, normal to high systemic vascular resistance index, and normal to high PCWP.

In summary, the true hemodynamic findings of preeclampsia remain unknown. The majority of the data indicate that both cardiac output and systemic vascular resistance appear to be elevated in women with severe preeclampsia. This finding suggests that the problem in preeclampsia is a systemic vascular resistance that is inappropriately high for the level of cardiac output. Both the PCWP and the CVP appear to be in the low to normal range; however, there is no correlation between the two values.

Doppler Velocimetry Studies

There are numerous reports describing the use of uteroplacental and umbilical arterial flow velocity waveforms (FVWs) in the prediction, diagnosis, and management of preeclampsia (see [Chapter 12](#)) and ([Chapter 25](#)). ^[186] Early studies suggested that Doppler ultrasound held great promise as a noninvasive, repeatable, and simple method of predicting hypertension in pregnancy and identifying those hypertensive pregnancies at high risk for maternal and fetal complications. ^[187] ^[188] ^[189] ^[190] However, subsequent studies have emphasized the multiplicity of factors that may influence the Doppler waveform pattern. ^[186]

Steel et al. ^[191] screened 1,014 nulliparous women with Doppler waveforms from the uteroplacental circulation at 18 to 20 weeks. One hundred eighteen (12 percent) had persistently abnormal tests at both 18 and 24 weeks' gestation. The incidence of hypertension among these 118 women was 25 percent. The sensitivity was high for hypertension associated with proteinuria (63 percent) or intrauterine growth restriction (100 percent).

Bower and associates ^[192] screened 2,430 women with continuous wave Doppler ultrasound of both uterine arteries at 18 to 20 weeks' gestation. An abnormal FVW in either uterine artery was used to predict preeclampsia and poor perinatal outcome. Including an early diastolic notch in the definition of an abnormal FVW increased

the sensitivity for moderate and severe preeclampsia to 79 to 88 percent and the specificity to 85 percent. However, the positive predictive value was only 4.3 to 6.9 percent. Another study was less encouraging. ^[193], ^[194]

Trudinger and Cook^[195] studied Doppler umbilical and uterine FVW in women with severe hypertension in pregnancy. They found that perinatal complications correlated more closely with umbilical artery indices than uteroplacental indices. More recently, Yoon and associates ^[196] examined umbilical artery waveforms in 72 women with preeclampsia. The Doppler studies were performed within 7 days of delivery. They found that an abnormal umbilical artery waveform was a strong and independent predictor of adverse perinatal outcome in patients with preeclampsia.

Pattinson and associates^[197] reported on a randomized controlled trial evaluating the role of umbilical artery Doppler velocimetry in the management of patients with hypertensive diseases or suspected fetal growth restriction. The

Doppler findings were revealed to the managing physicians of 108 patients, but blinded in another 104 patients. Knowledge of Doppler velocimetry results was beneficial only in the subset of patients with absent end-diastolic velocities.

In summary, the data regarding examination of the uteroplacental circulation for the prediction of preeclampsia indicate that the presence of abnormal tests at 18 to 20 weeks' and at 24 weeks' gestation, particularly the presence of a diastolic notch, may be helpful as a screening test in selected, high-risk populations. On the other hand, evaluation of the umbilical artery is valuable in identifying those pregnancies that might require frequent monitoring with traditional tests of fetal well-being such as the nonstress test and biophysical profile. In general, the presence or absence of end-diastolic frequencies or reverse flow patterns in the umbilical artery is usually associated with poor perinatal outcome. ^[198]

The Management of Preeclampsia

Once the diagnosis of preeclampsia has been made, definitive therapy in the form of delivery is the only cure. The primary considerations of therapy must always be the safety of the mother and then the delivery of a live, mature newborn who will not require intensive and prolonged neonatal care. However, in some cases such an approach is not in the best interest of the fetus. As a result, the decision between immediate delivery and expectant management will depend on one or more of the following: the severity of the disease process, maternal and fetal status at the time of initial evaluation, fetal gestational age, presence of labor, the Bishop score, and the wishes of the mother.

Mild Preeclampsia

Patients with diagnosed preeclampsia should ideally be hospitalized at the time of diagnosis for evaluation of maternal and fetal conditions. These pregnancies may be associated with reduced uteroplacental blood flow jeopardizing the fetus. In addition, the mother is at a slightly increased risk for the development of abruptio placentae or convulsions, particularly in cases remote from term. Thus, women with mild disease who have a favorable cervix at or near term should undergo induction of labor for delivery. The pregnancy should not continue past 40 weeks' gestation, even if conditions for induction of labor are unfavorable.

The optimal management of mild preeclampsia remote from term (<37 weeks' gestation) is controversial. There is considerable disagreement regarding the need for hospitalization versus ambulatory management, the use of antihypertensive drugs, and the use of sedatives. ^[14], ^[15]

In the past, management of these patients has involved bed rest in the hospital for the duration of pregnancy because this approach enhanced fetal survival and diminished the frequency of progression to severe disease. ^[199], ^[200] On the other hand, the benefits of prolonged antepartum hospitalization for women with mild gestational hypertension without proteinuria were challenged by several European investigators who reported that most of these patients can be safely managed on an ambulatory basis or in a day-care facility.

Two studies reported on pregnancy outcome in women with mild hypertension without proteinuria remote from term who were randomized to either bed rest in the hospital or normal activity at home. ^[201], ^[202] Both studies questioned the value of hospitalization and came to the conclusion that management at home was safe and cost effective. Two other studies reported that management of these women can be done safely and efficiently in day-care units, thereby diminishing the number of hospitalization days. ^[203], ^[204] Finally, a recent review analyzing the value of bed rest in obstetrics including mild hypertension suggested that this approach is not cost effective and might be potentially harmful. ^[205]

There are numerous clinical reports, both controlled and uncontrolled, describing the use of various drugs in an attempt to prolong gestation and improve perinatal outcome in women with mild preeclampsia remote from term. However, it is almost impossible to evaluate and compare the results because of the heterogeneous populations studied, and the absence of a placebo group in most reports. ^[2], ^[19] Overall, these studies have revealed lower rates of progression to severe disease with no impact on perinatal outcome. ^[130], ^[200] Of note, the sample size was inadequate in any of these studies to evaluate small differences in adverse perinatal outcome. ^[2], ^[16]

In a prospective, randomized trial, Sibai et al. ^[130] compared no therapy to the use of nifedipine in the management of mild preeclampsia remote from term (Table 28-11). They found that nifedipine was effective in reducing maternal systolic and diastolic blood pressures in women with mild preeclampsia. However, this reduction in maternal blood pressure was not associated with a reduction in antepartum hospital days in the nifedipine group. In addition, while the use of nifedipine led to a lower incidence of delivery for severe hypertension (9 percent vs. 18 percent), there was no difference in the gestational age at delivery.

Our management plan at the University of Tennessee, Memphis, for women with mild preeclampsia is summarized in Figure 28-4. Patients who are unreliable are hospitalized at the time of their diagnosis. During hospitalization, patients receive a regular diet with no salt restriction and no activity limits. Diuretics and antihypertensive drugs are not prescribed, and sedatives

GA, gestational age; SGA, small for gestational age.

are not used. Patients initially undergo evaluation of maternal and fetal well-being. The frequency of subsequent testing usually depends on the gestational age and maternal response following hospitalization. Subsequent fetal evaluation includes serial ultrasonography for fetal growth every 3 weeks, daily fetal movement count, nonstress testing every week, and a biophysical profile if needed. Maternal evaluation includes blood pressure monitoring (every 4 hours during the day) and daily assessment of maternal weight to detect excessive weight gain. In addition, women are questioned regarding symptoms of impending eclampsia (persistent headache, visual disturbances, or epigastric pain). Laboratory evaluation includes measurements of urine protein, hematocrit, platelet count, and liver function tests once or twice weekly. This evaluation is extremely important because patients may develop thrombocytopenia and elevated liver enzymes with minimal blood pressure elevation.^[155]

If the patient's blood pressure remains stable in the absence of either significant proteinuria (<1,000 mg/24 h) or maternal symptoms (headaches, visual disturbances, or epigastric pain), then outpatient observation may be considered on a selective basis. This form of management is appropriate in a reliable patient only during the early stages of the disease and in the absence of fetal jeopardy (abnormal testing or abnormal fetal growth).^[15] Patients are instructed to rest at home and have daily urine dipstick measurements of proteinuria and blood pressure monitoring they perform or by a nurse. The patient is also instructed to keep fetal movement counts and to report any symptoms of impending eclampsia. The patient is then evaluated in the antepartum testing area for maternal and fetal well-being at

Figure 28-4 University of Tennessee, Memphis, management plan for patients with mild preeclampsia.

least two times per week. If there is any evidence that her condition is worsening such as acute hypertension or substantial proteinuria, then prompt hospitalization is indicated.

The success rate of outpatient management will depend on the gestational age and maternal status at time of diagnosis. Patients diagnosed with mild hypertension only (diastolic pressure <100 mm Hg, absent proteinuria) will have a longer duration of pregnancy prolongation than those diagnosed with moderate elevations of hypertension (diastolic >100 mm Hg) and significant proteinuria.^[206] After 37 weeks gestation, labor should be induced as soon as the cervix is favorable (Bishop score 6).

The prophylactic use of magnesium sulfate in women with mild gestational hypertension or mild preeclampsia to prevent eclamptic convulsions remains controversial. There are few retrospective studies evaluating the frequency of eclampsia in women not receiving seizure prophylaxis.^[19] There is only one randomized, placebo-controlled study in a limited number of women with mild preeclampsia ($n = 135$).^[207] A large trial compared the use of phenytoin to magnesium sulfate in a heterogeneous group of women ranging from mild gestational hypertension to severe preeclampsia.^[208] This trial revealed magnesium sulfate to be superior to phenytoin for the prevention of eclamptic convulsions.^[208] Women with mild preeclampsia should be considered for prophylactic therapy if they have symptoms. At present, there is a need for a large randomized, placebo-controlled trial to investigate the efficacy of magnesium sulfate seizure prophylaxis in women with mild preeclampsia.^[18]

Severe Preeclampsia

The clinical course of severe preeclampsia may be characterized by progressive deterioration in both maternal and fetal conditions. Because these pregnancies have been associated with increased rates of perinatal mortality and significant risks for maternal morbidity and mortality, there is universal agreement that all such patients should be delivered if the disease develops after 34 weeks' gestation or prior to that time if there is evidence of maternal or fetal distress.^[209] There is also agreement on delivery of such patients prior to 35 weeks' gestation in the presence of any of the following: premature rupture of membranes, labor, or severe fetal growth restriction (<5th percentile for age). In this situation, appropriate management consists of parenteral medications to prevent convulsions, control of maternal blood pressure within a relatively safe range, and then induction of labor to achieve delivery.^[131] If delivery of a preterm infant less than 34 weeks' gestation is anticipated at a Level I or Level II hospital, the mother should be transferred to a tertiary care center with adequate neonatal intensive care facilities.

On the other hand, there is considerable disagreement about management of patients with severe disease prior to 34 weeks' gestation. Some authors consider delivery as the definitive therapy for all cases, regardless of gestational age, whereas others recommend prolonging pregnancy in all severe preeclamptic gestations remote from term until development of fetal lung maturity, fetal or maternal distress, or a gestational age of 34 to 36 weeks is achieved.^[169], ^[170], ^[209], ^[210], ^[211], ^[212], ^[213] Some of the measures used in these latter cases have included one or more of the following: antihypertensive agents, diuretics, sedatives, chronic parenteral magnesium sulfate, plasma volume expanders, and antithrombotic agents.

Severe Preeclampsia at 28 to 32 Weeks' Gestation

There are several retrospective studies describing expectant management of women with severe preeclampsia at 28 to 32 weeks' gestation.^[209] In general, these studies suggest that expectant management can improve outcome in selected patients.^[209]

There are three randomized trials describing expectant management in patients with severe preeclampsia. In the first study, the results of individualized management were reported in 58 women with severe preeclampsia at 28 to 34 weeks' gestation.^[214] These patients were treated initially with magnesium sulfate, hydralazine, and corticosteroids to accelerate fetal lung immaturity. All received intensive maternal and fetal care in a high-risk obstetric ward. Nonstress tests were done at least three times daily, and laboratory tests were evaluated at least twice weekly. Twenty of the 58 women were delivered because of maternal or fetal reasons within 48 hours after hospitalization. The remaining 38 were then randomized to either aggressive or expectant management ($n = 20$). Patients assigned to the aggressive management group received steroids and were delivered within 72 hours. Patients assigned to the expectant management group were treated with hydralazine to maintain blood pressure between 140/90 and 150/100 mm Hg. In addition, they received frequent evaluations for maternal and fetal well-being. These patients were delivered at 34 weeks' gestation or before in the presence of maternal or fetal distress. The authors found lower neonatal complications and lower number of days spent in the neonatal intensive care unit in the expectant-management group.^[214]

In a second study,^[215] a randomized clinical trial was conducted in which patients with severe preeclampsia between 26 and 36 weeks' gestation were assigned to be treated with either nifedipine ($n = 24$) or hydralazine ($n = 25$). Patients assigned to the nifedipine group

TABLE 28-12 -- PREGNANCY OUTCOME

	Aggressive Management (n = 46)	Expectant Management (n = 49)	Significance

From Sibai BM, Mercer BM, Schiff E, Friedman SA: Aggressive versus expectant management of severe preeclampsia at 28 to 32 weeks' gestation: a randomized controlled trial. *Am J Obstet Gynecol* 171:818, 1994.

received 10 to 30 mg sublingually initially, then 40 to 120 mg/day orally. Those assigned to the hydralazine group received 6.25 to 12.5 mg intravenously initially. Maternal evaluation included frequent measurements of blood pressure, heart rate, patellar reflexes, urine output, and laboratory tests. Fetal evaluation included daily fetal heart rate monitoring, biophysical profile three times a week, and weekly ultrasonographic assessment of fetal growth. The authors found better control of blood pressure and a lower incidence of nonreassuring fetal testing in the group managed with nifedipine.^[215] In addition, the group receiving nifedipine had a better perinatal outcome than those receiving hydralazine. They concluded that nifedipine is a safe and effective drug in the management of patients with severe preeclampsia remote from term.^[215]

Sibai et al.^[131] studied 95 women with severe preeclampsia at 28 to 32 weeks' gestation who were randomly assigned to either aggressive management (AM) (n = 46) or expectant management (EM) (n = 49). The two groups were similar at the time of randomization with respect to several clinical and laboratory findings.

The average pregnancy prolongation in the EM group was 15.4 ± 6.6 days (range, 4 to 36 days), which was significantly higher than the average in the AM group of 2.6 days (p < 0.0001; range, 2 to 3 days). In the EM group, the average pregnancy prolongation period was not affected by the amount of proteinuria at randomization. Indications for delivery in the EM group were worsening maternal status (n = 16), fetal compromise (n = 13), attainment of 34 weeks' gestation (n = 10), preterm labor or rupture of membranes (n = 7), or vaginal bleeding (n = 3). The maternal indications for delivery were thrombocytopenia (n = 5), uncontrolled severe hypertension (n = 3), headache/blurred vision (n = 3), epigastric pain (n = 2), severe ascites (n = 1), and maternal demand (n = 2).

Table 28-12 compares the pregnancy outcomes in the two groups. Gestational age at delivery, placental weight, and birth weight were significantly higher in the EM group. The two cases of abruptio placentae in the AM group were found at the time of cesarean delivery, whereas the two cases in the EM group were suspected because of abnormal fetal heart rate testing and vaginal bleeding. There were no cases of eclampsia, pulmonary edema, renal failure, or disseminated coagulopathy in either group.

No fetal or neonatal deaths occurred in either group. The number of infants admitted to a neonatal intensive care unit (37 vs. 46 percent), average duration of stay in that unit (20 vs. 37 percent), and the frequency of respiratory distress syndrome (22 vs. 50 percent) and necrotizing enterocolitis (0 vs. 11 percent) were significantly lower in the EM group.^[131]

Mid-Trimester Severe Preeclampsia

Severe preeclampsia developing in the mid-trimester is associated with high perinatal mortality and morbidity.^{[216], [217]} Aggressive management with immediate delivery will result in high neonatal mortality. In addition, all surviving neonates will develop significant neonatal complications and will require prolonged hospitalization in neonatal intensive care units. On the other hand, attempts to prolong pregnancy may result in fetal demise or asphyxial damage in utero. Moreover, this management may expose the mother to severe morbidity and even mortality. The perinatal survival rate is usually poor when the disease develops before 24 weeks' gestation (2 percent); however, it is better when the disease occurs at or beyond 25 weeks' gestation.^{[216] [217] [218]}

Initially, Sibai et al.^[217] reviewed pregnancy outcome in 60 such patients who had had conservative management over a 7-year period. The mean gestational age at

time of management was 24.8 weeks (range, 17 to 27), and average days of pregnancy prolongation was 11.4 days (range, 2 to 40). The perinatal outcomes of these pregnancies were poor, with 31 of the 60 resulting in fetal demise and 21 ending in neonatal death, for a total perinatal mortality of 87 percent. In addition, maternal morbidity was significantly high. This study was retrospective, most patients were managed at Level I hospitals, and few of these pregnancies had antepartum fetal evaluation.

Pattinson et al.^[219] described the results of conservative management in 34 patients who had severe preeclampsia before 28 weeks. The patients were managed by bed rest, antihypertensive drugs, and intensive fetal and maternal monitoring. Eleven patients presented before 24 weeks, all of them resulting in perinatal deaths, and the remaining 23 were between 24 and 37 weeks' gestation, with 13 (38 percent) resulting in a surviving infant. Maternal complications included three cases (9 percent) of pulmonary edema and one case (3 percent) with pleural effusion.

More recently, Sibai et al.^[219] described a new protocol for managing severe preeclampsia in the mid-trimester. The study included 109 patients with severe preeclampsia at 19 to 27 weeks' gestation. All patients were first admitted to labor and delivery and were evaluated carefully for the presence of either maternal or fetal compromise. Pregnancy termination was recommended for patients with gestational ages of 24 weeks or less (n = 25), whereas expectant management was recommended for patients with gestational age over 24 weeks (n = 84). Of the 25 patients with gestational age 24 weeks or less, 10 accepted termination and the other 15 elected to continue with their pregnancies. The latter patients were managed with bed rest, antihypertensive drugs, and frequent evaluation of maternal and fetal well-being. The average days of pregnancy prolongation in these 15 pregnancies was 19.4 days; 11 ended in stillbirths, and 3 resulted in neonatal deaths, for an overall perinatal survival of 6.7 percent. Of the 84 patients with gestational ages more than 24 weeks, 30 had immediate delivery either because of patient's desire or because of attending staff decision. These patients received magnesium sulfate, antihypertensive drugs, and steroids and then were delivered within 48 hours. The other 54 patients were managed conservatively with antihypertensive drugs and daily evaluation of maternal and fetal well-being. The conservative management group had significantly higher perinatal survival (64.5 vs. 23.6 percent) and lower neonatal complications. In addition, the two groups had similar frequencies of maternal complications. They concluded that expectant management for women with severe preeclampsia should be selective and done only in a tertiary care center with adequate intensive care facilities.^[219]

At the University of Tennessee, Memphis, patients with severe preeclampsia remote from term are admitted initially to the labor and delivery area for continuous evaluation of maternal and fetal conditions for at least 24 hours. Subsequent management is based on gestational age (Fig. 28-5). During observation, they receive continuous infusion of magnesium sulfate to

Figure 28-5 University of Tennessee, Memphis, management plan for patients with severe preeclampsia.

prevent convulsions and bolus doses of hydralazine (5 to 10 mg), labetalol (20 to 40 mg), or oral nifedipine (10 mg) as needed to keep diastolic blood pressure below 110 mm Hg. Patients at gestational age less than 34 weeks' gestation are given corticosteroids to accelerate fetal lung maturity. Maternal evaluation includes continuous monitoring of blood pressure, heart rate, urine output, cerebral status, and the presence of epigastric pain. Laboratory evaluation includes a platelet count and liver enzymes. Fetal evaluation includes continuous fetal heart monitoring, a biophysical profile, and ultrasonographic assessment of fetal growth. Patients with resistant severe hypertension or other signs of maternal or fetal deterioration are delivered within 24 hours, irrespective of gestational age or fetal lung maturity. [209] In addition, patients in labor, or those with fetuses with a gestational age greater than 35 weeks, and those with evidence of fetal lung maturity by amniocentesis at 33 to 35 weeks also are delivered within 24 hours. [209] Patients at 33 to 35 weeks' gestation with immature fluid receive steroids to accelerate fetal lung maturity and are delivered 24 hours after the last dose of steroids in the absence of any change in maternal or fetal condition.

It is a commonly held clinical impression that fetuses of preeclamptic women have accelerated lung maturation as a result of stress in utero. This phenomenon, however, has never been documented in a well-controlled study. The effect of hypertension during pregnancy on the incidence of neonatal respiratory distress syndrome is highly controversial. [219] Schiff and associates [219] compared fetal lung maturity indices in 127 preterm patients with preeclampsia and 127 normotensive controls matched by gestational age, race, and fetal gender. They found no differences in the incidences of immature results between the two groups. They concluded that fetuses of preeclamptic women do not exhibit accelerated lung maturation. [219] Similar findings were also reported by Piazze et al. from Italy. [220]

Corticosteroids have been suggested as safe and effective drugs for preventing respiratory distress syndrome, treating thrombocytopenia, and improving perinatal outcome in severe preeclampsia. A review of the literature reveals substantial differences in methodology and drug selection among investigators who advocate the use of steroids for preeclampsia. [221] A patient may be considered suitable for steroid therapy if there is no evidence of maternal or fetal jeopardy and if delivery is not expected to occur within 48 hours. Maximum benefit is achieved when steroid therapy is given in appropriate doses and the last dose is given at least 24 hours before delivery. Different regimens of steroids have been suggested for preventing respiratory distress syndrome, but we prefer betamethasone given as 12 mg as soon as possible and the dose repeated 24 hours later.

Patients at 28 to 32 weeks' gestation receive individualized management based on their clinical response during the observation period. All of these patients receive steroids to accelerate fetal lung maturity, as there is still benefit even if the delivery occurs in less than 24 hours or more than 1 week later. Some demonstrate marked diuresis and improvement in blood pressure during the observation period. If the blood pressure remains below 100 mm Hg diastolic without antihypertensive therapy after the observation period, magnesium sulfate is discontinued, and the patients are followed closely on the antepartum high-risk ward until fetal maturity is achieved. During hospitalization, they receive antihypertensive drugs, usually oral nifedipine 40 to 120 mg/day, to keep their diastolic blood pressure between 90 and 100 mm Hg, with daily evaluation of maternal and fetal well-being. In general, most of these patients will require delivery within 2 weeks. [131] However, some patients may continue their pregnancies for several weeks. It is important to note that such pregnancies should be managed at tertiary care centers because their courses are unpredictable.

There is one placebo-controlled trial evaluating the use of magnesium sulfate in women with severe preeclampsia. [222] The trial revealed a significant reduction in eclampsia in the treated group (1 of 345 vs. 11 of 340; relative risk, 0.09; confidence interval, 0.01 to 0.69). Therefore, all women with severe preeclampsia should receive magnesium sulfate during labor and for 24 hours postpartum. Magnesium sulfate is administered by a controlled continuous intravenous infusion with a loading dose of 6 g in 100 ml over 15 to 20 minutes. We believe that the intravenous route for magnesium therapy permits more precise control of the patient's blood level and avoids the pain of intramuscular injections. Maintenance therapy is given at a rate of 2 g in 100 ml of fluid per hour. Treatment is continued for 12 to 24 hours after delivery.

The magnesium ion goes beyond extracellular fluid and enters bones and cells as well. [223] Magnesium circulates largely unbound to protein and is excreted in the urine. Therefore, an accurate record of maternal urine output must be maintained. In patients with normal renal function, the half-life for magnesium excretion is about 4 hours. In the therapeutic range (4.8 to 9.6 mg/dl), magnesium sulfate slows neuromuscular conduction and depresses central nervous system irritability. For this reason, maternal respiratory rate, deep tendon reflexes, and state of consciousness must be frequently monitored to detect magnesium toxicity. An ampule of calcium gluconate, 1 g (10 ml of 10 percent solution) should be drawn up in a syringe, clearly labeled, and kept at the bedside in case of magnesium toxicity. If magnesium toxicity is suspected, the infusion of magnesium sulfate should be discontinued. If respiratory depression occurs, the calcium gluconate should be given intravenously over 3 minutes. If respiratory

arrest develops, the patient should receive mechanical ventilatory support as needed (see the box "Magnesium Toxicity").

Magnesium Toxicity	
Loss of patellar reflex	812 mg/dl
Feelings of warmth, flushing	912 mg/dl
Somnolence	1012 mg/dl
Slurred speech	1012 mg/dl
Muscular paralysis	1517 mg/dl
Respiratory difficulty	1517 mg/dl
Cardiac arrest	3035 mg/dl

We carefully monitor the volume of intravenous fluids used in women with preeclampsia or eclampsia. Intake and output should be assessed hourly. We give a 5 percent dextrose in lactated Ringer's solution at 100 to 125 ml/h. A Foley catheter should be inserted to permit accurate evaluation of urine output. We are particularly cautious when treating women with chronic hypertension or renal disease. Frequently, in the active phase of labor, urine output may drop below 30 ml/h. In those cases, in which the cervix is continuing to dilate, we have not given a fluid challenge or diuretics. Typically in these women, urine output will increase to 30 ml/h after 2 to 3 hours. Our goal is to maintain the urine output at 30 ml/h. If urine output drops below 100 ml in 4 hours, the dose of magnesium sulfate and intravenous fluids should be reduced accordingly. Another cause of decreased urine output is a drop in maternal blood pressure due to repeated injections of hydralazine. Hydralazine has a relatively long duration of action and, when multiple bolus injections of hydralazine are used to control blood pressure, the diastolic blood pressure may be reduced more than intended, that is, below 90 mm Hg. This action will frequently reduce urine output for 2 to 3 hours. One of the potential problems when attempting to limit intravenous fluids to 125 ml/h is that high concentrations of drugs must be used if the woman is receiving intravenous magnesium sulfate, oxytocin, and hydralazine.

To control severe maternal hypertension intrapartum, we use bolus injections of hydralazine 5 to 10 mg every 20 to 30 minutes to lower the diastolic blood pressure to the 90 to 100 mm Hg range. This requires monitoring of blood pressure every 5 minutes for at least 30 minutes after the drug is given. Recently, Patterson-Brown and

associates described 70 women with severe preeclampsia who received bolus injections of hydralazine for the treatment of sustained severe hypertension (mean arterial pressure >125 mm Hg for 45 minutes or >140 mm Hg for 15 minutes).^[224] Each treatment episode consisted of hydralazine 5 mg given as an intravenous bolus dose, repeated after 15-minute intervals until the mean arterial pressure fell below 125 mm Hg, up to a maximum of three boluses. All women received a 400- to 500-ml albumin solution (5 percent) over 20 minutes prior to hydralazine. They found that this protocol was effective in lowering maternal blood pressure in 89 percent of the cases. In addition, they observed no significant maternal or fetal side effects from such therapy. They concluded that hydralazine given in 5-mg boluses is a safe and effective method for treating severe hypertension in preeclampsia.^[224] An alternative regimen is to use bolus injections of labetalol hydrochloride, 20 to 80 mg. Unlike hydralazine, labetalol does not cause maternal tachycardia, flushing, or headaches. We have found this drug to be safe and effective in the management of these patients.^[225] Oral nifedipine in doses of 10 to 20 mg every 4 to 6 hours may also be used (Table 28-13).^[226],^[227] Other potent antihypertensive medications such as sodium nitroprusside, or nitroglycerin are rarely needed in managing these patients. Diuretics such as furosemide are not used except in the presence of pulmonary edema.^[228]

Anesthesia in Severe Preeclampsia

Maternal analgesia can be provided by the intermittent use of small doses (25 to 50 mg) of intravenous meperidine or segmental epidural analgesia. Local infiltration anesthesia with or without pudendal block or epidural can be used for all cases of vaginal delivery for patients with mild disease. In addition, continuous epidural anesthesia or balanced general anesthesia can be used for all cesarean deliveries. The use of epidural anesthesia for patients with severe preeclampsia/eclampsia is controversial. It is important to emphasize that the administration of epidural requires the availability of personnel with special expertise in obstetric anesthesia. In addition, in selected cases it requires the availability of central hemodynamic monitoring, since infusions of large amounts of crystalloids or colloids are usually used as precautionary measures before its administration. Moreover, the use of conduction anesthesia is contraindicated in the presence of coagulopathy.

On the other hand, significant hypertension and tachycardia are frequently observed after laryngoscopy and endotracheal intubation as well as during extubation in patients undergoing general anesthesia. Transient but severe hypertension after tracheal intubation can result in a significant increase in maternal intracranial pressures with the dangers of cerebral edema and hemorrhage and increased afterload with the dangers of pulmonary edema. These responses can be prevented or attenuated by the use of labetalol prior to endotracheal intubation. Labetalol should be used in a dose of 20 mg intravenously followed by 10-mg increments up to a total dose of 1 mg/kg.^[229] In addition, endotracheal

TABLE 28-13 -- PARENTERAL AND ORAL DRUGS FOR TREATMENT OF SEVERE HYPERTENSION IN PREGNANCY

Drug	Dose	Onset of Action	Duration of Action	Adverse Effects
Hydralazine	510 mg IV q 20 min	1020 min	36 h	Tachycardia, headache, flushing, aggravation of angina
Labetalol	2040 mg IV q 10 min 1 mg/kg as needed	1020 min	36 h	Scalp tingling, vomiting, heart block
Nifedipine	1020 mg PO q 2030 min	1015 min	45 h	Headache, tachycardia, synergistic interaction with magnesium sulfate
Nicardipine	515 mg/h IV	510 min	14 h	Tachycardia, headache, phlebitis
Sodium nitroprusside	0.255 g/kg/min IV	Immediate	12 min	Nausea, vomiting, muscle twitching, thiocyanate and cyanide intoxication
Nitroglycerin	5100 g/min IV	25 min	35 min	Headache, methemoglobinemia, tachyphylaxis

intubation increases the risk of aspiration, and there is the potential for failed intubation in the presence of airway edema, morbid obesity, and a short neck.^[230] In such situations, it is preferable to perform awake intubation using fiberoptic guidance.

Ramanathan and associates^[231] conducted a prospective evaluation of the hemodynamic and neuroendocrine stress responses at the time of cesarean delivery in 21 women with severe preeclampsia. Eleven received epidural anesthesia and 10 general anesthesia. The authors found that epidural anesthesia caused blunting of the hemodynamic and neuroendocrine stress responses to cesarean delivery in women with severe preeclampsia. The findings support the concept that epidural anesthesia should be the method of choice in these patients.

Recent data also suggest that epidural, spinal, and combined spinal-epidural techniques offer many advantages for labor analgesia and for cesarean delivery in women with preeclampsia/eclampsia.^[232],^[233],^[234] Hypotension can usually be avoided by meticulous attention to technique and proper volume expansion. In addition, a recent study indicates that epidural appears to be a safe and effective technique in women with severe hypertension in pregnancy.^[234] It must be emphasized, however, that there are no randomized studies comparing the safety of conduction to general anesthesia for cesarean delivery in women with severe preeclampsia/eclampsia.

For patients with the HELLP syndrome, the use of pudendal block or epidural anesthesia is contraindicated, since these patients are at risk of bleeding into these areas. In case of cesarean delivery, platelet transfusions are usually indicated to correct severe thrombocytopenia. Our policy is to transfuse 6 to 10 units of platelets in all patients with a platelet count less than 50,000/mm³ prior to intubation. Generalized oozing from the operative site is common, and, to minimize the risk of hematoma formation, we recommend that a subfascial drain be used, the bladder flap be left open, and the wound be left open with sutures in situ above the fascia. These wounds can be successfully closed within 72 hours. Failure to adhere to these recommendations may result in a 25 percent incidence of hematoma formation.

Some investigators recommended the use of invasive hemodynamic monitoring in managing patients with severe preeclampsia. Clark and Cotton^[235] reported that indications for such monitoring should include pulmonary edema, persistent oliguria unresponsive to a fluid challenge, intractable severe hypertension and, in some patients, epidural anesthesia. Others have recommended using Swan-Ganz catheters to monitor fluid therapy and response to antihypertensive drugs. These authors utilize plasma volume expansion with colloid plasma substitute to increase cardiac index and pulmonary capillary wedge pressure prior to the use of epidural or vasodilator drugs in an attempt to avoid the potential of severe hypotension.

We believe that the use of invasive hemodynamic monitoring is rarely indicated in managing these patients. Its use for the above indications is empiric, and its benefit has not been conclusively proven. We believe that only a select group of women with pulmonary edema may benefit from invasive hemodynamic monitoring.^[236]

Management

If the patient is already in spontaneous labor, continuous electronic fetal heart rate and uterine activity monitoring

should be instituted in all cases. If labor is not well established, and in the absence of fetal malpresentation or a nonreassuring fetal heart rate tracing, intravenous oxytocin can be administered to induce labor. This approach is used in patients with a favorable cervix and with a gestational age of 30 weeks or more irrespective of cervical status. In patients with an unripe cervix and a gestational age of less than 30 weeks, either cervical ripening agents or elective cesarean delivery may be used for patients with severe preeclampsia or eclampsia. This approach is based on our experience of a high incidence of intrapartum complications such as abruptio placentae and nonreassuring fetal heart rate tracings in these patients.

At delivery, blood loss may be increased above that expected in normal patients. Magnesium sulfate may impair uterine contractility after delivery. The woman with severe preeclampsia or eclampsia has a contracted blood volume and tolerates blood loss poorly. For these reasons, these patients should have blood typed and

cross-matched and available in the delivery area. A sudden drop in blood pressure following delivery may be due to hypovolemia and require prompt transfusion.

Following delivery, the patient should be kept in the recovery room under close observation for about 24 hours, during which magnesium sulfate should be continued. Most patients will show evidence of resolution of the disease process within 24 hours. However, some patients, especially those with the HELLP syndrome or severe disease in the mid-trimester, may require intensive monitoring for several days. Such patients will require magnesium sulfate administration for more than 24 hours. These patients are at increased risk for the development of pulmonary edema from fluid overload, fluid mobilization, and compromised renal function.

Maternal and Perinatal Outcome with Preeclampsia

Perinatal outcome in preeclampsia is usually dependent on one or more of the following factors: gestational age at the onset of preeclampsia and at the time of delivery, the severity of the disease process, the presence of multiple gestation, and the presence of underlying hypertensive or renal disease. For patients with mild disease at term, the perinatal mortality, incidence of fetal growth restriction, and neonatal morbidity are similar to those of normotensive pregnancies. At the E.H. Crump Women's Hospital in Memphis, the perinatal mortality rate in these pregnancies is 1 in 1,000, and the incidence of fetal growth restriction is only 4 percent.

In contrast, in women with severe preeclampsia remote from term, perinatal outcome will depend on gestational age at the time of delivery (Table 28-14). Overall, perinatal outcome is good if disease develops beyond 32 weeks' gestation, whereas it is less favorable for women requiring delivery at less than or equal to 28 weeks.^[237]

Severe preeclampsia is a major cause of maternal mortality and morbidity. Complicated or mismanaged cases are responsible for most deaths. Patients with onset in the mid-trimester and those with the HELLP syndrome and pulmonary edema are at significant risk for maternal mortality and morbidity.^[170]

Counseling Women Who Have Had Preeclampsia in Prior Pregnancies

There appears to be a strong familial predisposition for preeclampsia. The incidence of severe preeclampsia was compared in the first pregnancies of sisters of primigravidas

with and without preeclampsia.^[238] In 273 primigravidas whose sisters did not have preeclampsia, the incidence of severe preeclampsia was 4.5 percent. However, the incidence of severe preeclampsia was 13.8 percent for women whose sisters had severe preeclampsia during their first pregnancies. The frequency of severe preeclampsia in the mothers and mothers-in-law of women in whom preeclampsia developed during their first pregnancies has been examined as well. The incidence of severe preeclampsia was 15.9 percent in the 126 mothers of primigravidas who had severe preeclampsia compared with 4.4 percent in the 136 mothers-in-law. The incidence of severe preeclampsia in a control group of primigravidas was 3.1 percent. The incidence of mild preeclampsia was higher in the mothers than in the mothers-in-law of these women, but this difference was not significant.

We have examined the pregnancy outcomes and incidences of preeclampsia in subsequent pregnancies, as well as the frequency of chronic hypertension and diabetes mellitus in women who had severe preeclampsia (287 women) or eclampsia (119 women) in their first pregnancies (aged 11 to 25 years) compared with 409 women (aged 12 to 25 years) who remained normotensive during their first pregnancies. Each woman had at least one subsequent pregnancy (range, 1 to 11) and was followed for a minimum of 2 years (range, 2 to 24). There was no significant difference in the incidences of diabetes mellitus in the two groups (1.3 vs. 1.5 percent). The incidence of chronic hypertension was significantly higher in the preeclampsia patients (14.8 vs. 5.6 percent; $p < 0.001$). This difference became even greater for those women followed for more than 10 years (51 vs. 14 percent; $p < 0.001$). The incidence of severe preeclampsia was also significantly higher in the second pregnancies (25.9 to 4.6 percent) as well as in the subsequent pregnancies (12.2 to 5.0 percent) of women with preeclampsia.^[239]

In a later report, subsequent pregnancy outcome and long-term prognosis were studied in 108 women who had severe preeclampsia in the second trimester.^[240] These women were followed for a minimum of 2 years (range, 2 to 12 years) and had a total of 169 subsequent pregnancies. Fifty-nine (35 percent) subsequent pregnancies were normotensive, and 110 (65 percent) were complicated by preeclampsia. Overall, 21 percent of all subsequent pregnancies were complicated by severe preeclampsia in the second trimester. In addition, these women had a high rate of chronic hypertension on follow-up, with the highest incidence being in those who had recurrent severe preeclampsia in the second trimester (55 percent).

Some women with preeclampsia remote from term may have abruptio placentae. The risk of this complication is increased significantly in those with severe preeclampsia before 34 weeks' gestation and particularly in those who have severe preeclampsia in the second trimester.^[241] For patients with preeclampsia complicated by abruptio placentae, the risk of subsequent abruptio ranges from 5 to 20 percent. In addition, these women are at increased risk for subsequent chronic hypertension.^[241]

Pregnancy outcome and long-term prognosis were studied in 37 women with severe preeclampsia complicated by pulmonary edema, and 18 of these women had subsequent pregnancies.^[229] Ten of the 18 were normotensive, four were complicated by chronic hypertension, and four by preeclampsia; one of the latter women also had pulmonary edema.

Pregnancy outcome and remote prognosis were also studied in 18 women with severe preeclampsia complicated by acute renal failure.^[242] All 18 had acute tubular necrosis, 9 required dialysis, and 2 died within 8 weeks after birth. All patients had serial evaluation of renal function, urine microscopic testing, and electrolyte studies at the onset of acute renal failure and during follow-up. All 16 surviving patients had normal renal function on long-term follow-up (average, 4 years). Four of the 16 women had seven subsequent pregnancies: one ended in miscarriage, one was complicated by preeclampsia at 35 weeks, and five were term pregnancies without complications.^[242]

Patients with preeclampsia and the HELLP syndrome can receive oral contraceptives without any risk of developing the syndrome again. In addition, the recurrence

risk for this syndrome in subsequent pregnancies is low. Sibai and associates [243] followed 152 patients with previous HELLP syndrome through their subsequent pregnancies. Thirteen patients with preexisting chronic hypertension had 20 subsequent pregnancies, whereas 139 normotensive women had 192 subsequent pregnancies following HELLP. The outcomes of these pregnancies are listed in Table 28-15. Overall, the risk for recurrent HELLP syndrome was 5 percent in women with preexisting chronic hypertension and 3 percent in normotensive women. [243] Two women with previous ruptured liver hematomas were followed through three subsequent pregnancies without complications. Two other case reports described successful pregnancy outcomes in women with previous ruptured liver hematomas. [244], [245]

Patients with preeclampsia remote from term are reportedly at increased risk for undiagnosed renal disease. In one report, renal function was studied 6 weeks to 6 months postpartum in 84 women who had severe preeclampsia at 24 to 36 weeks' gestation. [248] Maternal evaluation included a 24-hour urine collection, urine microscopic testing, intravenous pyelography, and renal biopsy when appropriate. The authors found a high incidence of renal disease and essential chronic hypertension (90 percent) in these women. In two thirds, the renal lesion was glomerulonephritis, mostly of the immunoglobulin

^aPercentage of pregnancies.

A variety. They concluded that women with severe preeclampsia remote from term may have underlying renal disease for which they should be evaluated after delivery.

Recently, several studies have suggested evaluating women with severe preeclampsia before 34 weeks' gestation for the presence of thrombophilias. [61] [62] [63] [64] [65] [66] [67] [68] [69] However, subsequent reports did not confirm a high rate of association between thrombophilias and severe early onset of preeclampsia. At present, more data are needed before such screening is recommended for all women with previous severe preeclampsia. [69]

ECLAMPSIA

Eclampsia is the occurrence of convulsions or coma unrelated to other cerebral conditions with signs and symptoms of preeclampsia. Early writings of both the Egyptians and Chinese warned of the dangers of convulsions encountered during pregnancy. ^[247] Hippocrates noted that headaches, convulsions, and drowsiness were ominous signs associated with pregnancy. The term *eclampsia* appeared in a treatise on gynecology written by Varandaeus in 1619. Clonic spasms in association with pregnancy were described by Pew in 1694. In 1772, De la Motte recognized that prompt delivery of pregnant women with convulsions favored their recovery. Stroganoff, in 1900, reported a 5.4 percent maternal mortality rate compared with 17 to 29 percent for European clinics and 21 to 49 percent for American clinics of the same period. ^[248] Stroganoff placed his patients in a darkened room and administered chloroform, chloral hydrate, and morphine to produce profound sedation and narcosis. Modifications were made in this regimen; eventually, magnesium sulfate was popularized by Pritchard and Zuspan as the drug of choice for eclampsia.

Pathophysiology

Although great advances have been made in treating eclampsia, the pathophysiologic events leading to convulsions remain unknown. Several theories have been advanced but are unproven. There is a functional derangement of multiple organ systems, such as the central nervous system and hematologic, hepatic, renal, and cardiovascular systems. ^[249] The degree of dysfunction depends not only on other medical or obstetric factors that may be present but on whether there has been a delay in the treatment of preeclampsia or iatrogenic complicating factors as well ([see the box "Organ System Derangements in Eclampsia"](#)).

Women in whom eclampsia develops exhibit a wide spectrum of signs and symptoms, ranging from extremely high blood pressure, 4+ proteinuria, generalized edema, and 4+ patellar reflexes to minimal blood pressure elevation, no proteinuria or edema, and normal reflexes.

Eclampsia usually begins as a gradual process, starting with rapid weight gain and ending with the onset of generalized convulsions or coma. Excess weight gain (with or without clinical edema) of more than 2 pounds per week during the last trimester may be the first warning sign. Hypertension is the hallmark of eclampsia and excess weight gain or edema are not necessary for the diagnosis. ^[8] In about 16 percent of

cases, hypertension may be "relative" (130 to 140/80 to 90 mm Hg), signified by a rise in blood pressure that is 25 mm Hg diastolic above the nonpregnant blood pressure reading. Eclampsia is usually associated with significant proteinuria (>2+ on dipstick). In eclamptic women, headache, visual disturbances, and right upper quadrant/epigastric pain are the most common premonitory symptoms before convulsions. Of interest was the absence of edema (26 percent) and proteinuria (14 percent) in 399 eclamptic women studied by the author. ^[8]

Organ System Derangements in Eclampsia

Cardiovascular

- Generalized vasospasm
- Increased peripheral vascular resistance
- Increased left ventricular stroke work index
- Decreased central venous pressure
- Decreased pulmonary wedge pressure

Hematologic

- Decreased plasma volume
- Increased blood viscosity
- Hemoconcentration
- Coagulopathy

Renal

- Decreased glomerular filtration rate
- Decreased renal plasma flow
- Decreased uric acid clearance

Hepatic (at autopsy)

- Periportal necrosis
- Hepatocellular damage
- Subcapsular hematoma

Central nervous system (at autopsy)

- Cerebral edema
- Cerebral hemorrhage

Convulsions may occur antepartum, intrapartum, or postpartum. Half of all cases of eclampsia usually occur before the onset of labor, with the other 50 percent equally divided between the intrapartum and postpartum periods. Analysis of 399 cases of eclampsia managed at our institution revealed that eclampsia developed before delivery in 289 patients (72 percent) and postpartum in 110 (28 percent).^[8] Although rare, atypical eclampsia may occur before the 20th week of gestation and more than 48 hours after delivery.^[250],^[251] [Table 28-16](#) summarizes the time of onset of eclampsia among 399 eclamptic women studied by the author.^[8]

Eclampsia is primarily a disease of the young primigravida. The incidence of eclampsia has ranged from 1 in 147 for 1 in 3,448 pregnancies,^[252] ^[253] with an incidence of 3.6 percent in twin gestations. The incidence depends on the socioeconomic status of the patient

population and the number of maternal referrals to the hospital. At the University of Mississippi Medical Center, the incidence of eclampsia was 1 in 147 from 1955 to 1960 and 1 in 254 from 1971 to mid-1973.^[254] Of interest, only 7.2 percent of these patients received prenatal care in the medical center's prenatal clinics. The incidence of eclampsia at the E. H. Crump Women's Hospital is now 1 in 337 deliveries; however, the hospital has a large number of referrals (approximately 2,000 women annually). [Table 28-17](#) shows the incidences of eclampsia reported from several institutions.

Cerebral Pathology of Eclampsia

Autoregulation of the cerebral circulation is a mechanism for the maintenance of constant cerebral blood flow during changes in blood pressure and may be altered in eclampsia. Through active changes in cerebrovascular resistance at the arteriolar level, cerebral blood flow normally remains relatively constant when cerebral perfusion pressure ranges between 60 and 120 mm Hg. In this normal range, vasoconstriction of cerebral vessels occurs in response to elevations in blood pressure,

TABLE 28-17 -- INCIDENCE OF ECLAMPSIA

while vasodilation occurs as blood pressure is lowered. Once cerebral perfusion pressure exceeds 130 to 150 mm Hg, however, the autoregulatory mechanism fails. In extreme hypertension, the normal compensatory vasoconstriction may become defective and cerebral blood flow increases. As a result, segments of the vessels become dilated, ischemic, and increasingly permeable. Thus, exudation of plasma occurs, giving rise to focal cerebral edema and compression of vessels, resulting in a decreased cerebral blood flow.^[254] Hypertensive encephalopathy, a possible model for eclampsia, is an acute clinical condition that results from abrupt severe hypertension and subsequent severe increases in intracranial pressure. Since this is an acute disturbance in the hemodynamics of cerebral arterioles, morphologic changes in anatomy may not be uniformly evident in pathology material. Several autopsy findings that are relatively constant include cerebral swelling and fibrinoid necrosis of vessel walls. Petechial hemorrhages and microinfarcts may appear in some cases, not dissimilar to those noted in eclampsia.

The mechanisms leading to the development of convulsions or coma in eclamptic patients may include cerebral edema, ischemia, hemorrhage, or transient vasospasm. However, none of these mechanisms has been conclusively proven.

Computerized Axial Tomography

The introduction of the CAT scan has provided an opportunity to investigate the nature of cerebral abnormalities in eclamptic patients, although CAT scan and other imaging studies have not proven helpful in patient care. This technique is considered safe in pregnancy when performed beyond the first trimester. There are several reports describing the CAT scan findings in complicated cases of eclampsia (see the box "Reported Abnormal CAT Scan Findings in Complicated Eclampsia").^[255],^[256]

Cerebral hemorrhage is a common autopsy finding in patients dying from eclampsia; however, it is an unusual finding on CAT scanning. Beck and Menezes^[256] reported a case of eclampsia in which CAT scan evaluation demonstrated the presence of periventricular sub-ependymal hemorrhage. Colosimo et al.^[257] reported abnormal CAT scan findings in five eclamptic women, one of whom demonstrated the presence of intracerebral hemorrhage. Will et al.^[258] reported on three patients with eclampsia who developed acute neurologic deterioration in the postpartum period. Two patients had subarachnoid hemorrhage, and one of them had a residual neurologic deficit. CAT scan demonstrated the presence of infarcts in two cases and intracerebral hemorrhage in the third case. In all three cases, cerebral angiography revealed widespread arterial vasoconstriction. In one case demonstrating hemorrhage on CAT scan, a magnetic resonance imaging (MRI) examination performed 1 week later was reported normal.

Reported CT Scan Findings in Complicated Eclampsia
Cerebral edema
Diffuse white matter low-density areas
Patchy areas of low density
Occipital white matter edema
Loss of normal cortical sulci
Reduced ventricular size
Acute hydrocephalus
Cerebral hemorrhage
Intraventricular hemorrhage
Parenchymal hemorrhage (high density)
Cerebral infarction
Low-attenuation areas
Basal ganglia infarctions

From Barton JR, Sibai BM: Cerebral pathology in eclampsia. In Sibai BM (ed): Clinics Perinatology, Vol. 18. Philadelphia, WB Saunders Company, 1991, p 891, with permission.

Richards et al.^[259] described the cranial CAT scan findings in 20 patients remaining in a coma for 6 hours or more after delivery. Scan appearance was normal in five patients (25 percent), while the remaining 15 patients (75 percent) had scans demonstrating low-density areas consistent with cerebral edema of varying degrees. A low-density pattern diffusely distributed throughout the white matter was regarded as the most severe form of edema. Three of four patients with this specific finding had significantly elevated intracranial pressure during monitoring.

Four large series presenting the CAT scan findings in eclampsia were reported. Abnormal CAT scan findings were found in 14 (29 percent) of 49 eclamptic patients studied by Brown and associates.^[260] These authors noted that the incidence of abnormal CAT scan findings significantly increased with the recent use of high-resolution CAT scan equipment. The CAT scans were performed over a 6-year period, with the highest incidence of abnormal findings (50 percent) being present during the final year of the study. This increased sensitivity was attributed to improved "fourth-generation" imaging equipment. Furthermore, they noted that 50 to 60 percent of scans performed within 2 days of a seizure were normal, implying rapid reversal of abnormalities detected by CAT scan. The authors noted, however, that CAT scan findings altered the clinical management in only one patient. Milliez et al.^[261] described cranial CAT scans in 44 women with eclampsia performed within 24

hours of seizure. Twenty-six scans (59 percent) were considered normal, while three (7 percent) had evidence of cerebral hemorrhage or thrombosis

and six (14 percent) revealed areas of localized hypodensity located in the cortical lobes and the subcortical white matter. Of the remaining nine scans (20 percent), the interpretation was of minimal cerebral atrophy with enlarging cerebral ventricles. Moodley and associates [262] documented cranial CAT scan findings in 31 women with eclampsia. Ten of these women also had focal neurologic findings. Fourteen (45 percent) of the scans were considered abnormal. Lesions consistent with cerebral edema and multifocal hemorrhages have been described in CAT scans reported by Drislane and Wang. [263]

Magnetic Resonance Imaging and Eclampsia

MRI is a recently developed noninvasive technique that appears superior to other processes for defining intracranial anatomy and pathophysiology. The technique provides images in multiple planes, avoids the use of ionizing radiation, and, except for selected contraindications (some aneurysm clips, pacemakers), there are no significant health risks associated with MRI when used at present operating conditions.

There are several case reports and three large series describing abnormal MRI findings in eclampsia. [264], [265] Sanders et al. [266] studied MRI findings in eight women with eclampsia. Abnormal findings were reported in seven of the eight women. Digre and associates [265] documented MRI findings in 16 women with severe preeclampsia and 10 women with eclampsia. They found that half of the women with severe preeclampsia had abnormal scans with nonspecific foci of increased signal in the deep cerebral white matter on T2-weighted images. In contrast, nine women with eclampsia had abnormal findings in the form of either a multifocal area of increased signal at the gray-white matter junction on T2-weighted images or cortical edema and hemorrhage. Dahmus et al. [255] compared MRI and CAT scan findings in 24 women with eclampsia. Forty-six percent of the MRIs were abnormal and 33 percent of the CAT scans were abnormal. The authors concluded that cerebral imaging is not necessary in women with uncomplicated eclampsia. [255] Hemorrhages and cerebral edema, particularly in the posterior hemispheres or in the watershed areas, were reported on MRI studies in women with eclampsia. [267] These findings are consistent with global ischemias probably induced by vasospasm. [267]

Angiography and Eclampsia

The use of cerebral angiography in the evaluation of eclampsia is limited. [264] Will et al. [258] described the cerebral angiographic findings in three patients with preeclampsia/eclampsia. All were significant for widespread arterial vasoconstriction of the intracranial vessels. Trommer et al. [269] reported cerebral angiography findings in a single eclamptic patient. Similarly, they reported diffuse vasospasm of large- and medium-caliber cerebral vessels. Cranial CAT scan obtained following the angiography revealed diffuse hypodensity throughout the brain stem, thalamus, and internal capsules bilaterally. These few studies support cerebral vasoconstriction as an important cause of neurologic complications in preeclampsia. Similar findings were also reported with the use of cerebral and retinal vascular Doppler flow studies.

Doppler Studies and Eclampsia

The use of ultrasonographic Doppler techniques to study cerebral vasoconstriction in women with severe preeclampsia-eclampsia suggests that this process plays an important role in the etiology of cerebral manifestations in women with preeclampsia/eclampsia. [269] [270] [271]

Electroencephalographic Findings

Abnormal electroencephalograms (EEGs) have been reported in women with eclampsia. [254] Most common were changes compatible with a recent convulsive state. We performed EEGs on 65 women with eclampsia. [272] Initial EEGs were obtained within 48 hours of hospitalization and then serially during the next 6 months. Three women also had normal cerebral arteriograms. Forty-nine of the 65 patients with eclampsia (75 percent) had abnormal findings. All patients had adequate serum magnesium levels (4.5 to 11 mg/dl). Five of the 65 women demonstrated seizure activity on EEG with serum magnesium levels in the therapeutic range. It appears that magnesium suppresses seizure activity by a mechanism that does not alter the EEG. All the abnormalities noted on EEG are nonspecific and have been reported in other conditions such as polycythemia, hypoxia, renal disease, hypocalcemia, hypercalcemia, and water intoxication. [273]

Abnormal EEG findings were confirmed in 90 percent of eclamptic women studied by Moodley and associates. [263] EEG abnormalities were directly related to the severity of maternal hypertension, with some abnormal EEGs becoming normal after lowering blood pressure to the normotensive range. We found no correlation between the degree of blood pressure elevation and EEG abnormalities and consider it unlikely that these abnormal EEG changes were due to hypertensive encephalopathy alone. [273]

Management of Labor and Delivery in Eclampsia

The woman with eclampsia should undergo continuous intensive monitoring. She should not be left alone in a darkened room. The guard rails should be up on the

bed and a padded tongue blade kept at the bedside. A large-bore peripheral intravenous line should be in place. No other anticonvulsants should be left at the bedside except for a syringe containing 2 to 4 g magnesium sulfate. Control of convulsions with magnesium sulfate is outlined below. We agree with Pritchard et al. [274] that no more than 8 g magnesium sulfate should be given over a short period of time to control convulsions.

No single test or set of laboratory determinations is useful in predicting maternal or neonatal outcome in women with eclampsia. Alterations in renal or hepatic function occur frequently. There is unlikely to be a significant disturbance in the integrity of the coagulation system. We previously recommended only a complete blood count including blood smear and platelet count, clot observation, and serum creatinine in women with eclampsia. [275] Liver function tests were obtained only in women with upper abdominal pain. However, because of an increase in the number of women with HELLP syndrome and eclampsia as well as those with serious medical problems, we have expanded the laboratory tests ordered in eclamptic women to include fibrinogen, electrolytes, and arterial blood gases.

Once convulsions have been controlled and the woman has regained consciousness, her general medical condition is assessed. When she is stable, induction of labor with oxytocin is initiated. Delivery is the treatment for eclampsia. Fetal heart rate and intensity of uterine contractions should be closely monitored. If labor is not well established, and in the absence of fetal malpresentation or fetal compromise, oxytocin may be used to induce labor in all patients beyond 30 weeks' gestation irrespective of cervical dilatation or effacement. The same approach is used for patients with a gestational age below 30 weeks if the cervix is favorable for induction. However, women with an unfavorable cervix and a gestational age of 30 weeks or less are stabilized with magnesium sulfate and are then delivered electively by cesarean section. This approach is based on our previous experience with high intrapartum complication rates in eclampsia that develops before 30 weeks' gestation. [276] These complications include a high incidence of fetal growth restriction (30 percent), abruption (23 percent), and fetal distress during labor (65 percent).

In a review of 10 women who had undergone electronic internal fetal monitoring during an eclamptic convulsion, 6 had fetal bradycardia (fetal heart rate <120 beats/min) that varied in duration from 30 seconds to 9 minutes. [277] The interval from onset of the seizure to the fall in fetal heart rate was 5 minutes. Transitory fetal tachycardia occurred frequently after the prolonged bradycardia. In addition, loss of beat-to-beat variability with transitory late decelerations occurred during the recovery phase. Uterine hyperactivity demonstrated by both increased uterine tone and increased frequency of uterine contractions occurs during an eclamptic seizure. The duration of the increased uterine activity varies from 2 to 14 minutes.

Fetal outcome is generally good after an eclamptic convulsion. The mechanism for the transitory fetal bradycardia may be a decrease in uterine blood flow caused by intense vasospasm and uterine hyperactivity. The absence of maternal respiration during the convulsion may also be a contributing factor to these fetal heart rate changes. Since the fetal heart rate pattern usually returns to normal after a convulsion, other conditions should be considered if an abnormal pattern persists. It may take longer for the heart rate pattern to return to baseline in an eclamptic woman whose fetus is preterm with growth restriction. Placental abruption may occur after the convulsion and should be considered if uterine hyperactivity remains or the bradycardia persists.

Treatment of Eclamptic Convulsions

Eclamptic convulsions are a life-threatening emergency and require proper care in order to minimize morbidity and mortality. The development of an eclamptic convulsion is frightening to observe. Initially, the patient's face becomes distorted with protrusion of the eyes. This is followed by a congested facial expression. Foam often exudes from the mouth. The woman usually bites her tongue unless it is protected. Respirations are absent throughout the seizure. Typically, the convulsion, which can be divided into two phases, will continue for 60 to 75 seconds. The first phase, which lasts 15 to 20 seconds, begins with facial twitching, proceeding to the body becoming rigid with generalized muscular contractions. The second phase lasts approximately 60 seconds and consists of the muscles of the body alternately contracting and relaxing in rapid succession. This phase begins with the muscles of the jaw and rapidly involves the eyelids, other facial muscles, and then all the muscles of the body. Coma follows the convulsion, and the woman usually remembers nothing of the recent events. If she has repeated convulsions, some degree of consciousness returns after each convulsion. She may enter a combative state and be agitated and difficult to control. Rapid and deep respirations usually begin as soon as the convulsions end. Maintenance of oxygenation is usually not a problem after a single convulsion; the risk of aspiration is low in the well-managed patient.

Several steps should be taken in managing an eclamptic convulsion:

1. *Do not attempt to shorten or abolish the initial convulsion:* Because eclampsia is so frightening, the natural tendency is to do something to abolish the convulsion. Drugs such as diazepam should not be

979

given in an attempt to stop or shorten the convulsion, especially if the patient does not have an intravenous line in place and someone skilled in intubation is not immediately available. Diazepam causes phlebitis and venous thrombosis and should not be given without secure intravenous access. In addition, no more than 5 mg should be given over a 60-second period. Rapid administration of diazepam may lead to apnea or cardiac arrest, or both. ^[279]

2. *Prevent maternal injury during the convulsion:* A padded tongue blade should be inserted between the patient's teeth to prevent biting of the tongue. Care should be taken to avoid stimulating the gag reflex with the blade. Its only purpose is to prevent the patient from biting her tongue. Place the woman on her left side and then suction the foam and secretions from her mouth. That serious maternal injuries may occur during eclamptic seizures is well demonstrated in the report from Magee-Women's Hospital. ^[279] Among the 52 women with eclampsia, one had a dislocated shoulder, fractured humerus, and multiple facial contusions from a fall in the emergency room following a convulsion. Two other women had severe airway obstruction.
3. *Maintain adequate oxygenation:* After the convulsion has ceased, the patient begins to breathe again and oxygenation is rarely a problem. Difficulty with oxygenation may occur in women who have had repetitive convulsions or who have received drugs in an attempt to abolish the convulsions. Such women should have a chest radiograph to rule out aspiration pneumonia.
4. *Minimize the risk of aspiration:* Aspiration should be a rare occurrence with eclamptic convulsions. It may be caused by forcing the padded tongue blade to the back of the throat, stimulating the gag reflex with resultant vomiting and aspiration. At our hospital, all the women who have had aspiration as a result of eclamptic convulsions had received many drugs in an attempt to control their convulsions. The lungs should always be auscultated after the convulsion has ended to ensure they are clear.
5. *Give adequate magnesium sulfate to control the convulsions:* As soon as the convulsion has ended, a large secure intravenous (IV) line should be inserted and a loading dose of magnesium sulfate given intravenously. In our institution, we use a 6-g intravenous loading dose given over 15 to 20 minutes. In addition to providing a good initial serum magnesium level, the serum magnesium level does not fall below the therapeutic range for several hours after the initial 6-g loading dose as often happens when using a 4-g loading dose. If the patient has a convulsion after the loading dose, another bolus of 2 g magnesium sulfate can be given intravenously over 3 to 5 minutes. Approximately 10 to 15 percent of women will have a second convulsion after receiving the intravenous loading dose of magnesium sulfate. Pritchard et al. ^[274] reported that 10 of 83 women who had eclampsia treated before delivery again suffered convulsions shortly after an initial injection of magnesium sulfate, 4 g IV and 10 g intramuscularly (IM). However, most remained free of seizures after an additional 2 g magnesium sulfate IV.

We use serum magnesium levels in the clinical management of the eclamptic woman. If the initial level, obtained 4 hours after the loading dose, is high, over 10 mg/dl, we reduce the 2-g maintenance dose of magnesium sulfate. This will occasionally occur in women with renal compromise. Similarly, in the rare patient with a brisk urine output, we give a maintenance dose of 3 g to keep levels in the therapeutic range.

In my series of 262 eclamptic women, 36 (14 percent) had an additional convulsion after receiving magnesium sulfate. ^[280] An occasional patient will have recurrent convulsions while receiving therapeutic doses of magnesium sulfate. In these cases, a short-acting barbiturate such as sodium amobarbital can be given in a dose of up to 250 mg IV over 3 to 5 minutes. We treated one patient who had recurrent convulsions with a serum magnesium level of 9.4 mg/dl and who had also received sodium amobarbital. She was given an intravenous sodium pentothal drip and experienced no further seizures.

Magnesium toxicity was responsible for the only death in the Pritchard et al. ^[274] series of eclamptic women and nearly led to a maternal death at the University of Tennessee, Memphis. ^[281] In both cases, the patients were supposed to have received a loading dose of 4 g magnesium sulfate but, because of an error in preparing the drug, received 20 g magnesium sulfate over a few minutes.

Rarely, a woman may have an eclamptic seizure, lapse into a coma, and die. Magnesium toxicity should be considered in those women who do not regain consciousness. A case report of magnesium sulfate toxicity details the features of this serious complication. ^[281] Within a few minutes of starting what was supposed to be a magnesium loading dose, 4 g magnesium sulfate in 250 ml saline, the patient went into cardiorespiratory arrest. Immediate resuscitation including intubation was performed. Approximately one half of the loading dose had been given. An intracerebral accident or eclampsia was thought to be the cause of the coma; the loading dose was continued and maintenance therapy started. Initial blood gases were normal, and the electrocardiogram (ECG) was normal 15 minutes after the arrest. Mechanical ventilatory support was required. The patient's vital signs were stable, but her pupils were nonreactive. Serum electrolytes, glucose,

980

blood urea nitrogen, and creatinine were normal. Computed tomographic scan of the head and cerebral angiograms were normal. A magnesium level of 35 mg/dl was reported 3.5 hours later from a blood sample taken via femoral venipuncture at the time of arrest. The magnesium sulfate infusion was stopped immediately. During the first 5 hours after the cardiorespiratory arrest, 1,344 mg of magnesium were excreted in the urine. Twelve hours after the arrest, an uncomplicated low vertical cesarean delivery was done for a breech presentation. The 3,160-g male infant had Apgar scores of 8 and 9 at 1 and 5 minutes, respectively. Maternal and cord blood magnesium levels at delivery were 5.8 mg/dl. Both mother and baby were discharged from the hospital with no apparent residual effects. Of interest, the patient reported she could hear and see what was occurring around her, but she could not make any movements while she had the endotracheal tube in place. [Figure 28-6](#) presents the maternal magnesium levels in this case. ^[281]

6. *Maternal acidemia should be corrected:* We obtain a blood gas reading on every patient who has had an eclamptic convulsion. Blood oxygenation and pH should be in the normal range. Patients who have had repeated convulsions may be acidotic and a low P_{O₂} may indicate aspiration pneumonitis. Sodium bicarbonate is not given unless the pH is below 7.10. Abnormal blood gases may be the result of respiratory depression.
7. *Avoid polypharmacy:* Polypharmacy is extremely hazardous in the woman with eclampsia, as addition of diazepam or phenytoin may lead to respiratory depression or respiratory arrest.

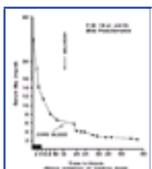

Figure 28-6 A patient with magnesium toxicity. (From McCubbin JH, Sibai BM, Abdella TN, et al: *Cardiopulmonary arrest due to acute maternal hypermagnesemia*, letter. *Lancet* 1:1058, 1981, with permission.)

During the past 60 years, numerous anticonvulsive drugs have been introduced and replaced due to the dissatisfaction with the results obtained with the use of these agents. These drugs have included bromethol, chloral hydrate, paraldehyde, phenothiazines, lytic cocktails, barbiturates, diazepam, chlordiazepoxide, and clonazepam. The overzealous use of these drugs in eclampsia can lead to significant maternal-neonatal central nervous system (CNS) and respiratory depression. ^[282] The use of large doses of diazepam (>30 mg) during labor is associated with loss of beat-to-beat fetal heart rate variability and significant neonatal morbidity including respiratory depression, apnea, hypotonia, cold stress, and poor sucking. The use of the barbiturate chlormethiozole, commonly used in Europe and Australia in anticonvulsive doses, may depress maternal laryngeal reflexes, thus increasing the likelihood of aspiration during convulsion. In addition, the use of intravenous

phenobarbital has the potential of producing laryngospasm and circulatory and respiratory depression. Moreover, none of these drugs has been proven to be superior to or as effective as magnesium sulfate in treating eclamptic convulsions.^[19]

There are five randomized studies comparing the use of magnesium sulfate to phenytoin or diazepam in eclampsia.^{[283] [284] [285] [286] [287]} Dommissse^[283] reported 22 patients with eclampsia who were randomly allocated to receive intravenous phenytoin or intravenous magnesium sulfate. None of 11 patients managed with magnesium sulfate had further convulsions, while 4 of 11 patients treated with phenytoin had another seizure. All four patients who failed phenytoin therapy were then effectively treated with magnesium sulfate, and the author suggested that magnesium sulfate is a more effective agent in eclampsia. Crowther,^[284] in a randomized controlled trial, compared the use of magnesium sulfate and diazepam as an anticonvulsant in 51 eclamptic patients. She noted that the use of magnesium sulfate was associated with less serious morbidity, but the difference was not statistically significant. Balla et al.^[285] compared magnesium sulfate to a lytic cocktail in 90 women with eclampsia, whereas Friedman et al.^[286] compared magnesium sulfate to phenytoin in 24 eclamptic women. Both studies revealed magnesium sulfate to be superior for the prevention of eclamptic convulsion. The Eclampsia Trial Collaborative Group studied 1,680 women randomized to receive magnesium sulfate, diazepam, or phenytoin after convulsions. Magnesium sulfate proved

superior in preventing recurrent seizures (Table 28-18).^[287]

Atypical Eclampsia

Eclampsia occurring before the 20th week of gestation or more than 48 hours postpartum is exceedingly rare and, for lack of a better term, has been called *atypical eclampsia*. Eclampsia occurring before the 20th week of gestation has usually been reported with molar or hydropic degeneration of the placenta. Chesley et al.^[288] observed 35 cases of probable eclampsia associated with molar degeneration of the placenta in a review of the literature through 1944. In 26 of these patients, eclampsia occurred during the first half of gestation. Six of the women had a coexistent fetus. A case report and a review of the literature was recently reported by Newman and Eddy.^[289] Two cases of eclampsia have been reported without molar degeneration of the placenta during the first half of gestation.^{[290] [291]} In one woman who had Rh isoimmunization, eclampsia developed at 16 weeks' gestation. The placenta revealed cystic hydropic degeneration of the villi but no molar changes.

Although rare, eclampsia can occur during the first half of gestation.^[8] These women may be misdiagnosed as having hypertensive encephalopathy or a seizure disorder. Women in whom convulsions develop in association with hypertension and proteinuria during the first half of pregnancy should be considered to have eclampsia. They should be treated with parenteral magnesium sulfate to control convulsions, with termination of pregnancy as the definitive goal.

Late postpartum eclampsia is eclampsia that occurs more than 48 hours after delivery. Of the women we have treated for eclampsia during the past 15 years, eclampsia developed in 54 patients more than 48 hours postpartum (16 percent). A review of the clinical course of late postpartum eclampsia has been reported.^[251] Thirty of the 54 women described in that report had been treated for preeclampsia and received standard intravenous magnesium sulfate therapy. The mean duration of magnesium sulfate therapy was 32 hours (range, 24 to 72 hours). Several women were at home when the convulsions developed. Forty-five had experienced headaches or visual disturbances, blurred vision, and scotomas from 2 to 72 hours before the onset of convulsions.^[251] The most striking finding in these women was the brisk diuresis that occurred immediately after the convulsion. Urinary outputs of 500 to 1,000 ml during the first hour after the seizure were common. Because of the unusual time of occurrence of eclampsia in these women, neurologic consultations are recommended to rule out abnormalities.^[251]

Of interest is the high rate of occurrence of late postpartum eclampsia in Nigerian women. In a report of 25 cases of postpartum eclampsia, 17 (68 percent) occurred more than 48 hours postpartum.^[292] Uric acid levels were elevated in these women with eclampsia before delivery or during the immediate postpartum period.

Maternity Morbidity and Mortality in Eclampsia

Pritchard et al.^[274] reported only 1 maternal death in 245 women treated for eclampsia at Parkland Hospital (Dallas, TX) from 1955 to 1983, a maternal mortality rate of 0.4 percent. This death was caused by magnesium toxicity. Endotracheal intubation was not accomplished promptly in this short, obese woman; as a result, respiratory arrest, cardiorespiratory arrest, and death ensued. Three other women had respiratory depression.

Two maternal deaths occurred in our series of 399 patients with eclampsia.^[8] One patient had five convulsions before arriving at our hospital and went into cardiorespiratory arrest in the parking lot. The patient was resuscitated, and her seizures were controlled with magnesium sulfate. However, the patient did not regain consciousness after cardiac arrest. She underwent a cesarean delivery for fetal distress and had a 3,090-g infant with normal Apgar scores. The child had no serious problems in the nursery and was discharged in good condition. DIC developed after the operation. The postoperative course was complicated by sepsis, continuing convulsions, and pulmonary insufficiency. An EEG on the second postoperative day demonstrated absent cortical activity. A CAT scan failed to demonstrate either intracerebral hemorrhage or cerebral edema. The patient remained comatose and died 8 weeks postpartum. The second patient also arrived with severe encephalopathy with cerebral herniation and subsequently died within 1 week postpartum from adult respiratory distress syndrome and multiorgan failure.^[8]

Harbert et al.^[293] reported 168 women treated for eclampsia between 1939 and 1963. Delivery within an arbitrary time limit after control of the convulsion was not an essential part of therapy. Forty-seven of the 83 patients in whom eclampsia occurred before the spontaneous onset of labor were delivered within 48 hours of the first convulsive episode. In the other 36 patients with eclampsia before delivery, the interval between occurrence of the convulsion and spontaneous onset of labor ranged from 93 hours to 43 days. During the first 6 years of the study, eight maternal deaths occurred. From December 1944 to termination of the study in 1963, 108 women with eclampsia were managed without another maternal death. The uncorrected perinatal mortality rate was 216 of 1,000, and 28 percent (14 fetal deaths and three neonatal deaths) in 60 patients delivered 72 hours or longer after admission.

Lopez-Llera^[294] reviewed 990 cases of eclampsia in Mexican women during a 22-year period ending in 1985. There were 138 deaths, for a mortality rate of 14 percent. Several factors were found to increase the risk of maternal death: eclampsia at an earlier gestational age, maternal age, underlying disease, and multiple gestation. In

addition, Douglas and Redman reported on maternal mortality and morbidity among women with eclampsia from the United Kingdom.^[295] They found that antepartum onset and onset before 37 weeks' gestation was associated with high maternal morbidity. We found similar results when eclampsia develops before 32 weeks' gestation.^[8]

In our experience, primigravid women with eclampsia have a lower incidence of serious complications than multigravid women. This is probably attributable to the higher incidence of chronic hypertension and underlying renal disease in the multigravid patients rather than to any effect of eclampsia per se. In particular, we believe that careful attention should be given to intravenous fluid therapy in multigravid women with eclampsia. In our experience, pulmonary edema is much more likely to develop in this group. Likewise, the incidence of renal failure is much higher in multigravid patients with eclampsia.

In our series, maternal transfers and patients who had received no prenatal care had higher complication rates. More than 90 percent of women with eclampsia who had no prenatal care were first seen in the emergency room of another hospital. Many were treated by a physician who was seeing his or her first case of eclampsia. Referral often occurred before the women had received adequate treatment with magnesium sulfate.

Perinatal Outcome in Eclampsia

The main risks to the fetus of the eclamptic woman are abruptio placentae, prematurity, intrauterine growth restriction, and hypoxic episodes during the convulsions.^[8],^[274],^[294],^[295]

Sibai et al.^[296] followed 28 premature infants and 14 full-term infants of eclamptic mothers for up to 50 months. Eight of the 12 infants who were small for gestational age by weight at birth showed catch-up growth at an average of 20.6 months (range, 2 to 48 months). In all, only two of the infants remained growth restricted by weight, height, and head circumference; both were mentally retarded. A total of three infants had major neurologic deficits resulting in cerebral palsy and mental retardation on follow-up evaluation. General health continued to be a problem for the premature infants during the first year of life. Several had multiple hospitalizations for either pulmonary or neurologic complications.

Maternal Transport of the Eclamptic Patient

During the past 20 years, there has been a marked reduction in the number of eclamptic patients. Consequently, most obstetricians have little or no experience in the management of eclampsia. A recent survey of a random sample of obstetricians from all 50 states indicated that about 50 percent of obstetricians in private practice had not seen an eclamptic patient during the past year.

Because management of the eclamptic patient requires the availability of neonatal and obstetric intensive care units and personnel with special expertise, we believe that eclamptic patients should not be managed

at Level I hospitals. We recommend that eclamptic patients with term gestations be cared for only at Level II or III hospitals with adequate facilities and with consultants from other specialties, if needed. For those eclamptic patients who are remote from term, referral should be made to a tertiary care center. We recommend that the following steps be taken before transfer of these critically ill patients:

1. The referring physician or nurse should consult with the physician at the perinatal center regarding the referral and appropriate treatment. All maternal records including prenatal data and a detailed summary of the patient's condition should be sent with the patient.
2. Blood pressure should be stabilized and convulsions controlled.
3. Adequate prophylactic anticonvulsive medications should be given. An accepted regimen is 4 g intravenous magnesium sulfate as a loading dose, with a simultaneous intramuscular dose of 10 g.
4. Such patients should be sent in an ambulance with medical personnel in attendance for proper management in case of subsequent convulsions.

Can Eclampsia Be Prevented?

Eclampsia is generally considered a preventable complication of pregnancy. Zuspan^[297] believes that the severe forms of preeclampsia should be preventable by appropriate prenatal care. He also contends that convulsions should not occur once the woman with preeclampsia is admitted to the hospital.

We recently reviewed 254 cases of eclampsia treated at the University of Tennessee in an attempt to determine the number of cases of preventable eclampsia.^[298] All factors that may have been involved in the development of eclampsia were reviewed. Patients were then grouped into categories of physician error, patient failure, and failure of magnesium sulfate therapy. We found that about 30 percent of cases were nonpreventable.

These findings are in agreement with those of Campbell and Templeton,^[297] who studied factors leading to the development of eclampsia in 66 patients. These workers found that in 28 patients (42.4 percent), eclampsia was not preventable.

Counseling Women with Eclampsia and Their Relatives

Bryans et al.,^[298] in their long-term follow-up study of women who had eclampsia treated at the Medical College of Georgia, found no increase in hypertension in these patients above that expected in the general female population. They concluded that preeclampsia/eclampsia did not cause hypertensive disease and was not a manifestation of subsequent essential hypertension in pregnant women. Chesley et al.^[299] followed women who developed eclampsia at the Margaret Hague Hospital from its opening in 1931 through 1951. They traced all but three of the women who survived to 1974. Chesley et al. also concluded that eclampsia does not cause hypertension. The average annual death rate was 5.11 per 1,000, with 31 deaths in the 187 Caucasian women who had eclampsia during their pregnancies. This was not significantly different from the number of deaths expected. However, 33 of 59 Caucasian women who had eclampsia as multiparas had died at an average rate of 21.3 per 1,000, which was significantly higher than the expected mortality rate. Eighty-two percent of the remote deaths were due to cardiovascular/renal disease in the multiparous group.

Chesley et al.^[300] reported that the prognosis for future pregnancies after eclampsia was good. Another 409 pregnancies occurred in the 158 women with eclampsia during their first pregnancy. Preeclampsia/eclampsia recurred in 34.5 percent of the women and in 20.6 percent of their subsequent pregnancies. When hypertension occurred in a future pregnancy, it was usually mild. Eclampsia developed in three women, for an incidence of 0.9 percent in pregnancies beyond 20 weeks' gestation.

The sisters and daughters of eclamptic women are at increased risk for the development of preeclampsia and eclampsia.^[301] Chesley et al.^[302] reviewed the incidence of preeclampsia in the first pregnancies of daughters of eclamptic mothers. Preeclampsia occurred in 63 of the 257 first pregnancies (24.9 percent), and eclampsia in seven pregnancies (2.7 percent). The outcomes of the first pregnancies carried to viability by sisters of eclamptic women were also studied. Preeclampsia was observed in 54 (37 percent) of first pregnancies, and eclampsia developed in six women (4.1 percent). Because of the increased risk of preeclampsia/eclampsia in these siblings, their pregnancies should be closely monitored.

During the past 20 years, four studies have described pregnancy outcomes after eclampsia.^[302]^[303]^[304] The incidence of preeclampsia is much higher in future pregnancies in women who have had eclampsia remote from term.

Sibai and associates^[305] studied the long-term effects of eclampsia on maternal blood pressure in 210 women who were normotensive prior to the eclamptic pregnancy. The average duration of follow-up in these women was 7.2 years (range, 2 to 13 years). The overall incidence of chronic hypertension on follow-up was only 9.5 percent.

CHRONIC HYPERTENSION

984

Pathophysiology of Chronic Hypertension

Patients with labile or borderline hypertension have several pathophysiologic alterations with elevated cardiac output, central redistribution of blood volume, enhanced activity of the autonomic nervous system, increased left ventricular ejection rate, and a normal total peripheral resistance.^[306] However, patients with mild to moderate hypertension have a normal cardiac output. In these cases, the increase in blood pressure is due to an increase in total peripheral resistance. Because vascular resistance and arterial pressure are elevated, ventricular workload is increased. The heart rate may be increased, while stroke volume and left ventricular ejection rate are normal. Over time, the patient with moderate essential hypertension will show evidence of cardiac strain. Stroke volume remains normal or may start to fall. Myocardial contractility remains normal, while ECG studies frequently show an increased thickness of the left ventricular wall. In the absence of renal disease, plasma volume contraction is proportionate to the increase in diastolic blood pressure. When the diastolic blood pressure equals or exceeds 105 mm Hg, a decrease in plasma volume becomes more apparent.

Clinical evidence of end organ damage characterizes severe essential hypertension. Cardiac enlargement is evident on chest radiograph and ECG. Total peripheral resistance becomes even higher, and cardiac output may begin to fall. Stroke volume decreases, and intravascular volume decreases still further. With the decrease in cardiac output and intravascular volume, plasma renin activity rises. These changes lead to a great increase in left ventricular tension, making myocardial contractions increasingly difficult. Pulmonary edema will occur if the patient is not treated.

Diagnosis of Chronic Hypertension

The diagnosis of chronic hypertension in pregnancy is usually made on the basis of either of the following:

1. Documented history of high blood pressure antedating pregnancy
2. Persistent elevation of blood pressure (at least 140/90 mm Hg) on two occasions more than 24 hours apart before the 20th week of gestation

When a firm diagnosis, by both or either of the above findings, cannot be made, other findings might be suggestive of the presence of chronic hypertension:

1. Retinal changes on funduscopic examination
2. Cardiac enlargement on chest radiograph and ECG
3. Compromised renal function or associated renal disease
4. Presence of medical disorders known to lead to hypertension
5. Multiparity with previous history of hypertensive pregnancies
6. Evidence of persistent hypertension beyond the 42nd day postpartum

Sometimes the diagnosis is difficult to make because of the marked and variable changes seen with blood pressure during midpregnancy. This becomes problematic in patients with no prior medical care and who are first seen in early third trimester. Chesley and Annitto^[307] observed that women with chronic hypertension show greater decreases in their blood pressure during pregnancy than do normotensive patients. They reported a marked decrease in 39 percent of 301 pregnancies studied. They also noted that during midpregnancy the blood pressure was in the normal range in women who were severely hypertensive prior to pregnancy. Similar findings were observed at our institution in the course of pregnancy in 211 patients with mild chronic hypertension.^[308]

Etiology and Classification of Chronic Hypertension

Essential hypertension is by far the most common cause of chronic hypertension during pregnancy. Chronic hypertension in pregnancy is classified as mild or severe depending on the systolic or diastolic blood pressure reading. The hypertension is classified as mild if systolic blood pressure is less than 160 mm Hg and the diastolic is less than 110 mm Hg. Hypertension is severe if either systolic pressure is more than 160 mm Hg or diastolic pressure is above 110 mm Hg.

Superimposed preeclampsia is defined as exacerbation of hypertension of at least 30 mm Hg in systolic or at least 15 mm Hg in diastolic blood pressure, together with the development of proteinuria during the course of the pregnancy (at least 500 mg/24 h), or exacerbation of preexisting proteinuria (at least 5 g/24 h), and elevation of serum liver enzymes, low platelets, or development of symptoms.^[10]

Maternal and Fetal Risks of Chronic Hypertension

Pregnancies complicated by chronic hypertension are at increased risk for the development of superimposed preeclampsia, abruptio placentae, and poor perinatal outcome. The reported incidence of superimposed preeclampsia ranges from 4.7 to 52 percent depending on

985

the severity of hypertension at the onset of pregnancy and on the criteria used to make the diagnosis.^[307] ^[308] ^[309] ^[310] As for the severity of hypertension in the first trimester, the reported incidence of superimposed preeclampsia ranged from 28.2 to 52 percent in severe chronic hypertension, and this rate was unaffected by the use of antihypertensive medication.^[310] ^[311] On the other hand, the reported incidence for patients with mild hypertension in pregnancy was as low as 4.7 percent.^[312] Three large observational studies have recently described the fetal risks in women with chronic hypertension.^[8] ^[313] ^[314] The rates of superimposed preeclampsia in these studies ranged from 17 to 25 percent. In addition, the risks of growth-restricted infants and perinatal deaths were increased, particularly in the presence of superimposed preeclampsia.

The criteria used to diagnose superimposed preeclampsia have included one or more of the following: exacerbation of hypertension, development of edema, appearance of proteinuria, and elevation of serum uric acid levels (>6 mg/dl). In general, the incidence of this complication will be high if only exacerbation of blood pressure is used in the diagnosis, whereas this incidence will be lower if significant proteinuria (>1 g/24 h) is added. This incidence is increased in severe disease (25 to 52 percent).^[315] Some pregnant chronic hypertensives may have silent undiagnosed chronic renal disease and may experience urinary protein excretion that

increases with advancing gestation, particularly in the third trimester (usually >300 mg, but <1 g/24 h); many of these women will also demonstrate an increase in either their systolic (>30 mm Hg) or diastolic (>15 mm Hg) blood pressure with advancing gestation.^[315] Therefore, it is recommended that superimposed preeclampsia be diagnosed on the basis of exacerbated hypertension *plus* the development of either substantial proteinuria (>1 g/24 h) or elevated serum uric acid levels. In women on antihypertensive medications where exacerbation of blood pressure is less common, the diagnosis should be based on the development of substantial proteinuria and abnormal laboratory tests or symptoms.^[10]

In general, pregnancies complicated only by exacerbation of blood pressure have a perinatal outcome similar to those in normotensive women, while the appearance of proteinuria is more significant for fetal prognosis since most of the poor perinatal outcomes are associated with proteinuria. Because many obstetricians consider superimposed preeclampsia an indication for delivery, it is important to use strict criteria to avoid unnecessary preterm delivery.

The incidence of abruptio placentae is reportedly increased in chronic hypertension and ranges between 0.45 and 10 percent depending on the duration and the severity of hypertension. For those with mild uncomplicated disease, the incidence has ranged from 0.45 to 2.0 percent,^{[313] [314] [315] [316] [317]} while in cases with severe hypertension the incidence was markedly increased from 2.3 to 10 percent.^{[307] [310]} This incidence is not influenced by the use of antihypertensive medications.^[317] In cases complicated by abruptio placentae, superimposed preeclampsia is associated with a higher perinatal mortality. This incidence is substantially increased in those with a history of abruptio in previous pregnancies.^[318]

The above-mentioned complications are responsible for most for the perinatal deaths as well as the increased incidence of fetal growth restriction and premature delivery in such pregnancies. In addition, these pregnancies are reportedly associated with increased frequency of midtrimester losses, particularly in those not receiving antihypertensive therapy.^{[313] [319] [320]} In general, perinatal mortality and morbidity are not increased in patients with uncomplicated mild chronic hypertension, whereas they are markedly increased in patients with severe disease, in those with renal disease, and in those complicated by superimposed preeclampsia.^{[2] [309]}

Pregnancy Outcome in Relation to Treatment of Chronic Hypertension

There is general agreement that chronic antihypertensive therapy will decrease the incidence of cardiovascular complications and cerebrovascular accidents in nonpregnant patients with diastolic blood pressures exceeding 105 mm Hg. In addition, since maternal mortality and morbidity are increased in pregnant women with diastolic blood pressures of 110 mm Hg or higher,^{[309] [310]} there are potential maternal and fetal benefits from treating severe chronic hypertension during pregnancy.^[321] However, it is not clear if antihypertensives are equally beneficial in pregnancies with mild uncomplicated hypertension, which is seen in about 95 percent of all pregnant women with chronic hypertension. In addition, neither controlled nor uncontrolled studies showed any reduction in the incidence of superimposed preeclampsia or abruptio placentae when antihypertensives were used.^{[2] [310]}

Severe Chronic Hypertension in Pregnancy

There are few reports describing pregnancy outcomes in women with severe chronic hypertension. Three retrospective studies described pregnancy outcomes in untreated women with severe chronic hypertension early in pregnancy.^{[307] [311] [322]} These studies were conducted during 1931 to 1953, before modern advances in obstetric and neonatal practices. The reported perinatal survival ranged from 19 to 50 percent, and most of the fetal losses occurred in women with superimposed preeclampsia. In addition, the studies reported an increased frequency of maternal mortality and morbidity, both acute and long term. As a result, the reported

maternal and perinatal outcome was invariably poor. Hence, concerns about the risk of acute renal failure and cerebrovascular accidents have led many obstetricians to recommend early termination of such pregnancies. A recent survey of American obstetricians (B.M. Sibai and D.L. Watson, unpublished data) found that 20 percent of the respondents recommended termination of such pregnancies regardless of renal function, while 45 percent did so only in the presence of impaired renal function.

In 1966, Kincaid-Smith et al.^[321] reported pregnancy outcomes in 32 patients with severe hypertension who were treated with methyldopa during their pregnancy. The perinatal survival was 90.7 percent, and there were no maternal complications. The authors attributed this good outcome to the control of maternal blood pressure with methyldopa. However, only five subjects were started on treatment during the first trimester, while 27 received treatment during the second or third trimester. Recently, Sibai et al.^[310] documented pregnancy outcomes in 44 patients with severe hypertension who were seen during the first trimester. Each was treated with methyldopa and oral hydralazine as needed to keep diastolic blood pressure below 110 mm Hg. The patients were observed closely throughout pregnancy, with frequent prenatal visits and intensive monitoring of the clinical status of both mother and fetus. Twenty-three women (52 percent) developed superimposed preeclampsia; there were no maternal deaths. The total perinatal survival was 75 percent; 31 infants (70 percent) were delivered preterm and 19 (43 percent) were small for gestational age (Table 28-19). However, among the subjects without superimposed preeclampsia, there were no perinatal deaths and only one infant (5 percent) was small for gestational age. These findings argue against the practice of recommending termination of pregnancy for severe hypertension in the first trimester. However, such women should be counseled regarding the potential maternal risks, and they must be observed

TABLE 28-19 -- PREGNANCY OUTCOME IN 44 WOMEN WITH SEVERE HYPERTENSION IN THE FIRST TRIMESTER

	With Preeclampsia (n = 23)	Without Preeclampsia (n = 21)
Gestational age (wk)	28.6 ± 2.4	36.5 ± 2.9
<37 weeks	23 (100%)	8 (38%)
Birth weight (g)	827 ± 314	2632 ± 743
SGA	18 (78%)	1 (5%)
Perinatal deaths	11 (48%)	0
Abruptio placentae	2 (8.7%)	0
Deterioration in renal function	15 (65%)	5 (24%)

and managed at a tertiary care center with adequate maternal-neonatal care facilities.

Mild Chronic Hypertension in Pregnancy

There are many reports, both retrospective and prospective, describing pregnancy outcome in women with mild to moderate hypertension. It is, however, difficult to evaluate or compare the benefits of antihypertensive therapy in the management of these pregnancies because of differences in definition, populations studied, and treatments used. Some of these studies were controlled, and others were selective; some studied chronic hypertension only, yet others included all forms of hypertension. Some compared treatment with no treatment or with placebo, others compared two different antihypertensive drugs, and still others used a combination of drugs. In addition, the gestational ages at treatment and the durations of therapy were highly variable.^{[2] [309]}

Methyldopa is the drug most commonly used to treat chronic hypertension during pregnancy.^{[2] [309]} As a result, most clinical trials have compared methyldopa with either no medication or -blockers. To evaluate the effects of antihypertensive drugs in pregnancy, we will describe only randomized trials in which adequate pregnancy data were available.^{[312] [317] [319] [323] [324] [325]}

Six prospective controlled trials compared methyldopa with either no medication or a placebo for the management of mild chronic hypertension in pregnancy, while in the sixth study atenolol was used (Table 28-20). Only two studies included a placebo in a double-blind fashion,^{[324] [325]} but the sample size was limited in both trials and the diagnosis of chronic hypertension in one of them was based on an increased blood pressure before 34 weeks' gestation. The other four studies were not placebo controlled, and only one included subjects who were randomized in the first trimester.^[317] It is evident from Table 28-20 that the use of antihypertensive medications did not affect perinatal outcome except for reducing second-trimester abortions. There were three second-trimester abortions in the control group of Leather et al.^[319] however, it was unclear whether these losses were the result of severe hypertension or were spontaneous abortions. Of the four second-trimester

abortions in the control group in the study reported by Redman et al.,^[312] none were directly related to hypertension, and none had evidence of preeclampsia. These losses might have been due to preterm labor or incompetent cervix. On the other hand, Sibai et al.^[317] noted only one second-trimester loss, which occurred in the methyldopa group. Also in the study of Butters et al.,^[325] the only stillbirth was in the atenolol group. In the six trials summarized in Table 28-20, there were no maternal benefits from antihypertensive therapy except for a reduction in the frequency

Excludes second-trimester losses.

of exacerbation of hypertension. The incidence of perinatal death among the controls ranged from 0 to 8.3 percent; this incidence was particularly low (<2 percent) in the two studies with the largest number of subjects. None of these trials had a sample size sufficient enough to permit direct assessment of the effects of antihypertensive drugs on perinatal death rate.

Recently, a double-blind, placebo-controlled trial compared the use of low-dose aspirin (n = 69) to aspirin plus ketanserin (n = 69) in women with mild chronic hypertension in pregnancy.^[326] The rate of preeclampsia was significantly lower in the ketanserin group (3 percent vs. 19 percent). In addition, the rate of abruptio placentae was reduced in the ketanserin group as compared to placebo (1 percent vs. 8 percent). The authors concluded that ketanserin improves pregnancy outcome in women with mild chronic hypertension.^[326]

Three prospective controlled trials have compared methyldopa with a -blocker for mild hypertension in pregnancy (Table 28-21).^[327]^[328]^[329] Gallery et al.^[327] found

greater plasma volume expansion, higher neonatal birth weights, and no perinatal deaths among 26 oxprenolol-treated patients. In contrast, Fidler et al.^[328] found no difference in pregnancy outcome and neonatal birth weight between 24 women treated with oxprenolol and 22 treated with methyldopa. They also found that the oxprenolol-treated group had a higher incidence of abnormal fetal heart tracings during labor. Plouin et al.^[329] found no difference in neonatal heart rate, blood pressure, and respiratory rate between the two treatment groups and concluded that labetalol is as safe as methyldopa for the fetus and newborn. However, all three studies included patients with all forms of hypertension; less than one third of the subjects had chronic hypertension, and few were enrolled during the first trimester.^[32] In addition, none of these trials had an adequate number of subjects to demonstrate a difference in either preeclampsia or perinatal death. In summary, superimposed preeclampsia and abruptio placentae are responsible for most of the poor perinatal outcome in women with mild chronic hypertension. Antihypertensive drugs do not reduce the frequency of either of these complications. Most patients with mild chronic hypertension will have a good outcome with proper obstetric followup without the use of antihypertensive agents.^[32]

Antihypertensive Drugs in Pregnancy

Many drugs are available for treating hypertension in pregnancy. Some have been studied extensively (methyldopa, α -blockers); others have been used infrequently or are still under clinical trial (calcium channel blockers, prazosin). The drugs used most often in pregnancy are adrenoceptor-blocking agents, thiazide diuretics, hydralazine, and recently, calcium channel blockers. There are potential adverse effects from the chronic use of any drug during pregnancy. When using antihypertensives, one must weigh the benefits of such treatment against the potential adverse effects on the mother, fetus, and neonate.

Methyldopa

Methyldopa is the only antihypertensive drug whose long-term safety for the mother and the fetus has been adequately assessed. It is the drug most commonly used to treat hypertension during pregnancy and is the standard against which other agents are compared. It lowers blood pressure by stimulation of central α_2 -receptors via α -methylnorepinephrine, which is the active form of α -methyldopa. In addition, it might act as an α_2 -peripheral blocker via a false neurotransmitter effect. It reduces systemic vascular resistance without causing physiologically significant changes in heart rate or cardiac output, while renal blood flow is maintained. Maternal side effects include dry mouth, lethargy, and drowsiness. Other side effects include liver function abnormalities, postural hypotension, hemolytic anemia, and a positive Coombs' test. The usual oral dosage in women with severe hypertension is an initial loading dose of 1 g followed by a maintenance dose of 1 to 2 g/day given in four divided doses, which can be increased to 4 g as needed. If used in mild hypertension, however, the usual dose is 250 mg three times daily. The plasma half-life is about 2 hours, and peak plasma levels occur within 2 hours after oral administration. The fall in blood pressure is maximal about 4 hours after an oral dose. Most of the drug is excreted via the kidney. It is considered a weak antihypertensive best suited for cases with mild hypertension, and if adequate blood pressure control is not achieved with the maximum dosage, additional antihypertensive agents, such as hydralazine, α -blockers, or nifedipine may be added.

Clonidine

Clonidine is a potent α_2 -adrenoceptor central stimulant, used primarily for treatment of mild to moderate hypertension. Approximately 40 to 60 percent of the oral dose is excreted in unaltered form in the urine. Its potential side effects include sedation, dry mouth, and rebound hypertension following abrupt discontinuation. The usual oral dose in pregnancy is 0.1 to 0.3 mg/day given in two divided doses, which can be increased up to 1.2 mg/day as needed. Its safety and efficacy during pregnancy are unknown. Horvath et al.^[330] reported a randomized study in 100 pregnant hypertensive women comparing clonidine to methyldopa. They found no significant difference in blood pressure control or maternal and fetal outcome. The authors concluded that clonidine was a safe and effective antihypertensive agent to use in pregnancy.

Prazosin

Prazosin is a selective α_1 -postsynaptic blocker. It reduces both systolic and diastolic blood pressures, while producing significantly less tachycardia and sodium retention than methyldopa. It causes vasodilation of both the resistance and capacitance vessels, thereby reducing cardiac preload and afterload without reducing renal blood flow or glomerular filtration rate. In addition, it produces a decrease in plasma renin activity and is probably the drug of choice for treatment of hypertension characterized by high plasma renin levels. It is metabolized in the liver and excreted almost completely in the bile. The usual dose of prazosin is 1 mg twice daily; however, the drug has been used in doses as high as 20 mg/day. The first dose in some individuals can produce syncope due to exaggerated hypotension. This can be avoided by decreasing the first dose. The median

time to peak concentration in nonpregnant individuals is 2 hours, and the mean elimination half-life is 2 to 3 hours. Side effects include fluid retention, orthostatic hypotension, and nasal congestion. Lubbe et al.^[331] assessed the pregnancy outcomes in 14 women receiving prazosin and oxprenolol. They reported no superimposed preeclampsia, and infant birth weights were higher than those receiving either methyldopa or no medication. Sibai and Tabb (unpublished data, 1984) compared pregnancy outcomes in 80 women with chronic hypertension who were treated with either prazosin ($n = 40$) or methyldopa ($n = 40$). Both drugs were effective in controlling hypertension, and the incidence of superimposed preeclampsia was similar. There were no differences in perinatal outcome between the two groups. However, patients receiving prazosin had higher plasma volume findings at term than those receiving methyldopa.

Calcium Channel Blockers

Calcium channel blockers act by inhibiting transmembrane calcium ion influx from the extracellular space into the cytoplasm, thus blocking excitation-contraction coupling in smooth muscle fibers and thereby causing vasodilation and reduction in the peripheral resistance. They also have mild tocolytic properties. They have been used extensively in the treatment of hypertensive emergencies as monotherapy or as a part of combination therapy. They have rapid onset of action following oral administration. Nifedipine has potent vasodilating properties without reduction in cardiac output. Few reports have described the use of nifedipine in a limited number of women with acute hypertension during pregnancy.^{[2], [130], [131], [213], [226], [227], [332], [333]} The drug was effective in controlling maternal blood pressure, and no adverse fetal or neonatal effects were noted. However, there is limited experience with nifedipine treatment of chronic hypertension. Common side effects include headache, flushing, tachycardia, and fatigue. Care should be exercised when using nifedipine with magnesium sulfate, which is a calcium channel blocker itself, since the use of both agents together could potentiate the antihypertensive action. There are a few recent reports that have described the use of other calcium channel blockers such as nifedipine^[334] and isradipine^[335] in women with hypertension. In addition, one report described the use of long-acting nifedipine.^[17]

Angiotensin-Converting Enzyme Inhibitors

Three angiotensin-converting enzyme (ACE) inhibitors are available in the United States: captopril, enalapril, and lisinopril. They induce vasodilation by inhibiting the enzyme that converts angiotensin I to angiotensin II, a potent vasoconstrictor, without reflex increase in the cardiac output. In addition, they increase the synthesis of vasodilating prostaglandins and diminish the rate of bradykinin inactivation. Because of their efficacy and low side effects, these agents are becoming widely used as first-line therapy for chronic hypertension in the nonpregnant state. In the experimental animal model, captopril causes abortion and fetal death, apparently by reducing the uteroplacental perfusion. In human pregnancy, the chronic use of ACE inhibitors has reportedly been associated with several fetal and neonatal complications: neonatal hypotension, fetal growth retardation, oligohydramnios, neonatal anuria and renal failure, and neonatal death.^{[336] [337] [338] [339]} Thus, it is recommended that the use of these agents in pregnancy be avoided.^[337] Similar recommendations apply to the use of angiotensin receptor blockers.

Hydralazine

Hydralazine is a potent vasodilator that acts directly on the vascular smooth muscle. It is the agent most commonly used to control severe hypertension in preeclampsia, where it is given intravenously in bolus injections. After its intravenous use, the hypotensive effect of this drug develops gradually over 15 to 30 minutes, peaking at 20 minutes. The elimination half-life is about 3 hours. The usual bolus dose is 5 to 10 mg to be repeated every 20 to 30 minutes as needed. Its main side effects are fluid retention, tachycardia, palpitation, headache, and a lupus-like syndrome, as well as neonatal thrombocytopenia. About 50 percent of the U.S. population are genetically determined slow acetylators and thus are at higher risk for hypotension. Many of these side effects are common with high chronic doses and are usually minimized when it is used in combination with other antihypertensives. Because oral hydralazine when used as a monotherapy is a weak antihypertensive, it is usually combined with diuretics, methyldopa, or α -blockers; however, the use of multiple agents is discouraged in pregnancy. The usual oral dose is 10 mg given four times daily, but this can be increased up to 300 mg/day.

α -Blockers

The drugs in this category have different hemodynamic effects that depend on their receptor selectivity, the presence of intrinsic sympathomimetic activity (ISA), and their lipid solubility. The mechanisms of action of these drugs are complex and highly controversial.^{[340] [341] [342]} Drugs without ISA reduce both cardiac output and heart rate in association with their antihypertensive effects. On the other hand, drugs with ISA reduce mean arterial blood pressure without influencing either cardiac output or heart rate. α -blockers have been used extensively to treat thyroid disease, mitral valve prolapse,

migraine headache, glaucoma, and chronic hypertension. Side effects in the nonpregnant state include bronchial spasm, hypoglycemia, cold extremities, as well as disturbances in the lipid metabolism. Their use in pregnancy has been reportedly associated with neonatal bradycardia, hypoglycemia, fetal growth restriction, altered adaptation to perinatal asphyxia, and neonatal respiratory depression.^[343] However, most of these neonatal effects could be attributed to maternal disease as well.

There are numerous reports describing the management of hypertension during pregnancy with various -blockers, but only a few are well controlled. This subject was recently reviewed by Rubin,^[343] who concluded that these drugs are safe when used in pregnancy. In addition, he reported that their use was associated with better perinatal outcome than that achieved with either methyldopa or hydralazine. However, we believe it is difficult to draw any conclusions regarding the safety and efficacy of these drugs from such studies because (1) they involved heterogeneous groups of patients with chronic hypertension, preeclampsia, and chronic hypertension with superimposed preeclampsia; (2) the -blockers were used in association with other antihypertensive agents such as diuretics, hydralazine, methyldopa, or prazosin; and (3) the blood pressure values at the time of initiating therapy and the duration of treatment were highly variable. It is important to note that the chronic use of atenolol during pregnancy has been consistently associated with reduced fetal weights as well as placental function.^[325],^[344]^[345]^[346]^[347] Therefore, its use for control of maternal blood pressure in women with chronic hypertension should be avoided.

Thiazide Diuretics

Thiazide diuretics are generally the first drugs selected in the treatment of nonpregnant hypertensive patients. Consequently, most women with chronic hypertension become pregnant while on diuretics. Initially, in the first 3 to 5 days of treatment, these drugs result in a 5 to 10 percent reduction in both plasma and extracellular fluid volumes with a concomitant decrease in the cardiac output and lowering of the blood pressure. However, these changes tend to return to pretreatment levels within 4 to 6 weeks. These effects are followed by a long-term reduction in peripheral resistance, which is thought to be related to reduced intracellular sodium concentration in vascular smooth muscle cells. A single 25-mg dose is usually given in the morning. Adverse maternal effects reported with diuretics during pregnancy include hypokalemia, hyponatremia, hyperglycemia, hyperuricemia, hyperlipidemia, hemorrhagic pancreatitis, and even death. Neonatal adverse effects are electrolyte imbalance, thrombocytopenia, and small size for gestational age.

Other harmful maternal and fetal effects reported with the use of diuretics during pregnancy include significant plasma volume depletion that may be detrimental to fetal growth.^[348]^[349]^[350] Sibai et al.^[351] noted that pregnant patients with chronic hypertension treated with diuretics have a marked reduction in plasma volume compared with a control group not receiving these medications. However, plasma volume expansion was normal after the discontinuation of diuretics. In a subsequent report, Sibai et al.^[351] measured the plasma volume in 20 hypertensive women who received diuretics before and early in pregnancy. Diuretics were continued in 10 of these subjects but were stopped in the remainder. In the group whose diuretics were continued, subsequent plasma volumes at various stages of gestation were markedly reduced compared with findings in the others. Collins et al.^[352] reviewed nine randomized trials of diuretics in pregnancy involving nearly 7,000 women and concluded that prophylactic thiazide therapy does not reduce the incidence of preeclampsia. Similar findings were reported by MacGillivray,^[353] who found that patients receiving diuretics delivered infants who weighed less than those born to control pregnant women.

Because the initiation of diuretic therapy causes a decrease in blood volume and cardiac output, adding a diuretic late in pregnancy is probably contraindicated unless it is needed for the treatment of pulmonary edema. On the other hand, continuing a diuretic as a part of therapeutic program in patients with chronic hypertension who become pregnant remains an unresolved issue. Our policy is to discontinue thiazide diuretics in such patients at the time of first visit. Since plasma volume depletion is associated with poor perinatal outcome, we have cautioned against the use of diuretics in pregnancies complicated by chronic hypertension. Furthermore, when diuretics are discontinued, few patients require additional medications during the remainder of the pregnancy.^[351]

Management of Chronic Hypertension

The primary objective in the management of pregnancies complicated with chronic hypertension is to reduce maternal risks and achieve optimal perinatal survival. This objective can be achieved by formulating a rational approach that includes preconceptional evaluation and counseling, early antenatal care, frequent antepartum visits to monitor both maternal and fetal well-being, timely delivery with intensive intrapartum monitoring, and proper postpartum management.

Preconceptional Evaluation of Chronic Hypertension

Management of patients with chronic hypertension should ideally begin before pregnancy, when extensive evaluation is undertaken to assess the etiology and the

severity of the hypertension, as well as the presence of other medical illnesses, and to rule out the presence of target organ damage of long-standing hypertension.^[309] An in-depth history should delineate in particular the duration of hypertension, the use of antihypertensive medications, their type, and the response to these medications. As some medications that have potentially harmful effects on the fetus are frequently used in the nonpregnant state (ACE inhibitors, ganglion blockers, atenolol), it is prudent to change these drugs to others with well-documented safety and to monitor the responses of the patients to these medications. Attention should also be given to the presence of cardiac or renal disease, diabetes mellitus, thyroid disease, and a history of a cerebrovascular accident or congestive heart failure. A detailed obstetric history should include maternal as well as neonatal outcome of previous pregnancies with emphasis on the history of development of abruptio placentae, superimposed preeclampsia, preterm delivery, small-for-gestational-age infants, intrauterine fetal death, and neonatal morbidity and mortality. A detailed physical examination should include the following: general physical examination, Funduscopic examination, measurement of blood pressure in the four extremities, measurement of blood pressure with changes in posture and after rest, detailed auscultation of chest and flanks, and checking of pulses in the four extremities.

Laboratory evaluation is obtained to assess the functions of different organ systems that are likely to be affected by chronic hypertension, and as a baseline for future assessments; these should include:

1. For all patients
 - a. Urinalysis
 - b. Urine culture and sensitivity
 - c. 24-hour urine evaluation for protein, sodium, potassium, and creatinine clearance
 - d. SMAC-20
 - e. CBC
 - f. Glucose tolerance test
2. Selectively
 - a. If hyperglycemia or wide blood pressure swings are evident, a 24-hour urine evaluation for vanillylmandelic acid (VMA) and metanephrines is recommended to rule out pheochromocytoma.
 - b. For patients with severe hypertension or significant proteinuria, chest x-ray, ECG, antinuclear antibody, and serum complement studies are indicated.
 - c. For patients with severe long-standing hypertension, or if there is a suspicion of heart disease, an echocardiogram is recommended.
 - d. Women with a history of poor pregnancy outcome (repetitive midpregnancy losses), and those with recent thromboembolic disease, should be evaluated for the presence of lupus anticoagulant, anticardiolipin antibodies, and other thrombophilias.

Pregnancies in women with chronic hypertension and renal insufficiency are associated with increased perinatal loss and a higher incidence of superimposed preeclampsia, preterm delivery, and fetal growth restriction.^[354]^[355]^[356]^[357] These risks rise in proportion to the severity of the renal insufficiency; women with severe renal insufficiency, particularly primary glomerular disease, risk rapid progression to end-stage renal disease during pregnancy or postpartum.^[354]^[355]^[356]^[357] Thus, women with renal disease desiring pregnancy should be counseled to conceive before renal insufficiency becomes severe. For women with hypertension and severe renal insufficiency in the first trimester, the decision to continue pregnancy should not be made without extensive counseling regarding the potential maternal and fetal risks, particularly the potential need for dialysis during pregnancy.^[357] Women who elect to continue their pregnancies must be observed and managed at a tertiary care center with adequate maternal - neonatal care facilities.

Initial and Subsequent Prenatal Visits for Patients with Chronic Hypertension

Early prenatal care will ensure accurate determination of gestational age as well as an assessment of the severity of hypertension in the first trimester, which have prognostic values for the outcome of such pregnancies. At the time of initial and subsequent visits, the patient should be counseled regarding the following aspects as they pertain to her pregnancy:

1. Instruction by a nutritionist regarding nutritional requirements, weight gain, and sodium intake
2. Instruction regarding the negative impact of maternal anxiety, smoking, and caffeine, as well as drugs, on maternal blood pressure and perinatal outcome
3. Counsel regarding the possible adverse effects and complications of hypertension during pregnancy
4. Counsel regarding the importance of frequent prenatal visits and their impact on preventing or minimizing the above adverse effects

If the patient is well motivated, she can be instructed in self-determination of blood pressure, as recommended by Zuspan and Rayburn.^[356] This approach avoids the phenomenon of "white coat hypertension," which is associated with a visit to the physician's office, and avoids the need to start or increase the dose of antihypertensive medications. It is recommended that patient-recorded measurements of blood pressure be used to supplement those recorded in the doctor's office.

During the course of pregnancy, the patient should

992

be seen once every 2 to 3 weeks in the first two trimesters and thereafter adjusted based on maternal and fetal conditions. Systolic and diastolic blood pressure readings should be carefully measured at each visit. At each visit, the urine should be checked for protein. Maternal evaluation should include serial measurements of hematocrit, serum creatinine, uric acid, and 24-hour urinary excretion of protein once every trimester. Other tests are obtained as needed. The occurrence of one or more of the following may be an indication for hospitalization:

1. Pyelonephritis
2. Significant elevations in blood pressure with levels in the range of severe hypertension
3. Severe fetal growth restriction

Based on the initial assessment, the patient is then classified as having low-risk or high-risk chronic hypertension depending on duration of hypertension, severity of hypertension early in pregnancy, and the extent of cardiovascular and renal involvement at the onset of pregnancy and other factors.

Managing Low-Risk Chronic Hypertension

As stated previously, most patients with uncomplicated mild chronic hypertension will have a good perinatal outcome irrespective of the use of antihypertensive drugs. A recent analysis of pregnancy outcome in 211 patients with mild chronic hypertension managed at our institution^[308] suggests that the use of antihypertensive drugs is not necessary to achieve a good pregnancy outcome. The changes in average mean arterial pressure (MAP) throughout the course of pregnancy is summarized in [Figure 28-7](#). It is of interest to note that 49 percent of patients will demonstrate a decrease in MAP and an additional 34 percent will demonstrate no change in MAP at 20 to 26 weeks' gestation without the use of antihypertensive medications. Furthermore, only 13 percent of patients will require antihypertensive medications for exacerbation of hypertension during the third trimester. In the same study, we found that most poor outcomes were related to the development of superimposed preeclampsia in such pregnancies. In addition, in the absence of superimposed preeclampsia, the perinatal outcome in patients with mild chronic hypertension was similar to that in the general obstetric population. We attribute the good perinatal outcome in these pregnancies to early onset of prenatal care, intensive antepartum and intrapartum monitoring, and timely delivery. Thus, it is our policy to discontinue all antihypertensive medications in all such patients at the time of first prenatal visit. Antihypertensive therapy is subsequently started only if the blood pressure exceeds 160 mm Hg systolic or 110 mm Hg diastolic. These patients are usually treated with methyldopa (750 mg to 4 g/day) given as needed to keep diastolic blood

Figure 28-7 Mean arterial blood pressure (MAP) during pregnancy. (Modified from Sibai BM, Abdella TN, Anderson GD: *Pregnancy outcome in 211 patients with mild chronic hypertension. Obstet Gynecol* 61:571, 1983.)

993

pressure consistently at or below 105 mm Hg. It is important to emphasize that the development of exacerbated hypertension alone is not an indication for delivery. Pregnancy in these patients may be continued until term or the onset of superimposed preeclampsia. In the absence of superimposed preeclampsia or fetal jeopardy, routine induction before 41 weeks' gestation is not warranted. Superimposed preeclampsia or suspected fetal growth restriction is an indication for close evaluation of maternal and fetal well-being. Subsequent management is similar to that in the high-risk group and will depend on gestational age and the result of antepartum fetal testing. Mild superimposed preeclampsia is an indication for delivery if the gestational age is at least 37 weeks. Otherwise, the pregnancy can be managed conservatively until the cervix is ripe for induction, onset of labor, or completion of 40 weeks' gestation.

Managing High-Risk Chronic Hypertension

Pregnancies in women at high risk are associated with increased maternal and perinatal complications (see the box "High Risk Characteristics").^[319] As a result, these patients should be managed in consultation with a maternal-fetal medicine specialist. Furthermore, patients with chronic renal disease particularly those with primary glomerular diseases and significant renal impairment (serum creatinine >2.5 mg/dl) should be managed in consultation with a nephrologist. All these patients should be hospitalized at the time of first prenatal visit for evaluation of cardiovascular and renal status and for regulation of antihypertensive treatment, as well as other prescribed medications (insulin, thyroid drugs, cardiac drugs). Antihypertensive agents should be used to keep systolic blood pressure between 140 and 160 mm Hg and diastolic blood pressure between 90 and 105 mm Hg. Maternal blood pressure can be controlled with methyldopa (1 to 4 g/day), labetalol (600 mg to 2.4 g/day), or nifedipine (40 to 120 mg/day). In some patients, blood pressure may be difficult to control, demanding the use of multiple oral drugs as well as intravenous therapy. Antihypertensives must be used in all women with severe hypertension. In addition, there are short-term maternal benefits from treating women with mild hypertension and target organ damage such as diabetes mellitus, renal disease, and cardiac dysfunction. As a result, we recommend treating mild chronic hypertension in pregnant women with these complications, keeping diastolic blood pressure below 90 mm Hg. For patients with significant proteinuria in the first trimester, antinuclear antibody and serum complement are performed to rule out the presence of lupus nephritis. Early and frequent prenatal care is the key to a successful outcome for patients with high-risk characteristics. These women need close monitoring throughout pregnancy and may require multiple hospital admissions for control of blood pressure or associated medical complications. Fetal evaluation should be started as early as 26 weeks and repeated as needed. Superimposed preeclampsia is an indication for immediate hospitalization. Subsequent management will depend on the severity of preeclampsia and fetal gestational age. Severe superimposed preeclampsia is an indication for delivery in all patients with a gestational age beyond 34 weeks. If preeclampsia develops before this time, the pregnancy may be followed conservatively with daily evaluation of maternal and fetal well-being.

High-Risk Characteristics

Maternal age >40 years
Duration of hypertension >15 years
Blood pressure 160/110 mm Hg early in pregnancy
Diabetes mellitus (White classes B-F)
Renal disease (all causes)
Cardiomyopathy
Connective tissue disease
Coarctation of the aorta
Presence of thrombophilias
Previous pregnancy with perinatal loss

Hypertensive Emergencies in Chronic Hypertension

On rare occasions, pregnant women may present with life-threatening clinical conditions that require immediate control of blood pressure, such as hypertensive encephalopathy, acute left ventricular failure, acute aortic dissection, or increased circulating catecholamines (pheochromocytoma, clonidine withdrawal, cocaine ingestion). Patients at highest risk for these complications include those with underlying cardiac disease, chronic glomerular renal disease, multiple drugs to control their hypertension, superimposed preeclampsia in the second trimester, and abruptio placentae complicated by DIC. Although a diastolic blood pressure of 115 mm Hg or greater is usually considered a hypertensive emergency, this level is actually arbitrary, and the rate of change of blood pressure may be more important than absolute level.^[359] The association of elevated blood pressure with evidence of new or progressive end-organ damage determines the seriousness of the clinical situation.^[360]

Hypertensive Encephalopathy

Untreated essential hypertension progresses to a hypertensive crisis in up to 1 to 2 percent of cases for unknown

994

reasons. Hypertensive encephalopathy is usually seen in patients with systolic blood pressure above 250 mm Hg or diastolic blood pressure above 150 mm Hg.^[360] Patients with acute onset of hypertension may develop encephalopathy at pressure levels that are generally tolerated by those with chronic hypertension. Normally, cerebral blood flow is approximately 50 ml/100 g tissue per minute. When the blood pressure falls, cerebral arterioles normally dilate, whereas when blood pressure increases, they constrict to maintain constant cerebral blood flow.^[361] This mechanism usually remains operative between 60 and 120 mm Hg diastolic blood pressure. Hypertensive encephalopathy is currently considered to be a derangement of the autoregulation of cerebral arterioles, which occurs when the upper limit of autoregulation is exceeded.^[359] With severe hypertension (130 to 150 mm Hg cerebral perfusion pressure), cerebral blood vessels constrict as much as possible and then reflex cerebral vasodilatation occurs. This results in overperfusion, damage to small blood vessels, cerebral edema, and increased intracranial pressure (breakthrough theory). Others believe that hypertensive encephalopathy results from an exaggerated vasoconstrictive response of the arterioles resulting in cerebral ischemia (overregulation theory). Patients who have impaired autoregulation involving the cerebral arterioles may experience necrotizing arteriolitis, microinfarcts, petechial hemorrhages, multiple small thrombi, or cerebral edema.^[360] Typically, hypertensive encephalopathy has a subacute onset over 24 to 72 hours.^[361]

During a hypertensive crisis, other evidence for end-organ damage may be present: cardiac, renal, or retinal dysfunction secondary to impaired organ perfusion and loss of autoregulation of blood flow.^[360] Ischemia of the retina (with flame-shaped retinal hemorrhages, retinal infarcts, or papilledema) may occur causing decreased visual acuity. Impaired regulation of coronary blood flow and marked increase in ventricular wall stress may result in angina, myocardial infarction, congestive heart failure, malignant ventricular arrhythmia, pulmonary edema, or dissecting aortic aneurysm. Necrosis of the afferent arterioles of the glomerulus results in hemorrhages of the cortex and medulla, fibrinoid necrosis, and proliferative endarteritis resulting in elevated serum creatinine (>3 mg/dl), proteinuria, oliguria, hematuria, hyaline or red blood cell casts, and progressive azotemia.^[359] Severe hypertension may result in abruptio placentae with resultant DIC. In addition, high levels of angiotensin II, norepinephrine, and vasopressin accompany ongoing vascular damage. These circulating hormones increase relative efferent arteriolar tone, resulting in sodium diuresis and hypovolemia. Because levels of renin and angiotensin II are increased, the aldosterone level is also elevated. The impact of these endocrine changes may be important in maintaining the hypertensive crisis.

Treatment of Hypertensive Encephalopathy

The ultimate goal of therapy is to prevent the occurrence of a hypertensive emergency. Patients at risk for hypertensive crisis should receive intensive management during labor and for a minimum of 48 hours after delivery. Although pregnancy may complicate the diagnosis, once the life-threatening conditions are recognized, pregnancy should not in any way slow or alter the mode of therapy. The only reliable clinical criterion to confirm the diagnosis of hypertensive encephalopathy is prompt response of the patient to antihypertensive therapy. The headache and sensorium often clear dramatically sometimes within 1 to 2 hours after the treatment. The overall recovery may be somewhat slower in patients with uremia and in whom the symptoms have been present for a prolonged period before the therapy is given. Sustained cerebrovascular deficits should suggest other diagnoses.^[361]

Patients with hypertensive encephalopathy or other hypertensive crisis should be hospitalized for bed rest. Intravenous lines should be inserted for fluids and medications. Although there is a tendency to restrict sodium intake in patients with a hypertensive emergency, volume contraction from sodium diuresis may be present. A marked drop in diastolic blood pressure with a rise in heart rate on standing from the supine position is evidence of volume contraction. Infusion of normal saline solution during the first 24 to 48 hours to achieve volume expansion should be considered. Saline infusion may help decrease the activity of the renin-angiotensin-aldosterone axis and result in better blood pressure control. Simultaneous repletion of potassium losses and continuous monitoring of blood pressure, volume status, urinary output, electrocardiographic readings, and mental status is mandatory. An intra-arterial line may provide the most accurate blood pressure information. Laboratory studies include complete blood count, differential, reticulocyte count, platelets, and blood chemistries. A urinalysis should be obtained for protein, glucose, blood, cells, casts, and bacteria. Assessment for end-organ damage in the central nervous system, retina, kidneys, and cardiovascular system should be done periodically. Antepartum patients should have continuous fetal monitoring.^[359], ^[362]

Lowering Blood Pressure

There are risks associated with too rapid or excessive reduction of elevated blood pressure. The aim of therapy is to lower mean blood pressure by no more than 15 to 25 percent. Small reductions in blood pressure in the first 60 minutes, working toward a diastolic level of 100 to 110 mm Hg, have been recommended.^[359], ^[360] Although

cerebral blood flow is maintained constantly over a wide range of blood pressures, there is a lower as well as an upper limit to autoregulation. In chronic hypertensive women who have a rightward shift of the cerebral autoregulation curve secondary to medial hypertrophy of the cerebral vasculature, lowering blood pressure too rapidly may produce cerebral ischemia, stroke, or coma. Coronary blood flow, renal perfusion, and uteroplacental blood flow also may deteriorate, resulting in acute renal failure, myocardial infarction, fetal distress, or death. Hypertension that proves increasingly difficult to control is an indication to end the pregnancy. If the patient's outcome appears to be grave, consideration of perimortem cesarean delivery should be made. ^[359]

The drug of choice in hypertensive crisis is sodium nitroprusside. Other drugs such as nitroglycerin, nifedipine, trimetaphan, labetalol, and hydralazine can also be used.

Sodium Nitroprusside

Sodium nitroprusside causes arterial and venous relaxation by interfering with both influx and the intracellular activation of calcium. It is given as an intravenous infusion of 0.25 to 8.0 µg/kg/min. The onset of action is immediate, and its effect may last 3 to 5 minutes after discontinuing the infusion. Hypotension caused by nitroprusside should resolve within a few minutes of stopping the infusion, because the drug's half-life is so short. If it does not resolve, other causes for hypotension should be suspected. The effect of nitroprusside on uterine blood flow is controversial. Nitroprusside is metabolized into thiocyanate, which is excreted in the urine. Cyanide can accumulate if there is either increased production due to large doses (>10 µg/kg/min) or prolonged administration (>48 hours), or if there is renal insufficiency or decreased metabolism in the liver. Signs of toxicity include anorexia, disorientation, headache, fatigue, restlessness, tinnitus, delirium, hallucinations, nausea, vomiting, and metabolic acidosis. When it is infused at less than 2 µg/kg/min, cyanide toxicity is unlikely. At a maximum dose rate of 10 µg/kg/min, infusion should never last more than 10 minutes. Animal experiments and the few reported cases of nitroprusside use in pregnancy have revealed that thiocyanate toxicity to mother and fetus rarely occur if it is used in a regular pharmacologic dose. Tachyphylaxis to nitroprusside usually develops before toxicity occurs. Whenever toxicity is suspected, therapy should be initiated with 3 percent sodium nitrite at a rate not exceeding 5 ml/min, up to a total dose of 15 ml. Then, infusion of 12.5 g of sodium thiosulfate in 50 ml of 5 percent dextrose in water over a 10-minute period should be started. ^[363]

Nitroglycerin

Nitroglycerin is an arterial but mostly venous dilator. It is given as an intravenous infusion of 5 µg/min that is gradually increased every 3 to 5 minutes to titrate blood pressure up to a maximum dose of 100 µg/min. It is the drug of choice in preeclampsia associated with pulmonary edema and for control of hypertension associated with tracheal manipulation. Side effects such as headache, tachycardia, and methemoglobinemia may develop. It is contraindicated in hypertensive encephalopathy because it increases cerebral blood flow and intracranial pressure. ^[360]

Postpartum Management of Hypertension

High-risk chronic hypertensive patients can develop hypertensive encephalopathy, pulmonary edema, and renal failure in the postpartum period. These risks are particularly increased in women with underlying cardiac disease, chronic glomerular renal disease, superimposed preeclampsia in the second trimester, abruptio placentae complicated by DIC, and those requiring multiple hypertensive agents. ^[310] Patients with these complications should receive intensive management for a minimum of 48 hours after delivery and intravenous hydralazine or labetalol for control of severe hypertension as needed. Moreover, diuretic therapy should be used in women who are at risk for delayed onset of postpartum circulatory congestion and pulmonary edema, including massively obese older women with long-standing hypertension and those with previous antepartum congestive heart failure.

Oral antihypertensive drugs may be needed to control maternal blood pressure after delivery. Some women may wish to breast-feed their infants while receiving these agents (see also Chapter 9). Unfortunately, data are limited concerning the excretion of these drugs into human breast milk and their effects on the infant. ^[364], ^[365] In addition, there are no published reports describing the long-term effects of antihypertensive agents on infants exposed to these drugs through breast-feeding. Most of the published data have described the milk/plasma ratio after a single measurement of the drug concentration. ^[364] ^[365] ^[366] The data in the literature indicate that all studied antihypertensive agents are excreted into human breast milk, although there are differences among these drugs in the milk/plasma ratio. ^[365] The available data also show that there are no short-term adverse effects on the breast-feeding infant exposed to methyl dopa, hydralazine, or β -blockers.

Key Points

Hypertension is the most common medical complication during pregnancy.

Preeclampsia is a leading cause of maternal mortality and morbidity worldwide.

The pathophysiologic abnormalities of preeclampsia are numerous, but the etiology is unknown.

At present, there is no proven method to prevent preeclampsia.

The HELLP syndrome may develop in the absence of maternal hypertension.

Expectant management improves perinatal outcome in a select group of women with severe preeclampsia before 32 weeks' gestation.

Magnesium sulfate is the ideal agent to prevent or treat eclamptic convulsions.

Rare cases of eclampsia can develop before 20 weeks' gestation and beyond 48 hours postpartum.

Antihypertensive agents do not improve pregnancy outcome in women with mild uncomplicated chronic hypertension.

Methyldopa is the drug of choice for the treatment of chronic hypertension; ACE inhibitors should be avoided.

Chapter 29 - Heart Disease

Thomas R. Easterling
Catherine Otto

Cardiovascular adaptations to pregnancy are well tolerated by healthy young women. However, these adaptations are of such magnitude that they can significantly compromise women with abnormal or damaged hearts. Without accurate diagnosis and appropriate care, heart disease in pregnancy can be a significant cause of maternal mortality. Under more optimal conditions, many women with significant disease can experience good outcomes and should not necessarily be discouraged from becoming pregnant. This chapter develops an understanding of cardiovascular physiology as a basis for appropriate care. While published experience with more common conditions can be used to support these principles, information regarding many other conditions is limited to case reports. In general, data from case reports will be biased toward more complicated cases with more adverse outcomes. The best care for women with heart disease is usually achieved from a thorough understanding of maternal cardiovascular physiology, knowledge of existing literature, and extensive clinical experience brought by the clinical management team.

MATERNAL HEMODYNAMICS

Hemodynamics refers to the relationship between blood pressure, cardiac output, and vascular resistance. Blood pressure is measured by auscultation, use of an automated cuff, or directly with an intra-arterial catheter. Cardiac output is measured by dilutional techniques requiring central venous access, by Doppler or two-dimensional echocardiographic techniques, or by electrical impedance. Peripheral resistance is calculated using Ohm's law:

where TPR is total peripheral resistance ($\text{dyne}\cdot\text{sec}\cdot\text{cm}^{-5}$), MAP is mean arterial pressure (mm Hg), and CO is cardiac output (L/min).

Pregnancy and events unique to pregnancy, such as labor and delivery, are associated with significant and frequently predictable changes in these parameters. The hemodynamic changes of pregnancy, while well tolerated by an otherwise healthy women, may be tolerated poorly by a woman with significant cardiac disease. Therefore, the importance of understanding these changes and placing them in the context of a specific cardiac lesion cannot be overstated.

The maternal hemodynamics of 89 nulliparous women who remained normotensive throughout pregnancy are described in [Figure 29-1](#).^[1] Mean arterial pressure falls sharply in the first trimester, reaching a nadir by midpregnancy. Thereafter, blood pressure increases slowly, reaching near nonpregnant levels by term. Cardiac output rises throughout the first and second trimesters, reaching a maximum by the middle of the third trimester. In the supine position, a pregnant woman in the third trimester may experience significant hypotension due to venocaval occlusion by the gravid uterus. In normal pregnancy, she may experience symptoms such as diaphoresis, tachycardia, or nausea but will rarely experience significant complications. Fetal heart rate decelerations may be observed but usually resolve when the mother, often spontaneously, shifts to a more comfortable position. Women with significant right or left ventricular outflow obstruction, such as aortic stenosis, may seriously decompensate in the supine position due to poor ventricular filling.

1006

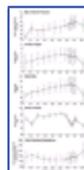

Figure 29-1 Changes in hemodynamic parameters throughout pregnancy (mean \pm SD).

Cardiac output is the product of heart rate (HR) and stroke volume (SV): $\text{CO} = \text{HR} \times \text{SV}$. Heart rate and stroke volume increase as pregnancy progresses to the third trimester. After 32 weeks, stroke volume falls, with the maintenance of cardiac output becoming more and more dependent on heart rate. Vascular resistance falls in the first and early second trimesters. The magnitude of the fall is sufficient to offset the rise in cardiac output, resulting in a net decrease in blood pressure.

Labor, delivery, and the postpartum period are times of acute hemodynamic changes that may result in maternal decompensation. Labor itself is associated with pain and anxiety. Tachycardia is a normal response. Significant catecholamine release will increase afterload. Each

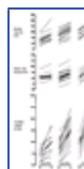

Figure 29-2 Changes in hemodynamic parameters at three different points during labor (3 cm, 4 to 7 cm, and 8 cm). Each line represents the change in an individual subject. B, before contraction; C, during contraction. (From Robson S, Dunlop W, Boys R, Hunter S: Cardiac output during labour. *BMJ* 295:1169, 1987, with permission.)

1007

uterine contraction acutely redistributes 400 to 500 ml of blood from the uterus to the central circulation. In [Figure 29-2](#), Robson et al. describe the hemodynamic changes associated with unmedicated labor.^[2] Heart rate, blood pressure, and cardiac output all increase with uterine contractions, with the magnitude of the change increasing as labor advances. Obstructive cardiac lesions impede the flow of blood through the heart, blunting the expected rise in cardiac output at the expense of increasing pulmonary pressures and pulmonary congestion. In [Figure 29-3](#), inpartum hemodynamic changes of a patient with aortic stenosis and a peak gradient of 160 mm Hg are shown.^[3] Note that pulmonary pressures rise in parallel with uterine contractions.

Immediately after delivery, blood from the uterus is returned to the central circulation. In normal pregnancy, this compensatory mechanism protects the parturient from the hemodynamic effects of postpartum hemorrhage. In the context of cardiac disease, this acute centralization of blood may increase pulmonary pressures and pulmonary congestion.^[4] During the first 2 postpartum weeks, extravascular fluid is mobilized and diuresis ensues. Decompensation during postpartum fluid mobilization is common in women with mitral stenosis and cardiomyopathy. Unsuspected cardiac disease may be diagnosed when a woman returns to the emergency room several days postpartum with dyspnea and oxygen desaturation. Maternal cardiac output has usually normalized by 2 weeks postpartum.^[5]

Three key features of the maternal hemodynamic changes in pregnancy are particularly relevant to the management of women with cardiac disease: (1) increased cardiac output, (2) increased heart rate, and (3) reduced vascular resistance. In conditions such as mitral stenosis where cardiac output is relatively fixed, the drive to achieve an elevated cardiac output may result in pulmonary congestion. If a patient has an atrial septal defect, the incremental increase in systemic flow associated with pregnancy will be magnified in the pulmonary circulation to the extent that pulmonary flow exceeds systemic flow. If, for example, a shunt ratio of 3:1 is maintained in pregnancy, pulmonary flow may be as high as 20 L/min and may be associated with increasing dyspnea and potential desaturation.

Many cardiac conditions are heart rate dependent. Flow across a stenotic mitral valve is dependent on time in diastole. Tachycardia reduces left ventricular filling and cardiac output. Coronary blood flow is also dependent on the length of diastole. Patients with aortic stenosis will have increased wall tension and therefore increased myocardial oxygen requirements. Tachycardia reduces coronary perfusion time in diastole while simultaneously further increasing myocardial oxygen requirements.

The

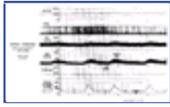

Figure 29-3 Hemodynamic monitoring of a patient with severe aortic stenosis in labor. (From Easterling T, Chadwick H, Otto C, Benedetti T: *Aortic stenosis in pregnancy*. *Obstet Gynecol* 72:113, 1988. Reprinted with permission from American College of Obstetricians and Gynecologists.)

1008

resulting imbalance between oxygen demand and supply may precipitate myocardial ischemia. Patients with complex congenital heart disease experience significant tachyarrhythmias. The increasing heart rate in pregnancy may be associated with a worsening of tachyarrhythmias.

Reduction in vascular resistance may be beneficial to some patients; afterload reduction reduces cardiac work. Cardiomyopathy, aortic regurgitation, and mitral regurgitation benefit from reduced afterload. Alternatively, patients with intracardiac shunts, where right and left ventricular pressures are nearly equal when not pregnant, may reverse their shunt during pregnancy and desaturate.

BLOOD VOLUME

Very early in the first trimester, pregnant women experience an expansion of renal blood flow and glomerular filtration rate. Filtered sodium increases by approximately 50 percent. Despite physiologic changes that would promote loss of salt and water and contraction of blood volume, the pregnant woman will expand her blood volume by 40 to 50 percent. In part, the stimulation to retain fluid may be a response to the fall in vascular resistance and reduction in blood pressure. The renin-angiotensin system is activated, and the plasma concentration of aldosterone is elevated. While the simplicity of this explanation is attractive, the actual process is probably much more complicated.^[6]

As plasma volume expands, the hematocrit falls, and hematopoiesis is stimulated. Red cell mass will expand from 18 to 25 percent depending on the status of individual iron stores. "Physiologic anemia" with a maternal hematocrit between 30 and 35 percent does not usually complicate pregnancy in the context of maternal heart disease. More significant anemia, however, may increase cardiac work and induce tachycardia. Microcytosis due to iron deficiency may impair perfusion of the microcirculation of patients who are polycythemic due to cyanotic heart disease, as microcytic red blood cells are less deformable. Iron and folate supplementation is appropriate.

In a similar fashion, serum albumin concentration falls by 22 percent despite an expansion of intravascular albumin mass by 20 percent. As a result, serum oncotic pressure falls in parallel by 20 percent to approximately 19 mm Hg. ^[7] In normal pregnancy, intravascular fluid balance is maintained by a fall in interstitial oncotic pressure. However, if left ventricular filling pressure becomes elevated or if pulmonary vascular integrity is disrupted, pulmonary edema will develop earlier in the disease process than in nonpregnant women.

DIAGNOSIS AND EVALUATION OF HEART DISEASE

Many women with heart disease have been diagnosed and treated prior to pregnancy. For example, in women with prior surgery for congenital heart disease, detailed historical information may be available. Others only know that they have a murmur or a "hole in my heart." Alternatively, heart disease may first be diagnosed during pregnancy due to symptoms precipitated by increased cardiac demands.

The classic symptoms of cardiac disease are palpitations, shortness of breath with exertion, and chest pain. Since these symptoms also may accompany normal pregnancy, a careful history is needed to determine if the symptoms are out of proportion to the stage of pregnancy. Symptoms are of particular concern in a patient with other reasons to suspect underlying cardiac disease, such as growing up in an area where rheumatic heart disease is prevalent.

A systolic flow murmur is present in 80 percent of pregnant women, most likely due to the increased flow volume in the aorta and pulmonary artery.^[6] Typically, a flow murmur is grade 1 or 2, midsystolic, loudest at the cardiac base, and not associated with any other abnormal physical examination findings. A normal physiologic split second heart sound is heard in patients with a flow murmur. Any diastolic murmur and any systolic murmur that is loud (grade 3/6) or radiates to the carotids should be considered pathologic. Careful evaluation for elevation of the jugular venous pulse, for peripheral cyanosis or clubbing, and for pulmonary crackles is needed in women with suspected cardiac disease.

Indications for further cardiac diagnostic testing in pregnant women include a history of known cardiac disease, symptoms in excess of those expected in a normal pregnancy, a pathologic murmur, evidence of heart failure on physical examination, or arterial oxygen desaturation in the absence of known pulmonary disease. The most appropriate next step in evaluation of pregnant women with suspected heart disease is transthoracic echocardiography. A chest radiograph is only helpful if congestive heart failure is suspected. An electrocardiogram (ECG) is likely to be nonspecific. If symptoms are consistent with a cardiac arrhythmia, an event monitor or 24-hour ECG monitor may be indicated. Rarely, cardiac catheterization is needed for full diagnosis of valvular or congenital heart disease. The exception is an acute coronary syndrome during pregnancy where the risk of radiation exposure with cardiac catheterization is small compared to the benefit of early diagnosis and early revascularization to prevent myocardial infarction.

Echocardiography provides detailed information or

cardiac anatomy and physiology that allows optimal management of women with heart disease. Basic data obtained on echocardiography include left ventricular ejection fraction, pulmonary artery systolic pressure, qualitative evaluation of right ventricular systolic function, and evaluation of valve anatomy and function. When valvular stenosis is present, the pressure gradient (P) across the valve is calculated from the Doppler-derived velocity (v) of flow across the valve: $P = 4v^2$. Similarly, pulmonary artery systolic pressure can be calculated from the maximal Doppler velocity obtained across a tricuspid regurgitant jet.

Aortic valve area is calculated using the continuity equation. Stroke volume is calculated from the product of the cross-sectional area of the left ventricular outflow tract and the time-velocity integral derived from Doppler evaluation of the outflow tract. A time-velocity integral is then derived from the stenotic valve. Since the left ventricular outflow tract and the aortic valve are in continuity, stroke volume across each are equal. Valve area can therefore be derived by dividing the stroke volume by the aortic valve time-velocity integral. Mitral valve area is measured directly by two-dimensional planimetry or by the Doppler pressure half-time method.^[9] In patients with congenital disease, detailed evaluation of anatomy and previous surgical repair is possible. When complex congenital heart disease is present or when image quality is suboptimal, transesophageal imaging provides improved image quality.

GENERAL CARE

Management of cardiac disease in pregnancy is frequently complicated by unique social and psychological concerns. Children with congenital heart disease may have experienced multiple hospitalizations and be fearful of the medical environment. Some have expected never to bear children. Women with rheumatic heart disease have frequently lived outside the traditional medical care system due to conditions of poverty and cultural differences. Not uncommonly, they are recent immigrants. Care must be exercised to facilitate their access to care and their comfort with the environment of care. Their practitioner must be patient but persistent in the face of deviations from more traditional standards of compliance and medical care.

Deterioration in cardiac status during pregnancy is frequently insidious. Continuity of care with a single provider facilitates early intervention prior to overt decompensation. Regular visits should include particular attention to heart rate, weight gain, and oxygen saturation. An unexpected increase in weight may indicate the need for more aggressive outpatient therapy. A fall in oxygen saturation will often precede a clearly abnormal chest exam or radiograph. Regular use of a structured history of symptoms (see the box "Structured Review of Cardiac Symptoms") will alert the physician to a change in condition. Regular review educates the patient and reinforces their role as "partners in care."

Structured Review of Cardiac Symptoms
"How many flights of stairs can you walk up with ease?" "Two? One? None?"
"Can you walk a level block?"
"Can you sleep flat in bed?" "How many pillows?"
"Does your heart race?"
"Do you have chest pain?"
"with exercise?"
"when your heart races?"

The physiologic changes of pregnancy are usually continuous and therefore offer adequate time for maternal compensation despite cardiac disease. Intercurrent events superimposed on pregnancy in the context of maternal heart disease are usually responsible for acute decompensation. Antepartum, the most common significant "intercurrent events" are febrile episodes. Screening for bacteriuria and vaccination against influenza and pneumococcus are appropriate. Patients should be instructed to report symptoms of upper respiratory infection, particularly fever. Many patients with heart disease (adolescents, recent immigrants, and those living in poverty), will also be at risk for iron deficiency. Prophylaxis against anemia with iron and folate supplementation may decrease cardiac work.

A strategy of "standard cardiac care" for labor and delivery is described in the box. The general principles for care are similar for most cardiac diagnoses. Physiologically, the ideal labor for a woman with heart disease is short and pain free. While induction of labor facilitates organization of care and early pain control, shortening the duration of pregnancy by 1 or 2 weeks at the cost of a 2 or 3 day induction of labor is not worthwhile. Induction of labor with a favorable cervix is therefore ideal. Some patients with severe cardiac disease will benefit from invasive hemodynamic monitoring with an arterial catheter and a pulmonary artery catheter. These will be discussed in detail below. Cesarean section is usually reserved for obstetric indications. The American Heart Association does not recommend routine antibiotic prophylaxis for the prevention of endocarditis, although it is optional in high-risk patients having a vaginal delivery ([Table 29-1](#)). Because bacteremia is common at the time of vaginal delivery and

cesarean section,^[19] ^[11] many practitioners will provide antibiotic prophylaxis in all patients at risk.

Standard Cardiac Care for Labor and Delivery

1. Accurate diagnosis
2. Mode of delivery based on obstetric indications
3. Medical management initiated early in labor
 - Prolonged labor avoided.
 - Induction with a **favorable** cervix
4. Maintenance of hemodynamic stability
 - Invasive hemodynamic monitoring when required
 - Initial, compensated hemodynamic reference point
 - Specific emphasis based on particular cardiac condition
5. Avoidance of pain and hemodynamic responses
 - Epidural analgesia with narcotic/low-dose local technique
6. Prophylactic antibiotics when at risk for endocarditis
7. Avoidance of maternal pushing
 - Caudal for dense perineal anesthesia
 - Low forceps or vacuum delivery
8. Avoidance of maternal blood loss
 - Proactive management of the third stage
 - Early but appropriate fluid replacement
9. Early volume management postpartum
 - Often careful but aggressive diuresis

Women with significant heart disease should be counseled prior to pregnancy regarding the risk of pregnancy, interventions that may be required, and potential risks to the fetus. However, women with significant uncorrected disease may present with an ongoing pregnancy. In this situation, the risks and benefits of termination of pregnancy versus those of continuing a pregnancy should be addressed. The decision to become pregnant or carry a pregnancy in the context of maternal disease is a balance of two forces: (1) the objective medical risk including the uncertainty of that estimate, and (2) the value of the birth of a child to an individual woman and her partner. The first goal of counseling is to educate the patient. Only a few cardiac diseases represent an overwhelming risk of maternal mortality: Eisenmenger's syndrome, pulmonary hypertension with right ventricular dysfunction, and Marfan syndrome with significant aortic dilation. Most other conditions require aggressive management and significant disruption in lifestyle. Intercurrent events such as antepartum pneumonia or obstetric hemorrhage pose the greatest risk of initiating life-threatening events. Fastidious care can reduce but not eliminate the risk of these events. Maternal congenital heart disease increases the risk of congenital heart disease in the fetus from 1 percent to approximately 4 to 6 percent.^{[12], [13]} Marfan syndrome and some forms of hypertrophic cardiomyopathy are inherited as autosomal dominant conditions; the children of these women will carry a 50 percent chance of inheriting the disease. The second goal of counseling is to help the woman integrate the medical information into her individual value system and her

TABLE 29-1 -- PROPHYLACTIC REGIMENS FOR LABOR AND DELIVERY

Patients	Regimens
High-risk patients	
Prosthetic valves both bioprosthetic and homografts	Ampicillin + gentamicin
Complex cyanotic congenital heart disease (CHD)	Ampicillin 2.0 g IM or IV
Surgically constructed systemic pulmonary shunts or conduits	Gentamicin 1.5 mg/kg (not to exceed 120 mg) in active labor; 6 h later, ampicillin 1 g IM/IV or amoxicillin 1 g PO
Previous bacterial endocarditis	
High-risk patients allergic to ampicillin/amoxicillin	Vancomycin + gentamicin
	Vancomycin 1.0 g IV over 12 h + gentamicin as above in active labor
Moderate-risk patients	
Most other CHD	Amoxicillin or ampicillin
Acquired valvular dysfunction (e.g., rheumatic heart disease)	Amoxicillin 2.0 g orally or ampicillin 2.0 g IM/IV in active labor
Hypertrophic cardiac myopathy	
Mitral valve prolapse with regurgitation	
Moderate-risk patients allergic to ampicillin/amoxicillin	Vancomycin
	Vancomycin 1.0 g IV over 12 h in active labor

individual desire to be a mother. Many women with significant but manageable heart disease will choose to carry a pregnancy. The basis for their decisions must be individualized.

VALVULAR DISEASE

The American College of Cardiology and the American Heart Association have published guidelines for the management of valvular heart disease including some guidelines for management during pregnancy.^[14] These guidelines create a general framework for preconceptional care and care during pregnancy, realizing that treatment of a specific patient must be individualized. Individualization is particularly important when one is balancing maternal and fetal risks against the desire to have children. An individual patient's value system will have a significant impact on the final direction of care.

MITRAL STENOSIS

Mitral stenosis is nearly always due to rheumatic heart disease. Valvular dysfunction progresses continuously throughout life. Deterioration may be accelerated by recurrent episodes of rheumatic fever. Rheumatic fever itself is an immunologic response to group A -hemolytic streptococcus infections. The incidence of rheumatic fever in a population is heavily influenced by conditions of poverty and crowding. These same individuals are at risk to have reduced access and utilization of health care resources and may present undiagnosed or untreated.

Patients with asymptomatic mitral stenosis have a 10-year survival of greater than 80 percent. Once significantly symptomatic, 10-year survival without treatment is less than 15 percent. In the presence of pulmonary hypertension, mean survival is less than 3 years. Death is due to progressive pulmonary edema, right heart failure, systemic embolization, or pulmonary embolism.^[14]

Stenosis of the mitral valve impedes the flow of blood from the left atrium to the left ventricle during diastole. The normal mitral valve area is 4.0 to 5.0 cm². Symptoms with exercise can be expected with valve areas less than or equal to 2.5 cm². Symptoms at rest are expected at less than or equal to 1.5 cm². The left ventricle responds with Starling mechanisms to increased venous return with increased performance, elevating cardiac output in response to demand. The left atrium is limited in its capacity to respond. Cardiac output is therefore limited by the relatively passive flow of blood through the valve during diastole; increased venous return results in pulmonary congestion rather than increased cardiac output. Thus, the drive for increased cardiac output in pregnancy cannot be achieved, resulting in increased pulmonary congestion. The relative tachycardia experienced in pregnancy shortens diastole, decreases left ventricular filling, and therefore further compromises cardiac output and increases pulmonary congestion.

The diagnosis of mitral stenosis in pregnancy prior to maternal decompensation is uncommon. Tiredness and dyspnea on exertion are characteristic symptoms of mitral stenosis but are also ubiquitous among pregnant women. While the presence of a diastolic rumble or jugular venous distention may suggest mitral stenosis, these findings are subtle and may be overlooked or not appreciated. Not uncommonly, an intercurrent event such as a febrile episode will result in exaggerated symptoms and the diagnosis of pulmonary edema or oxygen desaturation. Under these circumstances, particularly in the context of a patient from an at-risk group, an echocardiogram should be performed to rule out mitral stenosis.

Echocardiographic diagnosis of mitral stenosis is based on the characteristic appearance of the stenotic, frequently calcified valve. Calculation of valve area from pressure half-time of the Doppler wave or by two-dimensional planimetry provides an objective measure of severity. Valve areas of 1.0 cm² or less will usually require pharmacologic management during pregnancy and invasive hemodynamic monitoring during labor. Valve areas of 1.4 cm² or less usually require careful expectant management. Left atrial enlargement identifies a patient at risk for atrial fibrillation, subsequent atrial thrombus, and the potential for systemic embolization. Pulmonary hypertension, a complication of worsening mitral disease, can be diagnosed and quantified with Doppler evaluation of the regurgitant jet across the tricuspid valve. Elevated pulmonary pressures may be due to hydrostatic forces associated with elevated left atrial pressures or, in more advanced disease, due to pathologic elevations of pulmonary vascular resistance (PVR). Hydrostatic pulmonary hypertension may respond to therapy that lowers left atrial pressure. Pulmonary hypertension due to elevated PVR is life threatening in pregnancy and may precipitate right heart failure in the postpartum period.

Pregnancy itself does not negatively affect the natural history of mitral stenosis. Chesley reviewed the medical histories of 134 women with functionally severe mitral stenosis who survived pregnancies between 1931 and 1943.^[15] His patients lived prior to modern management of mitral stenosis and therefore represent the natural history of the disease. By 1974, only nine of the cohort remained alive. Their death rate was exponential; during each year of follow-up, the rate for the remaining

1012

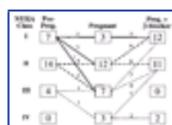

Figure 29-4 The effects of β -blockade on functional status of women with mitral stenosis. (From Al Kasab S, Sabag T, Al Zaibag M, et al: *Beta-adrenergic receptor blockade in the management of pregnant women with mitral stenosis. Am J Obstet Gynecol* 163:37, 1990, with permission.)

cohort was 6.3 percent. Women with subsequent pregnancies had comparable survival to those who did not again become pregnant, allowing the authors to conclude that pregnancy itself did not negatively affect long-term outcome.

The goal of antepartum care in the context of mitral stenosis is to achieve a balance between the drive to increase cardiac output and the limitations of flow across the stenotic valve. Most women with significant disease will require diuresis with a drug such as furosemide. In addition, β -blockade reduces heart rate, improves diastolic flow across the valve, and relieves pulmonary congestion. Kasab et al. evaluated the impact of β -blockade on 25 pregnant women with significant mitral stenosis.^[16] Figure 29-4 describes the functional status of women prior to pregnancy, during pregnancy prior to β -blockade, and after β -blockade. Note the deterioration associated with pregnancy and the improvement with treatment. Fastidious antepartum care as described above should supplement pharmacologic management.

Women with a history of rheumatic valvular disease who are at risk for contact with populations with a high prevalence of streptococcal infection should receive prophylaxis with daily oral penicillin G or monthly benzathine penicillin.^[14] Most pregnant women will live in close contact with groups of children and will usually be considered at risk. Atrial fibrillation is a complication associated with mitral stenosis due to left atrial enlargement. Rapid ventricular response to atrial fibrillation may result in sudden decompensation. Digoxin, β -blockers, or calcium channel blockers can be used to control ventricular response. In the context of hemodynamic decompensation, electrical cardioversion may be necessary. Anticoagulation with heparin should be used before and after cardioversion to prevent systemic embolization. Patients with chronic atrial fibrillation and a history of an embolic event should also be anticoagulated.^[14]

Labor and delivery can frequently precipitate decompensation in patients with critical mitral stenosis. Pain induces tachycardia. Uterine contractions increase venous return and therefore pulmonary congestion. Women frequently cannot tolerate the work of pushing in the second stage. Clark et al. described the abrupt elevation in pulmonary artery pressures in the immediate postpartum period associated with centralization of uterine blood (Fig. 29-5).^[4] Aggressive, anticipatory diuresis will reduce pulmonary congestion and the potential for oxygen desaturation.

The hemodynamics of women with symptomatic stenosis or a valve area of 1 cm² or less should be managed with the aid of a pulmonary artery catheter. Ideally, hemodynamic parameters are assessed when the patient is well compensated, early in labor. These findings serve as a reference point to guide subsequent therapy. Pain

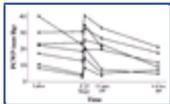

Figure 29-5 The changes in pulmonary capillary wedge pressure associated with delivery and subsequent diuresis in women with mitral stenosis. (From Clark S, Phelan J, Greenspoon J, et al: *Labor and delivery in the presence of mitral stenosis: central hemodynamic observations. Am J Obstet Gynecol* 152:384, 1985, with permission.)

control is achieved with an epidural. Heart rate control is maintained through pain control and β -blockade. To avoid pushing, the second stage is shortened with low forceps or vacuum delivery. Aggressive diuresis is initiated immediately postpartum. Cesarean section is reserved for obstetric indications.

Aggressive medical management including hospital bed rest will be sufficient to manage most women with mitral stenosis. The woman with uncommonly severe disease may require surgical intervention. While successful valve replacement and open commissurotomy have been reported in pregnancy,^[17] ^[18] they are now rarely needed. Two centers have reported successful balloon valvotomy in a series of 40 and 44 women with minimal complications.^[19] ^[20] Complications of balloon valvuloplasty outside of pregnancy occur at the following rates: mortality (0.5 percent), cerebrovascular accident (1 percent), and mitral regurgitation requiring surgery (2 percent).^[14] Medical management should be clearly exhausted before assuming these risks during pregnancy, where emergent intervention such as valve replacement will be more complicated and carries a significant risk to the fetus.

Rheumatic disease can affect the aortic valve. Management of significant mitral stenosis, which limits ventricular filling, in the context of aortic stenosis that is critically dependent on ventricular filling, is particularly complicated.

MITRAL REGURGITATION

Mitral regurgitation may be due to a chronic progressive process such as rheumatic valve disease or mitral valve prolapse. As regurgitation increases over time, forward flow is maintained at the expense of left ventricular dilation with eventual impaired contractility. Left atrial enlargement may be associated with atrial fibrillation that should be managed with ventricular rate control and anticoagulation. The patient with chronic mitral regurgitation may remain asymptomatic even with exercise. Preconceptional counseling should include consideration of valve replacement in consultation with a cardiologist. In general, valve replacement is recommended for: (1) symptomatic patients, (2) atrial fibrillation, (3) ejection fraction less than 50 to 60 percent, (4) left ventricular end-diastolic dimension greater than 45 to 50 mm, or (5) pulmonary systolic pressure greater than 50 to 60 mm Hg.^[14] As discussed below, the benefits of valve replacement prior to pregnancy must be balanced against the risks associated with prosthetic valve in pregnancy and the potential for prosthetic valve deterioration in pregnancy. If surgery is required, valve repair rather than replacement is preferred to avoid the need for anticoagulation.

Acute mitral regurgitation in young patients is uncommon and may be associated with ruptured chordae tendineae due to endocarditis. Without time for left ventricular compensation, forward flow may be severely compromised. Urgent valve surgery is usually required. Inotropic left ventricular support and systemic afterload reduction can be used to stabilize the patient.

The hemodynamic changes associated with pregnancy can be expected to have mixed effects. A reduction in systemic vascular resistance will tend to promote forward flow. The drive to increase cardiac output will exacerbate left ventricular volume overload. Increased atrial dilation may initiate atrial fibrillation. Pulmonary congestion can be managed by careful diuresis with the knowledge that adequate forward flow is usually dependent on a high preload to achieve adequate left ventricular filling. Atrial fibrillation should be managed consistent with care outside pregnancy. An increase in systemic vascular resistance due to progressive hypertension secondary to preeclampsia may significantly impair forward flow and should be treated. Labor and delivery should be managed with "standard cardiac care." Catecholamine release due to pain or stress will impair forward flow. Particular attention should be paid to left ventricular filling. Excessive preload will result in pulmonary congestion. Insufficient preload will not fill the enlarged left ventricle and will result in insufficient forward flow. A pulmonary artery catheter can be used to determine appropriate filling pressure in early labor or prior to induction. While a large v-wave may complicate the interpretation of pulmonary artery wedge pressure, the pulmonary artery diastolic pressure can be used as a reference point. Diuresis in the early postpartum period may be required.

Mitral valve prolapse is a common condition, affecting as many as 12 percent of young women.^[21] In the absence of conditions of abnormal connective tissue such as Marfan and Ehler-Danlos syndrome and clinically significant mitral regurgitation, women with mitral prolapse can be expected to have uncomplicated pregnancies. They may experience an increase in tachyarrhythmias that can be treated with β -blockers. Prophylactic antibiotics are usually used at the time of delivery.

AORTIC STENOSIS

Most patients who develop calcific stenotic tricuspid aortic valves do so outside their childbearing years (age 70 to 80). Patients with bicuspid valves develop significant stenosis after the age of 50 to 60 years. Rheumatic

1014

disease can also affect the aortic valve, usually after the development of significant mitral disease. The majority of pregnant women with significant aortic stenosis have congenitally stenotic valves: bicuspid valves with congenitally fused leaflets, unicuspid valves, or tricuspid valves with fused leaflets. ^[22]

The natural history of aortic stenosis is characterized by a long, asymptomatic period. With increasing outflow obstruction, patients develop angina, syncope, and left ventricular failure. Without valve replacement, only 50 percent of patients will survive 5 years after the development of angina; 3 years after the development of syncope; and 2 years after the development of left ventricular failure. ^[23] While valve replacement is the only definitive treatment for calcific aortic stenosis, valvuloplasty may prove beneficial in some young adults whose valves are not calcified. Medical management of symptomatic patients is not generally efficacious. Mechanical valve replacement requires anticoagulation, complicating subsequent pregnancies.

Young women with aortic stenosis are usually asymptomatic. While they may develop increasing exercise intolerance in pregnancy, the progression is insidious and not easily distinguished from the effects of normal pregnancy. The diagnosis is usually made by the auscultation of a harsh systolic murmur. The murmur can easily be distinguished from a physiologic murmur of pregnancy by its harshness and radiation into the carotid arteries. Diagnosis is confirmed by echocardiography where the gradient across the valve can be measured by Doppler, and the valve area can be calculated with the continuity equation. Many women with significant aortic stenosis will experience the expected increase in cardiac output associated with pregnancy. ^[3] Increased flow across the fixed, stenotic valve will result in a proportionately increased gradient across the valve. While the pressure gradient during pregnancy may be higher than that observed postpartum, these differences are not significant.

Four series of patients with aortic stenosis in pregnancy have been reported. ^[3], ^[24] ^[25] ^[26] The reports summarize experiences with wide ranges in severity of disease and management ranging from the 1960s and 1970s to the present. Arias described a series of 23 cases managed prior to 1978 with a maternal mortality of 17 percent. ^[24] While this report confirms the potential for maternal mortality associated with aortic stenosis in pregnancy, more recent series do not. ^[3], ^[25], ^[26] The potential for adverse outcome reported by Arias should certainly serve as an indication for intensive management. However, the rate of mortality should not necessarily be used as an indication for termination or surgical intervention. Pregnant patients have been successfully managed with aortic gradients in excess of 160 mm Hg. ^[3] In general, patients with a peak aortic gradient of 60 mm Hg or less had uncomplicated courses. Those with higher gradients required increasingly intensive management.

Aortic valve replacement and balloon valvotomy have been reported during pregnancy. Balloon valvotomy in a young patient without valve calcification can provide significant long-term palliation. Valvotomy prior to pregnancy may provide an interval of hemodynamic stability sufficient to complete a pregnancy without the complications associated with a prosthetic valve. Consideration for valve replacement or valvotomy during pregnancy should be reserved for patients who remain clinically symptomatic despite hospital care. In general, intervention should not be based entirely on a pressure gradient or valve area.

Aortic stenosis is a condition of excess left ventricular afterload. Ventricular hypertrophy increases cardiac oxygen requirement, while increased diastolic ventricular pressure impairs diastolic coronary perfusion. Each increases the potential for myocardial ischemia. The left ventricle requires adequate filling to generate sufficient systolic pressure to produce flow across the stenotic valve. Given a hypertrophied ventricle and some degree of diastolic dysfunction, the volume-pressure relationship will be very steep. A small loss of left ventricular filling will result in a proportionately large fall in left ventricular pressure and therefore a large fall in forward flow, cardiac output. The pregnant patient with significant aortic stenosis will be very sensitive to loss of preload associated with hemorrhage or an epidural. The window of appropriate filling pressure is narrow. Excess fluid may result in pulmonary edema; insufficient fluid may result in hypotension and coronary ischemia. In general, pulmonary edema associated with excess preload is much easier to manage than hypotension due to hypovolemia.

Appropriate antepartum care is described above. Given that most aortic stenosis in young women is congenital in origin, fetal echocardiography is indicated. While some controversy persists, cesarean section is generally reserved for obstetric indications. Pain during labor and delivery can be safely managed with regional analgesia using a low-dose bupivacaine and narcotic technique. Dense anesthesia during the second stage can be obtained with minimal hemodynamic complications using a caudal. Patients with gradients above 60 to 80 mm Hg will benefit from the use of a pulmonary artery and an arterial catheter during labor. Ideally, the woman is admitted the day before induction of labor with a favorable cervix. A prolonged induction should be avoided. Pulmonary artery and radial artery catheters as well as epidural and caudal catheters are placed. The patient should be gently hydrated overnight to achieve a pulmonary artery wedge pressure (PAWP) of 12 to 15 mm Hg. Some patients with milder disease

1015

will spontaneously diurese in the face of a volume load such that an elevation in PAWP cannot be achieved. An elevated PAWP will serve as a buffer against a loss of preload. If with bleeding or the onset of anesthesia PAWP sags, volume can be administered prior to a reduction in forward flow. In general, pushing is minimized, and the second stage is shortened with low forceps. Antibiotics are administered for the prevention of endocarditis.

Postpartum, patients should be monitored hemodynamically for 24 to 48 hours. Diuresis will usually be spontaneous; the patient can be allowed to find her predelivery compensated state. When diuresis must be induced to treat pulmonary edema, it should be done gently and carefully. Predelivery hemodynamic parameters should be used as an endpoint. Some have found that a significant delay in valve replacement after the postpartum period is associated with maternal complications. ^[3] These observations may be the result of accelerated valve deterioration due to pregnancy. For this reason, valve replacement within weeks of delivery may be indicated.

Gabbe: Obstetrics - Normal and Problem Pregnancies, 4th ed. , Copyright © 2002 Churchill Livingstone, Inc.

AORTIC REGURGITATION

Aortic regurgitation is most often due to a congenitally abnormal valve. Other causes include Marfan syndrome, endocarditis, and rheumatic disease. As with mitral regurgitation, the left ventricle compensates for a loss in forward flow with an increase in left ventricular end-diastolic volume. Afterload reduction will prevent progressive left ventricular dilation and is recommended for patients with left ventricular dysfunction or dilation. Valve replacement is generally recommended for: (1) New York Heart Association (NYHA) functional class III and class IV symptoms, (2) an ejection fraction less than 50 percent, or (3) left ventricular end-systolic dimension greater than 55 mm.^[1,4] Acute regurgitation may be due to aortic root dissection or endocarditis and usually represents a medical emergency requiring urgent valve replacement.

The reduction in vascular resistance associated with pregnancy will tend to improve cardiac performance. If afterload reduction has been achieved with an angiotensin-converting inhibitor before pregnancy, hydralazine should be substituted. Modest elevations of heart rate should be tolerated. Bradycardia may be associated with increased regurgitation due to prolongation of diastole. Labor and delivery is managed with "standard cardiac care." Pulmonary artery catheterization is not usually required. As the hemodynamic changes associated with pregnancy resolve, a rise in vascular resistance should be anticipated and afterload reduction maintained.

Gabbe: Obstetrics - Normal and Problem Pregnancies, 4th ed. , Copyright © 2002 Churchill Livingstone, Inc.

PROSTHETIC VALVES

Definitive therapy for significant valvular disease requires surgical repair, or more commonly replacement. Mechanical valves are durable but require anticoagulation. Porcine tissue valves, when used in a young woman, will usually require replacement in her lifetime. Reports of pregnancies associated with prosthetic valves suggest significant variability in outcomes. [Table 29-2](#) summarizes a review of 151 pregnancies complicated by a prosthetic valve. ^[27] Mechanical valves and anticoagulation were associated with a moderate increase in miscarriage and thromboembolic events. A report from France of 55 pregnancies suggests a less favorable prognosis. ^[28] Mechanical valves were associated with a maternal mortality rate of 3.7 percent and a thromboembolic rate of 14.8 percent. Thromboembolism was increased fourfold with heparin rather than Coumadin. Mitral valves accounted for 81 percent of thrombotic complications.

The impact of pregnancy on the life of a porcine valve has been studied. ^[27] Ten-year graft survival following two pregnancies was 16.7 percent compared with 54.8 percent following a single pregnancy. Pregnancy, in and of itself, seems to adversely affect the life of a porcine valve.

Decisions surrounding the timing and choice of valve replacement for a woman of reproductive age are complex. Managing a pregnancy with moderate valve disease may be less complicated than managing a pregnancy with a prosthetic valve. The durability of a mechanical valve has considerable advantages for a young person, but it is associated with more adverse outcomes in pregnancy. Delay in valve replacement until child bearing is completed is appropriate when the

TABLE 29-2 -- PREGNANCY OUTCOMES WITH PROSTHETIC VALVES

	Mechanical	Porcine
Women	31	57
Pregnancies	56	95
Fetal loss	27.7%	12.3%
Premature birth	5.9%	7.7%
Valve deterioration	5.3%	7.0%
Thromboembolic event	5.3%	

severity of heart disease is felt to be manageable in pregnancy.

Anticoagulation is required with a mechanical valve. Oral anticoagulation in the first trimester is associated with congenital anomalies; potentially serious fetal bleeding may be encountered in the second and third trimesters. The American College of Cardiology/American Heart Association guidelines recommend consideration of subcutaneous heparin in the first trimester to avoid warfarin embryopathy, and the use of warfarin until 36 weeks, when subcutaneous heparin is substituted until after delivery. ^[14] These recommendations remain controversial in that they may underestimate the risk of fetal intracerebral bleeding in the absence of labor. ^[29] The fetus exposed to Coumadin in the second and third trimesters is at risk for developmental toxicity. Individual patients should be counseled regarding the risks of either strategy and participate actively in a final choice of therapy. If heparinization is chosen, the activated partial thromboplastin time (aPTT) should be increased to two to three times control at mid-dosing interval. Intravenous heparin can be administered on an ambulatory basis and should be considered for mitral valves, which are more likely to clot, and for patients who may be noncompliant with subcutaneous administration. Women treated for prolonged periods with heparin should be counseled regarding the risk of osteoporosis.

Successful thrombolytic therapy of a clotted valve in pregnancy has been reported. ^[30] , ^[31] While significant uterine bleeding has been occasionally encountered, fibrinolysis is probably safer in pregnancy than emergent valve replacement.

CONGENITAL HEART DISEASE

Congenital heart disease is present in 0.7 to 1 percent of live births, accounting for as many as 30 percent of infants with birth anomalies. Prior to the development of corrective surgery, many children died shortly after birth or in childhood. In 1939, the first patent ductus arteriosus was ligated. In 1945, the first Blalock-Taussig shunt was performed for palliation of cyanotic heart disease. In 1953, cardiac bypass was introduced. Introduction of surgery under hypothermia in the late 1960s permitted longer and more complex repairs.^[32] ^[33] Of children who survived surgery to correct tetralogy of Fallot between 1955 and 1960, the 23-year survival is 86 percent, approaching the expected survival rate of 96 percent for normal children.^[34] Prior to the 1960s, the prevalence of rheumatic heart disease in pregnancy exceeded the incidence of congenital disease by a ratio of 4:1. By the 1980s, the ratio was 1:1.^[26] Currently, congenital disease is estimated to exceed rheumatic disease by 1:4. While many will enter pregnancy with known heart disease, some women will have their disease first recognized due to the hemodynamic demands of pregnancy.

Increased survival of children with congenital disease has created a population of young women with complex medical and psychosocial conditions entering their childbearing years. Those whose congenital heart disease was diagnosed in infancy have frequently experienced multiple cardiothoracic surgeries and extended hospitalizations. They have lived with continued concerns from parents and health care professionals regarding their ongoing health. Their childhoods have been restricted. At an early age, they faced the possibility of their own death. The psychosocial impact of this experience has been described as "growing up heart sick."^[35] Young women describe a childhood of overprotectiveness and "being watched." They describe a lack of information regarding childbearing and contraception. They "seemed to believe that someone else could and would decide whether they should become pregnant."^[35] Body image disorders over "eternal skinniness," scars from surgery, and delayed development of secondary sex characteristics are common. Health care providers should strive to (1) objectively share information regarding reproductive health care, (2) direct decision making towards the patient rather than towards parents and health care professionals, and (3) improve self-esteem and body image. "Women with congenital heart disease want some way of being normal in their lives. Helping them to gain knowledge so that they can make responsible choices concerning contraception, pregnancy, and childbearing may be a way of assisting them to regain normalcy through feelings that they have control of their own bodies and lives."^[35] When treating congenital heart disease during pregnancy, one must be willing to acknowledge and address the impact of the patient's disease on her life.

[Table 29-3](#) summarizes the distribution of congenital heart disease in childhood and in pregnancy.^[26] ^[33] The

TABLE 29-3 -- INCIDENCE OF CONGENITAL HEART DEFECTS IN CHILDHOOD AND IN PREGNANCY

	Childhood	Pregnancy
Ventricular septal defect	35%	13%
Atrial septal defect	9%	9%
Patent ductus arteriosus	8%	2.7%

Transposition of the great vessels	4%	5.4%

1017

spontaneous closure of lesions such as ventricular septal defect and correction of patent ductus are reflected by reduced reporting in pregnancy. The increased reporting of aortic stenosis in pregnancy is probably due to a worsening of disease with age and the ease of recognition in pregnancy. The complexity and diversity of congenital heart disease confounds our ability to describe the prognosis or a management plan for the breadth of conditions. Major risks in pregnancy include (1) cyanosis, (2) left (or systemic) ventricular dysfunction, and (3) pulmonary hypertension, particularly with right ventricular dysfunction.

Outcomes have been most clearly described based on the presence or absence of maternal cyanosis. [Table 29-4](#) is derived from a report of 482 pregnancies from 233 women with congenital heart disease who delivered between 1968 and 1982.^[13] The rate of terminations was higher in the group of women with cyanotic heart disease and particularly high (42 percent) in those with uncorrected lesions. This reflects the anticipated poor neonatal outcome and maternal risks associated with uncorrected cyanotic disease. One should assume that patients with more severe disease are overly represented in the group of women who chose to terminate, which would bias the group who continued pregnancy towards a better outcome. Eighty-six to 90 percent of pregnancies without cyanosis ended in a live birth compared to 71 percent with an uncorrected lesion. Given an expected baseline rate of miscarriage, these outcomes are quite good. Corrected cyanotic disease was associated with outcomes comparable to noncyanotic disease. [Table 29-5](#) is derived from a report of 144 pregnancies from women with congenital heart disease delivered between 1976 and 1986.^[26] Adverse outcomes are again concentrated among women with uncorrected cyanotic heart disease.

Common maternal complications include congestive heart failure and pulmonary edema (4 percent), arrhythmia (4 percent), and hypertension (6 percent). Congestive heart failure and hypertension were commonly

TABLE 29-4 -- NEONATAL OUTCOME WITH CONGENITAL HEART DISEASE: LIVE-BORN VERSUS TERMINATION

	Live-Born Infant	Termination
Noncyanotic	86%	5%
Cyanotic	85%	26%
Corrected	95%	17%
Palliative	87%	17%
Uncorrected	71%	42%

Termination rate = No. of terminations / No. of pregnancies

Live-born rate = No. of live-born infants / No. of pregnancies-No. of terminations

TABLE 29-5 -- NEONATAL OUTCOME WITH CONGENITAL HEART DISEASE BY SAB, SGA, PRETERM, AND BIRTH WEIGHT

	SAB	SGA	Preterm	Birth Weight
Noncyanotic	12%	6%	9%	3,300 ± 600
Cyanotic	21%	52%	35%	2,400 ± 800
Corrected	11%	25%	0%	
Uncorrected/palliative	25%	67%	53%	

SAB, spontaneous abortion; SGA, small for gestational age; Preterm, preterm birth.

associated with uncorrected left ventricular outflow obstruction.^[13],^[26] Arrhythmias were observed after surgery in and about atrial or ventricular septums. Maternal death was uncommon, 0 per 482 pregnancies in one series^[13] and 1 per 144 pregnancies in a second.^[26] Maternal deaths are most commonly reported in association with Eisenmenger's syndrome, discussed more fully below.

Men and women with congenital heart disease are at increased risk for having children with congenital heart disease. In a prospective study with aggressive pediatric evaluation, Whittemore estimated the incidence to be as high as 14.2 percent.^[13] In a retrospective study, Rose found the risk to be 8.8 percent.^[12] The rate of congenital heart disease associated with an affected mother was 2 to 3.5 times that observed with an affected father. Specific parental defects are not generally associated with the same defect in the child. The risk for cardiac maldevelopment is inherited rather than the risk for a specific defect. The risk of congenital heart disease and the character of the risk should be discussed with an affected mother. In Whittemore's report, 58 of 60 affected infants were diagnosed with relatively benign correctable lesions (atrial septal defect, ventricular septal defect, pulmonary stenosis, aortic stenosis, patent ductus arteriosus, or mitral valve prolapse). Only 2 infants from 372 pregnancies (0.5 percent) were diagnosed with complex congenital heart disease.^[13] All women who have congenital heart disease should have a fetal echocardiogram performed at midpregnancy.

Contraceptive counseling should be offered to all women with congenital heart disease. Given the problems experienced growing up with heart disease, contraceptive education should probably be initiated as part of general health care education, prior to the overt need for birth control. In the context of congenital heart disease, complications associated with pregnancy are usually greater than those associated with any form of birth control. Cyanosis, pulmonary hypertension, low cardiac output, dilated cardiac chambers, sluggish venous conduits (e.g., Fontan), and atrial fibrillation

place patients at risk for thrombosis. This small group of women should probably avoid combined estrogen/progestin oral contraceptives. Progestin-only pills are not associated with risk for thrombosis but require regular dosing to achieve optimal efficacy. Parenteral progestins are safe for women with cardiac disease and are extremely effective. They do cause irregular bleeding, which may be significant if the patient is anticoagulated. The intrauterine device carries a risk for pelvic inflammatory disease and therefore a theoretical risk of bacteremia and endocarditis. The actual risk has been estimated to be 1 per 1 million patient-years.^[36]

ISOLATED SEPTAL DEFECTS

Ventricular and atrial septal defects represent greater than 40 percent of congenital heart disease identified in childhood. Many defects identified in children will close with advancing age. In adulthood, 50 percent of large ventricular septal defects (>1.5 cm) lead to the development of Eisenmenger's syndrome. Ten percent of uncorrected atrial septal defects will also develop pulmonary hypertension. The management of Eisenmenger's syndrome in pregnancy is discussed below.

A harsh systolic murmur that radiates to the left sternal border but not to the carotids suggests the presence of a ventricular septal defect. The diagnosis can be confirmed by color flow Doppler echocardiography demonstrating a small, high-velocity lesion. The peak velocity of the jet across the septum can be used to assess the pressure gradient between the ventricles. A high velocity between ventricles indicates a large pressure gradient and low pressure in the right ventricle and the absence of pulmonary hypertension. In the absence of associated cardiac lesions and pulmonary hypertension, the presence of a ventricular septal defect does not usually complicate pregnancy. Small defects create loud murmurs but are not usually hemodynamically significant. The high-velocity jet of a small lesion does create a risk for endocarditis.

Atrial septal defects are more difficult to diagnose by auscultation. The characteristic finding, a split S₂ that is fixed with respiration, is subtle and usually not appreciated without specific attention. Increased right-sided flow secondary to shunting across the defect may create a flow murmur that will be augmented in pregnancy. Other endocardial cushion defects may be associated with ostium primum defects. In the absence of other anomalies, the significance of the atrial septal defect is related to its size rather than to its etiology. Hemodynamically significant defects result in significant shunting from the systemic circulation to the pulmonary circulation. As with the ventricular septal defect, Eisenmenger's syndrome may develop, but usually at an older age. Increased pulmonary blood flow may result in dyspnea on exertion and restriction of activity. Atrial arrhythmias are commonly associated with atrial enlargement or intrinsic conduction abnormalities in the case of ostium primum defects.

The patient with a significant pulmonary/systemic shunt ratio can be expected to normally expand her cardiac output during pregnancy. However, the price of a normal systemic cardiac output is a high pulmonary flow. The pregnant patient may begin to experience symptoms at rest that she previously noted with exercise. She may also experience an increase in tachyarrhythmias. Heart rate control with a β -blocker may provide symptomatic relief. Early diuresis may benefit the patient postpartum. Elevated pulmonary blood flow associated with pregnancy could, in theory, accelerate the progression of pulmonary vascular disease. In the absence of associated anomalies, arrhythmias, and pulmonary hypertension, the presence of an atrial septal defect does not usually complicate pregnancy.

Gabbe: Obstetrics - Normal and Problem Pregnancies, 4th ed. , Copyright © 2002 Churchill Livingstone, Inc.

PATENT DUCTUS ARTERIOSIS

The diagnosis of a patent ductus arteriosis is suggested by the characteristic continuous murmur at the upper left sternal border. Most are identified and ligated in childhood. Of patients with an uncorrected patent ductus, as many as 50 percent will develop Eisenmenger's syndrome, the majority in childhood. In adults with a small patent ductus, the major risk is endocarditis. In the absence of Eisenmenger's syndrome, pregnancy is not usually complicated. As with the atrial septal defect, the increase in pulmonary blood flow associated with the increase in cardiac output in pregnancy may result in increased dyspnea with exertion and at rest. Early diuresis may benefit the patient postpartum.

TRANSPOSITION OF THE GREAT VESSELS

Transposition of the great vessels represents only 5 percent of pregnant women with congenital heart disease but is overrepresented in the publication of case reports and case series. The attention received in publication permits a more systematic analysis of outcomes. In transposition of the great vessels (TGV), systemic venous blood returns to the right atrium, and passes through the tricuspid valve, into the right ventricle, and directly into the transposed aorta. Although an adequate circulation for fetal life, infants decompensate at

1019

birth due to an inadequate pulmonary circulation. Some will have a sufficiently large ventricular septal defect to achieve adequate pulmonary blood flow and oxygenation; others will require an immediate palliative procedure, an atrial septotomy.

Transposition of the great vessels was first definitively corrected in 1964 with the Mustard operation.^[37] A baffle is constructed through the left and right atriums so that systemic venous return is channeled through the mitral valve into the left ventricle, and pulmonary venous return is directed through the tricuspid valve into the right ventricle. With a modest surgical intervention, the right and left pumps are placed in series with physiologic flow of systemic venous return through the pulmonary circulation. The right ventricle, as the systemic ventricle, must work against systemic resistance, and the tricuspid valve is exposed to systemic pressures. Long-term complications are associated with failure of the systemic ventricle and arrhythmia. Of patients surviving the first 30 days after repair, 90 percent will be alive in 10 years and 87 percent will be alive in 20 years. After 13 years, only 5 percent suffer significant disability (NYHA class II to IV).^[38] A more physiologic repair can be achieved when transposition is accompanied by a ventricular septal defect. The ventricular septum is reconstructed so that the aortic outflow tract lies within the left ventricle and a conduit is constructed to connect the right ventricle to the pulmonary artery (Rastelli repair).^[39] The pulmonary conduit is prone to stenosis and deterioration of the transplanted valve. More recently, a direct surgical switch between the pulmonary artery and the aorta has been performed. Given the time when these operations were introduced, most young women entering pregnancy will have a Mustard repair. Increasing numbers will have a Rastelli repair or a great vessel switch.

The hemodynamic changes of pregnancy will have a mixed impact on a patient with a Mustard repair. Increased cardiac output will increase the volume load on the right heart. Decreased vascular resistance reduces afterload on the right heart. The box "Pregnancy Outcomes with Transposition of the Great Vessels" summarizes nine papers reporting a total of 49 pregnancies in 36 women.^{[26], [38], [40], [41], [42], [43], [44], [45], [46]} No maternal mortality was reported. Neonatal outcomes were good. Two women entered pregnancy with disability due to their heart disease (NYHA class III to IV). One delivered at 26 weeks due to preterm labor. The other developed severe congestive failure near term and died 19 months postpartum. Congestive heart failure was frequently associated with uncontrolled tachyarrhythmias.

[*] Miscarriages and premature births concentrated among cyanotic mothers.	

Congenitally corrected transposition of the great vessels (ventricular inversion) is characterized by the passage of systemic venous blood into the right atrium, directly into the left ventricle and out through the transposed pulmonary artery. Pulmonary venous return passes directly from the left atrium into the right ventricle and out through the aorta. The right ventricle again serves as the systemic ventricle. Congenitally corrected TGV may be an isolated anomaly but may also be associated with other anomalies that result in cyanosis. See box for summary of two series of pregnancies with congenitally corrected transposition of the great vessels. ^[47], ^[48] Again, maternal and neonatal outcomes are good. Consistent with outcomes associated with other cyanotic forms of congenial heart disease, miscarriage and premature birth are concentrated among the cyanotic lesions.

Young women with surgically or congenitally corrected transposition of the great vessels can be expected to successfully complete pregnancy. Women who are functionally impaired or who are cyanotic prior to pregnancy can expect more adverse outcomes and may deteriorate postpartum. Evaluation prior to pregnancy

should include assessment of functional status; evaluation of right, systemic, heart function; and confirmation of normal oxygenation. When the right heart is the systemic heart, pharmacologic afterload reduction should be maintained until pregnancy is confirmed. Angiotensin-converting enzyme inhibitors should be discontinued early in the first trimester.

The reported experience with transposition of the great vessels is to date the most extensive for any complex defect. The conclusions drawn from this experience are probably applicable to other less common conditions. Functional status and cyanosis are the most reliable predictors of complicated pregnancies. Arrhythmia is common and is frequently the initiator of cardiac decompensation.

FONTAN REPAIR

The Fontan repair was initially performed to achieve a physiologic correction of tricuspid atresia by connecting the right atrium directly to the pulmonary artery. ^[49] The Fontan repair and subsequent modifications are currently used to correct a variety of complex congenital heart conditions characterized by a single functional ventricle. The repair achieves a noncyanotic, functional flow of systemic venous return through the lungs and a functionally systemic ventricle. Without a pulmonary pump, the cardiac price for this result is elevated systemic and right atrial pressure (12 to 14 mm Hg).

Experience with pregnancy in women with the Fontan repair is limited. Young women have been discouraged from attempting pregnancy due to concerns regarding the ability of a single ventricle system to adapt to the demands of pregnancy. In a survey of 76 women of reproductive age, Canobbio et al. reported that 66 percent were counseled not to become pregnant despite a stable surgical outcome and a strong desire to have children. ^[50] The remaining 34 percent were not counseled regarding pregnancy. Contraceptive usage, despite counseling against pregnancy, was inconsistent. The box "Pregnancy Outcomes with Fontan Repair" summarizes the outcomes of 33 pregnancies from 21 women reported by this group. While the miscarriage rate was higher than the general population, the preterm birth rate was low. Maternal complications were limited to arrhythmia, usually atrial, and congestive heart failure in the postpartum period. While not reported in these small series, sluggish flow through the right atrial and pulmonary circulation may increase the risk for thrombosis.

EISENMENGER'S SYNDROME

The pathophysiology known as Eisenmenger's syndrome was first described in 1897. Viktor Eisenmenger described a 32-year-old patient who was short of breath and cyanotic from childhood and died from hemoptysis. Autopsy revealed a ventricular septal defect and severe pulmonary vascular disease.^[51] The term is now used to describe pulmonary-to-systemic shunting associated with cyanosis and increased pulmonary pressures secondary to pulmonary vascular disease. Eisenmenger's syndrome may develop from any intracardiac shunt resulting in blood from the high-pressure systemic circulation being directed into the pulmonary circulation. Systemic pressure and excessive flow lead to microvascular injury, obliteration of pulmonary arterioles and capillaries and, in the end, elevated pulmonary vascular resistance. The time to onset of shunt reversal is variable, but most patients who have a large ventricular septal defect or large patent ductus arteriosus will develop shunt reversal in infancy. Those who have an atrial septal defect will be delayed until early adulthood. Survival at 10 years from diagnosis is 80 percent; at 25 years, it is 42 percent.^[51]

Patients with Eisenmenger's syndrome are at risk for congestive heart failure, hemoptysis due to pulmonary hemorrhage, sudden death due to arrhythmia, cerebrovascular accident, and hyperviscosity syndrome. The diagnosis should be considered in any cyanotic patient and is confirmed by echocardiography with the demonstration of increased pulmonary pressure and an intracardiac shunt. If the shunt is due to an atrial septal defect or a patent ductus arteriosus, transesophageal examination may be necessary. Treatment is nonspecific, and includes supportive care and avoidance of destabilizing events such as surgery and unnecessary medications. Symptomatic hyperviscosity syndrome due to an elevated hematocrit can be treated with phlebotomy. Iron deficiency, preexisting or secondary to phlebotomy,

1021

can exacerbate hyperviscosity; microcytic cells are less deformable and therefore more prone to occlude the microcirculation. Definitive therapy can only be achieved with heart/lung or lung transplantation. However, the 4-year survival with lung transplantation is less than 50 percent, a less favorable prognosis than that for many patients with Eisenmenger's syndrome.

Ventricular septal defect (VSD), atrial septal defect, and patent ductus arteriosus (PDA) are responsible for 89 percent of reported cases of Eisenmenger's syndrome in pregnancy.^[52] Each lesion is initially associated with shunting from the systemic, oxygenated circulation to the pulmonary circulation. As pulmonary vascular resistance and pulmonary pressures increase over time and approach systemic pressures, the characteristic murmurs of a VSD or PDA diminish. Reversal of flow from the right to the left, the development of hypoxemia, and increasing hematocrit herald the development of Eisenmenger's syndrome. The fall in systemic vascular resistance associated with pregnancy may initiate shunt reversal in a patient not previously cyanotic.

In 1979, Gleicher reviewed published cases of Eisenmenger's syndrome in pregnancy.^[53] Seventy pregnancies from 44 women were evaluated. Fifty-two percent of the women died during pregnancy. Thirty percent of the pregnancies resulted in maternal death. The risk of death associated with first, second, and third pregnancies were 36 percent, 27 percent, and 33 percent, respectively. A first successful pregnancy did not confirm the safety of subsequent pregnancies. Most deaths (70 percent) occurred at the time of delivery or within 1 week postpartum. Excessive blood loss was associated with 35 percent of deaths, while thromboembolic conditions were responsible for 44 percent. Maternal mortality associated with cesarean delivery (80 percent) exceeded that associated with vaginal delivery (34 percent). Maternal death was not reported with first-trimester termination of pregnancy. Only 26 percent of pregnancies resulted in a term birth. Fifty-five percent of newborns were delivered preterm, and thirty-two percent were small for gestational age.

A more modern review of cases in the United Kingdom between 1991 and 1995 confirms the poor prognosis for pregnant women with Eisenmenger's syndrome despite considerable advancement in the management of cardiac disease in pregnancy.^[54] Mortality remains extremely high; forty percent of the women died. In addition, 85 percent of the births were preterm. A review of published cases from 1978 to 1996 again confirmed a mortality rate of 36 percent.^[52] The majority of deaths (96 percent) occurred within the first 35 days postpartum. Late diagnosis (relative risk [RR], 5.4) and delayed hospitalization (RR, 1.1/wk of delay) significantly increased maternal mortality.^[52]

While the risks associated with Eisenmenger's syndrome in pregnancy are clear, appropriate management is not. Decreased activity, hospital observation, and oxygen supplementation are usually employed. Reduction of pulmonary pressures and improved systemic oxygen saturation after oxygen supplementation indicates that pulmonary vascular resistance is not fixed and suggests a better prognosis. Intercurrent antepartum events such as pneumonia or urinary tract infection will be poorly tolerated. Preventing microcytosis with iron supplementation may decrease the risk of microvascular slugging.

Cesarean section is reserved for obstetric indications and is avoided whenever possible. Hemodynamic stability must be maintained during labor and the postpartum period. When pulmonary vascular resistance is not fixed, oxygen supplementation may decrease pulmonary pressures. Systemic hypotension from hemorrhage or sympathectomy from epidural analgesia will result in increased right-to-left shunting, increasing hypoxemia, increasing pulmonary vascular resistance, and worsening shunt. Volume overload or excessive systemic resistance, particularly postpartum, may further tax a failing right heart. A pulmonary artery catheter and a peripheral arterial catheter are usually used to guide hemodynamic management. Narcotic-based regional analgesia provides adequate pain relief without excessive hemodynamic instability. Anticoagulation remains controversial. If patients are anticoagulated, caution should be exercised to avoid excessive treatment and associated hemorrhage.

While use of a selective pulmonary vasodilator, inhaled nitric oxide, has been reported to reduce pulmonary pressures, increase cardiac output, and improve systemic oxygenation, maternal death was not averted.^[55] Unlike many cardiac conditions in pregnancy, meticulous care will frequently fail to prevent maternal death.

COARCTATION OF THE AORTA

Coarctation of the aorta results from a constriction of the aorta at or about the level of the ductus arteriosus or left subclavian artery. Patients have a characteristic discrepancy in blood pressure between their right arm and lower extremities. Complications include dissection at the site of coarctation, cephalic hypertension, and rupture of associated berry aneurysms.

Modern reports of coarctation in pregnancy are limited. Historically, pregnancy was associated with a maternal mortality of 9 percent due to aortic rupture, congestive heart failure, cerebrovascular accidents, and endocarditis. ^[56] -Blockade may serve to protect against dissection and promote diastolic flow through the aortic narrowing.

1022

Pediatric screening identifies most significant coarctations leading to repair. After repair, systemic hypertension may persist and require treatment. In a series of 18 patients and 36 pregnancies, the prematurity rate was not elevated. Preeclampsia was diagnosed in 14 percent of all pregnancies, and 17 percent of nulliparous pregnancies. One infant in 36 was diagnosed with congenital heart disease. ^[57]

An increasing cohort of young women with corrected congenital heart disease will be presenting to their obstetricians pregnant and desiring to bear children. Some basic conclusions can be drawn from our experience with congenital heart disease to date. First, Eisenmenger's syndrome and pregnancy remain a lethal combination. New, effective strategies for therapy are not anticipated. Second, cyanotic heart disease in the absence of pulmonary hypertension is associated with increased rates of miscarriage and preterm birth. Third, mothers with cardiac disability (NYHA class III to IV) or with evidence of right heart dilation will have a more complicated course in pregnancy. Fourth, arrhythmias may become worse in pregnancy and precipitate cardiac decompensation. Aggressive pharmacologic treatment is appropriate. Finally, many young women who are initially well compensated and acyanotic can have successful pregnancies.

Gabbe: Obstetrics - Normal and Problem Pregnancies, 4th ed. , Copyright © 2002 Churchill Livingstone, Inc.

CARDIOMYOPATHY

Dilated cardiomyopathy is characterized by the development of pulmonary edema in the context of left ventricular dysfunction and dilation. Patients usually present with signs and symptoms of pulmonary edema: dyspnea, cough, orthopnea, tachycardia, and occasionally hemoptysis. These symptoms of pulmonary edema, while characteristic of heart failure, may also be due to previously undiagnosed congenital or rheumatic heart disease, preeclampsia, embolic disease, intrinsic pulmonary disease, tocolytic use, or sepsis. The diagnosis of cardiomyopathy is made in the clinical circumstances of characteristic signs and symptoms and findings of left ventricular dysfunction and dilation on echocardiographic examination. Ventricular dysfunction may be due to conditions extrinsic to the heart such as thyrotoxicosis or hypertension or due to intrinsic myocardial dysfunction. Accurate diagnosis will direct appropriate therapy and permit assessment of long-term prognosis.

Peripartum cardiomyopathy is a rare syndrome of heart failure presenting in late pregnancy or postpartum. The diagnosis is made after excluding other causes of pulmonary edema and heart failure. Failure to adhere to a rigorous definition of disease in the literature confounds conclusions regarding etiology and prognosis. A definition based on criteria for idiopathic dilated cardiomyopathy has been suggested ([see the box "Diagnostic Criteria for Peripartum Cardiomyopathy"](#)).^[58] The incidence is estimated to be between 1 in 1,300 and 1 in 15,000.^[59] While some of the variability in reported incidence is due to regional and ethnic differences, much is due to the imprecise definition of the disease. The cause of peripartum cardiomyopathy is unknown. Nutritional and immunologic mechanisms have been proposed. The prevalence of antibodies to echovirus and coxsackievirus is not higher among women with cardiomyopathy compared to controls.^[60]

Diagnostic Criteria for Peripartum Cardiomyopathy

1. Heart failure within the last month of pregnancy or 5 months postpartum
2. Absence of prior heart disease
3. No determinable cause
4. Echocardiographic indication of left ventricular dysfunction

Ejection fraction <45 percent or fractional shortening <30 percent
Left ventricular end-diastolic dimension >2.7 cm/m²

The mortality rate for peripartum cardiomyopathy is reported to be 25 to 50 percent. Death is usually due to progressive congestive heart failure, arrhythmia, or thromboembolism.^[59] Within 6 months, half of patients will demonstrate resolution of left ventricular dilation. Their prognosis is very good. Of those who do not, 85 percent will die within the next 4 to 5 years.^[60] The magnitude of risk for subsequent pregnancies after peripartum cardiomyopathy is unclear. A recent survey of 67 pregnancies in 63 women suggests a mortality rate of 8 percent when left ventricular dysfunction has not resolved, and 2 percent in patients with normal function.^[61]

Acute treatment of cardiomyopathy is directed at improving cardiac function and, when present, treating the inciting event. Diuretics are used to decrease preload and relieve pulmonary congestion. Digoxin may improve myocardial contractility and facilitate rate control when atrial fibrillation is present. Afterload reduction is achieved with angiotensin-converting enzyme inhibitors^[62],^[63] postpartum, or hydralazine before delivery. β -Blockade has been clearly demonstrated to improve cardiac function and survival outside of pregnancy^[64]^[65]^[66] and should not be withheld from pregnant women. Significantly dilated and hypokinetic cardiac chambers are at risk for clot formation. Anticoagulation with heparin antepartum or Coumadin postpartum should be considered. Implanted defibrillators have been used in pregnancy

without significant complications.^[67] Hemodynamic management during labor and delivery is frequently directed by a pulmonary artery catheter. Pain control decreases cardiac work and reduces tachycardia. A carefully dosed epidural is appropriate. Cesarean section is reserved for obstetric indications.

MYOCARDIAL INFARCTION

Myocardial infarction is a rare event among women of reproductive age. From a population base of 3.6 million women-years, Petitti et al. identified 186 cases (5.0 per 100,000 women-years).^[69] The incidence was very low prior to 35 years of age, (1 per 100,000 women-years), but increased to 5.3 for ages 35 to 39 and to 18.4 for ages 40 to 44. The risk for myocardial infarction in pregnancy from this population was 1.5 per 100,000 deliveries. Based on a 9-month exposure per pregnancy, the incidence is comparable to nonpregnant women less than 35 years old.^[69] Earlier estimates have been as high as 10 per 100,000 pregnancies.^[69]

Due to the rarity of the event, information regarding myocardial infarction in pregnancy is derived from case reports and is therefore subject to considerable reporting bias. Routh and Elkayam have summarized information from reports of 123 pregnancies (see the box "Myocardial Infarction in Pregnancy").^[70] Coronary dissection and normal coronary arteries are observed in almost 50 percent of cases. Delivery within 2 weeks of infarction may be associated with maternal mortality as high as 50 percent. Myocardial infarction has been reported in association with diabetes mellitus, pheochromocytoma, Ehlers-Danlos type IV, antiphospholipid syndrome, multiple gestation, and sickle cell anemia.^[70] Medications such as ergot alkaloids given for bleeding, bromocriptine for lactation suppression, ritodrine and nifedipine for tocolysis, and prostaglandin E₂ in conjunction with severe hypertension have also been associated with myocardial infarction.^{[71] [72] [73] [74] [75] [76] [77] [78]}

The diagnosis of myocardial infarction in pregnancy is often delayed due to the rarity of the event and due to common symptoms of pregnancy. During normal pregnancy, most women experience some increase in exercise intolerance and dyspnea. Chest pain due to reflux is common. Electrocardiographic changes that suggest ischemia have been reported in as many as 37 percent of women having a repeat cesarean delivery.^[70] The MB fraction of creatine kinase isoenzymes may be elevated at cesarean section as well.^[79] Troponin I levels are not elevated during labor and delivery.^[80] Given a constellation of findings suggestive of myocardial infarction, an echocardiogram can be used to confirm abnormal wall motion in the ischemic region.

Myocardial Infarction in Pregnancy	
Pregnancies	123
Mean age ± SD	32 ± 6 years
Age range	1645 years
Anterior infarction	73%
Multiparous	84%
Hypertension	19%
Diabetes mellitus	5%
Smoking	26%
Family history of MI	8%
Hyperlipidemia	2%
Preeclampsia	11%
CHF after MI	19%
Coronary anatomy	
Stenosis	43%
Thrombus	21%
Dissection	16%
Aneurysm	4%
Spasm	1%
Normal	29%
Death	
Maternal	21%
Infant	13%
* 62% of infant deaths associated with mother's death.	

Acute therapy is based on rapid coronary reperfusion. Coronary angioplasty and stenting have been reported in pregnancy and should not be withheld when appropriate for the mother's condition.^{[81] [82] [83] [84]} Thrombolytic therapy has also been utilized in pregnancy.^[70] While effective, there may be a small but real incidence of associated maternal bleeding, preterm delivery, or fetal loss. Surgery after thrombolytic therapy is associated with significant risk for hemorrhage.

Medications commonly used in the management of myocardial infarction such as morphine, organic nitrates, lidocaine, -blockers, aspirin, magnesium sulfate, and calcium antagonists may be used in appropriate doses in pregnancy. Care should be taken to avoid the supine position and maternal hypotension during procedures. The fetus, if viable, should be monitored.

Elective delivery within 2 weeks of infarction should be avoided. Cesarean section is reserved for obstetric indications. Labor and delivery is managed with "standard cardiac care." Pain is controlled, usually with carefully administered regional analgesia. Tachycardia is prevented with pain control and treated with -blockers as needed. Hemodynamic stability is maintained frequently using information from pulmonary and peripheral arterial catheters. Maternal pushing is avoided, and the second stage of labor is shortened

1024

with low forceps or vacuum. Diuresis is gently initiated postpartum with diuretics.

The experience with pregnancy after a remote myocardial infarction is limited. Of 33 reported cases, recurrent infarction and significant complications have not been reported.^[65]

MARFAN SYNDROME

Marfan syndrome is an autosomal dominant genetic disorder caused by an abnormal gene for fibrillin on chromosome 15.^[86] Disease prevalence is estimated to be 4 to 6 per 10,000. Sporadic cases represent 15 percent of those diagnosed. The production of abnormal connective tissue results in the characteristic feature of the disease: aortic root dilation, dislocation of the optic lens, deformity of the anterior thorax, scoliosis, long limbs, joint laxity, and arachnodactyly. Diagnosis is usually based on family history, and ocular, cardiovascular, and skeletal features.

Untreated, life expectancy is reduced by a third, with the majority of deaths due to aortic dissection and rupture. Elective aortic repair is associated with a low mortality (1.5 percent), while emergent repair results in a much higher mortality (11.7 percent).^[87] Elective repair has therefore been recommended when the aortic root diameter measures 5.5 to 6.0 cm. Using an absolute aortic diameter as an indication for surgery ignores relevant differences in aortic size associated with patients of different stature.^[88] These considerations are particularly important when caring for young women. An aortic ratio between measured and predicted aortic diameter (AD) can be calculated. The predicted diameter for young adults can be calculated: $AD_{\text{predicted}} = 1.02 + (0.98 \times \text{body surface area [BSA]})$. A ratio of less than 1.3 with a dilation rate of less than 5%/y suggests a low risk for a cardiovascular event.^[89]

The risk for aortic dissection is associated with the rate of change of blood pressure in the aorta over time in systole. While simple reduction in blood pressure does not reduce the risk for dissection, β -blockade lowers the risk of reaching a clinical cardiac endpoint at 10 years from approximately 20 percent to 10 percent.^[89]

Literature surveys of case reports suggest a maternal mortality rate associated with Marfan syndrome in pregnancy in excess of 50 percent.^[90] These case reports probably represent a bias of reporting more severely affected pregnancies. Three population-based studies are summarized in the box "Marfan Syndrome in Pregnancy".^[91] Aortic events, dissection or rapid dilation, occurred in 8 percent of cases. In seven of nine, the aortic diameter was known to be greater than 4.0 cm. Of the remaining two, one died due to aortic dissection and rupture without a diagnosis and without a measurement of aortic diameter; the other had a prior graft replacement. A second death was due to endocarditis associated with mitral valve prolapse.

Women	84
Pregnancies	241
Live births	181 (75%)
Miscarriages	38 (16%)
Terminations	17 (7%)
Fetal deaths	2 (0.8%)
Aortic events	8 (4.3%)
Dissection	6 (3.3%)*
Rapid dilation	2 (1.1%)*
Death	2 (1.1%)*

* Observed in patients with an aortic root diameter >4 cm.

These studies suggest that women with mild disease, an aortic diameter less than 4.0 cm, can attempt pregnancy with only modest risk. The risk associated with more advanced disease is certainly greater. Given the data available, a precise risk of death from an aortic event cannot be quantified. Women with aortic diameters greater than 5.5 cm should certainly be counseled to have graft and valve replacement prior to pregnancy. They will then assume the risk associated with an artificial valve and the risk associated with the remaining aorta. These risks are not trivial but data do not exist to quantify the risk. Women with aortic roots greater than 4.0 cm but less than or equal to 5.5 cm are at significant risk, but aortic replacement may be premature. Fifty percent of children born to mothers with Marfan syndrome should be expected to have the disease.

Management of pregnancies affected by Marfan syndrome should begin with an accurate assessment of the aortic root. An absolute diameter or preferably an aortic ratio can be used to assess specific risk. The aortic root should be protected from hemodynamic forces with β -blockade. A resting heart rate of approximately 70 beats per minute can usually be achieved. While β -blockade may contribute to impaired fetal growth, this risk is small compared to the maternal risk without treatment.

Labor and delivery is managed with "standard cardiac care," with particular emphasis on the prevention of tachycardia. Patients with aortic roots less than 4.0 cm can certainly be delivered vaginally, reserving cesarean section for obstetric indications. Some authors have recommended cesarean delivery for women with larger roots based on concerns about increased pressure

PULMONARY HYPERTENSION

Although pulmonary hypertension is fundamentally a pulmonary disease, the major pathologic impact is on the right heart. The incidence of primary pulmonary hypertension is 1 to 2 per 1 million, with women affected more commonly than men.^[94] Secondary pulmonary hypertension may develop as a complication of cardiac disease such as mitral stenosis or secondary to intrinsic pulmonary disease. Drugs such as cocaine or appetite suppressants may also be responsible.^[94] Untreated, the median survival after diagnosis is 2.5 years.^[95] Pulmonary vasodilator therapy with oral nifedipine or intravenous prostacyclin have improved this prognosis. Of those who initially respond to nifedipine, the 5-year survival is 95 percent.^[96] The 5-year survival for those who require treatment with prostacyclin is 54 percent.^[97] The maternal mortality with severe pulmonary hypertension is reported to be as high as 50 percent.^[98]^[99]^[100] Sudden, irreversible deterioration in the postpartum period is common.^[98]^[99]^[101]

The symptoms of pulmonary hypertension are nonspecific. Increasing fatigue and shortness of breath are associated with progressive right heart failure but are also ubiquitous in pregnancy. They can easily be attributed to a presumed upper respiratory infection. Hoarseness may be present due to impingement on the laryngeal nerve by an enlarged pulmonary artery. Patients may exhibit disproportionate lower extremity edema or oxygen desaturation out of proportion for a presumed illness. The diagnosis can be confirmed with echocardiography, where the velocity of the regurgitant jet across the tricuspid valve can estimate pulmonary systolic pressure. A dilated, hypokinetic right ventricle with displacement of the intraventricular septum into the left ventricle suggests right heart failure.

Pulmonary hypertension with right ventricular dysfunction is poorly tolerated in pregnancy. A mortality rate approaching 50 percent should be expected. Should antepartum management be required, hospitalization is probably indicated. Oxygen therapy may reduce pulmonary vascular resistance and improve right ventricular performance. Pharmacologic treatment with nifedipine or intravenous prostacyclin may also be effective.^[102] Anticoagulation with heparin should be considered. Worsening disease will usually be manifest by falling cardiac output rather than rising right ventricular pressure. Labor and delivery should be managed with "standard cardiac care," with particular attention to right ventricular filling as assessed by measurement of central venous pressure (CVP). While the right ventricle will require adequate filling to generate forward flow against an elevated pulmonary vascular resistance, modest elevations in CVP may precipitate increasing right ventricular dysfunction. Given fluid mobilization postpartum and the potential need to treat volume loss associated with delivery, appropriate filling may be difficult to achieve. Gentle diuresis may be required. Modest unloading or overloading of the right ventricle may result in rapid decompensation and death.

Women with pulmonary hypertension and right ventricular dysfunction should be strongly discouraged from becoming pregnant. Since pulmonary artery pressures will fall as the right ventricle fails, the condition of the right ventricle may be a more important consideration than an absolute systolic pulmonary pressure. Some women may consider pregnancy after a favorable response to treatment with nifedipine or prostacyclin. In a small series, two women whose pulmonary pressures and right ventricular function had normalized carried three pregnancies successfully while being treated with nifedipine or prostacyclin.^[102] Neither experienced a deterioration in their condition over the first year postpartum.

OTHER CONDITIONS

Young women may experience malignant ventricular arrhythmias due to idiopathic ventricular fibrillation, cardiomyopathy, long-QT syndrome, congenital heart disease, or hypertrophic cardiomyopathy. Implantable defibrillators can effectively protect them from sudden death. In a report of 44 pregnancies, no women experienced generator erosion or lead fractures due to the expanding pregnancy. Twenty-five percent experienced discharges during pregnancy without complication.^[67]

Hypertrophic cardiomyopathy is a genetic condition usually inherited in an autosomal dominant pattern with variable penetrance. While the condition can be subclassified, the physiologic impact of different forms is similar. Patients are at risk for failure and ischemia due to ventricular obstruction and arrhythmia. The ventricular septum hypertrophies such that the left ventricular outflow tracts is increasingly obstructed during systole. While in some regards, the impact of obstruction is similar to aortic valvular disease, the degree of obstruction is variable under different physiologic conditions. Reduced ventricular filling associated with blood loss, dehydration, or tachycardia will increase the functional obstruction. Reviews of case reports suggest a maternal mortality rate of 1 to 2 percent in these cases.^[103], ^[104] Given the biases associated with case report-derived data, this estimate probably sets an upper

1026

limit of expected mortality. In pregnancy, increased blood volume and left ventricular dimension will tend to benefit the patient. Increased heart rate will not. -Blockers are generally used to manage tachycardia and some arrhythmias. Implantable defibrillators may also be used. Labor and delivery is managed with "standard cardiac care," with particular emphasis to ensure generous left ventricular filling. Supine hypotension must be carefully avoided. Obstetric bleeding should be treated early and aggressively with volume replacement.

CRITICAL CAREHEMODYNAMIC MONITORING AND MANAGEMENT

Diseases unique to pregnancy, the physiologic stresses of pregnancy, and the special conditions surrounding labor and delivery operate to create circumstances where intensive care may be necessary more frequently than would be required among young nonpregnant individuals. Specialists in intensive care may not be familiar with the physiology of pregnancy and the associated unique conditions such as preeclampsia or amniotic fluid embolus. They may also be unfamiliar with maternal-fetal physiologic relationships and decision making that must balance the needs of the mother and the fetus. Therefore, obstetricians must be familiar with basic principles and techniques of critical care medicine in order to manage critically ill pregnant women themselves or to serve as valuable consultants to a critical care team.

Acute indications for invasive hemodynamic monitoring can be broadly categorized based on questions of physiology ([see the box "Indications for Hemodynamic Monitoring"](#)). Severe preeclampsia, sepsis, adult respiratory distress syndrome (ARDS), pneumonia, previously undiagnosed heart disease, and fluid management after resuscitation from obstetric hemorrhage are the most common conditions that will require hemodynamic monitoring. Certain conditions, particularly maternal heart disease as discussed above, will require a planned, prospective decision for invasive monitoring. In these cases, the therapeutic window for hemodynamic management is narrow and knowledge of the patient's baseline, compensated hemodynamic status can serve as a goal for intrapartum management.

In many cases, initial therapy can and should be made empirically based on an understanding of the patient's pathophysiology. If subsequent interventions are needed, specific data from hemodynamic monitoring may be required. Physicians with a large experience treating a particular disease will often need the benefits of invasive monitoring less and less as an improved understanding makes the clinical course more predictable. Physicians who find themselves in unfamiliar territory may benefit more than those who have experience. Therefore, understanding principles of management is particularly important for obstetricians who do not necessarily anticipate critically ill patients in their practice.

Indications for Hemodynamic Monitoring

1. **1. Why is the patient hypoxic?**

Are pulmonary capillary pressures high due to relative volume overload? (e.g., mitral stenosis postpartum)
 Are pulmonary capillary pressures high due to depressed cardiac function? (e.g., cardiomyopathy)
 Is capillary membrane integrity intact? (e.g., ARDS, pneumonia)

2. **2. Why is the patient persistently hypertensive?**

Is vascular resistance elevated?
 Is cardiac output elevated?

3. **3. Why is the patient hypotensive?**

Is left ventricular filling pressure low? (e.g., after hemorrhage)
 Is vascular resistance low? (e.g., septic shock)

4. **4. Why is the patient's urine output low?**

Is left ventricular filling pressure low resulting in low cardiac output?

5. **5. Is the patient expected to be unstable in labor?**

Is the window of left ventricular filling narrow? (e.g., aortic stenosis)
 Will normal physiologic changes associated with delivery be tolerated poorly? (e.g., volume loading postpartum mitral stenosis, pulmonary hypertension)

Hemodynamic Monitoring

The objective of hemodynamic monitoring is to provide continuous assessment of systemic and intracardiac pressures and to provide the means to determine cardiac output and, therefore, to calculate systemic and pulmonary resistances. An arterial catheter is usually placed in the radial artery to measure systemic pressure. The diastolic pressure obtained will usually correlate well with noninvasive measurements. Systolic pressure may be significantly higher than noninvasive measurements due to a very brief peak in pressure in early systole. (The spike in pressure contributes little to mean arterial pressure.) The noninvasive measurement is usually more clinically relevant to the patient's condition. The arterial catheter permits easy access to arterial

blood sampling and relieves the patient from the discomfort of frequent blood draws.

Measurement of intracardiac pressures and cardiac output are obtained through the insertion of a catheter into the central venous circulation and advancement into and through the right heart. Venous access is most commonly obtained through the right internal jugular vein; a subclavian approach may also be used. Traditionally,

insertion is guided by using the sternocleidomastoid muscle and the clavicle as landmarks. The higher frequency ultrasound transducer found on a vaginal probe can also be used to facilitate insertion under direct visualization. Once central venous access has been obtained and confirmed, a pulmonary artery catheter can be "floated" into the right heart and pulmonary artery. [Figure 29-6](#) demonstrates the waveforms and normal pressure values found as the catheter passes through the heart. Success in "floating" the catheter is initially confirmed by observation of characteristic waveforms in the right ventricle, pulmonary artery, and wedged position, and subsequently with a radiograph. In experienced hands, complications from pulmonary artery catheterization are uncommon: pneumothorax (<0.1 percent), pulmonary infarction (0 to 1.3 percent), pulmonary artery rupture (<0.1 percent), and septicemia (0.5 to 2.0 percent). [\[105\]](#) Arrhythmias are usually transient and associated with passage of the catheter through the right ventricle. If the patient has significant pulmonary hypertension, difficulty may be encountered maintaining placement in the pulmonary artery.

Once the catheter has been successfully placed, continuous readings of central venous pressure and pulmonary artery pressures can be obtained. By inflating the balloon at the catheter tip, the catheter can be wedged in the pulmonary artery to obtain a PAWP. PAWP reflects the filling pressure, preload, in the left ventricle. CVP measured in the right atrium is a measure of right ventricular filling pressure. In pregnant women, CVP cannot be assumed to accurately reflect left ventricular filling. Right atrial pressures and systolic pulmonary pressures can be measured noninvasively by echocardiography.

Cardiac output is measured by thermodilution. A bolus of cold fluid is injected into the right atrium, and a curve of temperature change over time is recorded as the bolus passes through the pulmonary artery. From the shape of the curve, cardiac output can be calculated; when the cardiac output is higher, the dilutional curve is shorter in time and greater in maximum temperature change. More recently, catheters have been equipped with a heating element in the right atrial segment so that continuous measurement of cardiac output can be performed. Cardiac output can be measured

Figure 29-6 Hemodynamic waveforms and normal pressure values associated with catheter positions during advancement of a pulmonary artery catheter.

noninvasively with Doppler and impedance techniques. Doppler technique has been validated under a wide range of clinical circumstances. [\[106\]](#) [\[107\]](#) [\[108\]](#) [\[109\]](#) Impedance technique tends to underestimate cardiac output in pregnancy but accurately reflects changes in hemodynamics in many conditions. In conditions of pathologically high flow, impedance may significantly underestimate cardiac output. [\[110\]](#) [\[111\]](#) [\[112\]](#) Cardiac index (CI) can be derived from cardiac output in order to adjust for maternal size: $CI = CO/BSA$ (body surface area). However, BSA does not seem to be related to cardiac output in pregnancy; therefore, cardiac output is usually preferred. [\[109\]](#) When cardiac output is measured noninvasively and central venous pressure is not available, resistance is expressed as total peripheral resistance (TPR) rather than systemic vascular resistance (SVR). In most clinical conditions, the differences between the two are not important.

[Table 29-6](#) summarizes formulas used to calculate hemodynamic parameters not directly measured. Normal values for cardiac output, mean arterial pressure, heart rate, stroke volume, and total peripheral resistance are summarized [in Figure 29-1](#). In a study of 10 normal pregnant women at term, Clark et al. determined that central venous pressure, pulmonary artery pressure, pulmonary artery wedge pressure, and left ventricular work index were not different from nonpregnant measurements made approximately 3 months postpartum.[\[113\]](#) The relationship between PAWP and left ventricular work index fell within the normal range for nonpregnant individuals, suggesting normal contractility in pregnancy. Pulmonary vascular resistance was 34 percent lower, and colloid osmotic pressure was reduced by 14 percent.

Hemodynamic Management

The goal of this section is to develop strategies of hemodynamic therapy that may be applicable to a variety of clinical circumstances rather than to discuss management of specific maternal conditions. As outlined above, the use of hemodynamic monitoring should be directed at answering specific questions of maternal pathophysiology. [Table 29-7](#) summarizes the most common clinical goals of therapy. To achieve each goal, a number of physiologic interventions are possible. Each of these interventions will precipitate a secondary or compensatory response. The secondary response, if excessive, may adversely affect the patient. The choice of intervention from available options will often be determined by the potential for and magnitude of adverse effect. Hemodynamic monitoring permits the physician to choose an intervention and subsequently assess the positive and negative impact.

Disruption of alveolar capillary fluid dynamics is frequently associated with acute oxygen desaturation due to excess alveolar fluid. Pulmonary edema is usually due to excess capillary pressure (e.g., cardiomyopathy, mitral stenosis) or to a disruption of alveolar capillary membrane integrity (e.g., pneumonia, ARDS). While a reduction in serum oncotic pressure is rarely a primary cause of pulmonary edema, the reduced serum albumin level in normal pregnancy will act in synergy with other forces, resulting in earlier or more severe pulmonary edema than would have been anticipated.

The use of pulse oximetry facilitates the early detection of maternal desaturation. Oxygen supplementation will improve maternal saturation but does not correct the underlying cause. If desaturation is progressive, further intervention will be required. In the normal heart, diuresis to reduce preload will work to decrease alveolar water in patients with elevated PAWP and in patients with capillary leak. A reduction in capillary pressure from high normal to low normal will reduce the egress of water across damaged membranes. In many circumstances, these interventions are made empirically based on a diagnosis and an understanding of maternal physiology. For example, tocolysis with β -mimetic

TABLE 29-6 -- CALCULATED HEMODYNAMIC VARIABLES

		Calculation	Units
Mean arterial pressure	MAP	$sBP + 2 \text{ dBP}$	mm Hg
		————	
		3	
Stroke volume	SV	$CO \cdot 1000$	ml
		————	
		HR	
Systemic vascular resistance	SVR	$(MAP - CVP) \cdot 80$	$\text{dyne} \cdot \text{sec} \cdot \text{cm}^5$
		————	
		CO	
Total peripheral resistance	TPR	$MAP \cdot 80$	$\text{dyne} \cdot \text{sec} \cdot \text{cm}^5$
		————	
		CO	
Pulmonary vascular resistance	PVR	$mPAP - PAWP$	$\text{dyne} \cdot \text{sec} \cdot \text{cm}^5$
		————	
		CO	

sBP, systolic blood pressure; dBP, diastolic blood pressure; CO, cardiac output; CVP, central venous pressure; mPAP, mean pulmonary artery pressure; PAWP, pulmonary artery wedge pressure.

TABLE 29-7 -- HEMODYNAMIC INTERVENTIONS

Clinical Goal	Physiological Interventions	Agents	Compensatory Response
	$F_{I_{O_2}}$	O_2	
Oxygenation	capillary pressure	Diuretic	BP, CO
	airway pressure	PEEP	CO
	resistance	Vasodilator	CO
Blood pressure	cardiac output		
	HR	-Blocker	CO
	SV	Diuretic	CO
Blood pressure	resistance	-Agonist	CO
	cardiac output	Inotropic	CO
		Volume	CO, O_2 saturation
	cardiac output		
	contractility	Inotropic	HR
Perfusion	preload	Volume	O_2 saturation
	resistance	Vasodilator	BP

agents can induce pulmonary edema. Timely diagnosis, discontinuation of the offending agent, oxygen supplementation, and a single diuretic dose will usually be sufficient therapy. When initial interventions do not achieve an adequate effect, invasive monitoring may be required to direct subsequent care. Maternal diuresis to improve oxygen saturation, when excessive, may lead to a reduction in cardiac output. Fetal decompensation will usually be encountered before a significant reduction in maternal perfusion and hypotension. The maternal PAWP and cardiac output can be used to direct maternal diuresis. If desaturation continues despite hemodynamic management, intubation may be required. Positive end-expiratory pressure (PEEP) can be used to increase intra-alveolar pressure to impede the forces driving water into alveolar spaces. PEEP may impede venous return and decrease cardiac output due to the effects of the associated increase in extracardiac intrathoracic pressure. A PAWP in excess of PEEP is required for adequate ventricular filling. Only in the sickest of pregnant women will PEEP have a clinically significant impact on cardiac output.

Disorders of blood pressure and perfusion can be managed with the knowledge of maternal hemodynamics. [Figure 29-7](#) describes the relationships between mean arterial pressure, cardiac output, and vascular resistance. Cardiac output and mean arterial pressure are represented on the x- and y-axes, respectively. Resistance is represented by diagonal isometric lines. Vasodilators or vasopressors that act on resistance produce vectors of change that run perpendicular to lines of resistance. Interventions that decrease cardiac output (-blockers, diuresis) or increase cardiac output (dopamine, volume) produce vectors of change that run roughly parallel to lines of resistance. The region labeled "normal" represents the goal of therapy. Plotting patient data on the chart allows one to visually determine the vector or combination of vectors that could return hemodynamics to normal.

Patient A represents a patient who is hypotensive with a low cardiac output as might be expected after hemorrhage. Given a low PAWP, volume administration would be expected to create a vector that would return hemodynamics to normal. Alternatively, the patient could have a normal or high PAWP and would need an inotropic agent such as dopamine. Patient B has a normal blood pressure but a high vascular resistance and low cardiac output such as might be expected with a cardiomyopathy. Afterload reduction with a drug such as hydralazine will produce a vector of vasodilation and return hemodynamics to normal. Patient C is hypertensive with a mixed hemodynamic

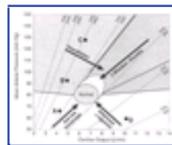

Figure 29-7 Hemodynamic flow chart. Cardiac output and mean arterial pressure are plotted on the x- and y-axes, respectively. Diagonal lines are isometric lines of vascular resistance. Anticipated vectors of change can be used to predict patient response to intervention.

pattern. She will need a combination of vectors to approach normal hemodynamics (e.g., hydralazine and -blocker). Patient D is hypotensive and hyperdynamic with a low vascular resistance. The hemodynamics might be found in a patient with early sepsis. Treatment with volume could increase pressure but at the expense of high filling pressures and a potentially negative impact on developing ARDS. Alternatively, a small dose of an -adrenergic agent such as norepinephrine would create a vector perpendicular to lines of resistance that return hemodynamics to normal. [Figure 29-7](#) allows one to see that vasoconstriction would achieve a normal blood pressure before adversely affecting cardiac output.

Key Points

Hemodynamic changes in pregnancy may adversely affect maternal cardiac performance.

Intercurrent events during pregnancy are usually the cause of decompensation.

Women with heart disease in pregnancy frequently have unique psychosocial needs.

Labor, delivery, and postpartum are times of hemodynamic instability.

Invasive hemodynamic monitoring should be used to address specific clinical questions.

Many maternal heart conditions can be medically managed during pregnancy. A few are associated with a very high risk of maternal mortality.

Many patients with congenital heart disease can successfully complete a pregnancy.

Preconceptual counseling is based on achieving a balance between medical information and the patient's value system.

Chapter 30 - Respiratory Diseases in Pregnancy

Janice E. Whitty
Mitchell P. Dombrowski

Pulmonary disease frequently complicates pregnancy. The occurrence of pulmonary disease during gestation may result in increased morbidity and/or mortality for both the mother and her fetus. Pregnancy may have an adverse or positive impact on the pulmonary function of the gravida depending on the particular complication that is being encountered. The cardiorespiratory changes that occur in pregnancy are reviewed [in Chapter 3](#) , and the obstetrician and his or her consultants would be wise to have a thorough understanding of these changes and the impact that the particular changes may have on the respiratory disease in question. It is extremely important to realize that the majority of diagnostic tests that need to be carried out to evaluate pulmonary function during gestation are not harmful to the fetus and, if indicated, should be performed. In this section, we discuss some of the respiratory complications that may be encountered during gestation, the impact of pregnancy on the disease, as well as the potential impact of the disease on pregnancy.

PNEUMONIA IN PREGNANCY

Pneumonia is a rare complication of pregnancy, complicating pregnancy in 1 per 118 deliveries to 1 per 2,288 deliveries.^[1],^[2] However, pneumonia contributes to considerable maternal mortality and is reportedly the most common nonobstetric infection to cause maternal mortality in the peripartum period.^[3] Maternal mortality was as high as 24 percent prior to the introduction of antibiotic therapy.^[4] However, research reports have documented a dramatic fall in maternal mortality with modern management and antibiotic therapy, ranging from 0 to 4 percent mortality.^[2],^[5],^[6] Preterm delivery is another significant complication of pneumonia complicating pregnancy and, even with antibiotic therapy and modern management, continues to occur in 4 to 43 percent of gravidas who have pneumonia.^[2],^[5],^[6]

The incidence of pneumonia in pregnancy may be increasing primarily as a reflection of the declining general health status of certain segments of the childbearing population.^[6] In addition, the epidemic of human immunodeficiency virus (HIV) infection has increased the number of potential mothers who are at risk for opportunistic lung infections. HIV infection is also associated with an increased risk of invasive pneumococcal disease, with an odds ratio of 41:8, and also an increased risk for legionnaires' disease, with a ratio of 41:8.^[7] HIV infection further predisposes the pregnant woman to the infectious complications of the acquired immunodeficiency syndrome (AIDS).^[7],^[8] Women with medical conditions that increase the risk of pulmonary infection, such as cystic fibrosis, are living to childbearing age more frequently than in the past. This disorder also contributes to the increased incidence of pneumonia in pregnancy.

Pneumonia can complicate pregnancy at any time during gestation and may be associated with preterm birth, poor fetal growth, and perinatal loss. In an early report by Hopwood,^[9] 17 of the 23 patients developed pneumonia between 25 and 36 weeks' gestation. In that series, seven gravidas delivered during the course of their acute illness, and there were two maternal deaths. Benedetti et al.^[5] described 39 cases of pneumonia in pregnancy. Sixteen gravidas presented before 24 weeks' gestation, 15 between 25 and 36 weeks' gestation, and 8 after 36 weeks' gestation. Twenty-seven patients in this series were followed to completion of pregnancy; only two required delivery during the acute phase of pneumonia. Of these 27 patients, 3 suffered a fetal loss

and 24 delivered live fetuses, although there was 1 neonatal death due to prematurity.^[5] Madinger et al.^[2] reported 25 cases of pneumonia occurring among 32,179 deliveries and observed that fetal and obstetric complications were much more common than in earlier studies. Preterm labor occurred in 11 of 21 patients who had complete follow-up data. Pneumonia was present at the time of delivery in 11 patients, particularly in those women who had bacteremia, needed mechanical ventilation, and had a serious underlying maternal disease. In addition to the complication of preterm labor, there were three perinatal deaths in this series. In Berkowitz and La Sala's report of 25 patients with pneumonia complicating pregnancy,^[6] full-term delivery occurred in 14 women, 1 delivered preterm, 3 had a voluntary termination of pregnancy, 3 had term deliveries of growth-restricted babies, and 4 were lost to follow-up. Birth weight was significantly lower in the study group in this series ($2,770 \pm 224$ g vs. $3,173 \pm 99$ g in the control group, $p < 0.01$). In this series, pneumonia complicated 1 in 367 deliveries, and Berkowitz and La Sala attributed the increase in the incidence of pneumonia in this population to a decline in general health status, including anemia, a significant incidence of cocaine use in the study group (52 percent vs. 10 percent in the general population), and HIV positivity in the study group (24 percent vs. 2 percent of the general population).

BACTERIOLOGY

Most series describing pneumonia complicating pregnancy have used incomplete methodologies to diagnose the etiologic pathogens for pneumonia, relying primarily on cultures of blood and sputum. In the majority of cases, no pathogen was identified; however, pneumococcus and *Haemophilus influenzae* remain the most common identifiable causes of pneumonia in pregnancy.^[2], ^[5], ^[6] Because comprehensive serologic testing has rarely been done, the true incidence of viral pneumonia, *Legionella*, and *Mycoplasma* pneumonia in pregnancy is difficult to estimate. The data presented by Benedetti et al.,^[5] Madinger et al.,^[2] and Berkowitz and La Sala^[6] all supported pneumococcus as the predominant pathogen causing pneumonia in pregnancy, with *H. influenzae* being the second most common organism. In Berkowitz and La Sala's series, one patient had *Legionella* species.^[6] Several unusual pathogens have been reported to cause pneumonia in pregnancy, including mumps, infectious mononucleosis, swine influenza, influenza A, varicella, coccidioidomycosis, and other fungi.^[10] Varicella pneumonia will complicate primary varicella infections in 9 percent of infections in pregnancy, as compared with 0.3 to 1.8 percent in the nonpregnant population.^[11] Influenza A has a higher mortality in pregnant than in nonpregnant patients.^[12] The increase in virulence of viral infections reported in pregnancy may be secondary to the alterations in maternal immune status that characterize pregnancy, including reduced lymphocyte proliferative response, reduced cell-mediated cytotoxicity by lymphocytes, and a decrease in the number of helper (T₄ T lymphocytes).^[12], ^[13] Viral pneumonias can also be complicated by superimposed bacterial infection, particularly with pneumococcus.

Chemical pneumonitis results after the aspiration of gastric contents. Chemical pneumonitis can be superinfected with pathogens present in the oropharynx and gastric juices, primarily anaerobes and gram-negative bacteria.^[10]

BACTERIAL PNEUMONIA

Streptococcus pneumoniae (pneumococcus) is the most common bacterial pathogen to cause pneumonia in pregnancy, with *H. influenzae* being the next most common. These pneumonias typically present as an acute illness accompanied by fever, chills, purulent productive cough, and a lobar pattern on the chest radiograph. Streptococcal pneumonia produces a "rusty" sputum, with gram-positive diplococci on Gram stain and asymmetric consolidation with air bronchograms on chest radiograph.^[13] *H. influenzae* is a gram-negative coccobacillus that produces consolidation with air bronchograms, often in the upper lobes.^[13] Less frequent bacterial pathogens include *Klebsiella pneumoniae* which is a gram-negative rod that causes extensive tissue destruction, with air bronchograms, pleural effusion, and cavitation noted on chest radiograph. Patients with *Staphylococcus aureus* pneumonia present with pleuritis, chest pain, purulent sputum, and consolidation without air bronchograms noted on chest radiograph.^[13]

Atypical pneumonia pathogens, such as *Mycoplasma pneumoniae*, *Legionella pneumophila*, and *Chlamydia pneumoniae* (TWAR agent) present with gradual onset, a lower fever, appear less ill, have a mucoid sputum, and a patchy or interstitial infiltrate on chest radiograph. The severity of the findings on chest radiograph are usually out of proportion to the mild clinical symptoms. *Mycoplasma pneumoniae* is the most common organism responsible for atypical pneumonia and is best detected by the presence of cold agglutinins in 70 percent of cases.

The normal physiologic changes in the respiratory system associated with pregnancy result in a loss of ventilatory reserve. This, coupled with the immunosuppression that accompanies pregnancy put the mother and fetus at great risk from respiratory infection. Therefore, any gravida suspected of having pneumonia should be managed aggressively. She should be admitted to the hospital and an investigation undertaken to determine the pathologic etiology. Work-up should include physical examination, arterial blood gases, chest radiograph, sputum Gram stain and culture, as well as blood cultures. Empiric antibiotic coverage should be started, usually with a third-generation cephalosporin such as ceftriaxone or cefotaxime. *Legionella* pneumonia has a high mortality and sometimes presents with consolidation, mimicking pneumococcal pneumonia. Therefore, it is recommended that a macrolide, such as azithromycin, be added to the empiric therapy. Once the results of the sputum culture, blood cultures, Gram stain, and serum studies are obtained and a pathogen has been identified, antibiotic therapy can be directed towards the identifiable pathogen. The third-generation cephalosporins are effective agents for the majority of pathogens causing a community-acquired pneumonia. They are also effective against penicillin-resistant *Streptococcus pneumoniae*. In addition to antibiotic therapy, oxygen supplementation should be given. Frequent arterial blood gas measurements should be obtained to maintain the P_{O_2} at 70 mm Hg, a level necessary to ensure adequate fetal oxygenation. Arterial saturation can be monitored with pulse oximetry as well. When the gravida is afebrile for 48 hours and has signs of clinical improvement, an oral cephalosporin can be started and intravenous therapy discontinued. A total of 10 to 14 days of treatment should be completed.

Pneumonia in pregnancy can be complicated by respiratory failure requiring mechanical ventilation. Should this occur, team management should include the obstetrician, maternal-fetal medicine specialist, and intensivist. In addition to meticulous management of the gravida's respiratory status, the patient should be maintained in the left lateral recumbent position to improve uteroplacental perfusion. The viable fetus should be monitored with continuous fetal monitoring. If positive end-expiratory pressure (PEEP) greater than 10 cm H_2O is required to maintain oxygenation, central monitoring with a pulmonary artery catheter should be instituted to adequately monitor volume status and maintain maternal and uteroplacental perfusion. There is no evidence that elective delivery results in an overall improvement in respiratory function.^[14] Therefore, elective delivery is probably not indicated. However, if there is clear evidence of fetal compromise or profound maternal compromise and impending demise, delivery should be accomplished.

VIRAL PNEUMONIAS

Influenza Virus

There are an estimated 4 million cases of pneumonia and influenza annually in the United States, and this is the sixth leading cause of death in this country.^[15] While three types of influenza virus can cause human disease, types A, B, and C, most epidemic infections are due to influenza A.^[16] Influenza A typically has an acute onset after a 1- to 4-day incubation period and first manifests as high fever, coryza, headache, malaise, and cough. In uncomplicated cases, the chest examination and chest radiograph remain clear.^[10] If symptoms persist longer than 5 days, especially in a pregnancy, complications should be suspected. Pneumonia may complicate influenza as the result of either secondary bacterial infection or viral infection of the lung parenchyma.^[10] In the epidemic of 1957, autopsies demonstrated that pregnant women died from fulminant viral pneumonia most commonly, while nonpregnant patients died most often from secondary bacterial infection.^[16] Primary influenza pneumonia is characterized by rapid progression from a unilateral infiltrate to diffuse bilateral disease. The gravida may develop fulminant respiratory failure requiring mechanical ventilation and PEEP. When pneumonia complicates influenza in pregnancy, antibiotics should be started, directed at the likely pathogens that can cause secondary infection, including *Staphylococcus aureus*, pneumococcus, *H. influenza*, and certain enteric gram-negative bacteria. Antiviral agents, such as amantadine and ribavirin, can be considered.^[17] It has been recommended that the influenza vaccine be given routinely to gravidas in the second and third trimesters of pregnancy in order to prevent the occurrence of influenza and the development of pneumonia secondary to that infection.

Varicella

Varicella zoster is a DNA virus that usually causes a benign self-limited illness in children but may infect up to 2 percent of all adults.^[18] Varicella infection occurs in 0.7 of every 1,000 pregnancies.^[19] Pregnancy may increase the likelihood of varicella pneumonia complicating the primary infection.^[11] Varicella pneumonia occurs most often in the third trimester, and the infection is likely to be severe.^[11], ^[19], ^[20] The maternal mortality from varicella pneumonia may be as high as 35 to 40 percent as compared to 11 to 17 percent in nonpregnant individuals.^[11], ^[20] While one recent review reported a decreased mortality with only 3 deaths in 28 women with varicella pneumonia,^[19] another recent study documented a maternal mortality of 35 percent.^[11]

Varicella pneumonia usually presents 2 to 5 days

Figure 30-1 This chest x-ray demonstrates bilateral nodular and interstitial pneumonia characteristic of varicella. The patient, a 27-year-old gravida 6, para 2, abortus 3 woman, was exposed to varicella infection in her two children. Characteristic skin vesicles of varicella occurred several days before the development of pulmonary symptoms. She required endotracheal intubation and mechanical ventilation for 6 days. She was also treated with intravenous acyclovir and ceftazidime for possible superimposed infection. The patient recovered fully and delivered a healthy infant at term.

after the onset of fever, rash, and malaise and is heralded by the onset of pulmonary symptoms including cough, dyspnea, pruritic chest pain, and hemoptysis.^[11] The severity of the illness may vary from asymptomatic radiographic abnormalities to fulminant pneumonitis and respiratory failure^[11], ^[21] (Fig. 30-1). All gravidas with varicella pneumonia should be aggressively treated with antiviral therapy and admitted to the intensive care unit for close observation or intubation if indicated. Acyclovir, a DNA polymerase inhibitor, should be started. The early use of acyclovir was associated with an improved hospital course after the fifth day and a lower mean temperature, lower respiratory rate, and improved oxygenation.^[11] Treatment with acyclovir is safe in pregnancy. Among 312 pregnancies, there was no increase in the number of birth defects and no consistent pattern of congenital abnormalities.^[22] A dose of 7.5 mg/kg intravenously every 8 hours has been recommended.^[23]

TUBERCULOSIS IN PREGNANCY

The incidence of tuberculosis in the United States began to decline in the early part of the 20th century and fell steadily until 1953, when the introduction of isoniazid led to a dramatic decrease in the number of cases, from 84,000 cases in 1953 to 22,255 cases in 1984.^[24] However, since 1984, there have been significant changes in tuberculosis morbidity trends. From 1985 through 1991, reported cases of tuberculosis increased by 18 percent, representing approximately 39,000 more cases than expected had the previous downward trend continued. This increase is due to many factors, including HIV epidemic, deterioration in the health care infrastructure, and more cases among immigrants.^[24] The emergence of drug-resistant tuberculosis has also become a serious concern. In New York City, in 1991, 33 percent of tuberculosis cases were resistant to at least one drug, and 19 percent were resistant to both isoniazid (INH) and rifampin (RIF).^[25] Between 1985 and 1992, the number of tuberculosis cases in women of childbearing age increased by 40 percent.^[26] One report noted tuberculosis-complicated pregnancies in 94.8 cases per 100,000 deliveries between 1991 and 1992.^[27]

Diagnosis

The majority of gravidas diagnosed with tuberculosis in pregnancy will be asymptomatic. All gravidas at high risk for tuberculosis ([see the box "High-Risk Factors for Tuberculosis"](#)) should be screened with subcutaneous administration of intermediate-strength purified protein derivative (PPD). If anergy is suspected, control antigens such as candida, mumps, or tetanus toxoids should also be placed.^[28] The sensitivity of the PPD is 90 to 99 percent for exposure to tuberculosis. The tine test should not be used for screening because of its low sensitivity.

High-Risk Factors for Tuberculosis
HIV infection
Close contact with persons known or suspected to have tuberculosis
Medical risk factors known to increase risk of disease if infected
Birth in a country with high tuberculosis prevalence
Medically underserved status
Low income
Alcohol addiction
Intravenous drug use
Residency in a long-term care facility (e.g., correctional institutions, mental institutions, nursing homes and facilities)
Health professionals working in high-risk health care facilities

The onset of the recent tuberculosis epidemic stimulated

the need for rapid diagnostic tests using molecular biology methods to detect *M. tuberculosis* in clinical specimens. Two direct amplification tests (DATs) have been approved by the Food and Drug Administration (FDA), the *Mycobacterium tuberculosis* Direct test (MTD) (Gen-Probe, San Diego, CA), and the Amplicor *Mycobacterium tuberculosis* (Amplicor MTB) test (Roche Diagnostic Systems, Inc., Branchburg, NJ). Both tests amplify and detect *M. tuberculosis* 16S ribosomal DNA.^[29] When testing acid-fast stain smear-positive respiratory specimens, each test has a sensitivity of greater than 95 percent and a specificity of essentially 100 percent for detecting the *M. tuberculosis* complex.^[30] When testing acid-fast stain smear-negative respiratory specimens, the specificity remains greater than 95 percent, but the sensitivity ranges from 40 to 77 percent.^[30] To date, these tests are FDA-approved only for testing acid-fast stain smear-positive respiratory specimens obtained from untreated patients or those who have received no more than 7 days of antituberculosis therapy. The PPD remains the most commonly used screening test for tuberculosis.

Immigrants from areas where tuberculosis is endemic may have received the bacille Calmette-Guérin (BCG) vaccine. Such individuals will likely have a positive response to the PPD. However, this reactivity should wane over time. Therefore, the PPD should be utilized to screen these patients for tuberculosis unless their skin tests are known to be positive.^[32] If the BCG vaccine was given 10 years earlier and the PPD is positive with a skin test reaction of 10 mm or more, that individual should be considered infected with tuberculosis and managed accordingly.^[32]

Women with a positive PPD skin test must be evaluated for active tuberculosis with a thorough physical examination for extrapulmonary disease and a chest radiograph once they are beyond the first trimester.^[33] Symptoms of active tuberculosis include cough (74 percent), weight loss (41 percent), fever (30 percent), malaise and fatigue (30 percent), and hemoptysis (19 percent).^[33] Individuals with active pulmonary tuberculosis may have radiographic findings including adenopathy, multinodular infiltrates, cavitation, loss of volume in the upper lobes, and upper medial retraction of hilar markings. The finding of acid-fast bacilli in early morning sputum specimens confirms the diagnosis of pulmonary tuberculosis. At least three first-morning sputum samples should be examined for the presence of acid-fast bacilli. If sputum cannot be produced, sputum-induction, gastric washings, or diagnostic bronchoscopy may be indicated.

Extrapulmonary tuberculosis occurs in up to 16 percent of cases in the United States; however, in patients with AIDS the pattern may occur in 60 to 70 percent of all

patients.^[34] Extrapulmonary sites include lymph nodes, bone, kidneys, and breasts. Extrapulmonary tuberculosis appears to be rare in pregnancy.^[35] Extrapulmonary tuberculosis that is confined to the lymph nodes has no effect on obstetric outcomes, but tuberculosis at other extrapulmonary sites does adversely affect the outcome of pregnancy.^[36] Rarely, mycobacteria invade the uteroplacental circulation, and congenital tuberculosis results.^[9], ^[26], ^[37] The diagnosis of congenital tuberculosis is based on one of the following factors: (1) demonstration of primary hepatic complex or cavitating hepatic granuloma by percutaneous liver biopsy at birth; (2) infection of the maternal genital tract or placenta; (3) lesions noted in the first week of life; and (4) exclusion of the possibility of postnatal transmission by a thorough investigation of all contacts, including attendants.^[26]

Prevention

The majority of gravidas with a positive PPD in pregnancy will be asymptomatic with no evidence of active disease and therefore classified as infected without active disease. The risk of progression to active disease is highest in the first 2 years of conversion. It is important to prevent the onset of active disease while minimizing maternal and fetal risk. An algorithm for management of the positive PPD is presented in [Figure 30-2](#).^[36] In women with a known recent conversion (2 years) to a positive PPD and no evidence of active disease, the recommended prophylaxis is isoniazid, 300 mg/day, starting after the first trimester and continuing for 6 to 9 months.^[13] Isoniazid should be accompanied by pyridoxine (vitamin B₆) supplementation, 50 mg/day, in order to prevent the peripheral neuropathy that is associated with isoniazid treatment. Women with an unknown or prolonged duration of PPD positivity (> 2 years) should receive isoniazid, 300 mg/day for 6 to 9 months after delivery. Isoniazid prophylaxis is not recommended for women older than 35 years of age who have an unknown or prolonged PPD positivity in the absence of active disease. The use of isoniazid is discouraged in this group because of an increased risk of hepatotoxicity. Isoniazid is associated with hepatitis in both pregnant and nonpregnant adults. However, monthly monitoring of liver function tests may prevent this adverse outcome. Among individuals receiving isoniazid, 10 to 20 percent will develop mildly elevated liver function tests. These changes resolve once the drug is discontinued.^[36]

Treatment

The gravida with active tuberculosis should be treated initially with isoniazid, 300 mg/day, combined with rifampin, 600 mg/day ([Table 30-1](#)).^[40] Resistant disease results from initial infection with resistant strains (33 percent) or can develop during therapy.^[41] If resistance

1038

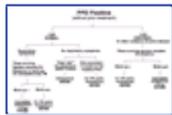

Figure 30-2 Algorithm for the management of positive PPD.

to isoniazid is identified or anticipated, ethambutol 2.5 g/day should be added and the treatment period should be extended to 18 months.^[40] Ethambutol is teratogenic in animals; however, this has not been noted in humans. The most common side effect of ethambutol therapy is optic neuritis. Streptomycin should be avoided during pregnancy because it is associated with eighth nerve damage in neonates.^[42] Antituberculous agents not recommended for use in pregnancy include ethionamide, streptomycin, capreomycin, kanamycin, cycloserine, and pyrazinamide.^[13]

Women who are being treated with antituberculous drugs may breast-feed. Only 0.75 to 2.3 percent of INH and 0.05 percent of rifampin are excreted into breast milk. Ethambutol excretion into breast milk is also minimal. However, if the infant is concurrently taking oral antituberculous therapy, excessive drug levels may be reached in the neonate, and breast-feeding should be avoided. Breast-fed infants of women taking isoniazid therapy should receive a multivitamin supplement, including pyridoxine.^[13] Neonates of women taking antituberculous therapy should have a PPD skin test at birth and again at 3 months of age. Infants born to women with active tuberculosis at the time of delivery should receive isoniazid prophylaxis (10 mg/kg/day) until maternal disease has been inactive for 3 months as evidenced by negative maternal sputum cultures.^[13] Active tuberculosis in the neonate should be treated appropriately with isoniazid and rifampin immediately upon diagnosis or with multiagent therapy should drug-resistant organisms be identified. Infants and children who are at high risk of intimate and prolonged exposure to untreated or ineffectively treated persons should receive the BCG vaccine.^[43]

Summary

In summary, high-risk gravidas should be screened for tuberculosis and treated appropriately with INH prophylaxis for infection without overt disease and with dual antituberculous therapy for active disease. In addition, the newborn should be screened for evidence of tuberculosis as well. Proper screening and therapy will lead to a good outcome for mother and fetus in the majority of cases.

ASTHMA IN PREGNANCY

Asthma, which may be the most common potentially serious respiratory complication of pregnancy, is characterized by chronic airway inflammation with increased airway responsiveness to a variety of stimuli, and airway obstruction that is partially or completely reversible. ^[44] Approximately 4 percent of women of child-bearing age have a history of asthma, but up to

1039

TABLE 30-1 -- ANTITUBERCULOSIS DRUGS

Drug	Dosage Forms	Daily Dose	Weekly Dose	Major Adverse Reactions
First-line drugs (for initial treatment):				
Isoniazid	PO, IM	10 mg/kg up to 300 mg	15 mg/kg up to 900 mg	Hepatic enzyme elevation, peripheral neuropathy hepatitis, hypersensitivity
Rifampin	PO	10 mg/kg up to 600 mg	10 mg/kg up to 600 mg	Orange discoloration of secretions and urine, nausea, vomiting, hepatitis, febrile reaction, purpura (rare)
Pyrazinamide	PO	1530 mg/kg up to 2 g	5070 mg/kg	Hepatotoxicity, hyperuricemia, arthralgias, skin rash, gastrointestinal upset
Ethambutol	PO	15 mg/kg up to 2.5 g	50 mg/kg	Optic neuritis (decreased red-green color discrimination, decreased visual acuity), skin rash
Streptomycin	IM	15 mg/kg up to 1 g	2530 mg/kg up to 1 g	Ototoxicity, nephrotoxicity
Second-line drugs (daily therapy):				
Capreomycin	IM	1530 mg/kg up to 1 g		Auditory, vestibular, and renal toxicity
Kanamycin	IM	1530 mg/kg up to 1 g		Auditory and renal toxicity, rare vestibular toxicity
Ethionamide	PO	1520 mg/kg up to 1 g		Gastrointestinal disturbance, hepatotoxicity, hypersensitivity
Para-aminosalicylic acid	PO	150 mg/kg up to 1 g		Gastrointestinal disturbance, hypersensitivity, hepatotoxicity, sodium load
Cycloserine	PO	1520 mg/kg up to 1 g		Psychosis, convulsions, rash

10 percent of the population appears to have nonspecific airway hyperresponsiveness. ^[45] In general, the prevalence, morbidity, and mortality from asthma are increasing.

Insight into the pathogenesis of asthma has changed with the recognition that airway inflammation is present in nearly all cases. The effects of pregnancy on asthma are controversial. Several studies noted that over 40 percent of patients required hospitalization during pregnancy for asthma exacerbations. ^[46], ^[47] In contrast, in a managed care setting with a higher socioeconomic population, Schatz et al. reported an emergency room visit rate of 12.6 percent but a hospitalization rate of only 1.1 percent for asthma exacerbations during pregnancy. ^[48]

Gravidas with asthma have an increased frequency of chronic hypertension ^[49] and maternal smoking, which may also complicate the effects of other influences. ^[49], ^[50] Ethnicity may be a particularly important confounding factor in assessing the relationship between asthma and pregnancy outcomes, since African Americans (ages 15 to 44) are five times more likely to die from asthma and are twice as likely to be hospitalized from asthma compared to Caucasians. ^[51] A summary of possible maternal, fetal, and neonatal complications related to asthma and asthma therapy is presented in the box "Reported Effects of Asthma and Asthma Treatment Regimens."

Studies have shown that patients with more severe asthma may have the greatest risk for complications during pregnancy. ^[47], ^[52] Quantitating this risk is problematic because most studies have not categorized the severity of asthma. In 1993, the National Asthma Education Program (NAEP) working group defined mild, moderate, and severe asthma according to symptomatic exacerbations (wheezing, cough, and/or dyspnea) and objective tests of pulmonary function. The most commonly used parameters are the peak expiratory flow rate (PEFR) and the forced expiratory volume in 1 second (FEV₁). The NAEP guidelines did not consider the need for regular medication to be a factor for classifying asthma severity during pregnancy. In a recent prospective observational study of 1,800 pregnant women with asthma and 900 control subjects, patients with mild asthma but who required regular medications (-agonist, theophylline, or inhaled corticosteroids) were similar to subjects with moderate asthma in respect to asthma exacerbations. ^[53] It seems prudent to

1040

consider pregnant patients requiring regular systemic corticosteroids to control asthma symptoms to have severe asthma ([see the box "Modified NAEP Asthma Severity Classification"](#)).

Reported Effects of Asthma and Asthma Treatment Regimens

Increased maternal

- Preeclampsia
- Cesarean delivery
- Asthma exacerbations
- Preterm rupture of membranes

Increased perinatal

- Mortality
- Prematurity
- Low birth weight
- Hypoxia/asphyxia
- Hypoadrenalism
- Theophylline toxicity

Asthma Management

The ultimate goal of asthma therapy is maintaining adequate oxygenation of the fetus by preventing hypoxic episodes in the mother. The effective management of asthma during pregnancy relies on four integral components outlined below.

Objective Measures for Assessment and Monitoring

Subjective measures of lung function by the patient and physician provide an insensitive and inaccurate assessment of airway hyperresponsiveness, airway inflammation, and asthma severity. The FEV₁ following a maximal inspiration is the single best measure of pulmonary function. However, measurement of FEV₁ requires a spirometer. The PEFr correlates well with the FEV₁, and has the advantages that it can be measured reliably with inexpensive, disposable, portable peak flowmeters. Patient self-monitoring of PEFr provides valuable insight to the course of asthma throughout the day, assesses circadian variation in pulmonary function, and helps detect early signs of deterioration so that timely therapy can be instituted.

Avoid or Control Asthma Triggers

Limiting adverse environmental exposures during pregnancy is important for controlling asthma. Irritants and allergens that provoke acute symptoms also increase airway inflammation and hyperresponsiveness. Avoiding or controlling such triggers can reduce asthma symptoms, airway hyperresponsiveness, and the need for medical therapy. Association of asthma with allergies is common; 75 to 85 percent of patients with asthma have positive skin tests to common allergens including animal dander, house dust mites, cockroach antigens, pollens, and molds. Other common nonimmunologic triggers include tobacco smoke, strong odors, air pollutants, food additives such as sulfites, and certain drugs including aspirin and β -blockers. Another trigger can be strenuous physical activity. For some patients, exercise-induced asthma can be avoided with inhalation of a β_2 -agonist 5 to 60 minutes before exercise. Specific measures for avoiding asthma triggers are listed [in the box "Limiting Exposure to Asthma Triggers."](#)

Patient Education

Patients should be made aware that controlling asthma during pregnancy is especially important for the well-being of the fetus. The patient should have a basic understanding of strategies to reduce asthma triggers and medical management during pregnancy, including self-monitoring of PEFrs and the correct use of inhalers.

Pharmacologic Therapy

The goal of asthma therapy is multiphasic: (1) relieve bronchospasm, (2) protect the airways from irritant

stimuli, (3) prevent the pulmonary and inflammatory response to an allergen exposure, and (4) resolve the inflammatory process in the airways leading to improved pulmonary function with reduced airway hyperresponsiveness. The therapeutic approach includes increasing the number and frequency of medications with increasing asthma severity.

Modified NAEP Asthma Severity Classification

Mild asthma

Brief (<1 hour) symptomatic exacerbations less than twice a week

PEFR 80% of personal best

FEV₁ 80% of predicted when asymptomatic

Moderate asthma

Symptomatic exacerbations more than twice a week

Exacerbations affect activity levels

Exacerbations may last for days

PEFR, FEV₁ range from 60 to 80% of predicted

Regular medications necessary to control symptoms

Severe asthma

Continuous symptoms/frequent exacerbations limit activity levels

PEFR, FEV₁ <60% of expected, and are highly variable

Regular oral corticosteroids necessary to control symptoms

Limiting Exposure to Asthma Triggers

Use plastic mattress and pillow covers

Weekly washing of bedding in hot water

Animal dander control

Weekly bathing of the pet

Keeping pets out of the bedroom

Remove the pet from the home

Cockroach control

Avoid tobacco smoke

Inhibit mite and mold growth by reducing humidity

Do not be present when home is vacuumed

Asthma Pharmacotherapy

Current medical treatment for asthma emphasizes reduction of airway inflammation to decrease airway hyperresponsiveness and prevent asthma symptoms. Although it is assumed that asthma medications are as effective in pregnant as in nonpregnant patients, differences in maternal physiology and pharmacokinetics may affect the absorption, distribution, metabolism and clearance of medications during pregnancy. Endocrinologic and immunologic changes during pregnancy include elevations in free plasma cortisol, possible tissue refractoriness to cortisol,^[54] and changes in cellular immunity.^[55] Although animal studies have indicated association of corticosteroids with an increased risk of cleft palate and decreased fetal survival, human studies have failed to suggest any increase in facial clefts or other birth defects.^[56] However, the use of oral corticosteroids has been associated with low birth weight.^[57],^[58] Potential adverse effects of oral or high-dose inhaled corticosteroids include adrenal suppression, weight gain, impaired fetal growth, hypertension, diabetes, cataracts, and osteoporosis.

In the United States, three classes of inhaled anti-inflammatory asthma medications are available at the present time: inhaled corticosteroids, nedocromil sodium, and cromolyn sodium. In separate controlled studies of nonpregnant subjects, use of inhaled corticosteroids or cromolyn sodium led to improvement in (1) asthma symptoms,^[59]^[60]^[61] (2) pulmonary function,^[59] (3) nonspecific bronchial hyperactivity,^[62] (4) emergency room relapses,^[61] and (5) hospitalizations^[59] ([see the box "Typical Dosages of Common Asthma Medications"](#)).

Inhaled Corticosteroids

Airway inflammation is present in nearly all cases; therefore, inhaled corticosteroids have even been advocated as first-line therapy for patients with mild asthma.^[63] The use of inhaled corticosteroids among nonpregnant asthmatics has been associated with a marked reduction in fatal and near-fatal asthma.^[64] In addition to their anti-inflammatory effect, corticosteroids increase the effectiveness of β_2 -adrenergic drugs by inducing formation of new β_2 -receptors.

Inhaled corticosteroids produce clinically important improvements in bronchial hyperresponsiveness that appear dose related,^[65] can occur as early as a few weeks but take months to attain maximal effect,^[66] and include prevention of increased bronchial hyperresponsiveness after seasonal exposure to an allergen.^[67],^[68] Continued administration is also effective in reducing the immediate pulmonary response to an allergen challenge. Inhaled corticosteroids are also more effective than β_2 -agonists, theophylline, nedocromil sodium, and cromolyn sodium in reducing airway hyperresponsiveness during maintenance treatment.^[60],^[63],^[69],^[70] In a prospective observational study of 504 pregnant subjects with asthma, 177 patients were not initially treated with either inhaled budesonide or inhaled beclomethasone.^[71] This cohort had a 17 percent acute exacerbation rate compared to only a 4 percent rate among those treated with inhaled corticosteroids from the start of pregnancy.

Typical Dosages of Common Asthma Medications	
Cromolyn sodium	2 inhalations qid
Beclomethasone	2-5 inhalations bid-qid
Triamcinolone	2 inhalations tid-qid or 4 inhalations bid
Budesonide	2-4 inhalations bid
Fluticasone	88-220 µg bid
Flunisolide	2-4 inhalations bid
Theophylline	Maintain serum levels of 8-12 g/ml; decrease dosage by half if treated with erythromycin or cimetidine
Prednisone	1 week 40 mg/day burst for active symptoms followed by 1 week taper
Albuterol	2 inhalations q 3-4 hours

Several studies have found that inhaled corticosteroids

1042

can cause adrenal suppression and changes in bone metabolism in nonpregnant patients. [72] [73] [74] [75] [76] [77] Their potential effects on fetal adrenal function and fetal bone development are unknown. There is concern that inhaled corticosteroids impair growth in children as measured by height or lower leg growth using a knemometer. [78] [79] [80] Inhaled corticosteroids can cause thrush and hoarseness, problems that may be mitigated by the use of metered-dose inhalers with spacers. Only about 10 to 20 percent of the inhaled dose of corticosteroid reaches the lungs, while approximately 50 percent is deposited in the oropharynx. [81] The use of spacers can increase delivery to the lungs, and mouth rinsing after inhalation will decrease oral absorption.

In 1993, the NAEP working group recommended inhaled beclomethasone during pregnancy because most clinical studies had been conducted with beclomethasone. [45] Since then, limited data during pregnancy and data from nonpregnant subjects suggest that the other inhaled corticosteroids may have therapeutic advantages compared to beclomethasone. Therefore, it seems reasonable to recommend beclomethasone as the preferred agent when commencing inhaled corticosteroids during pregnancy, but to continue either triamcinolone acetonide, budesonide, fluticasone propionate, or flunisolide during pregnancy in a patient who is well controlled by that inhaled corticosteroid prior to pregnancy. All of the above inhaled corticosteroids are currently labeled FDA pregnancy class C.

BECLOMETHASONE DIPROPIONATE.

Inhaled beclomethasone has not been associated with increased rates of fetal malformations. [82] [83] [84] A case analysis of 12,301 nonpregnant asthmatics [64] reported that use of beclomethasone for at least 1 year resulted in a significantly lower risk of fatal and near-fatal asthma compared to therapies not including inhaled corticosteroids. Inhaled beclomethasone has been associated with a reduced readmission rate for asthma exacerbations in a randomized study of 84 pregnant patients. [84] Beclomethasone is identical to betamethasone except for a chlorine at the 9-position instead of fluorine. This is significant, since betamethasone is known to effectively cross to the fetus.

TRIAMCINOLONE ACETONIDE.

Data on inhaled triamcinolone use during pregnancy are limited to a single retrospective analysis of 15 women treated with inhaled triamcinolone, 14 treated with inhaled beclomethasone, and 25 receiving oral theophylline therapy. [85] There was a significantly lower incidence of hospital admissions for asthma exacerbations among gravidas receiving inhaled triamcinolone (33 percent) compared with those treated with an inhaled beclomethasone group (79 percent; $p < 0.05$) but not compared to the theophylline group. The finding of a lower hospitalization rate among the group treated with inhaled triamcinolone may be due to confounding factors in this small retrospective study. Triamcinolone has been shown to have minimal systemic absorption following oral administration via metered dose inhalers with spacers. [86]

BUDESONIDE.

To study possible teratogenic risks, the Swedish Medical Birth Registry was utilized in 2,014 infants whose mothers had used inhaled budesonide in early pregnancy. A 3.8 percent (95 percent confidence interval [CI] 2.9 to 4.6) frequency of congenital malformations was observed, which was similar to the general population rate of 3.5 percent. [87] Budesonide and theophylline may have synergistic effects. In a double-blind, placebo-controlled trial of nonpregnant subjects with moderate asthma, high-dose budesonide (800 µg) was compared to low-dose budesonide (400 µg) with theophylline at serum concentrations below the recommended therapeutic range (8.7 g/ml). [88] Compared to high-dose budesonide, the low-dose budesonide with theophylline regimen resulted in a significantly improved FEV₁. Serum cortisol concentrations were significantly reduced in the group treated with high-dose budesonide, but not the low-dose theophylline group.

FLUTICASONE PROPIONATE AND FLUNISOLIDE.

Both fluticasone propionate and flunisolide are potent anti-inflammatory corticosteroids. There are no published studies of their use during human pregnancy. However, in contrast to the association of growth decelerations in adolescent children treated with inhaled beclomethasone, [78] inhaled fluticasone propionate therapy was not found to be associated with a decrease in growth velocity. [89] In a randomized double-blind study of nonpregnant adults and adolescents, inhaled fluticasone propionate was found to be significantly more effective than theophylline in the treatment of mild to moderate asthma. [90]

CROMOLYN SODIUM AND NEDOCROMIL SODIUM.

Given the potential for systemic effects of inhaled corticosteroids, even at low doses, it is important to identify nonsteroidal anti-inflammatory medications. At the present time, cromolyn sodium and nedocromil sodium are the only approved medications that fit into this category. Nedocromil sodium, a pyranoquinolone, exerts a number of anti-inflammatory effects in vivo and in vitro. [91] Cromolyn sodium, which is virtually devoid of significant side effects, blocks both the early- and late-phase pulmonary response to allergen challenge as well as preventing the development of airway hyperresponsiveness. [62] Cromolyn sodium does not have any intrinsic bronchodilator or antihistaminic activity. Compared to inhaled corticosteroids, the time to maximal clinical benefit is longer for cromolyn sodium, 4 weeks versus 2 weeks. Nedocromil sodium and cromolyn sodium appear to be less effective than inhaled corticosteroids

1043

in reducing objective and subjective manifestations of asthma.

Bronchodilators

In some respects, these medications are now viewed as supplementary to nonbronchodilator antiasthma medications. An increased frequency of bronchodilator use could indicate the need for additional anti-inflammatory therapy.

THEOPHYLLINE.

Theophylline has anti-inflammatory actions^[92] that may be mediated by the inhibition of leukotriene production and its capacity to stimulate prostaglandin E (PGE₂) production.^[93] Theophylline has been used for over 50 years, and no increased risk of developmental problems in exposed offspring has been identified. The NAEP Working Group on Asthma and Pregnancy recommended that theophylline be considered a second-line drug to be used to supplement inhaled corticosteroids when control is not achieved. High doses have been observed to cause jitteriness, tachycardia, and vomiting in both mothers and neonates.^[94], ^[95] New dosing guidelines have recommended that serum concentrations be maintained at 8 to 12 g/ml during pregnancy.^[45] Subjective symptoms of adverse theophylline effects including insomnia, heartburn, palpitations, and nausea may be difficult to differentiate from typical pregnancy symptoms. Theophylline can have significant interactions with other drugs, causing decreased clearance and resultant toxicity. Two commonly used drugs, cimetidine and erythromycin, can cause a 70 percent and a 35 percent increase, respectively, in theophylline serum levels.^[96]

The main advantage of theophylline is its long duration of action, 10 to 12 hours with the use of sustained-release preparations. These are especially useful in the management of nocturnal asthma.^[97] Theophylline should be added when β_2 -agonists and inhaled anti-inflammatory agents do not adequately control symptoms. Theophylline is only indicated for chronic therapy and is not effective for the treatment of acute exacerbations during pregnancy.^[84]

INHALED β_2 -AGONISTS.

β_2 -Agonists are currently recommended for use with all degrees of asthma during pregnancy.^[48], ^[51] This group of medications has evolved from those that are relatively short acting (epinephrine, isoproterenol) to those with a longer duration of action (albuterol, terbutaline, pirbuterol), of 4 to 6 hours.^[97] Their greatest advantage is a rapid onset of effect in the relief of acute bronchospasm via smooth muscle relaxation. They are also excellent bronchoprotective agents for pretreatment prior to exercise. Prior to allergen exposure, they effectively block the pulmonary response, but are of insufficient duration of action to prevent the late-phase pulmonary response unless administered in high doses.^[98]

While β_2 -agonists are associated with tremor, tachycardia, and palpitations, recent studies have found more serious complications including an association with an increased risk of death with chronic use.^[99], ^[100] They do not block the development of airway hyperresponsiveness.^[63] Indeed, a comparison of an inhaled glucocorticoid, budesonide, with the inhaled β_2 -agonist terbutaline, raised the question whether routine use of this medication could result in increased airway hyperresponsiveness.^[63]

LEUKOTRIENE PATHWAY MODERATORS.

Leukotrienes are arachidonic acid metabolites that have been implicated in transducing bronchospasm, mucus secretion, and increased vascular permeability.^[101] Bronchoconstriction associated with aspirin ingestion can be blocked by leukotriene receptor antagonists.^[102] Treatment with the leukotriene receptor antagonist montelukast has been shown to significantly improve pulmonary function as measured by FEV₁.^[102] The leukotriene receptor antagonists zafirlukast (Accolate), and montelukast (Singulair) are both rated FDA pregnancy category B. The 5-lipoxygenase inhibitor zileuton (Zyflo) is rated FDA pregnancy category C because of reduced weight and skeletal variations among rats at 18 times the recommended maximum human dosage. It should be noted that there are no data regarding the efficacy or safety of these agents during human pregnancy.

Step Therapy

The step-care therapeutic approach increases the number and frequency of medications with increasing asthma severity ([see the box "Step Therapy Medical Management of Asthma"](#)). A burst of oral corticosteroids is indicated for exacerbations not responding to initial β_2 -agonist therapy regardless of asthma severity. Additionally, patients who require increasing inhaled β_2 -agonist therapy (more than 12 puffs per day) to control their symptoms may benefit from oral corticosteroids. In such cases, a short course of oral prednisone, 40 to 60 mg/day for 1 week followed by 7 to 14 days of tapering may be effective.

Antenatal Management

Patients with moderate and severe asthma should be considered to have high-risk pregnancies. Adverse outcomes can be increased by underestimation of asthma severity and under treatment of asthma exacerbations. The first prenatal visit should include a detailed medical history with attention to medical conditions that could complicate the management of asthma, including diabetes mellitus, hypertension, cardiac disease, adrenal disorders,

hyperthyroidism, HIV, hemoglobinopathies, hepatic disease, and active pulmonary problems (cystic fibrosis, bronchiectasis, tuberculosis, sarcoidosis, recurrent sinus and pulmonary infections, bronchitis). The patient should be questioned about the presence and severity of symptoms, episodes of nocturnal asthma, the number of days of work missed due to asthma exacerbations, history of acute asthma emergency care visits, and smoking history. The type and amount of asthma medications including the number of puffs of β_2 -agonists used each day should be recorded. Asthma severity should be determined ([see the box "Modified NAEP Asthma Severity Classification"](#)).

Step Therapy Medical Management of Asthma

Mild

Inhaled β_2 -agonist as needed[†]

Moderate

Inhaled β_2 -agonist as needed[†]

Inhaled corticosteroids (or cromolyn)

Theophylline for nocturnal asthma or increased symptoms

Severe

Inhaled β_2 -agonist as needed[†]

Inhaled corticosteroids (or cromolyn)

Theophylline for nocturnal asthma or increased symptoms

Oral systemic corticosteroids

[†] PEFR or FEV₁ <80 percent, asthma exacerbations, or exposure to exercise or allergens (oral corticosteroid burst if inadequate response to β_2 -agonist regardless of asthma severity).

Gravidas with mild, well-controlled asthma may receive routine prenatal care. Moderate and severe asthmatic women should have scheduling of prenatal visits based on clinical judgment; most will need prenatal visits at least every 2 weeks, then weekly at 36 weeks' gestation. In addition to routine care, each antenatal visit should include an evaluation of (1) asthma severity and symptom frequency, nocturnal asthma; (2) FEV₁ or PEFR; (3) medications (assessing compliance and dosage); and (4) emergency visits and hospital admissions for asthma exacerbations. Patients should be instructed on proper dosing and administration of their asthma medications. The step-care therapeutic approach includes increasing the number and frequency of medications with increasing asthma severity ([see the box "Step Therapy Medical Management of Asthma"](#)). The least number of medications needed to control asthma symptoms should be used.

Patients should be instructed on proper peak flowmeter technique; PEFR should be determined with peak flowmeters prior to medications, in the morning, and after dinner. At each of these times the patient should make the measurement while standing, to take a maximum inspiration and to note the reading on the instrument. Personal best PEFR should be determined, and personalized green, yellow, and red zones should be established and explained ([see the box "Individualized PEFR Zones"](#)). Those with moderate to severe asthma should be instructed to maintain an asthma diary containing daily assessment of asthma symptoms, including morning and evening peak flow measurements, symptoms and activity limitations, indication of any medical contacts initiated, and a record of regular and as-needed medications taken.

As previously discussed, avoidance and control of asthma triggers ([see the box "Limiting Exposure to Asthma Triggers"](#)) are particularly important in pregnancy, since pharmacologic control of asthma potentially has adverse fetal effects. Specific recommendations should be made for appropriate environmental controls, based on the patient's history of exposure and, when available, demonstrated skin test reactivity.

Moderate and severe asthmatics require additional fetal surveillance in the form of ultrasound examinations and antenatal fetal testing. Because asthma has been associated with intrauterine growth restriction and preterm birth, it is critical to accurately establish pregnancy dating. Ultrasound examinations also are needed to evaluate fetal viability, anatomy, amniotic fluid volume, placental location, and interval fetal growth. Repeat ultrasound examinations are recommended for patients with suboptimally controlled asthma, and following asthma exacerbations to evaluate fetal activity, growth, and amniotic fluid volume. The intensity of antenatal fetal surveillance should be based on the severity of the asthma. All patients should be instructed to be attentive to fetal activity and keep a record of fetal kick counts. In most cases, patients with moderate and severe asthma should have fetal testing starting by 32 weeks' gestation.

HOME MANAGEMENT OF ASTHMA EXACERBATIONS

An asthma exacerbation that causes minimal problems for the mother may have severe sequelae for the fetus. Indeed, an abnormal fetal heart rate tracing may be the

1045

initial manifestation of an asthmatic exacerbation. A maternal PO₂ below 60 mm Hg or hemoglobin saturation less than 90 percent may be associated with profound fetal hypoxia. Therefore, asthma exacerbations in pregnancy must be aggressively managed. Patients should be given an individualized guide for decision making and rescue management.

Individualized PEFR Zones

Establish "personal best" PEFR, then calculate:

1. Green zone >80 percent of personal best PEFR
2. Yellow zone 50-80 percent of personal best PEFR
3. Red zone <50 percent of personal best PEFR

(Typical PEFR = 380-550 L/min)

Home Management of Acute Asthma Exacerbations

Use inhaled albuterol 24 puffs and check PEFr in 20 minutes

If PEFr <50 percent predicted or symptoms are severe, obtain emergency care

If PEFr is 50-70 percent predicted:

Repeat albuterol treatment, check PEFr in 20 minutes

If PEFr <50 percent predicted

Contact care giver or go for emergency care

If PEFr >70 percent predicted:

Continue inhaled albuterol (24 puffs q 3-4 h for 6-12 h as needed)

If decreased fetal movement:

Contact care giver or go for emergency care

Patients should be educated to recognize signs and symptoms of early asthma exacerbations such as coughing, chest tightness, dyspnea, or wheezing, or by a 20 percent decrease in their PEFr. This is important so that prompt home rescue treatment may be instituted in order to avoid maternal and fetal hypoxia. In general, patients should use inhaled albuterol 2 to 4 puffs every 20 minutes up to 1 hour. A good response is considered if symptoms are resolved or become subjectively mild, normal activities can be resumed, and the PEFr is greater than 70 percent of personal best. The patient should seek further medical attention if the response is incomplete, or if fetal activity is decreased ([see the box "Home Management of Acute Asthma Exacerbations"](#)).

HOSPITAL AND CLINIC MANAGEMENT

The principal goal should be the prevention of hypoxia. Continuous electronic fetal monitoring should be initiated if gestation has advanced to the point of potential fetal viability. Albuterol should be delivered by nebulizer (2.5 mg = 0.5 ml albuterol in 2.5 ml normal saline) driven with oxygen; treatments are given every 20 minutes.^{[103] [104] [105]} Occasionally, nebulized treatment is not effective because the patient is moving air poorly. In such cases, terbutaline 0.25 mg can be administered subcutaneously every 15 minutes for three doses. The patient should be assessed for general level of activity, color, pulse rate, use of accessory muscles, and airflow obstruction determined by auscultation and FEV₁ and/or PEFr before and after each bronchodilator treatment. Measurement of oxygenation via pulse oximeter or arterial blood gases is essential. Arterial blood gases should be obtained if oxygen saturation remains below 95 percent. Chest x-rays are not commonly needed. Guidelines for the management of asthma exacerbations are presented in the box "Emergency Assessment and Management of Asthma Exacerbations."

LABOR AND DELIVERY MANAGEMENT

Asthma medications should not be discontinued during labor and delivery. Although asthma is usually quiescent during labor, consideration should be given to assessing PEFrs on admission and at 12-hour intervals. The patient should be kept hydrated and should receive adequate analgesia in order to decrease the risk of bronchospasm. If systemic corticosteroids have been used in the previous 4 weeks, then hydrocortisone (100 mg every 8 hours intravenously) should be administered during labor and for the 24-hour period following delivery to prevent adrenal crisis (NAEP).

Emergency Assessment and Management of Asthma Exacerbations

1. Initial evaluation:

History, examination, PEFr, oximetry

Fetal monitoring if potentially viable

2. Initial treatment

Inhaled β_2 -agonist \times 3 doses over 60-90 minutes

O₂ to maintain saturation >95 percent

If no wheezing and PEFr or FEV₁ >70 percent baseline, discharge with follow-up

3. If oximetry <90 percent, FEV₁ <1.0 L, or PEFr <100 L/min on presentation:

Continue nebulized albuterol

Start intravenous corticosteroids

Consider intravenous aminophylline

Obtain arterial blood gases

Admit to intensive care unit

Possible intubation

4. If PEFr or FEV₁ >40 percent but <70 percent baseline after β_2 -agonist:

Obtain arterial blood gases

Continue inhaled β_2 -agonist every 4-6 hours

Start intravenous corticosteroids in most cases

Consider intravenous aminophylline

Hospital admission in most cases

It is rarely necessary to deliver a fetus via cesarean section for an acute asthma exacerbation. Usually, maternal

and fetal compromise can be managed by aggressive medical management. Occasionally, delivery may improve the respiratory status of a patient with unstable asthma who has a mature fetus. PGE₂ or PGE₁ can be used for cervical ripening, the management of spontaneous or induced abortions, or postpartum hemorrhage; however, 15-methyl PGF₂ and methylergonovine can cause bronchospasm. Magnesium sulfate, which is a bronchodilator, is a safe choice for treating preterm labor. Indomethacin can induce bronchospasm in the aspirin-sensitive patient. There are no reports of the use of calcium channel blockers for tocolysis among patients with asthma.

Lumbar anesthesia has the benefit of reducing oxygen consumption and minute ventilation during labor. ^[106] A 2 percent incidence of bronchospasm has been reported with regional anesthesia. ^[107] Fentanyl may be a better analgesic than meperidine, which causes histamine release, but meperidine is rarely associated with the onset of bronchospasm during labor. Ketamine is useful for the induction of general anesthesia because it can prevent bronchospasm. ^[108] Communication between the obstetric, anesthetic, and pediatric care givers is important for optimal care.

BREAST-FEEDING

In general, only small amounts of medications used to treat asthma enter breast milk. Prednisone, theophylline, antihistamines, beclomethasone, β_2 -agonists, and cromolyn are not considered to be contraindications for breast-feeding. ^[109] However, among sensitive individuals, theophylline may cause toxic effects in the neonate including vomiting, feeding difficulties, jitteriness, and cardiac arrhythmias.

VENOUS THROMBOSIS AND PULMONARY EMBOLISM

Venous thromboembolic diseases, which include superficial and deep thrombophlebitis, pulmonary embolus, septic pelvic thrombophlebitis, and thrombosis account for almost one half of all obstetric morbidity.^[110] The leading cause of pregnancy-related mortality in the United States, pulmonary embolism is responsible for 17 percent of maternal deaths.^[111] Thromboembolic disease occurs more frequently during gestation, and the likelihood of venous thromboembolism in normal pregnancy and the puerperium is increased by a factor of 5 when compared with nonpregnant women of similar age.^[112] An untreated deep vein thrombosis (DVT) is associated with a 15 to 25 percent incidence of pulmonary embolus, with a 12 to 15 percent mortality rate.^[113]

The diagnosis of venous thromboembolism is difficult during pregnancy; however, with the recognition of thrombophilic states and the current thrust toward more accurate diagnosis of those patients who are at high risk for thromboembolic disease secondary to the hereditary thrombophilias, we may soon have better diagnostic tools with which to identify women who may be at increased risk. In this section we review the pathogenesis of thromboembolism in pregnancy, as well as the diagnosis and therapy of this dreaded condition.

Pathogenesis

Normal pregnancy is accompanied by a hypercoagulable state. The concentrations of factors XII, X, IX, VIII, VII, and V, and fibrinogen levels are increased during pregnancy, while factors XI and XIII decrease. Plasma fibrinolytic inhibitors are produced by the placenta, and there is a marked reduction in the release of tissue plasminogen activator (t-PA) in response to venous occlusion throughout pregnancy when compared with nonpregnant subjects.^[114], ^[115] There is also a rapid inhibition of released t-PA.^[116], ^[117] Protein S is markedly decreased during normal pregnancy; however, protein C is either unaltered or moderately increased.^[118] These changes serve to prepare for the major hemostatic challenge of placental separation. Compression of the inferior vena cava and iliac veins by the pregnant uterus produces venous obstruction and results in increased venous capacitance and provides an element of stasis. This stasis may contribute to endothelial cell damage. In addition, local damage to pelvic veins may occur during vaginal and cesarean delivery. Therefore, all the elements of Virchow's triad are present during normal pregnancy and contribute to the increased risk of thromboembolism during pregnancy and the puerperium.^[119] There are also hypercoagulable conditions that increase the risk of thromboembolism.

Hypercoagulable Conditions

Preeclampsia

Thrombin-antithrombin complex and fibrinopeptide A concentrations increase markedly in women with preeclampsia.^[120] ^[121] ^[122] Antithrombin III (AT-III) levels are decreased.^[123] A recent study examining the incidence of inherited thrombophilias in pregnancy complications reported a 68 percent incidence of inherited or acquired thrombophilias in women whose pregnancies were complicated by severe preeclampsia.^[124] Thus, aberrations in the coagulation profile and a high incidence of thrombophilias serve to make the woman with preeclampsia at high risk for thromboembolic complications.

Inherited Thrombophilias

ANTITHROMBIN III DEFICIENCY.

Six genetic defects have been identified that are associated with an increased

risk of venous thrombosis. AT-III deficiency is inherited as an autosomal dominant trait with heterozygotes having an increased risk of venous thrombosis. This is a heterogeneous defect, and 79 different mutations have been identified in the antithrombin gene.^[125] The incidence of AT-III deficiency in the general population is between 1 in 2,000 and 1 in 4,000, making AT-III deficiency the most common congenital clotting disorder in women.^[126] Up to 70 percent of individuals with AT-III deficiency develop symptomatic thrombi, and 2 to 3 percent of patients hospitalized for recurrent thrombi will have AT-III deficiency.^[126], ^[127] Approximately two thirds of pregnant women with congenital AT-III deficiency will suffer a thrombosis, and the majority of these will occur antepartum.^[128] The fetus has a 50 percent risk of inheriting AT-III deficiency and should be tested after birth. AT-III levels less than 30 percent are an indication for neonatal treatment with AT-III concentrate or fresh frozen plasma to prevent a fatal neonatal thrombosis.^[113]

PROTHROMBIN 20210A ALLELE.

Recently, a new genetic risk factor for venous thrombosis was identified by sequencing the prothrombin genes from families with unexplained familial thrombophilia.^[129] The sequence variation observed in these subjects was a G to A transposition in position 20210 of the prothrombin gene.^[129] This allele was associated with an increased risk of a first DVT (odds ratio [OR], 2.8; 95 percent CI, 1.4 to 5.6). This mutation was found in 1 to 2 percent of healthy controlled subjects, 6.2 percent of consecutive patients with a first DVT, and in 18 percent of patients that had been selected for unexplained familial thrombophilia.^[129] The laboratory diagnosis for the presence of the prothrombin 20210A allele relies completely on DNA analysis.^[129] In addition to increasing the risk of thromboembolic phenomena, this gene has been associated with an increased risk of pregnancy complications. The gene was found in 10 percent of women with preeclampsia, abruptio placentae, and fetal growth restriction and stillbirth, as compared with 3 percent of women without these complications.^[124]

PROTEIN C DEFICIENCY.

Protein C is a vitamin K-dependent protein that attaches to endothelial cells, promotes fibrinolysis, and limits coagulation by inactivation of factors Va and VIIIa.^[130] Protein C deficiency is inherited as an autosomal dominant disorder. It is genetically heterogeneous, with more than 160 different mutations in the protein C gene.^[125] Heterozygosity for protein C deficiency is a significant risk factor for venous thrombosis. Heterozygotes have protein C antibody levels 50 percent that of normal individuals.^[131] Autosomal recessive inheritance of protein C has been observed in families from newborns with severe thrombosis resulting from homozygous or compound heterozygous protein C deficiency.^[132] In normal pregnancy, protein C activity is not altered. In patients with protein C deficiency, pregnancy and delivery increase the risk of a thromboembolic event. The incidence of thromboembolism in pregnant heterozygous women is approximately 25 percent.^[133] Protein C deficiency is also associated with an increased risk of pregnancy complications.^[124]

PROTEIN S DEFICIENCY.

Protein S is a cofactor for protein C. Protein S deficiency is inherited as an autosomal dominant disorder. Seventy different mutations in the protein S gene have been reported.^[134] The prevalence of heterozygotes for a type I protein S deficiency is 6 percent in families with an inherited thrombophilia, and 1 to 2 percent in patients with a first DVT.^[125] Heterozygous patients have a protein S level 50 percent that of the normal population.^[113] Protein S concentration declines during normal pregnancy, and pregnancy seems to increase the risk of a thromboembolic event with women with a protein S deficiency.^[113] The neonate is at risk to inherit this disorder and should be tested after birth. Protein S deficiency is associated with an increased risk of pregnancy complications as well.^[124]

FACTOR V LEIDEN.

Activated protein C (APC) resistance is associated with the factor V Leiden mutation. More than 80 percent of cases with APC resistance are carriers of the same mutation in a gene of factor V, a G to A transposition.^[135] The factor V Leiden mutation occurs in 3 percent of healthy subjects and 19 percent of consecutive patients admitted with DVT.^[125] The risk of first DVT is reportedly increased 7.9-fold in heterozygotes and 91-fold in homozygotes.^[136] In addition to an increased risk of thromboembolic phenomena, the gravida with factor V Leiden mutation is also subject to an increased risk of pregnancy complications. The factor V Leiden mutation was detected in 20 percent of women with obstetric complications, as compared with 6 percent without complications.^[124]

DYSFIBRINOGENEMIA.

Dysfibrinogenemia is a rare disorder with a prevalence of 1 percent among selected thrombosis patients. Both autosomal dominant and recessive inheritances have been reported.^[125] Although most patients with congenital dysfibrinogenemia are either asymptomatic or develop a pure bleeding diathesis, the rare patient may present with venous or arterial thromboembolism that is sometimes accompanied by mild bleeding.^[137] Individuals with dysfibrinogenemia are most commonly identified by an abnormal reptilase time and/or thrombin time.^[137]

HYPERHOMOCYSTEINEMIA.

Hyperhomocysteinemia is a recently described condition associated with an increase of premature atherosclerosis and thromboembolism.^[138], ^[139] The inherited form of hyperhomocysteinemia is commonly the result of an abnormality in a key enzyme known as methylenetetrahydrofolate reductase. A common mutation in this enzyme is a C-T substitution at nucleotide 677. This results in a heat-labile form

of the enzyme that does not efficiently convert homocysteine to methionine.^[140] Hyperhomocysteinemia may also be acquired as the result of a dietary deficiency of folate. The mechanism by which homocysteine induces atherosclerosis and thrombosis is not fully understood. In vivo studies, as well as studies in animals and humans, indicate that hyperhomocysteinemia induces dysfunction of the vascular endothelium with loss of endothelium-dependent vasodilatation and endothelial antithrombotic properties as well as proliferation of vascular smooth muscle cells, all of which are key processes in current models of atherogenesis and thrombosis.^[141] Studies have shown that normal antithrombotic endothelium is converted into a more prothrombotic venotype with increased factor V and factor XII activity, decreased activity of protein C, and antithrombin pathways with an accompanying inhibition of thrombomodulin expression, induction of tissue factor expression, and suppression of heparin sulfate expression.^[142] All of these changes lead to facilitation of thrombin generation.

In one study, hyperhomocysteinemia was found in 31 percent of women with abruptio placentae or placental infarction as compared with 9 percent of a control group.^[142] In another recent report examining the relationship between thrombophilia and adverse outcomes of pregnancy, homozygosity for the mutation in the methylenetetrahydrofolate reductase gene was found in 22 percent of women with obstetric complications as compared with 8 percent of women with normal pregnancies.^[124]

Acquired Thrombophilias

LUPUS ANTICOAGULANT.

The lupus anticoagulant was first identified in plasma of patients with systemic lupus erythematosus, hence the term lupus anticoagulant. The lupus anticoagulant is a monoclonal autoantibody that reacts to the phospholipid from blood platelet membrane platelet factor 3. Interference by lupus anticoagulant with platelet phospholipid causes incomplete generation of the activated prothrombin complex. Plasma from patients with the lupus anticoagulant interferes with the coagulation of normal plasma. Paradoxically, in vivo these antibodies are associated with thrombosis rather than anticoagulation. The lupus anticoagulant is associated with recurrent fetal demise, congenital heart block, and intrauterine growth restriction.^[143] The antiphospholipid syndrome is associated with either recurrent embryonic pregnancy loss or death of the fetus at or beyond 10 weeks of gestation. The latter presentation may be more specific for the antiphospholipid syndrome.^[144] The antiphospholipid syndrome is diagnosed when the patient tests positive for the lupus anticoagulant, or has immunoglobulin G (IgG) anticardiolipin antibody in medium to high levels (Table 30-2).^[145] Because

TABLE 30-2 -- CLINICAL AND LABORATORY CRITERIA FOR THE DIAGNOSIS OF ANTIPHOSPHOLIPID SYNDROME

Criterion	Definition
Clinical	
Fetal loss	Three or more spontaneous abortions with no more than one live birth, or unexplained second- or third-trimester fetal death
Thrombosis	Unexplained venous or arterial thrombosis, including stroke and arterial insufficiency due to arterial thrombosis
Autoimmune thrombocytopenia	Other causes of thrombocytopenia excluded
Other features	Otherwise unexplained transient ischemic attacks or amaurosis fugax, livedo reticularis, Coombs'-positive hemolytic anemia, chorea, and chorea gravidarum
Laboratory	
Lupus anticoagulant	Detected by phospholipid-dependent clotting assays, without correction with normal plasma, and confirmed by demonstration of phospholipid dependency
Anticardiolipin antibodies	IgG isotype >1520 GPL units (medium to high positive) detected in standardized assay using standard serum calibrators

GPL, IgG phospholipid units.

in many instances tests may be only transiently positive, antiphospholipid antibodies should be detected on two occasions more than 12 weeks apart.^[147] The diagnosis of antiphospholipid syndrome should be considered in women with venous thrombosis in unusual sites, such as the portal, mesenteric, splenic, subclavian and cerebral veins. Antiphospholipid antibodies are detected in approximately 2 percent of patients with non-traumatic venous thrombosis.

The therapy of antiphospholipid syndrome in pregnancy will vary depending on the clinical situation (Table 30-3). The majority of women with documented antiphospholipid syndrome will require prophylactic therapy with subcutaneous heparin and low-dose aspirin daily.^[146]

All of the thrombophilias are associated with an increased incidence of thromboembolic phenomena in pregnancy. They are also associated with high-risk conditions including preeclampsia, intrauterine fetal demise, intrauterine growth restriction, and abruptio placentae.^[124] Therefore, any patient with a known history of a thrombophilia should be monitored closely for the above-mentioned complications of pregnancy. In particular, fetal growth should be assessed frequently and the

TABLE 30-3 -- PROPOSED MANAGEMENT FOR WOMEN WITH ANTIPHOSPHOLIPID ANTIBODIES

Feature	Management*	
	Pregnant	Nonpregnant
Antiphospholipid syndrome (APS)	Heparin in prophylactic doses (15,000-20,000 units of unfractionated heparin or equivalent per day) administered subcutaneously in divided doses and low-dose aspirin daily	Optimal management uncertain; options include no treatment or daily treatment with low-dose aspirin
APS with prior fetal death or recurrent pregnancy loss	Calcium and vitamin D supplementation	
APS with prior thrombosis or stroke	Heparin to achieve full anticoagulation <i>or</i>	Warfarin administered daily in doses to maintain INR 3:0
	Heparin in prophylactic doses (15,000-20,000 units of unfractionated heparin or equivalent per day) administered subcutaneously in divided doses <i>plus</i>	
	Low-dose aspirin daily	
	Calcium and vitamin D supplementation	
APS without prior pregnancy loss or thrombosis	Optimal management uncertain; options include no treatment, daily treatment with low-dose aspirin, daily treatment with prophylactic doses of heparin and low-dose aspirin	Optimal management uncertain; options include no treatment or daily treatment with low-dose aspirin
Antiphospholipid antibodies without APS		
Lupus anticoagulant (LA) or medium to high positive IgG aCL	Optimal management uncertain; options include no treatment, daily treatment with low-dose aspirin, daily treatment with prophylactic doses of heparin and low-dose aspirin	Optimal management uncertain; options include no treatment or daily treatment with low-dose aspirin
Low levels of IgG, only IgM aCL, only IgA aCL without LA, antiphospholipid antibodies other than LA, or aCL	Optimal management uncertain; options include no treatment or daily treatment with low-dose aspirin	Optimal management uncertain; options include no treatment or daily treatment with low-dose aspirin

* The medication shown should not be used in the presence of contraindications. Close obstetric monitoring of mother and fetus is necessary in all cases. The patient should be counseled in all cases regarding symptoms of thrombosis and thromboembolism.

obstetrician must be alert to any signs or symptoms consistent with preeclampsia. Any signs or symptoms suspicious for a DVT or pulmonary embolus should be thoroughly investigated.

Diagnosis of Deep Vein Thrombosis

The diagnosis of a DVT during pregnancy can be challenging. Clinical suspicions are aroused by signs and symptoms including pain, tenderness to palpation, and edema. Edema of the lower extremities occurs frequently in normal pregnancy, particularly in the third trimester. However, should edema be asymmetric, that is, more than 2 cm difference in circumference between the affected and normal leg, or if there is a positive Homans' sign or Lowenberg test, an investigation to rule out a DVT should be undertaken.

Venography

Ascending contrast venography is the reference standard for the diagnosis of a DVT.^[149] The technique involves injection of a radiographic contrast dye into a distal, dorsal foot vein while the patient is relaxed, non-weight bearing, and in 40 percent of reversed Trendelenburg position. The diagnosis of DVT requires visualization in at least two different views of a well-defined intraluminal filling defect. False-positive studies can result from poor technique, leg muscle contraction, Baker's (popliteal) cyst, hematoma, local edema, and other conditions.^[149] Pressure from the gravid uterus can cause a false-positive venogram. Therefore, uterine displacement is imperative during the procedure. False-negative results can occur if the contrast does not fill all the deep veins.^[149]

If indicated during pregnancy, a limited venogram can be performed using pelvic and abdominal shielding with lead aprons. This can protect the fetus from potential hazards of radiation exposure. Visualization of the iliac veins may be compromised, and isolated iliac vein thrombosis cannot be diagnosed.^[149] If complete visualization of the entire deep venous system is indicated, a complete venogram can be done. The estimated amount of radiation absorbed by the fetus with an

unshielded unilateral venogram was 0.314 rad in one study.^[149] This compared with less than 0.050 rad with a limited venogram. In utero exposure to radiation may be associated with a slight increase in the risk of childhood cancer following in utero exposure to radiation doses of less than 5 rad.^[149] There is no increase in congenital malformations or increase in stillbirths or infant deaths following such radiation exposure. Therefore, venography is likely to be relatively safe for the fetus, particularly when pelvic shielding is used.

Fibrinogen Scanning

^[125] fibrinogen scanning is not recommended for diagnosis of deep vein thrombosis in pregnancy. It is associated with a relatively high level of radiation exposure to the fetus, estimated at approximately 2 rad.^[149] In addition, radiolabeled iodine crosses the placenta, is taken up by the fetal thyroid, and is also secreted into breast milk. Therefore, ^[125] fibrinogen scanning should also be avoided during breast-feeding.

Impedance Plethysmography

Impedance plethysmography (IPG) is a safe, inexpensive, and relatively sensitive and specific test for the detection of a proximal DVT. However, it is not sensitive for detecting proximal nonobstructive thrombi or calf DVT.^[150] IPG measures electrical impedance resulting from changes in blood volume within a limb. It involves the inflation of a thigh cuff to trap blood in the leg. In the absence of venous obstruction, rapid deflation of the cuff permits a rapid outflow of blood and is associated with a concomitant sudden increase in the electrical resistance of the limb.^[113] A more gradual increase in electrical resistance is observed when there is a partial or complete obstruction to venous outflow. IPG is 95 percent sensitive and 98 percent specific for the detection of proximal vein thrombi.^[151] In pregnancy, compression of the inferior vena cava by the gravid uterus can produce false-positive results despite position changes.^[152] Therefore, a positive IPG after 20 weeks of gestation requires confirmation by venography before initiating anticoagulant therapy.^[113]

Venous Duplex Doppler Ultrasound

Venous duplex Doppler ultrasound is a safe, simple, and inexpensive method to indirectly assess the competency of the deep venous system in the lower extremities. However, this technique is subjective and requires considerable expertise.^[149] A Doppler shift is recorded during changes in venous blood flow that occur within

patent vessels. Changes in venous blood flow can be augmented by compressing and releasing a vein, or by observing changes in flow with breathing or the Valsalva maneuver. An occluded vein will not produce a Doppler shift. Venous Doppler assessment has a sensitivity of 76 to 94 percent and a specificity of 90 to 95 percent for a proximal DVT, but has a low sensitivity for a calf DVT.^[148], ^[153] This technique is limited by an inability to distinguish thrombotic from nonthrombotic forms of venous occlusion. In one study, venous Doppler abnormalities occurred in 25 percent of pregnant patients who were scanned in the supine position.^[153] Therefore, the study should be performed with left lateral uterine displacement.

Real-time ultrasound is also useful for the diagnosis of a DVT.^[113] Criteria for diagnosis of a DVT by ultrasound includes an intraluminal soft tissue mass, non-compressibility of the vein, and a dampened or absent increase in diameter during a Valsalva maneuver.^[154] These criteria are useful only in the proximal veins (femoral and popliteal). In the proximal veins, the sensitivity of real-time B-mode ultrasonography has been reported to range from 94 to 100 percent with a 100 percent specificity.^[113]

When there is clinical suspicion of DVT, the diagnostic approach should be such that disease can be diagnosed while minimizing potentially harmful fetal irradiation. One approach to diagnosis is to use Doppler ultrasound as the initial diagnostic test. If the test is positive, anticoagulant therapy should be given. If the ultrasound is normal, the patient's symptoms may be due to a calf DVT, which may be undetected by ultrasound. Serial ultrasound testing may then be done to assess for progression of a calf DVT into the proximal veins.^[148] If repeat ultrasound identifies a newly formed proximal DVT, anticoagulation therapy should be initiated.

If isolated iliac vein thrombosis is suspected, Doppler ultrasound or IPG can be used for diagnosis. If IPG is available, this can be used as the initial test. If IPG is positive during the first or second trimester of pregnancy, then a DVT can be diagnosed and anticoagulation can be started.^[148] A positive test in the third trimester may be falsely positive because of outflow obstruction caused by the gravid uterus. In this circumstance, further investigation with a limited venogram should be considered and, if a DVT is seen, treatment can be started. If limited venogram does not demonstrate a thrombus, a complete venogram should be considered, given the possibility of proximal femoral vein thrombosis or isolated iliac DVT. If the initial IPG is negative and the pretest clinical likelihood of DVT is low or moderate, then serial IPG testing should be done over a 7- to 14-day period.^[148] If the repeat IPG becomes positive, then this can provide sufficient basis for diagnosing a DVT. If the initial IPG is negative and the pretest clinical likelihood for a DVT is high, a limited

TABLE 30-4 -- SIGNS AND SYMPTOMS OF PULMONARY EMBOLISM

Finding	Patients with Proven Pulmonary Embolism (%)
Tachypnea	89
Dyspnea	81

Apprehension	59
Cough	54
Tachycardia	43
Hemoptysis	34
Temperature >37°C	34

venogram or Doppler ultrasound should be performed.^[148] If either of these examinations is positive, therapy should be started.

Pulmonary Embolism

Pulmonary embolus (PE) contributes to significant maternal morbidity and mortality and, therefore, clinical suspicion should be high. Signs and symptoms may include dyspnea, tachypnea, cough, pleuritic chest pain, tachycardia, pleural friction rub, diaphoresis, cyanosis, hemoptysis, or a new murmur (Table 30-4). Of these, the most common sign is tachypnea.^[155] Any gravida presenting with signs and symptoms consistent with a pulmonary embolus requires further evaluation. An initial evaluation should include auscultation, pulse oximetry, and an arterial blood gas. Additional tests should include a chest radiograph and electrocardiogram. A Po₂ greater than 85 mm Hg on room air is reassuring; however, it does not rule out the possibility of a PE. As many as 14 percent of patients with a pulmonary embolus have a Po₂ greater than 85 mm Hg.^[155] Any patient with an oxygen saturation less than 95 percent on room air without obvious clinical conditions associated with hypoxia, such as atelectasis, pneumonia, or asthma, deserves an investigation. A chest radiograph is useful to rule out pneumonia and atelectasis; however, even the presence of an infiltrate does not rule out the possibility of PE and, again, investigation should be continued if clinical suspicion is high. The most frequent electrocardiographic finding is tachycardia; however, findings consistent with acute cor pulmonale (right axis shift and nonspecific T-wave inversions) may be seen after massive pulmonary embolism. If clinical suspicion for PE is moderate to high, the gravida should be anticoagulated while the diagnosis is pursued.

When pulmonary embolus is suspected, Doppler ultrasound or IPG may be performed to identify a DVT. If these tests are diagnostic for DVT, one can assume the patient does indeed have a pulmonary embolus and anticoagulation therapy should be instituted. If the diagnosis of DVT has not been established, ventilation-perfusion (V/Q) lung scanning should be performed. The perfusion scan is performed by injecting ^{99m}Tc-labeled albumin. These particles are aggregated within the pulmonary precapillary arteriolar bed. A ventilation scan using ¹³³Xe isotope is done after the perfusion scan to document ventilatory defects. The V/Q scans are then examined for matching defects. These scans are interpreted as normal, indeterminate, or revealing low, moderate, or high suspicion of pulmonary embolus. If there are abnormalities on the chest radiograph that coincide with areas of perfusion defect, the scan is considered indeterminate. When there is V/Q mismatching or multiple defects, the probability of pulmonary embolism is considered high.

When the Doppler examination is negative, the V/Q scan is low probability, and the clinical suspicion of PE is low as well, the test can be considered negative, and therapy need not be initiated. If the V/Q scan is indeterminate, low or moderately suspicious for PE, and clinical suspicion is high, a pulmonary arteriogram should be performed (Fig. 30-3). If a pulmonary arteriogram is diagnostic of PE, therapy should be instituted with heparin. If the V/Q scan is consistent with high probability, the patient can be considered as having a positive test for PE, and therapy should be instituted.

Pulmonary angiography is the definitive test for pulmonary embolism. Risks of the procedure are related to the catheterization and injection of contrast dye. The morbidity rate is reportedly between 4 and 5 percent, with a 0.2 to 0.3 percent mortality rate.^[113] The radiation dose to the fetus is low, and even when V/Q scanning is performed in addition to pulmonary angiography, the total radiation dose to the fetus is well below the lowest dose associated with any adverse fetal effect.^[156]

When pulmonary embolus is diagnosed, therapy should be initiated immediately. Heparin is the anticoagulant of choice during pregnancy. Because of its large molecular weight (6,000 to 20,000 Da), it does not cross the placenta and is not excreted in breast milk. Heparin must be given parenterally, and intravenous therapy achieves therapeutic levels most quickly. The initial loading dose should be 70 units/kg, administered intravenously, followed by a continuous infusion of 1,000 units/h. The dose of heparin should be adjusted to keep the activated partial thromboplastin time (aPTT) approximately twice normal or the heparin level at 0.2 to 0.4 units/ml. This therapy should be continued for approximately 10 days. The patient can then be switched to subcutaneous heparin at a dose sufficient to

Figure 30-3 Diagnostic algorithm using ventilation-perfusion lung scanning in the evaluation of the patient suspected of having pulmonary embolism. (Modified from Senior RM:

keep the aPTT about 1 ½ times normal and the heparin titer 0.1 to 0.2 units/ml. In general, a dose of 7,500 to 10,000 units of heparin administered every 8 to 12 hours will achieve therapeutic levels.^[157] This therapy should be continued throughout gestation because the risk of a recurrent thrombus remains high. Therefore, a DVT and/or PE should be treated with full anticoagulation for at least 3 to 6 months. Subsequently, both therapeutic and prophylactic regimens of heparin have been advocated until 6 to 12 weeks postpartum.^[158]

Hemorrhage is the major risk of heparin therapy. This occurs in approximately 4 percent of properly monitored nonsurgical patients receiving intravenous heparin.^[159] Osteoporosis and compression fractures can occur when heparin has been administered in doses greater than 15,000 units/day for more than 6 months.^[160] This side effect can be diminished by administration of adequate amounts of calcium and vitamin D and may be reversible following cessation of therapy.^[158] Thrombocytopenia can also complicate heparin therapy but occurs in only 3 percent of patients treated with porcine heparin.^[161] A platelet count should be obtained periodically during the first 3 weeks of therapy. Low-molecular-weight heparin has been used during gestation. Patients treated with low-molecular-weight heparin may be less likely to develop heparin-induced thrombocytopenia. Low-molecular-weight heparin has the advantage of only single daily dosing, but is 10 times more expensive than heparin therapy.^[162]

In the postpartum period, treatment can be switched to warfarin (Coumadin). This oral anticoagulant inhibits regeneration of active vitamin K in the liver. It has a molecular weight of 1,000 Da and does not cross the placenta (see Chapter 9). Its use is not recommended during pregnancy. However, in the postpartum period, it can be used for anticoagulation and does not enter breast milk in significant amounts. A starting dose of 5 mg/day for the first 2 days is followed by daily dosing adjusted to the international normalized ratio (INR) of 2.0 to 3.0. An overlap of 3 to 5 days with a therapeutic INR and aPTT is recommended. Warfarin is continued for approximately 3 months or indefinitely if risk factors are still present or if thromboembolism is recurrent.^[163]

Prophylaxis

Women with a previous venous thromboembolism have a 7 to 30 percent risk of recurrence during a subsequent pregnancy.^[164], ^[165] Heparin, given in a dose of 5,000 units subcutaneously twice daily has been shown to be effective for prevention of thromboembolic disease in the postoperative patient.^[166] This prophylaxis has been recommended for gravidas with a history of

thromboembolic phenomena; however, a recent report of 72 pregnant patients showed a 15 percent frequency of recurrent thromboembolism in patients receiving this prophylaxis, not significantly different from the 11.9 percent incidence in a control group. Therefore, the 5,000 units twice-daily dosing is considered to be inadequate, and it has been recommended that heparin prophylaxis during pregnancy be increased to 7,500 units every 12 hours, from 13 weeks of gestation, and 10,000 units every 12 hours from 30 weeks of gestation.^[167]

Gravidas with known hypercoagulable states will require some prophylaxis during pregnancy. AT-III deficiency should be treated with heparin throughout gestation. The best regimen has remained controversial. The therapeutic goal for patients with AT-III deficiency is a prolongation of the partial thromboplastin time (PTT) 5 to 10 seconds above baseline, just prior to the next injection.^[129] AT-III concentrate is now available in the United States and may be used to augment heparin therapy in the event of thrombosis and should be administered to gravidas with AT-III deficiency in labor.

If protein C deficiency is diagnosed, therapeutic subcutaneous heparin therapy to prolong the PTT to 1.5 to 2 times the control is recommended throughout gestation.^[168] However, others have recommended low-dose heparin prophylaxis of 7,500 units subcutaneously twice daily.^[169] Protein S deficiency is also associated with an increase of thromboembolic events during pregnancy and, therefore, heparin prophylaxis should be instituted once protein S deficiency is identified. For patients with protein S and protein C deficiencies, therapy should be switched to warfarin in the postpartum period.

Patients with recent pulmonary emboli or recurrent or recent iliofemoral thrombosis should continue to receive heparin intravenously during delivery. They should be converted to a regimen of continuous intravenous heparin and the dose should be adjusted to achieve a PTT of 1.5 times control during labor and delivery.^[158] Continuing this regimen does not increase the incidence of postpartum hemorrhage in a normal delivery. There is a slight increase in the incidence of an episiotomy hematoma. Heparin therapy may contribute to blood loss in patients with uterine atony or a retained placenta.^[158]

Alternative Therapy

Both streptokinase and urokinase produce rapid resolution of pulmonary emboli and improvement in pulmonary hemodynamics.^[159] There is very limited experience with the use of these agents during pregnancy,^[170], ^[171] and they should be reserved for circumstances of significant hemodynamic instability in a patient with pulmonary embolus.^[158] Postpartum hemorrhage from the placental site may be a risk when fibrinolytic agents are used during pregnancy. When pulmonary embolus is recurrent despite adequate anticoagulation, vena caval interruption is indicated. Caval interruption via ligation, plication, or insertion of an umbrella can be safely carried out during pregnancy.^[172], ^[173]

RESTRICTIVE LUNG DISEASE

Restrictive ventilatory defects occur when lung expansion is limited because of alterations in the lung parenchyma or because of abnormalities in the pleura, chest wall, or the neuromuscular apparatus.^[174] These conditions are characterized by a reduction in lung volumes and an increase in the ratio of FEV₁ to forced vital capacity (FVC).^[175] The interstitial lung diseases include idiopathic pulmonary fibrosis, sarcoidosis, hypersensitivity pneumonitis, pneumoniosis, drug-induced lung disease, and connective tissue disease. Additional conditions that cause a restrictive ventilatory defect include pleural and chest wall diseases, and extrathoracic conditions such as obesity, peritonitis, and ascites.^[175] Restrictive lung disease in pregnancy has not been well studied. Consequently, little is known about the effects of restrictive lung disease on the outcome of pregnancy or the effects of pregnancy on the disease process itself. A recent study presented data on nine pregnant women who were prospectively managed with interstitial and restrictive lung disease.^[176] Diagnoses included idiopathic pulmonary fibrosis, hypersensitivity pneumonitis, sarcoidosis, kyphoscoliosis, and multiple pulmonary emboli. Three of the gravidas presented in this paper had severe disease characterized by a vital capacity of 1.5 L or less (50 percent predicted) or a diffusing capacity less than or equal to 50 percent predicted. Five of the patients had exercise-induced oxygen desaturation, and four patients required supplemental oxygen. Of the group, one patient had an adverse outcome and was delivered at 31 weeks. She subsequently required mechanical ventilation for 72 hours. All other patients were delivered at or beyond 36 weeks with no adverse intrapartum or postpartum complications. All babies were at or above the 30th percentile for growth.^[176] The authors concluded that restrictive lung disease was well tolerated in pregnancy. However, exercise intolerance was common, and patients may require early oxygen supplementations.^[176]

Sarcoidosis

Sarcoidosis is a systemic granulomatosis disease of undetermined etiology that often affects young adults. Pregnancy outcome for the majority of patients with

sarcoidosis is good.^[177],^[178] In another study, 35 pregnancies in 18 patients with sarcoidosis were evaluated retrospectively.^[177] In nine patients, there was no effect of the disease process during pregnancy; in six patients, improvement was demonstrated, and in three there was a worsening of the disease. During the postpartum period, no relapse was noted in 15 patients; however, in three women, a progression of the disease continued. Another retrospective study presented 15 pregnancies complicated by maternal sarcoidosis over a 10-year period.^[178] Eleven of these patients remained stable, two experienced disease progression, and two died due to severe complications of severe sarcoidosis. In this group, factors indicating a poor prognosis reportedly included parenchymal lesions on chest radiograph, advanced radiographic staging, advanced maternal age, low inflammatory activity, requirement for drugs other than steroids, and the presence of extrapulmonary sarcoidosis.^[178] Both of the patients who succumbed during gestation had severe disease at the onset of pregnancy. The overall cesarean section rate was 40 percent and, in addition, 4 of 15 infants (27 percent) weighed under 2,500 g. None of the patients developed preeclampsia. One possible explanation for the commonly observed improvement in sarcoidosis may be the increased concentration of circulating corticosteroids during pregnancy. However, because sarcoidosis improves spontaneously in many nonpregnant patients, the improvement may be coincident with but not due to pregnancy.

Maycock et al. reported on 16 pregnancies in 10 patients with sarcoidosis.^[179] Eight of the 10 patients showed improvement in at least some of the manifestations of sarcoidosis during the antepartum period. In two patients, no effect was noted. A recurrence of the abnormal findings was observed in the postpartum period within several months after delivery in approximately half of the patients. In addition, some had new manifestations of sarcoidosis not previously noted. Another study examined 17 pregnancies in 10 patients and concluded that pregnancy had no consistent effect on the course of the disease.^[180] Scadding separated patients into three categories based on characteristic patterns of their chest radiographs. When the chest radiograph had resolved before pregnancy, the normal radiograph persisted throughout gestation. In women with resolving radiographic changes before pregnancy, resolution continued throughout the prenatal period. Patients with inactive fibrotic residual disease had stable chest radiographs and those with active disease tended to have partial or complete resolution of those changes during pregnancy. Most patients in this later group, however, experienced exacerbation of the disease within 3 to 6 months after delivery.^[181]

Patients with pulmonary hypertension complicating restrictive lung disease may suffer a mortality of as much as 50 percent during gestation. These patients need close monitoring during the labor, delivery, and postpartum period. Invasive monitoring with a pulmonary artery catheter may be indicated to optimize cardiorespiratory function. Gravidas with restrictive lung disease including pulmonary sarcoidosis may benefit from early institution of steroid therapy for evidence of worsening pulmonary status. Individuals with evidence of severe disease will need close monitoring and may require supplemental oxygen therapy during gestation as well.

During labor, consideration should be given to early use of epidural anesthesia if not contraindicated. The early institution of pain management in this population will minimize pain, decrease sympathetic response, and therefore decrease oxygen consumption during labor and delivery. The use of general anesthesia should be avoided if possible, as these patients may develop pulmonary complications after general anesthesia including pneumonia and difficulty weaning from the ventilator. In addition, close fetal surveillance throughout gestation is indicated, as impaired oxygenation may lead to impaired fetal growth and the development of fetal heart rate abnormalities during labor and delivery.

An additional consideration is the need to counsel all women with restrictive lung disease about the potential for continued impairment of their respiratory status during pregnancy, particularly if their respiratory status is deteriorating when they conceive. Certainly, the individual with clinical signs consistent with pulmonary hypertension and/or severe restrictive disease should be cautioned about the possibility of maternal mortality resulting from worsening pulmonary function during gestation.

In summary, although the literature on restrictive lung disease in pregnancy is limited, it supports the conclusion that the majority of patients with restrictive lung disease complicating pregnancy including those with pulmonary sarcoidosis will have a favorable pregnancy outcome. However, the clinician should keep in mind that patients with restrictive lung disease can have worsening of their clinical condition and may succumb during gestation.

CYSTIC FIBROSIS

Cystic fibrosis involves the exocrine glands and epithelial tissues of the pancreas, sweat glands, and mucous glands in the respiratory, digestive, and reproductive tracts. Chronic obstructive pulmonary disease, pancreatic exocrine insufficiency, and elevated sweat electrolytes are present in most patients with cystic fibrosis. ^[182] The disease is genetically transmitted with an autosomal

1055

recessive pattern of inheritance. The cystic fibrosis gene was identified and cloned in 1989. The gene is localized to chromosome 7, and the molecular defect accounting for the majority of cases has been identified. ^[183] ^[184] ^[185] In the United States, approximately 4 percent of the Caucasian population are heterozygous carriers of the cystic fibrosis gene. The disease occurs in 1 in 3,000 live Caucasian births. ^[186] Morbidity and mortality in cystic fibrosis is usually secondary to progressive chronic bronchial pulmonary disease. Pregnancy and the attendant physiologic changes can stress the pulmonary, cardiovascular, and nutritional status of women with cystic fibrosis. The purpose of this section is to familiarize the obstetrician/gynecologist with the physiologic effects of this complex disease and the impact of the disease on pregnancy and the impact of pregnancy on the disease. Additional factors that need to be addressed are the genetics of this disorder and the implications for the newborn, as well as social issues including who will raise the child should the mother succumb to her disease.

Survival for patients with cystic fibrosis has increased dramatically since 1940. According to the Cystic Fibrosis Foundation's Patient Registry, survival in 1992 had increased to 29.6 years. ^[182] Females had a slightly lower median age of survival (27.3 years) as compared with males (29.6 years). The reasons for sex differences in mortality are unclear. This increase in survival of patients with cystic fibrosis is likely secondary to earlier diagnosis and intervention and also to advances in antibiotic therapy and nutritional support. Therefore, more women with cystic fibrosis are entering reproductive age. In contrast to males with cystic fibrosis who, for the most part are infertile, women with cystic fibrosis are more often fertile. Infertility in women with cystic fibrosis may occasionally be due to anovulatory cycles and secondary amenorrhea, which result from significant malnutrition, associated with advanced disease. A more common reason for infertility appears to result from alteration in the physiologic properties of cervical mucus. ^[187]

The first case of cystic fibrosis complicating pregnancy was reported in 1960, and a total of 13 pregnancies in 10 patients with cystic fibrosis were reported in 1966. ^[188] ^[189] Cohen conducted a survey of 119 cystic fibrosis centers in the United States and Canada and identified a total of 129 pregnancies in 100 women by 1976. ^[190] Hillman surveyed 127 cystic fibrosis centers in the United States, between 1976 and 1982. ^[182] A total of 191 pregnancies were reported during this period in women with cystic fibrosis, ranging in age from 16 to 36 years, with a mean age of 22.6 years. ^[182] The annual number of cystic fibrosis pregnancies reported to the Cystic Fibrosis Foundation's Patient Registry doubled between 1986 and 1990, with 52 pregnancies reported in 1986, compared with 111 pregnancies reported in 1990. Because the number of women with cystic fibrosis achieving pregnancy is steadily increasing, it is imperative that the obstetrician be familiar with the disease.

The Effect of Pregnancy on Cystic Fibrosis

The physiologic changes associated with pregnancy (see Chapter 3) are well tolerated by healthy gravidas; however, those with cystic fibrosis may adapt poorly. During pregnancy, there is an increase in resting minute ventilation that at term may approach 150 percent of control values. ^[191] This increase in minute ventilation occurs secondary to the increased oxygen consumption and increased carbon dioxide burden that occur during pregnancy. An additional impact occurs secondary to circulating progesterone, which stimulates the respiratory drive. Enlargement of the abdominal contents and upward displacement of the diaphragm leads to a decrease in functional residual volume and a decrease in residual volume. ^[191] Pregnancy is also accompanied by subtle alterations in gas exchange with widening of the alveolararterial oxygen gradient that is most pronounced in the supine position. ^[191] These alterations in pulmonary function are of little consequence in the normal pregnant woman. However, in the gravida with cystic fibrosis, these changes may contribute to respiratory decompensation that can lead to increase in morbidity and mortality for the mother and the fetus as well.

During normal pregnancy, blood volume increases by an average of 50 percent. Cardiac output increases as well, reaching a plateau in midpregnancy. ^[192] During labor, blood volume rises acutely, in large part due to the release of blood from the contracting uterus and is additionally increased after delivery, secondary to augmented venous return with the release of caval obstruction. Women with cystic fibrosis and advanced lung disease may suffer from pulmonary hypertension with high pulmonary artery pressures. Whatever the cause, pulmonary hypertension is associated with unacceptable maternal risk during pregnancy and is considered to be a contraindication to pregnancy. ^[192] Women with significant pulmonary hypertension may develop cardiovascular collapse at the time of labor and delivery, with a maternal mortality exceeding 25 percent. ^[193] Additionally, patients with pulmonary hypertension may not be able to adequately increase cardiac output during pregnancy and, therefore, suffer uteroplacental insufficiency, leading to intrauterine growth restriction and stillbirth. ^[186]

Nutritional requirements are increased during pregnancy, with approximately 300 kcal/day in additional fuel being needed to meet the requirements of mother and fetus. ^[194] Most patients with cystic fibrosis have

1056

pancreatic exocrine insufficiency. As a result, digestive enzymes and bicarbonate ions are diminished, resulting in maldigestion, malabsorption, and malnutrition. ^[194]

The 1966 report by Grand et al. included 13 pregnancies in 10 women with cystic fibrosis. Of these, five women had a progressive decline in their pulmonary function, two of whom died of cor pulmonale in the immediate postpartum period. In another report, pregnancy was well tolerated in 5 of 10 women, two of whom went on to have subsequent pregnancies that were similarly well tolerated. ^[189] In this study, the pregravid pulmonary status of the patient was the most important predictor of outcome. However, there was no quantification of pulmonary function. A case report by Novy and colleagues in 1967 described in detail the pulmonary function and gas exchange in a pregnant woman with cystic fibrosis. ^[195] The patient had severe disease as evidenced by a vital capacity of only 0.72 L and an arterial P_{O₂} of 50 mm Hg at presentation. The patient suffered a progressive increase in residual volume and decline in vital capacity that was accompanied by worsening hypoxemia and hypercapnea, resulting in respiratory distress and right-sided heart failure in the early postpartum period. ^[195] Based on the experience with this patient and a review of the literature, the authors recommended therapeutic abortion in any patient demonstrating progressive pulmonary deterioration and hypoxemia despite maximal medical management. ^[195] In 1980, Cohen et al. described 100 patients and a total of 129 pregnancies. ^[190] Ninety-seven of 129 (75 percent) pregnancies were completed, and 89 percent delivered viable infants. Twenty-seven percent of these fetuses were delivered preterm. There were 11 perinatal deaths and no congenital anomalies. In this study, 65 percent of patients required antibiotic therapy prior to delivery. In 1983, Palmer et al. retrospectively reviewed the prepregnancy status of eight women with cystic fibrosis who subsequently completed 11 pregnancies. ^[196] She found that five women tolerated pregnancy without difficulty, but three had irreversible deterioration in their clinical status. She identified four maternal factors that were predictive of outcome: clinical status (Shwachman score), nutritional status (percentage of predicted weight for height), the extent of chest radiographic abnormalities (assessed by the Brasfield chest radiograph score), and the

magnitude of pulmonary function impairment. Women with good clinical studies, good nutritional status (within 15 percent of their predicted ideal body weight for height), with nearly normal chest radiographs and only mild obstructive lung disease tolerated pregnancy well without deterioration. ^[196]

There are several reports suggesting that patients with mild cystic fibrosis, good nutritional status, and less impairment of lung function tolerate pregnancy well. However, those with poor clinical status, malnutrition, hepatic dysfunction, and/or advanced lung disease are at increased risk from pregnancy. ^[197] ^[198] ^[199] Kent and Farquharson reviewed the literature and reported 217 pregnancies. ^[199] In this series, the frequency of preterm delivery was 24.3 percent, and the perinatal death rate was 7.9 percent. Poor outcomes were associated with a maternal weight gain of less than 4.5 kg and an FVC of less than 50 percent of that predicted. Edenborough et al. also reported on pregnancies in women with cystic fibrosis. ^[200] There were 18 live births (81.8 percent), one third of which were preterm deliveries, and 18.2 percent of patients had abortions. There were four maternal deaths within 3.2 years after delivery. In this series, lung function was available before delivery, immediately after delivery, and after pregnancy. They demonstrated a decline of 13 percent in FEV₁, and 11 percent in FVC during pregnancy. Most patients returned to baseline pulmonary function after pregnancy. While most of the women in this series tolerated pregnancy well, those with moderate to severe lung disease, an FEV₁ of less than 60 percent of predicted, more often had preterm infants and had increased loss of lung function compared to those with milder disease. ^[200] In two series, prepregnancy FEV₁ was found to be the most useful predictor of outcome in pregnant women with cystic fibrosis. ^[200] ^[201] In addition, there was also a positive correlation of prepregnancy FEV₁ and maternal survival.

Pulmonary involvement in cystic fibrosis includes chronic infection of the airways and bronchiectasis. There is selective infection with certain microorganisms, such as *Staphylococcus aureus*, *Haemophilus influenzae*, *Pseudomonas aeruginosa*, and *Berkholderia cepacia*. *Pseudomonas aeruginosa* is the most frequent pathogen. ^[182] Parenteral antibiotics are the mainstays of treatment of these acute infections. However, pregnancy and cystic fibrosis-associated alterations in pharmacokinetics can have grave consequences for these patients. It is well known that pregnant subjects have lower serum levels and higher urine levels of antibiotics than nonpregnant subjects. The lower levels in plasma are attributed to the increase in volume of distribution and an increase in glomerular filtration and renal clearance of the drugs. ^[202] Cloxacillin, dicloxacillin, ticarcillin, and methicillin are cleared more rapidly in patients with cystic fibrosis. ^[203] ^[204] ^[205] Plasma ceftazidime and gentamicin levels are likewise decreased in patients with cystic fibrosis. ^[206] ^[207]

Counseling Patients with Cystic Fibrosis in Pregnancy

There are several factors that must be considered when counseling a woman who has cystic fibrosis and is considering pregnancy, including the possibility that her fetus will have cystic fibrosis (see Chapter 8). Approximately

1057

4 percent of the Caucasian population in the United States are heterozygous carriers of the cystic fibrosis gene. The disease occurs in 1 in 3,000 Caucasian births. When the mother has cystic fibrosis and the proposed father is a Caucasian of unknown genotype, the risk of the fetus having cystic fibrosis is 1 in 50, as compared with 1 in 3,000 in the general Caucasian population. If the prospective father is a known carrier of a cystic fibrosis mutation, the risk to the fetus increases to 1 in 2. If, however, DNA testing does not identify a cystic fibrosis mutation in the prospective father, it is still possible that the father is a carrier of an unidentified cystic fibrosis mutation, making the risk to the offspring 1 in 492. ^[208]

It is important that the woman with cystic fibrosis be advised about the potential adverse effects of pregnancy on maternal health status. Factors that may predict poor outcome include prepregnancy evidence of poor nutritional status, significant pulmonary disease with hypoxemia, and pulmonary hypertension. Liver disease and diabetes mellitus are also poor prognostic factors. Gravida with poor nutritional status, pulmonary hypertension (cor pulmonale), and deteriorating pulmonary function early in gestation should consider therapeutic abortion, as the risk of maternal mortality may be unacceptably high.

The woman with cystic fibrosis who is considering pregnancy should also give consideration to the need for strong psychosocial and physical support after delivery. The rigors of child-rearing may add to the risk of maternal deterioration during this period. Her family should also be willing to provide physical and emotional support, and should be aware of the potential for deterioration in the mother's health and the potential for maternal mortality. In addition, the need for care of a potentially preterm growth-restricted neonate with all of its attendant morbidities and potential mortality should be discussed. Long-term, the woman and her family should also consider the fact that her life expectancy may be shortened by cystic fibrosis, and plans should be made for rearing of the child in the event of maternal death.

Management of the Pregnancy Complicated by Cystic Fibrosis

Care of the gravida with cystic fibrosis should be a coordinated, team effort. Physicians familiar with cystic fibrosis, its complications, and management should be included, as well as a maternalfetal medicine specialist and neonatal team. The gravida should be assessed for potential risk factors such as severe lung disease, pulmonary hypertension, poor nutritional status, pancreatic failure, and liver disease, preferably prior to attempting gestation, but certainly during the early months of pregnancy. Gravida should be advised to be 90 percent of ideal body weight prior to conception if possible. A weight gain of 11 to 12 kg is recommended. ^[182] Frequent monitoring of weight, blood glucose, hemoglobin, total protein, serum albumin, prothrombin time, and fat-soluble vitamins A and E is suggested. ^[182] At each visit, the history of caloric intake and symptoms of maldigestion and malabsorption should be taken, and pancreatic enzymes should be adjusted if needed. Patients who are unable to achieve adequate weight gain through oral nutritional supplements may be given nocturnal enteral nasogastric tube feeding. In this situation, the risk of aspiration should be considered, especially in patients with a history of gastroesophageal reflux, which is common in cystic fibrosis. ^[182] If malnutrition is severe, parenteral hyperalimentation may be necessary for successful completion of the pregnancy. ^[209] Baseline pulmonary function should be assessed, preferably prior to conception. Assessment should include FVC, FEV₁, lung volumes, pulse oximetry, and arterial blood gases if indicated. These values should be serially monitored during gestation and deterioration in pulmonary function addressed immediately. An echocardiogram can assess the patient for pulmonary hypertension and cor pulmonale. If pulmonary hypertension (cor pulmonale) is diagnosed, the gravida should be advised of the high maternal risk.

Early recognition and prompt treatment of pulmonary infections are important in the management of the pregnant woman with cystic fibrosis. Treatment includes intravenous antibiotics in the appropriate dose, keeping in mind the increased clearance of these drugs secondary to pregnancy and cystic fibrosis. Plasma levels of aminoglycosides should be monitored and adjusted as indicated. Chest physical therapy and bronchial drainage are also important components of the management of pulmonary infections in cystic fibrosis. Because *Pseudomonas aeruginosa* is the most frequently isolated bacteria associated with chronic endobronchitis and bronchiectasis, antibiotic regimens should include coverage for this organism.

If the patient with cystic fibrosis has pancreatic insufficiency and diabetes mellitus, careful monitoring of blood glucose and insulin therapy are indicated. As previously mentioned, pancreatic enzymes may need to be replaced in order to optimize the patient's nutritional status. Because of malabsorption of fats and frequent use of antibiotics, the cystic fibrosis patient is prone to vitamin K deficiency. Therefore, prothrombin time should be checked regularly, and parenteral vitamin K should be administered if the prothrombin time is elevated.

It is imperative when managing pregnancy in a woman with cystic fibrosis to recognize that the fetus is at risk for uteroplacental insufficiency and intrauterine growth restriction. The maternal nutritional status and

1058

weight gain during pregnancy will likewise impact fetal growth. Therefore, fundal height should be measured routinely, and serial ultrasound evaluations of fetal growth and amniotic fluid volume should be made. Maternal kick counts may be useful for monitoring fetal status starting at 28 weeks. Nonstress testing should be started at 32 weeks or sooner, if there is evidence of fetal compromise. If there is evidence of severe fetal compromise such as no interval fetal growth, persistent decelerations, or poor biophysical profile scoring, delivery should be accomplished. Likewise, evidence of profound maternal deterioration such as a marked and sustained decline in pulmonary function, development of right-sided heart failure, refractory hypoxemia, and progressive hypercapnea and respiratory acidosis may be maternal indications for early delivery. If the fetus is potentially viable, the administration of betamethasone may be beneficial. Vaginal delivery should be attempted when possible.

Labor, delivery, and the postpartum period can be particularly dangerous for the patient with cystic fibrosis. The augmentation in cardiac output stresses the cardiovascular system and can lead to cardiopulmonary failure in the patient with pulmonary hypertension and cor pulmonale. These patients are also more likely to

develop right-sided heart failure. Heart failure should be treated with aggressive diuresis and supplemental oxygen. Management may be optimized by insertion of a pulmonary artery catheter to monitor right- and left-sided filling pressures. Pain control will reduce the sympathetic response to labor and tachycardia. This will benefit the patient who is demonstrating pulmonary or cardiac compromise. In the patient with a normal PTT, insertion of an epidural catheter for continuous epidural analgesia may be beneficial. This is also useful in the event a cesarean delivery is indicated, as general anesthesia and its possible effects on pulmonary function can be avoided. If general anesthesia is needed, preoperative anticholinergic agents should be avoided because they tend to promote drying and inspissation of airway secretions. Close fetal surveillance is also extremely important, as the fetus who may have been suffering from uteroplacental insufficiency during gestation will be more prone to develop evidence of fetal compromise during labor. Delivery by cesarean section should be reserved for the usual obstetric indications.

In summary, more women with cystic fibrosis are living to childbearing age and are capable of conceiving. Clinical experience thus far has demonstrated that pregnancy in women with cystic fibrosis and mild disease is well tolerated. Women with severe disease have an associated increase in maternal and fetal morbidity and mortality. The potential risk to any individual with cystic fibrosis desirous of pregnancy should be assessed and discussed with the patient and her family in detail.

Key Points

Pneumonia is the most common nonobstetric infection to cause maternal mortality. Preterm delivery complicates pneumonia in up to 43 percent of cases.

Streptococcus pneumoniae is the most common bacterial pathogen to cause pneumonia. Empiric antibiotic coverage should be started, including a third-generation cephalosporin and a macrolide, such as azithromycin, to cover atypical pathogens.

High-risk gravidas should be screened for tuberculosis and treated appropriately with INH prophylaxis for infection without overt disease and with dual antituberculosis therapy for active disease. If resistant tuberculosis is identified, ethambutol 2.5 g/day should be added to therapy and the treatment period should be extended to 18 months.

Asthma is characterized by chronic airway inflammation with increased airway responsiveness to a variety of stimuli and airway obstruction that is partially or completely reversible. Patients with severe asthma have the greatest risk for complications during pregnancy. Complications include preeclampsia, asthma exacerbation, preterm rupture of the membranes, increased perinatal mortality, prematurity, and low birth weight. Therapy should include education, bronchodilators, and the addition of inhaled steroids.

Asthma medications should be continued during labor and delivery. PEFr should be measured on admission and at 12-hour intervals. If systemic corticosteroids have been used in the previous 4 weeks, hydrocortisone (100 mg every 8 hours) should be administered during labor and for the 24-hour period following delivery to prevent adrenal crisis.

Thromboembolic disease is the leading cause of pregnancy-related mortality in the United States. An untreated deep vein thrombosis (DVT) is associated with a 15 to 25 percent incidence of pulmonary embolus with a 12 to 15 percent mortality rate. Pregnancy is accompanied by a hypercoagulable state. Hypercoagulable conditions, such as AT-III deficiency, prothrombin 20210A allele, protein C deficiency, protein S deficiency, factor V Leiden, dysfibrinogenemia, hyperhomocysteinemia, and the antiphospholipid syndrome may increase the risk of deep vein thrombosis and pulmonary embolus.

1059

Investigation for deep vein thrombosis in pregnancy should include impedance plethysmography, venous Doppler ultrasound, real-time ultrasound, and venography. ¹²⁵I fibrinogen scanning should be avoided during pregnancy because of high levels of fetal radiation exposure and concentration of the radiolabeled iodine in the fetal thyroid.

A high index of suspicion for pulmonary embolus is necessary. Diagnosis should be undertaken with venous Doppler ultrasound of the extremities to identify a DVT and V/Q scanning and pulmonary arteriography if indicated.

Therapy for thrombosis and pulmonary embolus in pregnancy should be accomplished with heparin. Coumadin may be used in the postpartum period. The aPTT and/or INR should be monitored closely.

The interstitial lung diseases include idiopathic pulmonary fibrosis, sarcoidosis, hypersensitivity pneumonitis, pneumonosis, drug-induced lung disease, and connective tissue disease. Restrictive lung disease is generally well tolerated in pregnancy; however, exercise intolerance and need for oxygen supplementation may develop. Gravidas with pulmonary hypertension complicating restrictive lung disease may suffer a high mortality.

An increasing number of women with cystic fibrosis are surviving to the reproductive years and usually maintain their fertility with meticulous management of pulmonary function, including pulmonary toilet and aggressive surveillance for signs of pulmonary infection and treatment of antibiotics in adequate doses. Close attention to nutrition is required secondary to maldigestion, malabsorption, and malnutrition, which can complicate cystic fibrosis. Gravidas with good clinical studies, good nutritional status, nearly normal chest radiographs, and only mild obstructive lung disease will tolerate pregnancy well. Fetal growth should be monitored closely.

Chapter 31 - Renal Disease

Philip Samuels
David F. Colombo

Of all the organ systems in the human body, one could argue that none are altered more in pregnancy than the kidney and urinary collecting system. Prior to the 1970s, patients with preexisting renal disease were strongly discouraged from even attempting pregnancy secondary to the expectation of increased perinatal morbidity and mortality and the likelihood of progression of renal disease. Currently, through our better understanding of renal disease in pregnancy, most of these women can look forward to a good outcome. This holds true even for women who have undergone a renal transplant.

This chapter discusses the normal changes in the kidney and urinary collecting system in pregnancy, the basic evaluation of renal status, acute and chronic renal disorders in pregnancy, and the treatment of the renal transplant patient.

ALTERED RENAL PHYSIOLOGY IN PREGNANCY

Pregnancy is associated with significant anatomic changes in the kidney and its collecting system (see Chapter 3). These changes begin to occur shortly after conception and may persist for several months postpartum.^[1], ^[2] The kidney itself is noted to increase in size and weight during the course of a pregnancy. Of more clinical significance is the marked dilatation of the collecting system including both the renal pelvis and ureters. This dilatation is most often greater on the right than on the left (Fig. 31-1). Etiologies for this change include hormonal changes (i.e., progesterone, endothelin, relaxin) and mechanical obstruction by the uterus itself.^[3]
^[4] ^[5]

Renal plasma flow (RPF) increases greatly during pregnancy.^[6] It peaks in the first trimester and, although it decreases near term, remains higher than in the nonpregnant patient. This change is due in part to increased cardiac output and decreased renal vascular resistance. The glomerular filtration rate (GFR) increases by 50 percent during a normal gestation.^[7] It rises early in pregnancy and remains elevated through delivery. The percentage increase in GFR is greater than the percentage increase in RPF. This elevation of the filtration fraction leads to a fall in the blood urea nitrogen (BUN) and serum creatinine values.

Because GFR increases to such a great degree, electrolytes, glucose, and other filtered substances reach the renal tubules in greater amounts. The kidney handles sodium efficiently, reabsorbing most of the filtered load in the proximal convoluted tubule. Glucose reabsorption, however, does not increase proportionately during pregnancy. The average renal threshold for glucose is reduced to 155 mg/dl from 194 mg/dl in the nonpregnant individual.^[8] Therefore, glycosuria can be seen in the normal gravida.

Urate is handled by filtration and secretion. Its clearance increases early in pregnancy, leading to lower serum levels of uric acid. In late pregnancy, urate clearance and serum urate levels return to their prepregnancy values. Serum urate levels are elevated in patients with preeclampsia. Whether this is due to decreased RPF, hemoconcentration, renal tubular dysfunction, or other renal circulatory changes remains uncertain. A summary of the renal changes in normal pregnancy is shown in [Table 31-1](#).^[9]

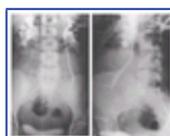

Figure 31-1 A, An intravenous pyelogram of a gravid patient presenting in late second trimester with flank pain. The image was taken in the anteroposterior view 15 minutes after the instillation of contrast dye. Note the dilatation of the renal pelvises bilaterally, with the right side more dilated than the left. The fetus is seen in the vertex position. B, The same patient in the right lateral view.

TABLE 31-1 -- SUMMARY OF RENAL CHANGES IN NORMAL PREGNANCY

Alteration	Manifestation	Clinical Relevance
Increased renal size	Renal length about 1 cm greater on radiographs.	Postpartum decreases in size should not be mistaken for parenchymal loss.
Dilatation of pelvis, calyces, and ureters	Resembles hydronephrosis on ultrasound or IVP (usually more prominent on the right).	Not to be mistaken for obstructive uropathy.
Changes in acid-base metabolism	Renal bicarbonate reabsorption threshold decreases.	Upper urinary tract infections are more virulent.
		Serum bicarbonate is 45 mM/L lower in pregnancy. P_{CO_2} is 10 mm Hg lower in normal pregnancy. P_{CO_2} of 40 mm Hg actually represents retention in pregnancy.
Renal water-handling	Osmoregulation altered as the osmotic thresholds for AVP release decreased.	Serum osmolarity decreased by approximately 10 mOsm/L.

IVP, intravenous pyelography; AVP, vasopressin; P_{CO_2} , carbon dioxide tension. Adapted from Lindheimer M, Grünfeld JP, Davison JM: Renal disorders. In Barron WM, Lindheimer M (eds): Medical Disorders During Pregnancy. St. Louis, Mosby, 2000, p 39.

EVALUATION OF RENAL STATUS

As in the nonpregnant population, the evaluation of the urine can give critical insights as to the function of the kidney as well as the presence of urinary tract infection. The most frequently utilized method to evaluate the urine is the spot *urinalysis*. With the exception of the glucose, the study can be utilized as it would in the nonpregnant patient. It is, however, only a screening tool. If there is a concern that a patient has a change in her renal status or the possibility of bacteruria, further testing is needed.

One of the best methods to evaluate kidney function is collection of a *24-hour urine sample* for total protein analysis. The nonpregnant patient will usually spill less than 150 mg/day of protein. Most investigators consider up to 260 mg/day of total urinary protein and 29 mg/day of albumin normal in the gravid patient. ^[19] It should be noted that when one is using serial 24-hour urine samples to evaluate a change in renal status, it is crucial that the collection is standardized. The best method of comparing two urine collections is to evaluate the total amount of creatinine excreted in the 24-hour period. The amount a creatinine cleared in a day should remain constant during the course of a pregnancy for a given patient. If there is a large discrepancy in total creatinine between two samples, the difference in protein measured should be suspect. Another factor that must be considered is postural proteinuria. A patient may have an elevation in her urinary protein when ambulatory that resolves once the patient is recumbent.

Urinalysis has also been used to screen bacteruria. A recent study by McNair et al. ^[20] compared urinalysis to urine culture in the diagnosis of asymptomatic bacteriuria. They found that urinalysis has a sensitivity of 80.6 percent with a specificity of 71.5 percent. Given the false-negative rate of 19.4 percent in their population and the significant morbidity of undiagnosed bacteriuria, it was their recommendation that a urine culture be used as the primary method of screening all pregnant patients.

INFECTION OF THE URINARY TRACT ([SEE CHAPTER 40](#))

Asymptomatic Bacteriuria

Asymptomatic bacteriuria has been associated with multiple complications in pregnancy including low birth weight, preterm delivery, hypertension, preeclampsia, and maternal anemia.^[12], ^[13] The diagnosis of asymptomatic bacteriuria (ASB) is based on a clean-catch voided urine culture revealing greater than 100,000 colonies/ml of a single organism.^[14] Some investigators have suggested that two consecutively voided specimens should contain the same organism before making the diagnosis of bacteriuria.^[15], ^[16] Between 1.2 and 5 percent of young girls will demonstrate ASB at some time before puberty.^[17] After puberty, with the onset of sexual activity, the prevalence of ASB may increase to 10 percent.^[17] Of women with ASB, approximately 35 percent have bacteria arising from the kidneys rather than from the lower urinary tract.

It is important to diagnose and treat ASB in pregnancy. Left untreated, a symptomatic urinary tract infection (UTI) will develop in up to 40 percent of these patients.^[18], ^[19] Recognition and therapy for ASB can eliminate 70 percent of acute UTIs in pregnancy. Nonetheless, 2 percent of pregnant women with negative urine cultures develop symptomatic cystitis or pyelonephritis. This group accounts for 30 percent of the cases of acute UTI that develop during gestation. We advocate screening of all women for ASB at their first prenatal visit.

Escherichia coli is the organism responsible for most cases of ASB. Patients can therefore be safely treated with nitrofurantoin, ampicillin, cephalosporins, and short-acting sulfa drugs (see the box "Antimicrobial Treatment for the Pregnant Patient with Bacteriuria.") Sulfa compounds should be avoided near term, as they compete for bilirubin-binding sites on albumin in the fetus and newborn and could cause kernicterus. Nitrofurantoin should not be used in patients with glucose-6-phosphate dehydrogenase deficiency, as there is a risk for hemolytic crisis. If the fetus has this enzyme deficiency, it may also experience hemolysis. Therapy for ASB should be continued for 3 to 7 days. The patient should have another culture performed 1 to 2 weeks after discontinuing therapy. Approximately 15 percent

1068

of patients will experience a reinfection and/or will not respond to initial therapy. Therapy should be reinstated after careful microbial sensitivity testing. Patients with recurrent UTI during pregnancy and those with a history of pyelonephritis should undergo radiographic evaluation of the upper urinary tract. This procedure should be delayed until the patient is 3 months postpartum so that the anatomic and physiologic changes of pregnancy can regress. Of women in the above categories, 20 percent will show a structural abnormality, but most will be insignificant.

Antimicrobial Treatment for the Pregnant Patient with Bacteriuria

Amoxicillin 500 mg three times a day
 Ampicillin 250 mg four times a day
 Cephalosporin 250 mg four times a day
 Nitrofurantoin 100 mg four times a day
 Sustained release nitrofurantoin 100 mg two times a day
 Trimethoprim (160 mg)/sulfamethoxazole (800 mg) two times a day

The agent of choice should be given for a 3- to 7-day course. A repeat urine culture is recommended 2 weeks after the treatment has been completed.

Pyelonephritis

Occurring in approximately 1 to 2 percent of all pregnancies, pyelonephritis is an important source of maternal morbidity. Pyelonephritis is the most common non-obstetric cause of hospitalization during pregnancy.^[20] Recurrent pyelonephritis has been implicated as a cause of fetal death and intrauterine growth restriction (IUGR). There appears to be an association between acute pyelonephritis and preterm labor.^[21], ^[22] Fan and coworkers,^[23] however, have shown that if pyelonephritis is aggressively treated, it does not increase the likelihood of preterm labor, premature delivery, or low-birth-weight infants.

Occasionally, it is difficult to distinguish severe cystitis from pyelonephritis. Although the drugs used for treatment are similar, pyelonephritis requires intravenous antibiotics. Sandberg et al.^[24] studied symptomatic UTI in 174 women. They found that C-reactive protein was elevated in 91 percent of pregnant women with acute pyelonephritis and only 5 percent of women with cystitis. They also noted that the urine-concentrating ability was lower in women with acute pyelonephritis. Because the erythrocyte sedimentation rate (ESR) is normally elevated in pregnancy, ESR was not a useful parameter for distinguishing pyelonephritis from cystitis. The most common symptoms of pyelonephritis include high fever, chills, acute tenderness over the kidneys in the costovertebral angle area (unilateral or bilateral), myalgias, nausea, and vomiting. During gestation, the right side is most often affected, as engorged blood vessels may inhibit ureteral drainage of the kidney. The fever curve noted in these patients will often have a "spiked" appearance, with periods of fever separated by periods of hypothermia. This pattern will usually persist even after treatment is initiated. The laboratory findings often include a urine sediment with numerous leukocytes and bacteria. In addition, patients will have a significantly elevated leukocyte count with a left shift.

Acute pyelonephritis should be initially treated on an inpatient basis, utilizing intravenous antibiotics. Empiric therapy should be begun as soon as the presumptive diagnosis is made. Therapy can be tailored to the specific organism after sensitivities have been obtained approximately 48 hours later. Because septicemia is present in approximately 15 percent of cases of pyelonephritis, blood cultures should be obtained if patients do not respond rapidly to initial antibiotic therapy. *E. coli* is the most common organism isolated in pyelonephritis. Generally, a broad-spectrum first-generation cephalosporin is the initial therapy of choice. Fan et al.^[23] reviewed 107 cases of pyelonephritis in 103 pregnant women. They reported that 33 percent were resistant to ampicillin and 13 percent to first-generation cephalosporins. Since this study was published 9 years ago, the resistance to ampicillin and first-generation cephalosporins has increased. That is why it is so important to treat these women initially as inpatients. If resistance to more common therapies is encountered, a later generation cephalosporin or an aminoglycoside can safely be administered. During the febrile period, acetaminophen should be employed to keep the patient's temperature below 38°C. Small doses of acetaminophen will not mask the fever and symptoms of a patient who is unresponsive to treatment.

Intravenous antibiotic therapy should be continued for 24 to 48 hours after the patient becomes afebrile and costovertebral angle tenderness disappears. After the

cessation of intravenous therapy, treatment with appropriate oral antibiotics should be continued for 1 to 2 weeks. Upon termination of therapy, urine cultures should be obtained on a regular basis for the remainder of gestation. After an episode of acute pyelonephritis, antibiotic suppression should be implemented and continued. Nitrofurantoin 100 mg once or twice daily is an acceptable regimen for suppression. In a study by Van Dorsten and colleagues,^[25] the overall frequency of positive urine cultures following hospitalization for pyelonephritis was 38 percent. Nitrofurantoin suppression reduced the rate to 8 percent. Nitrofurantoin did not lower the rate of positive cultures if the inpatient antibiotic selection was inappropriate or if the culture was positive at the time of discharge.^[26] Today, there is increased pressure to treat pregnant women with pyelonephritis as outpatients. Although not ideal, this approach is possible if daily nursing contact is maintained during the acute phase of the disease and appropriate laboratory parameters are followed.

Cunningham and co-workers^[26] point out that pulmonary injury resembling adult respiratory distress syndrome (ARDS) can occur in patients with acute pyelonephritis. Clinical manifestations of this complication usually occur 24 to 48 hours after the patient is admitted for pyelonephritis.^[26],^[27] Some of these patients will require endotracheal intubation, mechanical ventilation,^[28] and positive end-expiratory pressure (PEEP). In Cunningham's series, there was no evidence that pulmonary edema was caused by intravenous fluid overload.^[26] This ARDS-type picture probably results from

endotoxin-induced alveolar capillary membrane injury. Towers et al. found pulmonary injury in 11 of 130 patients with pyelonephritis. A fever of greater than 103°F, a maternal heart rate above 110 bpm, and a gestation greater than 20 weeks placed the patient at increased risk for pulmonary injury. The most predictive factors for ARDS were fluid overload and tocolytic therapy.^[29]

Austenfeld and Snow^[30] studied 64 pregnancies in 30 women who had previously undergone ureteral reimplantation for vesicoureteral reflux. During pregnancy, 57 percent of these women had one or more UTIs, and 17 percent had more than one UTI or an episode of pyelonephritis.^[30] More frequent urine cultures and aggressive therapy during pregnancy are recommended for this group of patients.

ACUTE RENAL DISEASE IN PREGNANCY

Urolithiasis

The prevalence of urolithiasis during pregnancy is 0.03 percent, with an incidence no higher than that of the general population.^[31] Colicky abdominal pain, recurrent UTI, and hematuria suggest urolithiasis. If the diagnosis is suspected, intravenous pyelography should be undertaken, limiting this study to the minimum number of exposures necessary to make the diagnosis. Ultrasound can often be used to establish the diagnosis without radiation exposure. Newer ultrasound flow studies can actually follow flow from the ureter to the bladder and detect obstruction without the use of ionizing radiation. Urine microscopy can often detect crystals and help distinguish the type of stone before it is passed. For any patient suspected or proved to have renal stones, serum calcium and phosphorous levels should be measured to rule out hyperparathyroidism. Serum urate should also be determined.

Because of the physiologic hydronephrosis characteristic of pregnancy, most patients with symptomatic urolithiasis will spontaneously pass their stones. Treatment should be conservative, consisting of hydration and narcotic analgesia for pain relief.^[32] Epidural anesthesia has been advocated to establish a segmental block from T11 to L2. While this approach may promote passage of the stone, it remains controversial. Lithotripsy is contraindicated during pregnancy.

Recurrent UTI with urease-containing organisms causes precipitation of calcium phosphate in the kidney that may lead to the development of staghorn calculi. Surgery is rarely indicated in these patients, especially during gestation. Patients with staghorn calculi should have frequent urine cultures, and bacteriuria should be treated aggressively. Recurrent infections can lead to chronic pyelonephritis with resultant loss of kidney function.

Glomerulonephritis

Acute glomerulonephritis is an uncommon complication of pregnancy, with an estimated incidence of 1 per 40,000 pregnancies.^[33] Poststreptococcal glomerulonephritis rarely occurs in adults. In this disorder, renal function tends to deteriorate during the acute phase of the disease, but usually later recovers.^[34] Acute glomerulonephritis can be difficult to distinguish from preeclampsia. Periorbital edema, a striking clinical feature of acute glomerulonephritis, is often seen in preeclampsia as well. Hematuria, red blood cell (RBC) casts in the urine sediment, and depressed serum complement levels indicate glomerular disease. In poststreptococcal acute glomerulonephritis, antistreptolysin O titers rise.

Treatment of acute glomerulonephritis in pregnancy is similar to that for the nonpregnant patient. Blood pressure control is essential, and careful attention to fluid balance is imperative. Sodium intake should be restricted to 500 mg/day during the acute disease. Serum potassium levels must also be carefully monitored.

Packham and co-workers^[35] extensively reviewed 395 pregnancies in 238 women with primary glomerulonephritis. Only 51 percent of infants were born after 36 weeks' gestation. Excluding therapeutic abortion, 20 percent of fetuses were lost, 15 percent after 20 weeks' gestation. IUGR was noted in 15 percent of these cases. Maternal renal function deteriorated in 15 percent of pregnancies and failed to resolve postpartum in 5 percent.^[35] Hypertension was recorded in 52 percent of the pregnancies and developed before 32 weeks' gestation in 26 percent. This blood pressure elevation was not an exacerbation of previously diagnosed hypertension, as in only 12 percent of pregnancies was there noted to be antecedent hypertension. Eighteen percent of the women who developed de novo hypertension in pregnancy remained hypertensive postpartum. Increased proteinuria was recorded in 59 percent of these pregnancies and was irreversible in 15 percent.^[35] The highest incidence of fetal and maternal complications occurred in patients with primary focal and segmental hyalinosis and sclerosis. The lowest incidence of complications was observed in non-immunoglobulin A (IgA) diffuse mesangial proliferative glomerulonephritis.^[35] The presence of severe vessel lesions on renal biopsy was associated with a significantly higher rate of fetal loss after 20 weeks' gestation.

Packham and co-workers^[36] also studied 33 pregnancies in 24 patients with biopsy-proven membranous glomerulonephritis. Fetal loss occurred in 24 percent of pregnancies, preterm delivery in 43 percent, and a term liveborn in only 33 percent of patients. Hypertension

was noted in 46 percent of these pregnant women. Thirty percent of patients had proteinuria in the nephrotic range in the first trimester.^[36] The presence of heavy proteinuria during the first trimester correlated with a poor fetal and maternal outcome.^[36] Jungers et al.^[37] described 69 pregnancies in 34 patients with IgA glomerulonephritis. The fetal loss rate in this group was 15 percent. Preexisting hypertension was statistically associated with poor fetal outcome. Hypertension at the time of conception also correlated with a deterioration of maternal renal function during pregnancy. Hypertension in the first pregnancy was highly predictive of recurrence of hypertension in a subsequent pregnancy.^[37]

Kincaid-Smith and Fairley^[38] analyzed 102 pregnancies in 65 women with IgA glomerulonephritis. They noted that hypertension occurred in 63 percent of pregnancies, with 18 percent being severe. They also observed a decrease in renal function in 22 percent of these women.^[38] Abe^[39] retrospectively studied 240 pregnancies in 166 women with preexisting glomerular disease between 1976 and 1988. Eight percent of the pregnancies resulted in a spontaneous abortion, 6 percent resulted in stillbirth, and 86 percent were liveborn. Most losses occurred in women with a GFR less than 70 ml/min and preexisting hypertension. Even though the majority of women with renal insufficiency had good pregnancy outcomes, the long-term prognosis of the kidney disease was worse if the GFR was less than 50 ml/min and the serum creatinine was more than 1.5 mg/dl.^[39] Renal complications were worse in patients with membranoproliferative glomerulonephritis, with 29 percent developing hypertension and 33 percent developing a long-term decrease in renal function.

Imbasciati and Ponticelli^[40] summarized six studies containing a total of 906 pregnancies in 558 women with preexisting glomerular disease. This review, of course, has the limitations of including patients from a wide span of years and varying geographic locations. Nonetheless, broad generalizations can be made. The overall perinatal mortality was 13 percent. Hypertension, renal insufficiency, and nephrotic range proteinuria were the strongest prognostic factors for a poor pregnancy outcome. Having two of these factors was a particularly strong harbinger of fetal loss. The histologic type of glomerulonephritis had little correlation with pregnancy outcome. Hypertension persisted in 3 to 12 percent of patients who developed hypertension for the first time during pregnancy. In 25 percent of patients, hypertension worsened during pregnancy and corrected postpartum.^[40] This presentation suggests superimposed preeclampsia, but that diagnosis is difficult to make in a patient who already has hypertension and proteinuria. In 3 percent of these 166 women, the course of their glomerular disease accelerated after pregnancy.

Acute Renal Failure in Pregnancy

Acute renal failure (ARF) is defined as a urine output of less than 400 ml in 24 hours. To make the diagnosis, ureteral and urethral obstruction must be excluded. The incidence of ARF during pregnancy is approximately 1 per 10,000. It is seen most frequently in septic first-trimester abortions and in cases of sudden severe volume depletion resulting from hemorrhage caused by placenta previa, placental abruption, or postpartum uterine atony.^[41] It is also observed in the marked volume

contraction associated with severe preeclampsia ^[42] and with acute fatty liver of pregnancy. ^[42], ^[43]

The incidence of ARF in pregnancy has decreased over the years. Stratta and colleagues ^[44] reported 81 cases of pregnancy-related ARF between 1958 and 1987, accounting for 9 percent of the total number of ARF cases needing dialysis during that interval. In three successive 10-year periods (1958 to 1967, 1968 to 1977, and 1978 to 1987), the incidence of pregnancy-related ARF fell from 43 percent to 2.8 percent of the total number of cases of ARF. The incidence changed from 1 in 3,000 to 1 in 15,000 pregnancies over the study period. ^[44] In these 81 ARF cases, 11.6 percent experienced irreversible renal damage, the majority of which involved severe preeclampsia/eclampsia. ^[44]

Renal ischemia is the common denominator in all cases of ARF. With mild ischemia, quickly reversible prerenal failure results. With more prolonged ischemia, acute tubular necrosis occurs. This process is also reversible, as glomeruli are not affected. Severe ischemia, however, may produce acute cortical necrosis. This pathology is irreversible, although on occasion a small amount of renal function is preserved. ^[45] Stratta and colleagues ^[46] have reported 17 cases of ARF occurring over 15 years, and all were due to preeclampsia/eclampsia. Cortical necrosis occurred in 29.5 percent of the cases. ^[46] Whether or not ARF was associated with cortical necrosis did not appear to be related to chronologic age, parity, gestational age at which preeclampsia commenced, duration of preeclampsia prior to delivery, or eclamptic seizures. The only statistically significant factor associated with the appearance of cortical necrosis was placental abruption. ^[46] In another study, Turney and co-workers ^[47] demonstrated that acute cortical necrosis, which occurred in 12.7 percent of their patients with ARF, carried a 100 percent mortality within 6 years.

Sibai and colleagues ^[48] studied the remote prognosis in 31 consecutive cases of ARF in patients with hypertensive disorders of pregnancy. Eighteen of the 31 patients had "pure" preeclampsia, while 13 pregnancies had other hypertensive disorders and renal disease. Five percent of the 18 patients with pure preeclampsia required dialysis during hospitalization, and all had acute

1071

tubular necrosis. Of the other 13 women, 42 percent required dialysis and three patients had bilateral cortical necrosis. The majority of pregnancies in both groups were complicated by placental abruption and hemorrhage. ^[48] All 16 surviving patients in the pure preeclampsia group had normal renal function on long-term follow-up. Conversely, 9 of the 11 surviving patients in the other group required long-term dialysis, and four ultimately died of end-stage renal disease. ^[48] Turney and colleagues ^[47] also performed follow-up examinations of their patients. They found that maternal survival was adversely affected by increasing age. Their 1-year maternal survival rate was 78.6 percent. Follow-up of survivors showed normal renal function up to 31 years after ARF. ^[47]

Clinically, patients with reversible ARF first experience a period of oliguria of variable duration. Polyuria then occurs. It is important to recognize that BUN and serum creatinine levels continue to rise early in the polyuric phase. During the recovery phase, urine output approaches normal. In these patients, it is important to monitor electrolytes frequently and to treat any imbalance carefully. The urine/plasma osmolality ratio should be determined early in the course of the disease. If the ratio is 1.5 or greater, prerenal pathology is likely, and the disorder tends to be of shorter duration and less severity. A ratio near 1.0 suggests acute tubular necrosis.

The main goal of treatment is elimination of the underlying cause. Volume and electrolyte balance must receive constant scrutiny. To assess volume requirements, invasive hemodynamic monitoring is useful and lessens the need for clinical guesswork. This is especially true during the polyuric phase. Central hyperalimentation may also be required if renal failure is prolonged.

Acidosis frequently occurs in cases of ARF. Arterial blood gases therefore should be followed regularly. Acidosis must be treated promptly to prevent hyperkalemia, which may develop rapidly and can be fatal. Absolute restriction of potassium intake should be instituted immediately. Sodium bicarbonate, used to treat acidosis, may overload the patient with sodium and water. In this case, peritoneal or hemodialysis may be instituted. The main indications for dialysis in ARF of pregnancy are hypernatremia, hyperkalemia, severe acidosis, volume overload, and worsening uremia.

Hemolytic Uremic Syndrome

The postpartum hemolytic uremic syndrome is a rare idiopathic disorder that must be considered when a patient shows signs of hemolysis and decreasing renal function in the postpartum period. This idiopathic syndrome was first described in 1968 and may occur as early as the first trimester and up to 2 months postpartum. ^[49] ^[50] ^[51] ^[52] In fact, it has even been reported following an ectopic pregnancy. ^[53] Most patients have no predisposing factors. Prodromal symptoms include vomiting, diarrhea, and a flu-like illness. Forty-nine cases have been reported, with a 61 percent mortality rate. ^[51] These cases date back to 1968; with improved intensive care monitoring and treatment, the prognosis has improved. Coratelli and co-workers ^[49] reported a case of hemolytic uremic syndrome that was diagnosed at 13 weeks' gestation and confirmed by renal biopsy. Circulating endotoxin was detected and was progressively reduced by hemodialysis performed daily from the third to the ninth days of the disease. Complete normalization of renal function occurred by day 34. These investigators propose that initiation of early dialysis may play an important role in supporting patients through the disease process. They also propose that endotoxins are key pathogenic factors in the disorder. ^[49] Conversely, Li and co-workers ^[54] discovered hemolytic uremic syndrome in a patient recovering from an uncomplicated cesarean delivery. No endotoxins were found in the patient's serum, stool, or renal biopsy material. The patient underwent dialysis and recovered. ^[54] Conte and co-workers ^[55] suggest that plasma exchange in cases of acute renal failure caused by the postpartum hemolytic uremic syndrome can play a vital role in supporting a patient through the illness. This does appear to be the key to therapy today.

Disseminated intravascular coagulation (DIC) with hemolysis usually accompanies the renal failure. However, DIC is not the cause of the syndrome. Microscopically, the kidney shows thrombotic microangiopathy. The glomerular capillary wall is thick, and biopsy specimens taken later in the course of the disease show severe nephrosclerosis and deposition of the third component of complement (C3).

Some researchers believe that this syndrome is due to decreased production of prostacyclin in the kidneys. ^[56], ^[57] Prostacyclin infusions have been used to treat patients, but this therapy still remains experimental. One observer noted a decrease in antithrombin III in a patient with postpartum hemolytic uremic syndrome. This patient was successfully treated with an infusion of antithrombin III concentrate, ^[58] a preparation that is readily available today.

Polycystic Kidney Disease

Adult polycystic kidney disease is an autosomal dominant disorder that usually manifests itself in the fifth decade of life. Patients may occasionally display symptoms earlier. Hypertension is part of this disorder. If a patient with adult polycystic kidney disease becomes pregnant, hypertension may be exacerbated and not

1072

improve postpartum. ^[49] The overall prognosis for the disorder does not appear to worsen with an increasing number of pregnancies.

Vesicoureteral Reflux

Vesicoureteral reflux increases with pregnancy. It usually does not cause problems unless the reflux is severe. If it is severe enough to warrant surgery, this should be done before pregnancy. Even with surgical correction, patients with ureterovesical reflux are at increased risk for pyelonephritis and should have cultures performed frequently. ^[40] If an individual was receiving antibiotic prophylaxis prior to pregnancy, this should be continued. If the patient was not on prophylaxis, the obstetrician may wish to begin treatment with nitrofurantoin, depending on the clinical situation.

Brandes and Fritsche ^[59] report a case of acute renal failure due to obstruction of the ureters by a gravid uterus. Only 13 other cases have been reported prior to this case, a twin pregnancy complicated by polyhydramnios at 34 weeks' gestation. The serum creatinine level peaked at 12.2 mg/dl, but resolved immediately after amniotomy. ^[59] In cases remote from term, ureteral stenting or dialysis may be necessary.

Renal Artery Stenosis

Renal artery stenosis is an extremely rare complication of pregnancy. ^[60] This disorder may present as chronic hypertension with superimposed preeclampsia or as

recurrent isolated preeclampsia. Although Doppler flow studies may be suggestive, renal angiography is the most specific and sensitive diagnostic procedure. Percutaneous transluminal angioplasty can be carried out at the time of angiography. Heyborne et al. ^[60] present a case in which this procedure was accomplished at 26½ weeks' gestation.

Nephrotic Syndrome

The nephrotic syndrome was initially described as a 24-hour urine protein excretion of 3.5 g or more, reduced serum albumin, edema, and hyperlipidemia. ^[61] Currently, the syndrome is defined by massive proteinuria alone, which is often the result of damage to the glomeruli. ^[61] The most common etiology of nephrotic syndrome in pregnancy (especially the third trimester) is preeclampsia. Other etiologies include proliferative glomerulonephritis, minimal change disease, lupus nephropathy, hereditary nephritis, diabetic nephropathy, renal vein thrombosis, and amyloidosis. ^[62]

Patients with newly diagnosed or persistent nephrotic syndrome must be followed closely in pregnancy. Whenever possible, the etiology of the proteinuria should be determined. In many cases, steroid therapy may be employed; however, its use can in some cases aggravate the underlying disease process. ^[62] One common complication of nephrotic syndrome in pregnancy is profound edema secondary to massive protein excretion in addition to the normal decline in serum albumin associated with pregnancy. ^[62] A second area of concern is a possible hypercoagulable state precipitated by urinary losses of antithrombin III, reduced levels of protein C and S, hyperfibrinogenemia, and enhanced platelet aggregation. ^[63]

CHRONIC RENAL DISEASE IN PREGNANCY

Chronic renal disease can be silent until its advanced stages. Because obstetricians routinely examine the patient's urine for the presence of protein, glucose, and ketones, they may be the first to detect chronic renal disease.

Any gravida with more than trace proteinuria should collect a 24-hour urine specimen for creatinine clearance and total protein excretion. This test is safe, inexpensive, and of only minor inconvenience to the patient. Creatinine clearance is elevated in pregnancy and, during the first trimester, may exceed 140 ml/min. Before pregnancy, 24-hour urinary protein excretion should not exceed 0.2 g. During gestation, quantities up to 0.3 g/day may be normal. Moderate proteinuria (<2 g/day) is seen in glomerular disease, most commonly lipid nephrosis, systemic lupus erythematosus, and glomerulonephritis.

Microscopic examination of the urine can reveal much about the patient's renal status. If renal disease is suspected, a catheterized specimen should be obtained. More RBCs than one to two per high-power field or RBC casts are indicative of renal disease. RBCs usually indicate glomerular disease or collagen vascular disease. Less frequently, they suggest trauma or malignant hypertension. Increased numbers of white blood cells (WBCs), more than one to two per high-power field, or the appearance of WBC casts is usually indicative of acute or chronic infection. Cellular casts are found in the presence of renal tubular dysfunction, and hyaline casts suggest significant proteinuria. A single bacterium seen in an unspun catheterized urine specimen is suggestive of significant bacteriuria, and a follow-up culture should be performed.

The obstetrician can easily be misled when relying solely on the BUN and serum creatinine to assess renal function. A 70 percent decline in creatinine clearance, an indirect measure of GFR, can be seen before a significant rise in the BUN or serum creatinine occurs. In fact, little change in the serum creatinine or the BUN is

seen until the creatinine clearance falls to 50 ml/min. Below that level, small decrements in creatinine clearance can lead to large increases in the BUN and creatinine. A single creatinine clearance value less than 100 ml/min is not diagnostic of renal diseases. An incomplete 24-hour urine collection is the most frequent cause of this finding. An abnormal clearance rate should therefore be restudied.

Serum urate is an often overlooked but helpful parameter in detecting renal dysfunction. Excretion of uric acid is dependent not only on glomerular filtration but also on tubular secretion. An elevated serum urate in the presence of a normal BUN and serum creatinine may therefore implicate tubular disease. A solitary increase in uric acid may also signify impending or early preeclampsia.

Effect of Pregnancy on Renal Function

Although baseline creatinine clearance is decreased in patients with chronic renal insufficiency, it should still rise during gestation. A moderate fall in creatinine clearance is often observed during late gestation in patients with renal disease. This decrease is typically more severe in patients with diffuse glomerular disease. It usually reverses after delivery.

The long-term effect of pregnancy on renal disease remains controversial. If the patient's serum creatinine is less than 1.5 mg/dl, pregnancy should have little effect on the long-term prognosis of the patient's kidney disease. Pregnancy, however, is associated with an increased incidence of pyelonephritis in patients with chronic renal disease. There are few data concerning the long-term effect of pregnancy on renal disease in women with true renal insufficiency. Occasionally, some patients with a baseline serum creatinine of more than 1.5 mg/dl will experience a significant decrease in renal function during gestation that does not improve during the postpartum period.^[40], ^[64], ^[69] This deterioration occurs more frequently in women with diffuse glomerulonephritis. It is not possible, however, to predict which patients with renal insufficiency will experience a permanent reduction in renal function. If renal function significantly worsens during gestation, termination of pregnancy may not reverse the process. Abortion therefore cannot be routinely recommended for patients who become pregnant and whose baseline serum creatinine level exceeds 1.5 mg/dl. Ideally, patients with chronic renal disease should be thoroughly counseled about the possible consequences of pregnancy before conception.

Severe hypertension is the greatest threat to the pregnant patient with chronic renal disease. Left uncontrolled, hypertension can lead to intracerebral hemorrhage as well as deteriorating renal function. In most pregnancies complicated by chronic renal dysfunction, some degree of hypertension is present.^[64], ^[66] Approximately 50 percent of these patients will have worsening hypertension as pregnancy progresses, and diastolic blood pressures of 110 mm Hg or greater will develop in about 20 percent of cases.^[67] Those patients with diffuse proliferative glomerulonephritis and nephrosclerosis are at greatest risk for the development of severe hypertension. Blood pressure control is the cornerstone of successful treatment of chronic renal disease in pregnancy.

Worsening proteinuria is common during pregnancy complicated by chronic renal disease and often reaches the nephrotic range.^[67] In general, massive proteinuria does not indicate an increased risk for mother or fetus.^[68] Low serum albumin, however, has been correlated with low birth weight.^[69] The development of massive proteinuria is not necessarily a harbinger of preeclampsia. Nevertheless, in late pregnancy it is often difficult to differentiate impending preeclampsia from worsening chronic renal disease.

Effect of Chronic Renal Disease on Pregnancy

More than 85 percent of women with chronic renal disease will have a surviving infant if renal function is well preserved. Earlier reports were more pessimistic, citing a 5.8 percent incidence of stillbirth, a 4.9 percent incidence of neonatal deaths, and an increase in second-trimester losses.^[67] If hypertension is not controlled and if renal function is not well preserved, there is still a high likelihood of pregnancy loss.^[35] Antepartum fetal surveillance and advances in neonatal care have made great strides in improving perinatal outcome in these patients. One study reported a total fetal loss rate of 13.8 percent, including miscarriage, stillbirths, and neonatal deaths,^[66] not very different from the general population.

The outlook for women with severe renal insufficiency whose baseline serum creatinine level exceeds 1.5 mg/dl is less clear. This is due in part to the limited number of pregnancies in such patients as well as to the large number who undergo elective abortion. One study reported no surviving infants when the maternal BUN was greater than 60 mg/dl.^[68] Other investigations, however, have found that about 80 percent of such pregnancies resulted in surviving infants.^[66], ^[70] Preterm births and IUGR remain important problems in these pregnancies. The reported incidence of preterm birth ranges from 20 to 50 percent.^[67], ^[71]

Imbasciati and Ponticelli^[40] summarize three studies containing 81 pregnancies in 78 women with serum creatinine concentrations less than 1.4 mg/dl.^[40] The perinatal loss rate was only 9 percent. However, 33 percent of the infants were growth restricted, and 50 percent were born preterm secondary to either maternal or fetal

women showed acceleration of their renal disease after delivery. Some researchers believe that growth restriction may be due to the lack of plasma volume increase as the pregnancy progresses. In one study, Cunningham et al.^[72] showed that women with moderate renal dysfunction did have increased creatinine clearances and plasma volumes during gestation, whereas women with severe renal dysfunction did not.^[72]

Hemodialysis in Pregnancy

Patients with chronic hemodialysis can have successful pregnancies.^{[73] [74] [75] [76] [77] [78] [79]} Many women with chronic renal failure, however, experience oligomenorrhea, and their fertility is often impaired.^[80] These women commonly fail to use a method of contraception. It is therefore important that a serum human chorionic gonadotropin (hCG) level be assessed whenever pregnancy is suspected.

As in all patients with impaired renal function, the most important aspect of care is meticulous control of blood pressure. During dialysis, wide fluctuations in blood pressure often occur. One case report describes fetal distress associated with hypotension during dialysis.^[81] Sudden volume shifts, therefore, should be avoided.^[79] In late pregnancy, continuous fetal heart rate monitoring should be carried out during dialysis. If possible, the patient should be positioned on her left side with the uterus displaced from the vena cava. During dialysis, one must pay particular attention to electrolyte balance. Pregnant patients are in a state of chronic compensated respiratory alkalosis, and large drops in serum bicarbonate should be prevented. Dialysates containing glucose and bicarbonate are preferred, and those containing citrates should be avoided.^[79]

Patients should be counseled that a successful pregnancy will require longer and more frequent periods of dialysis.^[74],^[79],^[81] Patients must also follow a careful diet, ingesting at least 70 g of protein and 1.5 g of calcium daily. Weight gain should be limited to 0.5 kg between dialysis sessions.

Chronic anemia is often a problem in hemodialysis patients. The hematocrit should be kept above 25 percent, and transfusion with packed RBCs or erythropoietin therapy may be necessary to accomplish this objective.^[74] Polyhydramnios appears to be a frequent complication in pregnant patients undergoing hemodialysis.^[79],^[82]

The point at which to initiate hemodialysis is controversial. Cohen and co-investigators^[76] believe that the early initiation of regular hemodialysis in patients with moderate renal insufficiency may improve pregnancy outcome. In two cases, when regular hemodialysis was begun in the second trimester, both patients carried to term, although the infants were growth restricted.^[76] Redrow and co-workers^[77] report 14 pregnancies in 13 women undergoing dialysis. Ten of those pregnancies were successful.

Chronic ambulatory peritoneal dialysis or chronic cycling peritoneal dialysis has also been associated with successful outcomes in pregnancy. Redrow et al.^[77] hypothesize several advantages for peritoneal dialysis. These include a more constant chemical and extracellular environment for the fetus, higher hematocrit levels, infrequent episodes of hypotension, and no heparin requirement. They also postulate that intraperitoneal insulin facilitates the management of blood glucose in diabetic patients and that intraperitoneal magnesium used in the dialysate reduces the likelihood of preterm labor.

Preterm birth does occur more frequently in patients undergoing dialysis.^[83] Progesterone is removed during dialysis, and at least one group has advocated that parenteral progesterone therapy should be administered to the patient undergoing dialysis.^[84] In their review, Yasin and Doun^[79] report a 40.7 percent incidence of premature contractions. Although it is tempting to consider cesarean delivery when the patient approaches term, this method should not be routine for these patients. Its use should be based only on obstetric indications.

The Europeans have compiled a registry of pregnant women requiring dialysis. There has been a 23 percent pregnancy success rate in 70 women with end-stage renal disease requiring dialysis.^[82] The mean gestational age was 33.2 weeks. Most preterm births were due to growth restriction, hypertension, preterm labor, and abruption. These findings suggest that more frequent dialysis results in more uniform control of uremia and less fluctuation in blood volume, which should result in better pregnancy outcomes.

MANAGEMENT OF CHRONIC RENAL DISEASE IN PREGNANCY

A 24-hour urine collection for creatinine clearance and total protein excretion should be obtained as soon as the pregnancy is confirmed. These parameters should be monitored monthly. The patient should be seen once every 2 weeks until 32 weeks' gestation and weekly thereafter. These are general guidelines, and more frequent visits may be necessary in individual cases.

Control of hypertension is critical in managing patients with chronic renal disease. -Blockers, calcium channel blockers, and hydralazine can be used to treat blood pressure effectively as long as the dosages are monitored carefully. Clonidine is occasionally useful in refractory patients. Doxazosin and prazosin may be used if necessary. Angiotensin-converting enzyme (ACE)

1075

inhibitors should be avoided during pregnancy. These drugs have been associated with fetal and neonatal oliguria/anuria.^[85],^[86] In one study, 1 of 19 infants had anuria and required dialysis.^[85] In another study, an infant required peritoneal dialysis.^[86] Furthermore, congenital anomalies, including microcephaly and encephalocele,^[85] have been associated with the use of ACE inhibitors.

The use of diuretics in pregnancy is controversial.^[87],^[88] For massive debilitating edema, a short course of diuretics can be helpful. Electrolytes must be monitored carefully. Salt restriction does not appear to be beneficial once edema has developed. Salt restriction, however, should be instituted without hesitation in pregnant women with true renal insufficiency.

Fetal growth should be assessed with serial ultrasonography, because growth restriction is common in women with chronic renal disease. Antepartum fetal heart rate testing should be started at 28 weeks' gestation.^[89]

Obstetricians should have a low threshold for hospitalizing patients with chronic renal disease. Increasing hypertension and decreasing renal function warrant immediate hospitalization. A sudden deterioration of renal function may be due to infection, dehydration, electrolyte imbalance, or obstruction.

The timing of delivery must be individualized. Maternal indications for delivery include uncontrollable hypertension, the development of superimposed preeclampsia, and decreasing renal function after fetal viability has been reached. Fetal indications are dictated by the assessment of fetal growth and fetal well-being.

Renal biopsy is rarely indicated during pregnancy. It is never indicated after 34 weeks' gestation, when delivery of the fetus and subsequent biopsy would be a safer alternative. Excessive bleeding secondary to the greatly increased renal blood flow has been reported by some^[90] but not all^[91] observers. If coagulation indices are normal and blood pressure is well controlled, morbidity should be no greater than that observed in the non-pregnant patient.^[92] Packham and Fairley^[93] report a series of 111 renal biopsies performed in 104 pregnant women over 20 years. The complication rate was 4.5 percent. The most likely clinical dilemma necessitating renal biopsy in a pregnant woman would be the development of nephrotic syndrome and increasing hypertension between 22 and 32 weeks' gestation. In this case, renal biopsy may distinguish chronic renal disease from preeclampsia and impact significantly on the treatment plan.

RENAL TRANSPLANTATION

Pregnancy following renal transplantation has become increasingly common. Many previously anovulatory patients begin ovulating postoperatively and regain fertility as renal function normalizes.^[94] As in the case of women on hemodialysis, many transplant recipients have failed to realize they are pregnant until well into the second trimester.

Upon learning they are pregnant, many women stop taking all medications. The importance of continuing immunosuppressive therapy cannot be emphasized strongly enough to renal allograft recipients. Glucocorticoids, especially prednisone, are metabolized in the placenta by 11 -ol-dehydrogenase, with only limited amounts reaching the fetus. No studies have documented an increased rate of malformations. Adrenocortical insufficiency has been rarely reported in infants born to mothers taking glucocorticoids.^[95] Nevertheless, a pediatrician should be present at the delivery and should be aware of this possibility.

Azathioprine cannot be activated in the fetus because of its lack of inosinate pyrophosphorylase.^[96] Azathioprine has been shown to cause decreased levels of IgG and IgM as well as a smaller thymic shadow on chest x-ray in these neonates.^[97] Chromosomal aberrations, which cleared within 20 to 32 months, have also been demonstrated in lymphocytes of infants exposed to azathioprine in utero.^[98] The long-term implications of this treatment are not yet known. IUGR has been reported in infants born to mothers receiving azathioprine.^[99] These risks are outweighed, however, by the disastrous consequences of allograft rejection that may occur if the patient stops her medication.

Cyclosporin A appears to be relatively safe for use during gestation, but does hold some risks. Patients may develop arterial hypertension secondary to its interference with the normal hemodynamic adaptation to pregnancy.^[100] Cyclosporin A crosses the placenta, but there is no evidence of teratogenesis.^[101],^[102] Intrauterine growth restriction, in the absence of maternal hypertension, has been reported in a patient taking cyclosporin A during pregnancy.^[103] Most women taking cyclosporin A have had no complications attributable to the drug, and the risk of allograft rejection certainly outweighs the fetal risk of the medication. Therefore, the medication should be continued throughout gestation.

Davison^[104] reviewed 1,569 renal transplants in 1,009 women. He found that 22 percent of the women elected to abort their pregnancies, 16 percent had a spontaneous abortion, and 8 percent experienced perinatal deaths. Furthermore, he observed that 45 percent of the surviving pregnancies were delivered preterm and 22 percent were complicated by intrauterine growth restriction.^[104] Three percent of the infants were born with major malformations, a rate no different from expected in the background population. Preeclampsia complicated 30 percent of the pregnancies but, as previously noted, the diagnosis is difficult to make in a patient who may already have hypertension and proteinuria. The

1076

allograft rejection rate in these women was 9 percent, no different from that expected in a nonpregnant population.^[104] Also, the long-term rejection rate was the same as for women who had not experienced a pregnancy.

During pregnancy, renal allograft recipients must be carefully watched for signs of rejection. As previously mentioned, significant episodes of rejection may occur in as many as 9 percent of transplant recipients during gestation. This figure is no greater than that expected in the nonpregnant population. Unfortunately, the clinical hallmarks of rejection—fever, oliguria, tenderness, and decreasing renal function—are not always exhibited by the pregnant patient. Occasionally, rejection may mimic pyelonephritis or preeclampsia, which occurs in approximately one third of renal transplant patients. In these cases, renal biopsy is indicated to distinguish rejection from preeclampsia. Rejection has been known to occur during the puerperium, when maternal immune competence returns to its prepregnancy level.^[105] Therefore, it may be advisable to increase the dose of immunosuppressive medications in the immediate postpartum period.

Infection can be disastrous for the renal allograft. Therefore, urine cultures should be obtained at least monthly during pregnancy, and any bacteriuria should be aggressively treated. It is crucial to remember that the allograft is denervated, and the patient may experience no pain with pyelonephritis. The only symptoms may be fever and nausea.

Renal function, as determined by 24-hour creatinine clearance and protein excretion, should be assessed monthly. Approximately 15 percent of transplant recipients will exhibit a significant decrease in renal function in late pregnancy.^[106] This condition usually, but not always, reverses after pregnancy. Proteinuria develops in about 40 percent of patients near term, but most often disappears soon after delivery unless significant hypertension is present.

As for patients with chronic renal disease, serial ultrasonography should be used to assess fetal growth, and antepartum fetal heart rate testing should be started at 28 weeks' gestation. Approximately 50 percent of renal allograft recipients will deliver preterm. Preterm labor, preterm rupture of membranes, and IUGR are common. Vaginal delivery should be accomplished when possible, with cesarean delivery reserved for obstetric indications. Allograft recipients may have an increased frequency of cephalopelvic disproportion from pelvic osteodystrophy,^[107] resulting from prolonged renal disease with hypercalcemia or extended steroid use. The transplanted kidney, however, rarely obstructs vaginal delivery despite its pelvic location.

Although there have been many successful pregnancies in renal allograft recipients, no group has devised criteria to determine when it is safest to conceive after transplantation. In a recent editorial, Lindheimer and Katz,^[108] leading authorities on renal disease in pregnancy, have suggested guidelines, which are summarized in [the box "Guidelines for Renal Allograft Recipients Who Wish to Conceive."](#)

Guidelines for Renal Allograft Recipients Who Wish to Conceive

Absolute Criteria

Wait 2 years after cadaver transplant or 1 year after graft from living donor
Immunosuppression should be at maintenance levels

Relative Criteria

Plasma creatinine <1.5 mg/dl
Absent or easily controlled hypertension
No or minimal proteinuria
No evidence of active graft rejection
No pelvicalyceal distention on a recent ultrasound or intravenous pyelogram
Prednisone dose 15 mg/day
Azathioprine dose 2 mg/kg/day
Cyclosporin A dose 24 mg/kg (available data on the use of this drug in pregnancy includes <150 patients)

Adapted from Lindheimer M, Katz A: Pregnancy in the renal transplant patient. Am J Kidney Dis 19:173, 2000.

Key Points

Asymptomatic bacteriuria complicates 10 percent of pregnancies, and if left untreated will result in symptomatic urinary tract infections in 40 percent of patients. Pyelonephritis complicates 1 to 2 percent of pregnancies, making it the most frequent nonobstetric cause of hospitalization during pregnancy. Patients with glomerulonephritis can have successful pregnancies, but pregnancy loss rates increase greatly if the patient has preexisting hypertension. Creatinine clearance can decline 70 percent before significant increases are seen in the BUN or

1077

serum creatinine level. Therefore, a 24-hour urine specimen for creatinine clearance should be collected in any patient when renal disease is suspected. The chance of successful pregnancy is reduced if the creatinine clearance is less than 50 ml/min or if the serum creatinine level is more than 1.5 mg/dl. Severe hypertension is the greatest threat to the pregnant woman with chronic renal disease. Growth restriction and preeclampsia are common in women with chronic renal disease. These patients should have frequent sonograms and should start antepartum fetal surveillance at 28 weeks' gestation. Patients with chronic renal disease are often anovulatory. After transplantation, as renal function returns, they ovulate and may become pregnant unexpectedly. Patients should wait 2 years after receiving a cadaver renal allograft and 1 year after receiving a living allograft before contemplating pregnancy. Furthermore, there should be no signs of allograft rejection. Renal transplant patients should remain on their immunosuppressive medications throughout gestation.

Chapter 32 - Diabetes Mellitus

Mark B. Landon
Patrick M. Catalano
Steven G. Gabbe

The introduction of insulin therapy 80 years ago remains an important landmark in the care of pregnancy for the diabetic woman. Before insulin became available, pregnancy was uncommon and was likely to be accompanied by fetal mortality and a substantial risk for maternal death. Management techniques have been developed over the past 30 years to prevent complications based on an understanding of the pathophysiology of diabetic pregnancy. These advances have resulted in perinatal mortality rates in optimally managed cases that approach that of the normal population. This dramatic improvement in perinatal outcome has been largely attributed to clinical efforts to establish improved maternal glycemic control both prior to conception and during gestation ([Fig. 32-1](#)). Excluding major congenital malformations, which continue to plague pregnancies in the insulin-dependent woman, perinatal loss for the diabetic woman has fortunately become an uncommon event.

While the benefit of careful regulation of maternal glucose levels is well accepted, failure to establish optimal glycemic control as well as other factors continue to result in significant perinatal morbidity. For this reason, both clinical and basic laboratory research efforts continue to focus on the etiology of congenital malformations, fetal growth disorders, and intrauterine death. Clinical experience has also resulted in a more realistic appreciation of the impact that vascular complications can have on pregnancy and the manner in which pregnancy may impact these disease processes. With modern management techniques and an organized team approach, successful pregnancies have become the norm even for women with the most complicated diabetes. Before considering these clinical issues, it is important to understand the metabolic effects of pregnancy in relation to the pathophysiology of diabetes mellitus.

PATHOPHYSIOLOGY

Normal Glucose Tolerance

There are significant alterations in maternal metabolism during pregnancy, which provide for adequate nutritional stores in early gestation in order to meet the increased maternal and fetal demands of late gestation and lactation. Although we are apt to think of diabetes mellitus as a disorder exclusively of maternal glucose metabolism, in fact diabetes mellitus affects all aspects of maternal nutrient metabolism. In this section we consider maternal glucose metabolism as it relates to pancreatic β -cell production of insulin and insulin clearance, endogenous (i.e., primarily hepatic) glucose production and suppression with insulin, and peripheral insulin sensitivity. We also address maternal protein and lipid metabolism. Lastly, the impact of these alterations on maternal metabolism is examined as they relate to maternal energy expenditure and fetal growth.

Glucose Metabolism

Normal pregnancy has been characterized as a "diabetogenic state" because of the progressive increase in postprandial glucose levels and insulin response in late gestation. However, early gestation can be viewed as an anabolic condition because of the increases in maternal fat stores and decrease in free fatty acid concentrations. Weiss et al.^[1] have described significant decreases in maternal insulin requirements early in gestation in insulin-dependent women with optimal glucose control prior to conception. The mechanisms for this decrease in insulin requirements have been ascribed to various factors including

1082

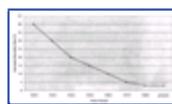

Figure 32-1 Perinatal mortality rates in pregnancy complicated by type 1 diabetes mellitus.

insulin sensitivity, decreased substrate availability secondary to factors such as nausea, the fetus acting as a glucose sink, or enhanced maternal insulin secretion. Longitudinal studies in women with normal glucose tolerance have shown significant progressive alterations in all aspects of glucose metabolism as early as the end of the first trimester.^[2]

There are progressive increases in insulin secretion in response to an intravenous glucose challenge with advancing gestation (Fig. 32-2). The increases in insulin concentration are more pronounced in lean as compared to obese women, most probably as a response to the greater decreases in insulin sensitivity in lean women as will be described later. Data regarding insulin clearance in pregnancy are limited. In separate studies Bellman and Hartman,^[3] Lind et al.,^[4] and Burt and Davidson^[5] reported no difference in insulin disappearance rate when insulin was infused intravenously in late gestation in comparison with nonpregnant subjects. In contrast, Goodner and Freinkel,^[6] using a radiolabeled insulin, described a 25 percent increase in insulin turnover in a pregnant as compared with a nonpregnant rat

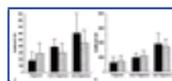

Figure 32-2 Longitudinal increase in insulin response to an intravenous glucose challenge in lean and obese women with normal glucose tolerance, pregravid, early and late pregnancy. A, First phase: area under the curve from 0 to 5 minutes. B, Second phase: area under the curve from 5 to 60 minutes.

1083

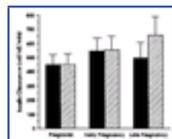

Figure 32-3 Longitudinal increases in metabolic clearance rate of insulin ($\text{ml}/\text{m}^2/\text{min}$) in lean and obese women with normal glucose tolerance; pregravid, early, and late pregnancy.

model. Catalano et al.^[7] using the euglycemic-clamp model reported a 20 percent increase in insulin clearance in lean women and a 30 percent increase in insulin clearance in obese women by late pregnancy (Fig. 32-3). Although the placenta is rich in insulinase, the exact mechanism for the increased insulin clearance in pregnancy remains speculative.

Although there is a progressive decrease in fasting glucose with advancing gestation, the decrease is most probably a result of the increase in plasma volume in early gestation and increase in fetoplacental glucose utilization in late gestation. Kalhan and Cowett^[8] using various stable isotope methodologies in cross-sectional study designs were the first to describe increased fasting hepatic glucose production in late pregnancy. Additionally, Catalano et al.^[10] using a stable isotope of glucose in a prospective longitudinal study design reported a 30 percent increase in maternal fasting hepatic glucose production with advancing gestation (Fig. 32-4), which remained significant even when adjusted for maternal weight gain. Tissue sensitivity to insulin involves both liver and peripheral tissues, primarily skeletal muscle. The increase in fasting maternal hepatic glucose production occurred despite a significant increase in fasting insulin concentration, thereby indicating a decrease in maternal hepatic glucose sensitivity in women with normal glucose tolerance. Additionally, in obese women there was a decreased ability of infused insulin to suppress hepatic glucose production in late gestation as compared with pregravid and early pregnancy measurements, thereby indicating a further decrease in hepatic insulin sensitivity^[11] in obese women.

Estimates of peripheral insulin sensitivity in pregnancy have included the measurement of insulin response to a fixed oral or intravenous glucose challenge

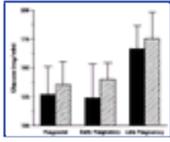

Figure 32-4 Longitudinal increase in basal endogenous (primarily hepatic) glucose production (mg/min) in lean and obese women with normal glucose tolerance; pregravid, early, and late pregnancy.

or the ratio of insulin to glucose under a variety of experimental conditions. In recent years, newer methodologies such as the Bergman minimal model^[12] and the euglycemic-hyperinsulinemic^[13] clamp have improved our ability to quantify peripheral insulin sensitivity. In lean women in early gestation, Catalano et al.^[14] reported a 40 percent decrease in maternal peripheral insulin sensitivity using the euglycemic-hyperinsulinemic clamp. However, when adjusted for changes in insulin concentrations during the clamp and residual hepatic glucose production (i.e., the insulin sensitivity index), insulin sensitivity decreased only 10 percent (Fig. 32-5). In

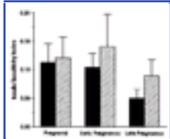

Figure 32-5 Longitudinal changes in the insulin sensitivity index (glucose infusion rate adjusted for residual endogenous glucose production and insulin concentrations achieved during the glucose clamp) in lean and obese women with normal glucose tolerance; pregravid, early, and late gestation.

contrast, there was a 15 percent increase in the insulin sensitivity index in obese women in early pregnancy as compared with pregravid estimates.^[15] Hence, the decrease in insulin requirements in early gestation observed in some women requiring insulin may be a consequence of a relative increase in insulin sensitivity, particularly in women with decreased insulin sensitivity prior to conception. As compared with the metabolic alterations in early pregnancy, there is a uniformity of opinion regarding the decrease in peripheral insulin sensitivity in late gestation. Spellacy and Goetz^[16] were among the first investigators to report an increase in insulin response to a glucose challenge in late gestation. Additionally, Burt^[17] demonstrated that pregnant women experienced less hypoglycemia in response to exogenous insulin in comparison with nonpregnant subjects. Later research by Fisher et al.^[18] using a high-dose glucose infusion test, Buchanan et al.^[19] using the Bergman minimal model, and Ryan et al.^[20] and Catalano et al.^[2] using the euglycemic-hyperinsulinemic clamp all have demonstrated a decrease in insulin sensitivity ranging from 33 to 78 percent. It should be noted, however, that all these quantitative estimates of insulin sensitivity are very likely overestimates due to non-insulin-mediated glucose disposal by the fetus and placenta. Hay et al.^[21] reported that in the pregnant ewe model, approximately one third of maternal glucose utilization was accounted for by uterine, placental, and fetal tissue. Additionally, Marconi et al.^[22] observed that based on human fetal blood sampling, fetal glucose concentration was a function of fetal size and gestational age in addition to maternal glucose concentration.

Placental glucose transport is a non-energy-requiring process and takes place through facilitated diffusion. Glucose transport is dependent on a family of glucose transporters referred to as the GLUT glucose transporter family. The principal glucose transporter in the placenta is GLUT 1, which is found in the syncytiotrophoblast.^[23] GLUT 1 is located on both the microvillus and basal membranes. Basal membrane GLUT 1 may be the rate-limiting step in placental glucose transport. There is a two- to threefold increase in the expression of syncytiotrophoblast glucose transporters with advancing gestation.^[24] Although GLUT 3 and GLUT 4 expression have been identified in placental endothelial cells and intervillous nontrophoblastic cells, respectively, the role they may play in placental glucose transport remains speculative.^[25],^[26]

DIABETES MELLITUS

Diabetes mellitus is a chronic metabolic disorder characterized by either absolute or relative insulin deficiency, resulting in increased glucose concentrations. Although glucose intolerance is the common outcome of diabetes mellitus, the pathophysiology remains heterogeneous. The two major classifications of diabetes mellitus are type 1, formerly referred to as insulin-dependent diabetes or juvenile onset diabetes, and type 2, formerly referred to as non-insulin-dependent or adult-onset diabetes. During pregnancy, classification of women with diabetes has often relied on the White classification,^[27] first proposed in the 1940s. This classification is based on factors such as the age of onset of diabetes and duration as well as end-organ involvement, primarily retinal and renal.

Type 1 Diabetes

Type 1 diabetes is usually characterized by an abrupt onset at a young age and absolute insulinopenia with lifelong requirements for insulin replacement. In some populations, the onset of type 1 diabetes may occur in individuals in the third or fourth decades of life. Patients with diabetes mellitus may have a genetic predisposition for antibodies directed against their pancreatic islet cells. The degree of concordance for the development of type 1 diabetes in monozygotic twins is 33 percent, suggesting that the events subsequent to the development of autoantibodies and appearance of glucose intolerance are also related to environmental factors. Because of the complete dependence on exogenous insulin, pregnant women with type 1 diabetes are at increased risk for the development of diabetic ketoacidosis. Additionally, because intensive insulin therapy is used in women with type 1 to decrease the risk for spontaneous abortion and congenital anomalies in early gestation, these women are at greater risk of hypoglycemic reactions. Studies by Diamond et al.^[28] and Rosenn et al.^[29] have shown that women with type 1 diabetes are at increased risk for hypoglycemic reactions during pregnancy because of diminished counterregulatory epinephrine and glucagon response to hypoglycemia. The deficiency in counterregulatory response may be in part due to an independent effect of pregnancy.

The alterations in glucose metabolism in women with type 1 diabetes are not well characterized. Because of maternal insulinopenia, insulin response during gestation can only be estimated relative to pregravid requirements. Estimates of the change in insulin requirements are complicated by the degree of preconceptional glucose control and frequent presence of insulin antibodies. Weiss and Hoffman^[30] reported on the change in insulin requirements in women with type 1 diabetes and strict glucose control either prior to conception or before 10 weeks' gestation. There was a 12 percent decrease in insulin requirements from 10 to 17 weeks' gestation and a 50 percent increase in insulin requirement from 17 weeks' until delivery as compared with

1085

pregravid requirements. After 36 weeks' gestation there was a decrease in insulin requirements. A 5 percent decrease in insulin requirements after 36 weeks' gestation was also noted by McManus and Ryan.^[31] The decrease in insulin requirements was associated with a longer duration of diabetes mellitus but not with adverse perinatal outcome. The fall in insulin requirements in early pregnancy in women with type 1 diabetes may be a reflection of decreased pregravid insulin sensitivity as will be described later.

Schmitz et al.^[32] have evaluated the longitudinal changes in insulin sensitivity in women with type 1 diabetes in early and late pregnancy as well as postpartum in comparison with nonpregnant women with type 1 diabetes. In pregnant women with type 1 diabetes there was a 50 percent decrease in insulin sensitivity only in late gestation. There was no significant difference in insulin sensitivity in pregnant women with type 1 diabetes in early pregnancy or within 1 week of delivery as compared with the nonpregnant women with type 1 diabetes. Therefore, based on the available data, women with type 1 diabetes appear to have a similar decrease in insulin sensitivity when compared with women with normal glucose tolerance.

Relative to the issue of placental transporters (GLUT 1), there is a report by Jansson and Powell^[33] describing an increase in both basal GLUT 1 expression and glucose transport activity from placental tissue in women with White Class D pregnancies.

Type 2 Diabetes/Gestational Diabetes

The pathophysiology of type 2 diabetes involves abnormalities of both insulin-sensitive tissues (i.e., a decrease in skeletal muscle and hepatic sensitivity to insulin) and β -cell response as manifested by an inadequate insulin response for a given degree of glycemia. Initially in the course of development of type 2 diabetes, the insulin response to a glucose challenge may be increased relative to that of individuals with normal glucose tolerance but is inadequate to maintain normoglycemia. Whether or not decreased insulin sensitivity (increased insulin resistance) precedes β -cell dysfunction in the development of type 2 diabetes continues to be debated. Arguments and experimental data support both hypotheses. As noted by Sims and Calles-Escadon,^[34] heterogeneity of metabolic abnormalities exists in any classification of diabetes mellitus.

Despite the limitations of any classification system, certain generalizations can be made regarding women with type 2 or gestational diabetes mellitus (GDM). These individuals are typically older and more often heavier as compared with individuals with type 1 diabetes or normal glucose tolerance. The onset of the disorder is usually insidious with few patients complaining of the classic triad of polydipsia, polyphagia, and polyuria. Individuals with type 2 diabetes are often initially recommended to lose weight, increase their activity (i.e., exercise), and follow a diet that is low in fats and high in complex carbohydrates. Oral agents are often used to either increase insulin response or, with newer drugs, enhance insulin sensitivity. Individuals with type 2 diabetes may eventually require insulin therapy to maintain euglycemia but are not at risk for diabetic ketoacidosis. Data from monozygotic twin studies have reported a lifetime risk of both twins developing type 2 diabetes that ranges between 58 percent and almost 100 percent, suggesting that the disorder has a strong genetic component.

Women with type 2 diabetes are usually classified as Class B diabetes according to the White classification system. Women developing gestational diabetes (i.e., glucose intolerance first recognized during pregnancy) share many of the metabolic characteristics of women with type 2 diabetes. Although earlier studies reported a 10 to 35 percent incidence of islet cell antibodies in women with gestational diabetes as measured by immunofluorescence techniques,^[35] ^[36] more recent data using specific monoclonal antibodies have described a much lower incidence on the order of 1 to 2 percent,^[36] suggesting a low risk of type 1 diabetes in women with gestational diabetes. Furthermore, postpartum studies of women with gestational diabetes have demonstrated defects in insulin secretory response^[37] and decreased insulin sensitivity,^[38] indicating that typical type 2 abnormalities in glucose metabolism are present in women with gestational diabetes. Of interest, the alterations in insulin secretory response and insulin resistance in women with a previous history of GDM as compared with a weight-matched control group may differ depending on whether or not the women with previous gestational diabetes are lean or obese.^[39] Thus, in women with gestational diabetes, the hormonal events of pregnancy may represent an unmasking of a genetic susceptibility to type 2 diabetes.

There are significant alterations in glucose metabolism in women who develop gestational diabetes relative to the changes in glucose metabolism in women with normal glucose tolerance. Decreased insulin response to a glucose challenge has been demonstrated by Yen et al.,^[40] Fisher et al.,^[41] and Buchanan et al.^[19] in women with gestational diabetes in late gestation. In prospective longitudinal studies of both lean and obese women with gestational diabetes, Catalano et al.^[14] also

showed a progressive decrease in first-phase insulin response in late gestation in lean women developing gestational diabetes as compared with a weight-matched control group (Fig. 32-6A). In contrast, in obese women developing gestational diabetes, there was no difference in first-phase insulin response but rather a significant increase in second-phase insulin response to an intravenous glucose challenge as compared with a

1086

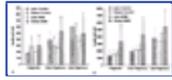

Figure 32-6 Longitudinal increase in insulin response to an intravenous glucose challenge in lean and obese women with normal glucose tolerance and gestational diabetes; pregravid, early, and late pregnancy. A, First phase: area under the curve from 0 to 5 minutes. B, Second phase: area under the curve from 5 to 60 minutes.

weight-matched control group (Fig. 32-6B). These differences in insulin response may be related to the ethnicity of the various study groups. Although there is an increase in the metabolic clearance rate of insulin with advancing gestation, there is no evidence that there is a significant difference between women with normal glucose tolerance and gestational diabetes.^[15]

There is a significant decline in fasting glucose concentrations with advancing gestation in women developing gestational diabetes. In late fasting, glucose and hepatic glucose production pregnancy increases in women with gestational diabetes in comparison with a control group.^[42] Whereas there was no significant difference in either fasting glucose concentration or hepatic glucose production in the longitudinal studies of Catalano et al.,^[14]^[15] these differences may again be population specific. However, to date all reports indicate that in late gestation, women with gestational diabetes have increased fasting insulin concentrations (Fig. 32-7) and less suppression of hepatic glucose production during insulin infusion, thereby indicating decreased hepatic glucose insulin sensitivity in women with gestational diabetes as compared with a weight-matched control group.^[14]^[15]^[42] In the studies of Xiang et al.,^[42] there was significant correlation between fasting free fatty acid concentrations and hepatic glucose production, suggesting that insulin resistance in fat cells may contribute to hepatic insulin resistance.

Women with gestational diabetes have decreased insulin sensitivity in comparison with weight-matched control groups. Ryan et al.^[20] was the first to report a 40 percent decrease in insulin sensitivity in women with gestational diabetes in comparison with a pregnant control group in late pregnancy using a hyperinsulinemic-euglycemic clamp. Xiang et al.^[42] found that women with gestational diabetes who had normal glucose tolerance within 6 months of delivery had significantly decreased insulin sensitivity as estimated by the glucose clearance rate during a hyperinsulinemic-euglycemic clamp, as compared with a matched control group with normal glucose tolerance during the third trimester. Catalano et al.^[14]^[15] using similar techniques described the longitudinal changes in insulin sensitivity in both lean and obese women developing gestational diabetes in comparison with a matched control group. Women developing gestational diabetes had decreased insulin sensitivity as compared with the matched control group

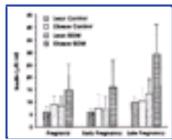

Figure 32-7 Longitudinal increase in basal or fasting insulin (U/ml) in lean and obese women with normal glucose tolerance and gestational diabetes; pregravid, early, and later pregnancy.

1087

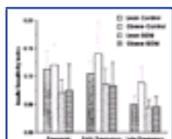

Figure 32-8 Longitudinal changes in the insulin sensitivity index (glucose infusion rate adjusted for residual endogenous glucose production and insulin concentrations achieved during the glucose clamp) in lean and obese women with normal glucose tolerance and gestational diabetes; pregravid, early, and late pregnancy.

(Fig. 32-8). The differences in insulin sensitivity were greatest before and during early gestation, and by late gestation the differences in insulin sensitivity between the groups were less pronounced but still significant. Of interest, there was an increase in insulin sensitivity from the time prior to conception through early pregnancy (12 to 14 weeks), particularly in those women with greatest decreases in insulin sensitivity prior to conception. The changes in insulin sensitivity from the time prior to conception through early pregnancy were significantly correlated with changes in maternal weight gain and energy expenditure.^[43] The relationship between these alterations in maternal glucose insulin sensitivity and weight gain and energy expenditure may help explain the decrease in maternal weight gain and insulin requirements in women with diabetes in early gestation.^[1]

Studies in human skeletal muscle and adipose tissue have demonstrated that postreceptor defects in the insulin signaling cascade are related to decreased insulin sensitivity in pregnancy. Garvey et al.^[44] were the first to demonstrate that there were no significant differences in the glucose transporter (GLUT 4) responsible for insulin action and skeletal muscle in pregnant as compared with nonpregnant women. Based on the studies of Friedman et al.^[45] in both pregnant women with normal glucose tolerance and gestational diabetes as well as weight-matched nonpregnant control subjects there appeared to be defects in the insulin signaling cascade in pregnancy as well as what may be additional abnormalities in women with gestational diabetes. All pregnant women appeared to have a decrease in insulin receptor substrate-1 (IRS-1) expression. The down-regulation of the IRS-1 protein closely parallels the decreased ability of insulin to induce additional steps in the insulin signaling cascade, resulting in movement of the GLUT 4 to the cell surface membrane and facilitating glucose transport into the cell. The down-regulation of IRS-1 protein closely parallels the ability of insulin to stimulate 2-deoxyglucose uptake in vitro. In addition to the above mechanisms, women with gestational diabetes mellitus demonstrate a distinct decrease in the ability of the insulin receptor (that component of the insulin receptor not on the cell surface) to undergo tyrosine phosphorylation. The additional defect in the insulin signaling cascade results in a 25 percent lower glucose transport activity.

Amino Acid Metabolism

Although glucose is the primary source of energy for the fetus and placenta, there are not appreciable amounts of glucose stored as glycogen in the fetus or placenta. However, accretion of protein is essential for growth of fetoplacental tissue. There is increased nitrogen retention in pregnancy in both maternal and fetal compartments. There is an increase of approximately 0.9 kg of maternal fat-free mass by 27 weeks.^[46] There is significant decrease in most fasting maternal amino acid concentrations in early pregnancy prior to the accretion of significant maternal or fetal tissue.^[47] These anticipatory changes in fasting amino acid metabolism occur after a shorter period of fasting in comparison with nonpregnant women, and may be another example of the accelerated starvation of pregnancy as described by Freinkel et al.^[48] Furthermore, amino acid concentrations such as serine correlate significantly with fetal growth in both early and late gestation.^[49] Maternal amino acid concentrations were significantly decreased in mothers of small-for-gestational-age neonates in comparison with maternal concentration in appropriately grown neonates.^[50]

There is also a significant conservation of nitrogen/protein in late gestation. There is a decrease in maternal plasma urea nitrogen concentrations as well as a decrease in urea nitrogen synthesis and excretion.^[51] In evaluating the balance between protein breakdown and resynthesis, estimates of amino acid turnover using stable isotopes of leucine are useful. Studies by Denne et al.^[52] have shown that the rates of basal or fasting proteolysis or protein turnover are similar in pregnant and nonpregnant subjects, indicating that there may be no change in fasting amino acid insulin sensitivity in pregnancy. Additionally, there are no published studies evaluating the effect of infused insulin on amino acid turnover during pregnancy in either pregnant women with normal or abnormal glucose tolerance. Therefore, based on studies of whole-body protein turnover in late gestation, there may be a slight decrease in the rate of

1088

protein breakdown during fasting^[53] and a small increase on protein turnover during the day.^[54] Additional studies will be required to understand the alterations in amino acid metabolism during pregnancy in normal and abnormal maternal and fetoplacental growth and development.

Amino acids are actively transported across the placenta from mother to fetus via energy-requiring amino acid transporters. These transporters are highly stereo-specific, but have low substrate specificity. Additionally, they may vary with location between the microvillus and basal membranes.^[55] Decreased amino acid concentrations have been reported in growth-restricted neonates in comparison with appropriately grown neonates. Decreased amino acid transporter activity has been implicated as a possible mechanism. However, the potential role if any of placental amino acid transporters in the development of fetal macrosomia in women with diabetes is currently unknown.^[56]

Lipid Metabolism

While there is ample literature regarding the changes in glucose metabolism during gestation, the data regarding the alterations in lipid metabolism are meager by comparison. Knopp et al.^[57] have reported that there is a two- to fourfold increase in total triglyceride concentration and a 25 to 50 percent increase in total cholesterol concentration during gestation. Additionally, there is a 50 percent increase in low-density lipoprotein (LDL) cholesterol and a 30 percent increase in high-density lipoprotein (HDL) cholesterol by midgestation, which decreases slightly in the third trimester. Maternal triglyceride and very-low-density lipoprotein (VLDL) triglyceride levels in late gestation are positively correlated with maternal estriol and insulin concentrations.

The increase in maternal lipid concentration in late gestation, in particular free fatty acids, has been hypothesized as one mechanism responsible for the decrease in maternal insulin sensitivity.^[58] Free fatty acids have been associated with fetal overgrowth, particularly of fetal adipose tissue. There is a significant difference in the arteriovenous free fatty acid concentration at birth much as there is with arteriovenous glucose concentration. Knopp et al.^[59],^[60] reported that neonatal birth weight was positively correlated with triglyceride and free fatty acid concentrations in late pregnancy. Similar conclusions were reached by Ogburn et al.,^[61] who showed that higher fetal insulin levels decrease free fatty acid concentrations, inhibit lipolysis, and result in increased fat deposition in the fetus. Lastly, Kleigman et al.^[62] reported that infants of obese women had an increased birth weight and skinfold thickness and higher free fatty acid levels when compared with infants of lean women.

Lipid metabolism in women with diabetes mellitus is influenced by whether the woman has type 1 or type 2 diabetes. This also applies when these women become pregnant. In women with type 2 diabetes and gestational diabetes, Knopp et al.^[63] reported an increase in triglyceride and decrease in HDL concentrations. However, Montelongo et al.^[64] reported little change in free fatty acid concentrations through all three trimesters after a 12-hour fast. Recently, Koukkou et al.^[65] reported an increase in total triglyceride but a lower LDL cholesterol in women with gestational diabetes. In women with type 1 diabetes, there was no change in total triglyceride, but a lower cholesterol concentration, secondary to a decrease in HDL. This is of interest because HDL acts as a plasma antioxidant and thus may be related to the increase in congenital malformations in women with type 1 diabetes. Oxidative stress has been implicated as a potential factor in the incidence of anomalies in women with type 1 diabetes.

Maternal Weight Gain and Energy Expenditure

Estimates of the energy requirements of pregnancy range from a cost of 80,000 kcal to a net saving of up to 10,000 kcal.^[66] As a result, the recommendations for nutritional intake in pregnancy are diverse and depend on the population being evaluated. Furthermore, based on more recent data, recommendations for individuals within a population may be more diverse than previously believed, making general guidelines for nutritional intake difficult.^[67]

The theoretical energy cost of pregnancy was originally estimated by Hytten^[46] using a factorial method. The additional cost of pregnancy consisted of (1) the additional maternal and fetoplacental tissue accrued during pregnancy and (2) the additional "running cost" of pregnancy (e.g., the increased cardiac output). In Hytten's model, the greatest increases in maternal energy expenditure occur between 10 and 30 weeks' gestation, primarily because of maternal accretion of adipose tissue. However, the mean increases in maternal adipose tissue vary considerably among various ethnic groups. Forsum et al.^[68] reported a mean increase of over 5 kg of adipose tissue in Swedish women, whereas Lawrence et al.^[69] found no increase in adipose tissue stores in women from the Gambia.

Basal metabolic rate accounts for 60 to 70 percent of total energy expenditure in individuals not engaged in competitive physical activity and correlates well with total energy expenditure. As with the changes in maternal accretion of adipose tissue, there are wide variations in the change in maternal basal metabolic rate during gestation, not only in different populations but again within relatively homogeneous groups. The cumulative energy changes in basal metabolic rate range from a high of 52,000 kcal in Swedish women^[70] to net

savings of 10,700 kcal in women from the Gambia^[69] without nutritional supplementation. The mean increase in basal metabolic rate in Western women relative to a nonpregnant, nonlactating control group averages approximately 20 percent.^[71] However, the coefficient of variation of basal metabolic rate in these populations during gestation ranges from 93 percent in women in the United Kingdom^[72] to over 200 percent in Swedish women.^[70] When assessing energy intake in relation to energy expenditure, however, estimated energy intake remains significantly lower than the estimates of total energy expenditure. These discrepancies have usually been explained by factors such as (1) increased metabolic efficiency during gestation,^[73] (2) decreased maternal activity,^[74] and (3) unreliable assessment of food intake.^[72]

Data in nonpregnant subjects may help us understand some of the wide variations in metabolic parameters during human gestation, even with homogeneous populations. Swinburn et al.^[75] reported that in the Pima Indian population, subjects with decreased insulin sensitivity gained less weight when compared with more insulin sensitive subjects (3.1 vs. 7.6 kg) over a period of 4 years. Furthermore, the percentage weight change per year was highly correlated with glucose disposal as estimated from clamp studies. Catalano et al.^[43] conducted a prospective longitudinal study in early pregnancy of the changes in maternal accretion of body fat and basal metabolic rate in women with normal glucose tolerance and gestational diabetes. Women with gestational diabetes had decreased glucose insulin sensitivity in early gestation as compared with the control group and had significantly smaller increases in body fat than women with normal glucose tolerance. There was a significant inverse correlation between the changes in fat accretion and insulin sensitivity (i.e., women with decreased pregravid insulin sensitivity had less accretion of body fat as compared with women with increased pregravid insulin sensitivity). These results are consistent with a previous report showing that total weight gain in women with gestational diabetes was 2.5 kg less as compared to a weight-matched control group.^[76]

In these same subjects there was also a significant inverse correlation between changes in basal metabolic rate and basal hepatic glucose production.^[43] In early gestation, there was a 7 percent increase in basal metabolic rate in women with normal glucose tolerance and only a 2 percent increase in women with gestational diabetes. As before, there was a significant negative correlation between the changes in basal metabolic rate and estimates of glucose metabolism, in this case basal hepatic glucose production. The results of these studies show that there is a relationship between the changes in maternal insulin sensitivity and changes in basal metabolic rate and accretion of adipose tissue in early gestation. The ability of women with decreased pregravid glucose insulin sensitivity to conserve energy, increase body fat, and make sufficient nutrients available to produce a healthy fetus supports the hypothesis that decreased maternal insulin sensitivity may have a reproductive metabolic advantage in women when food availability is marginal. In contrast, decreased maternal insulin sensitivity before conception in areas where food is plentiful and a sedentary lifestyle is more common may manifest itself as gestational diabetes and increase the long-term risk for both diabetes and obesity in the woman and her offspring.

PERINATAL MORBIDITY AND MORTALITY

Fetal Death

In the past, sudden and unexplained stillbirth occurred in 10 to 30 percent of pregnancies complicated by type 1 (insulin-dependant) diabetes mellitus. ^{[77], [78]} Although relatively uncommon today, such losses still plague the pregnancies of patients who do not receive optimal care. Stillbirths have been observed most often after the 36th week of pregnancy in patients with vascular disease, poor glycemic control, hydramnios, fetal macrosomia, or preeclampsia. Women with vascular complications may develop fetal growth restriction and intrauterine demise as early as the second trimester. In the past, prevention of intrauterine death led to a strategy of scheduled preterm deliveries for type 1 diabetic women. This empiric approach reduced the number of stillbirths, but errors in estimation of fetal size and gestational age as well as the functional immaturity characteristic of the infant of the diabetic mother (IDM) contributed to many neonatal deaths from hyaline membrane disease (HMD).

The precise cause of the excessive stillbirth rate in pregnancies complicated by diabetes remains unknown. Because extramedullary hematopoiesis is frequently observed in stillborn IDMs, chronic intrauterine hypoxia has been cited as a likely cause of these intrauterine fetal deaths. Recent studies of fetal umbilical cord blood samples from pregnant women with type 1 diabetics have demonstrated "relative fetal erythremia and lactic acidemia." ^[79] Maternal diabetes may also produce alterations in red blood cell oxygen release and placental blood flow. ^[80]

Reduced uterine blood flow is thought to contribute to the increased incidence of intrauterine growth restriction (IUGR) observed in pregnancies complicated by diabetic vasculopathy. Investigations using radioactive tracers have also suggested a relationship between poor maternal metabolic control and reduced uteroplacental

TABLE 32-1 -- FREQUENCY OF CONGENITAL MALFORMATIONS IN INFANTS OF DIABETIC MOTHERS

Study	Frequency	%

Simpson et al. ^[87]	9/106	8.5
Albert et al. ^[86]	29/289	10.0

blood flow. ^[81] Ketoacidosis and preeclampsia, two factors known to be associated with an increased incidence of intrauterine deaths, may further decrease uterine blood flow. In diabetic ketoacidosis, hypovolemia and hypotension caused by dehydration may reduce flow through the intervillous space, while in preeclampsia, narrowing and vasospasm of spiral arterioles may result.

Alterations in fetal carbohydrate metabolism also may contribute to intrauterine asphyxia. ^{[82] [83] [84]} There is considerable evidence linking hyperinsulinemia and fetal hypoxia. Hyperinsulinemia induced in fetal lambs by an infusion of exogenous insulin produces an increase in oxygen consumption and a decrease in arterial oxygen content. ^[85] Persistent maternalfetal hyperglycemia occurs independent of maternal uterine blood flow, which may not be increased enough to allow for enhanced oxygen delivery in the face of increased metabolic demands. Thus, hyperinsulinemia in the fetus of the diabetic mother appears to increase fetal metabolic rate and oxygen requirement in the face of several factors such as hyperglycemia, ketoacidosis, preeclampsia, and maternal vasculopathy, which can reduce placental blood flow and fetal oxygenation.

Congenital Malformations

With the reduction in intrauterine deaths and a marked decrease in neonatal mortality related to HMD and traumatic delivery, congenital malformations have emerged as the most important cause of perinatal loss in pregnancies complicated by type 1 and type 2 diabetes mellitus. In the past, these anomalies were responsible for approximately 10 percent of all perinatal deaths. At present, however, malformations account for 30 to 50 percent of perinatal mortality. ^[79] Neonatal deaths now exceed stillbirths in pregnancies complicated by pregestational diabetes mellitus, and fatal congenital malformations account for this changing pattern.

Most studies have documented a two- to sixfold increase in major malformations in infants of type 1 and type 2 diabetic mothers. At The Ohio State University Diabetes in Pregnancy Program, we have observed 29 congenital anomalies in 289 (10 percent) women enrolled from 1987 through 1993. ^[86] In a prospective analysis, Simpson et al. observed an 8.5 percent incidence of major anomalies in the diabetic population, while the malformation rate in a small group of concurrently gathered control subjects was 2.4 percent. ^[87] Similar figures were obtained in the Diabetes in Early Pregnancy Study in the United States. ^[88] The incidence of major anomalies was 2.1 percent in 389 control patients and 9.0 percent in 279 diabetic women. In general, the incidence of major malformations in worldwide studies of offspring of diabetic mothers has ranged from 5 to 10 percent (Table 32-1).

The insult that causes malformations in IDM impacts on most organ systems and must act before the seventh week of gestation. ^[82] Central nervous system malformations, particularly anencephaly, open spina bifida and, possibly, holoprosencephaly, are increased 10-fold. ^[89] Cardiac anomalies, especially ventricular septal defects and complex lesions such as transposition of the great vessels, are increased fivefold. The congenital defect thought to be most characteristic of diabetic embryopathy is sacral agenesis or caudal dysplasia, an anomaly found 200 to 400 times more often in offspring of diabetic women (Fig. 32-9). However, this defect is not pathognomonic for diabetes, since it also occurs in nondiabetic pregnancies.

Impaired glycemic control and associated derangements in maternal metabolism appear to contribute to abnormal embryogenesis. The notion of excess glucose as the single teratogenic agent in diabetic pregnancy has thus been replaced with the view of a multifactorial etiology ^[89] (see the box "Proposed Factors Associated with

Maternal hyperglycemia has been proposed by most investigators as the primary teratogenic factor, but hyperketonemia, hypoglycemia, somatomedin inhibitor excess, and excess free oxygen radicals have also been

Figure 32-9 Infant of a diabetic mother with caudal regression syndrome. The mother of this infant presented with class F diabetes at 26 weeks, in poor glycemic control. Ultrasound examination revealed absent lower lumbar spine and sacrum and hypoplastic lower extremities.

suggested.^[89] The profile of a woman most likely to produce an anomalous infant would include a patient with poor periconceptional control, long-standing diabetes, and vascular disease.^[90] Genetic susceptibility to the teratogenic influence of diabetes may be a factor. Koppe and Smoremborg-School as well as Simpson and colleagues have suggested that certain maternal HLA types may be more often associated with anomalies.^[91], ^[92]

Proposed Factors Associated with Teratogenesis in Pregnancy Complicated By Diabetes Mellitus
Hyperglycemia
Ketone body excess
Somatomedin inhibition
Arachidonic acid deficiency
Free oxygen radical excess

Several mechanisms have been proposed by which the above teratogenic factors produce malformations. Freinkel et al. suggested that anomalies might arise from inhibition of glycolysis, the key energy-producing process during embryogenesis. He found that D-mannose added to the culture medium of rat embryos inhibited glycolysis and produced growth restriction and derangement of neural tube closure.^[93] Freinkel et al. stressed the sensitivity of normal embryogenesis to alterations in these key energy-producing pathways, a process he labeled "fuel-mediated" teratogenesis. Goldman and Baker have suggested that the mechanism responsible for the increased incidence of neural tube defects in embryos cultured in a hyperglycemic medium may involve a functional deficiency of arachidonic acid, because supplementation with arachidonic acid or myoinositol will reduce the frequency of neural tube defects in this experimental model.^[94] Pinter and Reece and Pinter et al. have confirmed these studies and demonstrated that hyperglycemia induced alterations in neural tube closure include disordered cells, decreased mitoses, and changes indicating premature maturation. These authors have further demonstrated that hyperglycemia during organogenesis has a primary deleterious effect on yolk sac function with resultant embryopathy.^[95], ^[96]

Altered oxidative metabolism from maternal diabetes may cause increased production of free oxygen radicals in the developing embryo, which are likely teratogenic. Supplementation of oxygen radical scavenging enzymes, such as superoxide dismutase to culture medium of rat embryos, protects against growth delay and excess malformations.^[97] It has been suggested that excess free oxygen radicals may have a direct effect on embryonic prostaglandin biosynthesis. Free oxygen radical excess may enhance lipid peroxidation and, in turn, generated hydroperoxides might stimulate thromboxane biosynthesis and inhibit prostacyclin production, an imbalance that could have profound effects on embryonic development.^[98]

Fetal Macrosomia

Macrosomia has been variously defined as birth weight greater than 4,000 to 4,500 g as well as large for gestational age where birth weight is above the 90th percentile for population and sex-specific growth curves. Fetal macrosomia complicates as many as 50 percent of pregnancies in women with gestational diabetes and 40 percent of pregnancies complicated by type 1 diabetes, including some women treated with intensive glycemic control (Fig. 32-10). Delivery of an infant weighing greater than 4,500 g occurs 10 times more often in women with diabetes as compared with a population of women with normal glucose tolerance.^[99]

According to the Pedersen hypothesis, maternal hyperglycemia results in fetal hyperglycemia and hyperinsulinemia, resulting in excessive fetal growth. Increased fetal -cell mass may be identified as early as the second trimester.^[99] Evidence supporting the Pedersen hypothesis has come from the studies of amniotic fluid and cord blood insulin and C-peptide concentrations. Both are increased in the amniotic fluid of insulin-treated women with diabetes at term^[100] and correlate with neonatal fat mass.^[101] Lipids and amino acids, which are elevated in pregnancies complicated by gestational

Figure 32-10 Two extremes of growth abnormalities in infants of diabetic mothers. The small growth-retarded infant on the left weighed 470 g and is the offspring of a woman with nephropathy and hypertension, delivered at 28 weeks' gestation. The neonate on the right is the 5,100-g baby of a woman with suboptimally controlled class C diabetes.

diabetes, may also play a role in excessive fetal growth by stimulating the release of insulin and other growth factors from the fetal pancreatic -cells and placenta. Infants of mothers with gestational diabetes have an increase in fat mass as compared with fat-free mass.^[102] Additionally, their growth is disproportionate, with chest/head and shoulder/head ratios larger than those of infants of women with normal glucose tolerance. This factor may contribute to the higher rate of shoulder dystocia and birth trauma observed in these infants.^[103]

The results of several clinical series have validated the Pedersen hypothesis inasmuch as tight maternal glycemic control has been associated with a decline in the incidence of macrosomia. In a series of 260 insulin-dependent women achieving fasting plasma glucose concentrations between 109 and 140 mg/dl, Gabbe et al.^[104] observed 58 (22 percent) macrosomic infants. Kitzmiller and Cloherty^[105] reported that 11 percent of 134 women achieving fasting glucose concentrations between 105 and 121 mg/dl were delivered of an infant with a birth weight in excess of 4,000 g. A more dramatic reduction in the rate of macrosomia has been reported when more physiologic control has been achieved. Roversi and Gargiulo^[106] instituted a program of "maximally tolerated" insulin administration and observed macrosomia in only 6 percent of cases. Jovanovic and coworkers^[107] eliminated macrosomia in 52 women who achieved mean glucose levels of 80 to 87 mg/dl throughout gestation. Landon and colleagues^[108] using daily capillary glucose values obtained during the second and third trimesters in insulin-dependent women reported a 9 percent rate of macrosomia when mean values were below 110 mg/dl compared with 34 percent when less optimal control was achieved. Jovanovic et al.^[109] have suggested that 1-hour postprandial glucose measurements correlate best with the frequency of macrosomia. After controlling for other factors, these authors noted that the strongest prediction for birth weight was third-trimester nonfasting glucose measurements.

In a series of metabolic studies, Catalano et al.^[110] estimated body composition in 186 neonates using anthropometry. Fat-free mass that comprised 86 percent of mean birth weight accounted for 83 percent of the variance in birth weight, and fat mass, which comprised only 14 percent of birth weight, accounted for 46 percent of the variance in birth weight. There was also significantly greater fat-free mass in male as compared with female infants. Using independent variables such as maternal height, pregravid weight, weight gain during pregnancy, parity, paternal height and weight, neonatal sex, and gestational age, the authors accounted for 29 percent of

30 percent of the variance in fat-free mass, and 17 percent of the variance in fat mass.^[111] Including estimates of maternal insulin sensitivity in 16 additional subjects, they were able to explain 48 percent of the variance in birth weight, 53 percent in fat-free mass, and 46 percent in fat mass.^[112] Studies by Caruso et al.^[113] have corroborated these findings, reporting that women with unexplained fetal growth restriction had greater insulin sensitivity as compared with a control group of women whose infants were appropriate weight for gestational age. A positive correlation between birth weight and weight gain has been observed in women with normal glucose tolerance, but there is a negative correlation in women with gestational diabetes. In women with normal glucose tolerance, the correlation was strongest in women who were lean before conception and became progressively weaker as pregravid weight for height increased.^[79] In women with gestational diabetes, there was no significant correlation between maternal weight gain and birth weight, irrespective of pregravid weight for height. These studies emphasize the role of the maternal metabolic environment and fetal growth.

In addition to an increased risk of birth trauma, fetal macrosomia in infants of women with abnormal glucose tolerance may be associated with significant long-term risks. The birth weight of these infants tends to normalize by 1 year of age but increases in early childhood.^[114] These children are at greater risk for obesity at ages 1 to 9 and in adolescence. Silverman and colleagues^[114] have reported a strong correlation between amniotic fluid insulin levels and increased body mass index (wt/ht²) at ages 14 to 17 years, indicating an association between islet cell activation in utero and development of childhood obesity. Childhood obesity then predisposes to obesity in the adult. Pettitt and colleagues have shown that infants born to Pima Indian women with impaired glucose tolerance were more obese as children than infants of women with normal glucose tolerance, even when the later group developed diabetes later in life.^[115] These data suggest that there are both in utero maternal metabolic factors as well as genetic factors leading to the later development of obesity and type 2 diabetes.

Hypoglycemia

Neonatal hypoglycemia, a blood glucose below 35 to 40 mg/dl during the first 12 hours of life, results from a rapid fall in plasma glucose concentrations following clamping of the umbilical cord. Hypoglycemia is particularly common in macrosomic newborns, with rates exceeding 50 percent. With near physiologic control of maternal glucose levels during pregnancy, overall rates of 5 to 15 percent have been reported.^[106],^[107] The degree of hypoglycemia may be influenced by at least two factors: (1) maternal glucose control during the latter half of pregnancy, and (2) maternal glucose control during labor and delivery. Maternal blood glucose levels greater than 90 mg/dl during delivery have been found to increase significantly the frequency of neonatal hypoglycemia.^[116] Presumably, prior poor maternal glucose control can result in fetal β -cell hyperplasia, leading to exaggerated insulin release following delivery. IDMs exhibiting hypoglycemia have elevated cord C-peptide and free insulin levels at birth and an exaggerated pancreatic response to glucose loading.^[117]

Respiratory Distress Syndrome

The precise mechanism by which maternal diabetes alters pulmonary development remains unknown. Experimental animal studies have focused primarily on the effects of hyperglycemia and hyperinsulinemia on pulmonary surfactant biosynthesis. An extensive review of the literature confirms that both of these factors are involved in delayed pulmonary maturation in the IDM.^[118]

In vitro studies have documented that insulin can interfere with substrate availability for surfactant biosynthesis.^[119],^[120] Smith has postulated that insulin interferes with the normal timing of glucocorticoid-induced pulmonary maturation in the fetus.^[120] Cortisol apparently acts on pulmonary fibroblasts to induce synthesis of fibroblast-pneumocyte factor, which then acts on type II cells to stimulate phospholipid synthesis.^[121] Carlson and coworkers have shown that insulin blocks cortisol action at the level of the fibroblast by reducing the production of fibroblast-pneumocyte factor.^[122]

Clinical studies investigating the effect of maternal diabetes on fetal lung maturation have produced conflicting data. With the introduction of protocols that have emphasized glucose control and antepartum surveillance until lung maturity has been established, respiratory distress syndrome (RDS) has become a less common occurrence in the IDM. Several studies agree that in well-controlled diabetic women delivered at term, the risk of RDS is no higher than that observed in the general population.^[123],^[124] Kjos et al. studied the outcome of 526 diabetic gestations delivered within 5 days of amniotic fluid fetal lung maturation testing and reported hyaline membrane disease in five neonates (0.95 percent), all of whom were delivered prior to 34 weeks' gestation.^[124] Mimouni et al. compared outcomes of 127 IDMs with matched controls and concluded that diabetes in pregnancy as currently managed is not a direct risk factor for the development of RDS. Yet, cesarean delivery not preceded by labor and prematurity, both of which are increased in diabetic pregnancies, clearly increase the likelihood of neonatal respiratory disease.^[125]

Calcium and Magnesium Metabolism

Neonatal hypocalcemia, serum levels below 7 mg/dl, occurs at an increased rate in the IDM when one controls for predisposing factors such as prematurity and birth asphyxia.^[58] Hypocalcemia in the IDM has been associated with a failure to increase parathyroid hormone synthesis following birth.^[126] Decreased serum magnesium levels have also been documented in pregnant diabetic women as well as their infants. Mimouni et al. described reduced amniotic fluid magnesium concentrations in women with diabetes.^[127] These findings may be explained by reduced fetal urinary magnesium excretion, which would accompany a relative magnesium-deficient state. Magnesium deficiency may paradoxically inhibit fetal parathyroid hormone secretion.

Hyperbilirubinemia and Polycythemia

Hyperbilirubinemia is frequently observed in the IDM. Neonatal jaundice has been reported in as many as 53 percent of pregnancies complicated by diabetes and 38 percent of pregnancies with GDM.^[128],^[129] Although several mechanisms have been proposed to explain these clinical findings, the pathogenesis of hyperbilirubinemia remains uncertain. In the past, the jaundice observed in the IDM was often attributed to prematurity. Studies that have analyzed morbidity carefully, according to gestational age, however, have rejected this concept.^[130]

Although severe hyperbilirubinemia may be observed independent of polycythemia, a common pathway for these complications most likely involves increased red blood cell production, stimulated by increased erythropoietin in the IDM. Presumably, the major stimulus for red cell production is a state of relative hypoxia in utero, as described previously. Although cord erythropoietin levels generally are normal in IDMs whose mothers demonstrate good glycemic control during gestation, Shannon and Ylinen found that glycosylated hemoglobin values in late pregnancy were significantly elevated in mothers of hyperbilirubinemic infants.^[129],^[131] Fetal hyperinsulinemia may also stimulate erythropoiesis.^[79]

MATERNAL CLASSIFICATION AND RISK ASSESSMENT

Priscilla White^[132] first noted that the patient's age at onset of diabetes, the duration of the disease, and the presence of vasculopathy significantly influenced perinatal outcome. Her pioneering work led to a classification system that has been widely applied to pregnant women with diabetes.^[132] A modification of this scheme is presented in Table 32-2. Counseling a patient and

Modified from White P: Pregnancy complicating diabetes. *Am J Med* 7:609, 1949.

formulating a plan of management requires assessment of both maternal and fetal risk. The White classification facilitates this evaluation.

Class A₁ diabetes mellitus includes those patients who have demonstrated carbohydrate intolerance during a 100-g 3-hour oral glucose tolerance test (OGTT); however, their fasting and 2-hour postprandial glucose levels are less than 95 mg/dl and 120 mg/dl, respectively. These patients are generally managed by dietary regulation alone. If the fasting value of the OGTT is elevated (>95 mg/dl) and/or 2-hour postprandial glucose levels exceed 120 mg/dl, patients are designated Class A₂. Insulin is most often required for these women.

The Second and Third International Workshop-Conferences on Gestational Diabetes sponsored by the American Diabetes Association in cooperation with the American College of Obstetricians and Gynecologists (ACOG) recommended that the term gestational diabetes rather than Class A diabetes be used to describe women with carbohydrate intolerance of variable severity with onset or recognition during the present pregnancy.^[133],^[134] The term gestational diabetes fails to specify whether the patient requires dietary adjustment alone or treatment with diet and insulin. This distinction is important because those patients who are normoglycemic while fasting appear to have a significantly lower perinatal mortality rate.^[135] Women with gestational diabetes who require insulin are at greater risk for a poor perinatal outcome than those controlled by diet alone.

Patients requiring insulin are designated by the letters B, C, D, R, F, and T. Class B patients are those whose onset of disease occurs after age 20. They have had

diabetes less than 10 years and have no vascular complications. Included in this subgroup of patients are those who have been previously treated with oral hypoglycemic agents.

Class C diabetes includes patients who have the onset of their disease between the ages of 10 and 19 or have had the disease for 10 to 19 years. Vascular disease is not present.

Class D represents women whose disease is of 20 years' duration or more, or whose onset occurred before age 10, or who have benign retinopathy. The latter includes microaneurysms, exudates, and venous dilation.

In summary, risk assessment may be simplified by evaluating the patient's blood glucose and blood vessels. Patients with excellent glucose control and no blood vessel disease should do well. Those in poor control and with vasculopathy are at increased risk for fetal death, IUGR, preeclampsia, and preterm delivery.

Nephropathy

Renal disease develops in 25 to 30 percent of women with type 1 diabetes mellitus, with a peak incidence after approximately 16 years of diabetes.^[136] Women with diabetic nephropathy have a significantly reduced life expectancy. In women with overt nephropathy, end-stage renal disease occurs in 50 percent by 10 years and in greater than 75 percent of cases by 20 years. Class F describes the 5 to 10 percent of pregnant patients with underlying renal disease. This includes those with reduced creatinine clearance and/or proteinuria of at least 400 mg in 24 hours measured during the first 20 weeks of gestation. Two factors present prior to 20 weeks' gestation appear to be predictive of perinatal outcome in these women (e.g., preterm delivery, low birth weight, or preeclampsia): proteinuria greater than 3.0 g/24 h and serum creatinine greater than 1.5 mg/dl.

In our series of 45 Class F women, 12 women had such risk factors.^[137] Preeclampsia developed in 92 percent, with a mean gestational age at delivery of 34 weeks compared to an incidence of preeclampsia of 36 percent in 33 women without these risk factors who reached an average gestational age of 36 weeks. Remarkably, perinatal survival was 100 percent in this series, and no deliveries occurred prior to 30 weeks' gestation. Comparable series detailing perinatal outcomes in Class F patients are presented in Table 32-3.

The management of the diabetic woman with nephropathy requires great expertise. Limitation of dietary protein, which may reduce protein excretion in nonpregnant patients, has not been adequately studied during pregnancy. Although controversial, some nephrologists recommend a modified reduction in protein intake for pregnant women with nephropathy. Control of hypertension in pregnant women with diabetic nephropathy is crucial to prevent further deterioration of kidney function and to optimize pregnancy outcome. Although debatable, some cautiously use diuretics when patients are extremely nephrotic, as this group may be prone to volume-dependent forms of hypertension. Angiotension-converting enzyme (ACE) inhibitors, which reduce intraglomerular pressure and improve proteinuria in nonpregnant diabetic patients, should be avoided during pregnancy, as these agents can affect fetal urine production resulting in oligohydramnios.

Several studies have failed to demonstrate a permanent worsening of diabetic renal disease as a result of pregnancy. ^[137] ^[138] ^[139] Furthermore, it has been suggested that pregnancy itself does not increase the risk of developing

1096

nephropathy, although development of proteinuria and poor glycemic control are markers for subsequent renal disease. Kitzmilller and colleagues reviewed 35 pregnancies complicated by diabetic nephropathy. ^[138] Proteinuria increased in 69 percent and hypertension developed in 73 percent. Following delivery, proteinuria declined in 65 percent of cases. In only two patients did protein excretion increase after gestation. In Gordon's series, 26 women (58 percent) had more than a 1-g increase in proteinuria, and by the third trimester, 25 (56 percent) excreted more than 3.0 g/24 h. ^[137] In the vast majority of cases, protein excretion returned to baseline levels following gestation. Changes in creatinine clearance during pregnancy are variable in Class F patients. Kitzmilller, in reviewing 44 patients from the literature, noted that about one third of women had an expected rise in creatinine clearance during gestation, compared to one third who had a decline of more than 15 percent by the third trimester. ^[140] In Gordon's series, 12 of 16 women whose clearance fell developed preeclampsia. Of interest, most patients with a severe reduction in creatinine clearance (<50 ml/min) do not demonstrate a further reduction in first-trimester clearance during pregnancy. ^[137] However, a decline in renal function can be anticipated in 20 to 30 percent of cases. Several authors have suggested that any deterioration of renal function after pregnancy is probably consistent with the natural course of diabetic nephropathy and is not related to pregnancy per se. ^[141] Thus, women with early stage nephropathy (<1 g/24 h of proteinuria and normal creatinine clearance) entering pregnancy are unlikely to manifest a decline in renal function in 1 to 2 years of follow-up. ^[137]

With improved survival of diabetic patients following renal transplantation, a small group of kidney recipients has now achieved pregnancy (Class T). Nine cases of pregnancy complicated by diabetes and prior renal transplantation have been described. ^[142] In this series, there were no episodes of renal allograft rejection. Prednisone and azathioprine were administered throughout gestation. A single maternal death and two fetal deaths did occur in patients with preexisting peripheral vascular disease. Superimposed preeclampsia occurred in six patients. All seven surviving infants were delivered prior to term, with fetal compromise evident in six of these cases.

Retinopathy

Class R diabetes designates patients with proliferative retinopathy. As with nephropathy, prevalence of retinal disease is highly related to the duration of diabetes. At 20 years, nearly 80 percent of diabetic individuals will have some element of retinopathy. Excellent glycemic control prevents retinopathy and may slow its progression. Parity is not associated with a risk for subsequent retinopathy. ^[143] However, pregnancy does convey a greater than twofold independent risk for progression of existing retinopathy. ^[144] Progression of diabetic retinopathy during pregnancy is associated with hypertensive disease. ^[145] Retinopathy may worsen significantly during pregnancy in spite of the major advances that have been made in diagnosis and treatment of existing retinopathy. Ideally, women planning a pregnancy should have a comprehensive eye examination and treatment prior to conception. For those discovered to have proliferative changes during pregnancy, laser photocoagulation therapy with careful follow-up has helped maintain many pregnancies to a gestational age at which neonatal survival is likely.

In a large series of 172 patients, including 40 cases with background retinopathy and 11 with proliferative changes, only one patient developed new-onset proliferative retinopathy during pregnancy. ^[146] A review of the literature by Kitzmilller confirms the observation that progression to proliferative retinopathy during pregnancy rarely occurs in women with background retinopathy or those without any eye ground changes. ^[147] Of the 561 women in these two categories, only 17 (3.0 percent) developed neovascularization during gestation. ^[147] In contrast, 23 of 26 (88.5 percent) with untreated proliferative disease experienced worsening retinopathy during pregnancy.

Pregnancy may increase the prevalence of some background retinal changes. ^[148] Characteristic streak-blob hemorrhages and soft exudates have been noted and retinopathy may progress despite strict metabolic control. At least two studies have related worsening retinal disease to plasma glucose at the first prenatal visit as well as the magnitude of improvement in glycemia during early pregnancy. ^[149] ^[150] In a subset of 140 women without proliferative retinopathy at baseline followed in the Diabetes in Early Pregnancy Study, progression of retinopathy was seen in 10.3, 21.1, 18.8, and 54.8 percent of patients with no retinopathy, microaneurysms only, mild nonproliferative retinopathy, and moderate to severe nonproliferative retinopathy at baseline, respectively. Elevated glycosylated hemoglobin at baseline and the magnitude of improvement of glucose control through week 14 was associated with higher risk of progression of retinopathy. ^[150] Women with an initial glycohemoglobin greater than 6 SD above the control mean compared with those within 2 SD of the mean were nearly three times as likely to experience worsening retinopathy. Whether improving control or simply suboptimal control itself contributes to a deterioration of background retinopathy remains uncertain. Hypertension may also be a significant risk factor for the progression of retinopathy during pregnancy. ^[149] Rosenn and colleagues reported that worsening of retinopathy

1097

occurred in 55 percent of women with a hypertensive disorder of pregnancy compared to 25 percent of women without chronic hypertension or preeclampsia.

For women with proliferative changes, laser photocoagulation is indicated and most will respond to this therapy. However, those women who demonstrate severe florid disc neovascularization that is unresponsive to laser therapy during early pregnancy may be at great risk for deterioration of their vision. Termination of

pregnancy should be considered in this group of patients.

In addition to background and proliferative eye disease, vaso-occlusive lesions associated with the development of macular edema have been described during pregnancy.^[151] Cystic macular edema is most often found in patients with proteinuric nephropathy, anemia, and hypertensive disease leading to retinal edema. Macular capillary permeability is a feature of this process. The degree of macular edema is directly related to the fall in plasma oncotic pressure present in these women. In Sinclair's series, seven women with minimal or no retinopathy before becoming pregnant developed severe macular edema associated with preproliferative or proliferative retinopathy during the course of their pregnancies. Although proliferation was controlled with photocoagulation, the macular edema worsened until delivery in all cases and was often aggravated by photocoagulation.^[151] While both macular edema and retinopathy regressed after delivery in some patients, in others these pathologic processes persisted, resulting in significant visual loss.

Coronary Artery Disease

Class H diabetes refers to the presence of diabetes of any duration associated with ischemic myocardial disease. There is evidence that the small number of women who have coronary artery disease are at an increased risk for mortality during gestation. This is particularly true for women who suffer an infarction during pregnancy.^[152] For these cases, the maternal mortality rate is approximately 50 percent and fetal loss is common as well.^[153] A high index of suspicion for ischemic heart disease should be maintained in women with long-standing diabetes, since anginal symptoms may be minimal and infarction may thus present as congestive heart failure.^[153] While there are a few reports of successful pregnancies following myocardial infarction in diabetic women, cardiac status should be carefully assessed early in gestation or preferably prior to pregnancy. If electrocardiographic abnormalities are encountered, echocardiography may be used to assess ventricular function or modified stress testing may be performed. The decision to undertake a pregnancy in a woman with diabetes and coronary artery disease needs to be made only after serious consideration. The potential for morbidity and mortality must be thoroughly reviewed with the patient and her family. The management of myocardial infarction during pregnancy is discussed in Chapter 29.

DETECTION OF DIABETES IN PREGNANCY

It has been estimated that 2 to 3 percent of pregnancies are complicated by diabetes mellitus and that 90 percent of the cases represent women with GDM. ^[154] An increased prevalence of GDM is found in women of Hispanic, African, Native American, South or East Asian, and Pacific Island ancestry. ^[155] Women with GDM represent a group with significant risk for developing glucose intolerance later in life. Whereas O'Sullivan projected that 50 percent of GDM would become diabetic in follow-up study of 22 to 28 years, more recent series by Dornhorst and Rossi suggest this level of risk may be manifest by 5 years after the index pregnancy. ^[156] ^[157] The likelihood for subsequent diabetes apparently increases when GDM is diagnosed in early pregnancy, and is accompanied by impaired β -cell function and obesity.

As noted above, GDM is a state restricted to pregnant women whose impaired glucose tolerance is discovered during pregnancy. Because, in most cases, patients with GDM have normal fasting glucose levels, some challenge of glucose tolerance must be undertaken. Traditionally, obstetricians relied on historical and clinical risk factors to select those patients most likely to develop GDM. This group included patients with a family history of diabetes, or those whose past pregnancies were marked by an unexplained stillbirth, or the delivery of a malformed or macrosomic infant. Obesity, hypertension, glycosuria, and maternal age over 25 were other indications for screening. Interestingly, over half of all patients who exhibit an abnormal GTT lack the risk factors mentioned above. Coustan and colleagues have reported in a series of 6,214 women that using historical risk factors and an arbitrary age cut-off of 30 years for screening would miss 35 percent of cases of GDM. ^[158]

In the summary and recommendations of the Second and Third International Workshop-Conference on GDM, screening was recommended for all pregnant women. Following the Fourth International Workshop-Conference in 1997, universal screening was recommended for women in ethnic groups with relatively high rates of carbohydrate intolerance during pregnancy and diabetes later in life. ^[159] It was recognized

1098

that certain features place women at low risk for GDM (see the box "Screening Strategy for Detection of GDM"), and it may not be cost-effective to screen this subgroup of women. Those at low risk include women who are not members of ethnic groups at increased risk for developing type 2 diabetes, those who have no previous history of abnormal glucose tolerance or poor obstetric outcomes usually associated with GDM, and those who have all of the following characteristics: age less than 25 years, normal body weight, and no family history of diabetes. Similarly, the ACOG first suggested that whereas selective screening for GDM may be appropriate in some clinical settings such as teen clinics (low-risk populations), universal screening may be more appropriate in other settings (high-risk populations). ^[160] It should be noted that in some countries, experts have questioned the benefit of GDM screening programs. ^[161]

Screening Strategy for Detection of GDM

Risk assessment for GDM should be ascertained at the first prenatal visit.

Low risk

Blood glucose testing is not routinely required if all of the following characteristics are present:

- Member of an ethnic group with a low prevalence of GDM
- No known diabetes in first-degree relatives
- Age <25 years
- Weight normal before pregnancy
- No history of abnormal glucose metabolism
- No history of poor obstetric outcome

Average risk

Perform blood glucose screening at 24 to 28 weeks using one of the following:

- Two-step procedure: 50-g GCT followed by a diagnostic OGTT in those meeting the threshold value in the GCT
- One-step procedure: diagnostic OGTT performed on all subjects

High risk

Perform blood glucose testing as soon as feasible, using the procedures described above.

If GDM is not diagnosed, blood glucose testing should be repeated at 24 to 28 weeks or at any time a patient has symptoms or signs suggestive of hyperglycemia.

Adapted from Fourth International Workshop-Conference on Gestational Diabetes Mellitus. Diabetes Care 21(Suppl 2):B161, 1998.

The criteria for the diagnosis of GDM originally designated a population at increased risk for the development of type 2 diabetes in later life. The fact that O'Sullivan's original work establishing the criteria used for the diagnosis of GDM failed to evaluate an association between mild carbohydrate tolerance and perinatal outcome has

led many to question the overall significance of this diagnosis. It has been further suggested that the criteria for the diagnosis of GDM are conceptually flawed in that they represent a dichotomous definition of normal and abnormal gestational glucose tolerance, when the risk of adverse maternal-fetal outcomes and later diabetes should be logically graded upward with higher values on the OGTT and with the degree of fasting hyperglycemia. ^[162] Two studies have in fact addressed the relationship between mild degrees of carbohydrate tolerance and rates of neonatal macrosomia. In a study of 3,637 women without GDM, Sermer and colleagues demonstrated a graded increase in adverse outcomes (including large infants) with increasing maternal carbohydrate intolerance. ^[163] Similarly, Sacks identified fasting and 2-hour glucose values as independent risk factors for macrosomia in a multivariate analysis of over 3,500 pregnant women. However, as no clinically meaningful glucose threshold could be identified, Sacks concluded that the criteria for GDM will likely be established by consensus. ^[164] There remains a compelling need to develop diagnostic criteria for GDM that are based on specific relationships between hyperglycemia and risk of adverse outcome. ^[165]

The screening test for GDM, a 50-g oral glucose challenge, may be performed in the fasting or fed state. Sensitivity is improved if the test is performed in the fasting state. ^[166], ^[167] A plasma value between 130 and 140 mg/dl is commonly used as a threshold for performing a 3-hour OGTT. Coustan et al. have demonstrated that 10 percent of GDM women will have screening test values between 130 and 139 mg/dl. ^[168] This study indicated that the sensitivity of screening would be increased from 90 percent to nearly 100 percent if universal screening were employed using a threshold of 130 mg/dl. The prevalence of positive screening tests requiring further diagnostic testing increases from 14 percent (140 mg/dl) to 23 percent (130 mg/dl), and is accompanied by an approximately 12 percent increase in the overall cost to diagnose each case of GDM.

Whereas most women can be screened for GDM at approximately 24 to 28 weeks' gestation, it is advisable to screen earlier in pregnancy those with strong risk factors such as morbid obesity, family history in first-degree relatives, or previous GDM. ^[168] If initial screening is negative, repeat testing is performed at 24 to 28 weeks. Utilizing the plasma cut-off of 140 mg/dl, one can expect approximately 15 percent of patients with an abnormal screening value to have an abnormal 3-hour OGTT. Patients whose 1-hour screening value

* Diagnosis of gestational diabetes is made when any two values are met or exceeded.

exceeds 190 mg/dl (10.5 mmol/L) rarely exhibit a normal OGTT. ^[169] In these women, it is preferable to check a fasting blood glucose level before administering a 100-g carbohydrate load. If the fasting glucose is 95 mg/dl or greater, the patient is treated for GDM.

The criteria for establishing the diagnosis of gestational diabetes are listed [in Table 32-4](#) . The U.S. National Diabetes Data Group criteria represent a calculated conversion of O'Sullivan's thresholds in whole blood. Carpenter and Coustan prefer to use another modification of these data that is supported by a comparison of the older Somogyi-Nelson method and current plasma glucose oxidase assays. ^[170] These criteria have been modified by the Fourth International Workshop-Conference on GDM. Several studies have confirmed that patients diagnosed using the less stringent Carpenter criteria experience as much perinatal morbidity as subjects diagnosed by the National Diabetes Data Group Criteria. ^[171] Using either criteria, the patient must have a normal fasting value and two abnormal postprandial glucose determinations to be designated as Class A₁ .

TREATMENT OF THE INSULIN-DEPENDENT PATIENT

As fetal glucose levels reflect those of the mother, it is not surprising that clinical efforts aimed at optimizing maternal control are considered paramount in the decline in perinatal death seen in pregnancies type 1 diabetics over the last few decades. Self-blood glucose monitoring combined with aggressive insulin therapy has made the maintenance of maternal normoglycemia (levels of 60 to 120 mg/dl) a therapeutic reality (Table 32-5). In most institutions, patients are taught to monitor their glucose control using glucose-oxidase-impregnated reagent strips and a meter.^[173]

To achieve the best glycemic control possible for each patient, conventional insulin therapy often needs to be abandoned during pregnancy in favor of intensive therapy. Insulin regimens have classically included multiple injections of insulin usually prior to breakfast, the evening meal, and often bedtime, complemented by self-blood glucose monitoring and adjustments of insulin dose according to glucose profiles. Patients are instructed on dietary composition, insulin action, recognition and treatment of hypoglycemia, adjusting insulin dosage for exercise and sick days, as well as monitoring for hyperglycemia and potential ketosis. These principles form the foundation for intensive insulin therapy in which an attempt is made to simulate physiologic insulin requirements. Insulin administration is provided for both basal needs and meals, and rapid adjustments are made in response to glucose measurements. The treatment regimen generally involves three to four daily injections or the use of a continuous subcutaneous insulin infusion (CSII) device, the insulin pump. With either approach, frequent self-blood glucose monitoring is fundamental to achieve the therapeutic objective of physiologic glucose control. Glucose determinations are made in the fasting state and before lunch, dinner, and bedtime. Postprandial and nocturnal values are also helpful. Patients are instructed on an insulin dose for each meal and at bedtime if necessary. Meal-time insulin needs are determined by the composition of the meal, the premeal glucose measurement, and the level of activity anticipated following the meal. Basal or intermediate-acting insulin requirements are determined by periodic 2 A.M. to 4 A.M. glucose measurements as well as late afternoon values, which reflect morning neutral protamine Hagedorn (NPH) or Lente action. During pregnancy, diabetic women should develop the self-management skills that are essential to an intensive insulin therapy regimen.

Glycosylated hemoglobin measurements in each trimester can be used to assess glucose control in the previous 6 to 8 weeks. A hemoglobin A_{1c} level of 5 to 6 percent is desirable. The mean glucose represented by the hemoglobin A_{1c} level can be calculated using the "rule of 8's." A value of 8 percent equals 180 mg/dl,

TABLE 32-5 -- TARGET PLASMA GLUCOSE LEVELS IN PREGNANCY

Before breakfast	60-90
Before lunch, supper, bedtime snack	60-105
Two hours after meals	120
2 A.M. to 6 A.M.	>60

1100

and each 1 percent increase or decrease represents \pm 30 mg/dl.

In patients who are not well controlled, a brief period of hospitalization is often necessary for the initiation of therapy. Individual adjustments to the regimens implemented can then be made. It is gratifying for many patients to feel they can take charge of their own diabetic control. Women who have previously followed a prescribed dosage regimen for years gain confidence in making adjustments in their insulin dosage after a short period of time. Patients are encouraged to contact their physician at any time if questions should arise concerning the management of their diabetes. During early pregnancy, patients are instructed to report their glucose values by telephone at least weekly.

Insulin therapy must be individualized with dosage determinations tailored to diet and exercise. Beef and pork insulin have largely been replaced by semisynthetic human insulin preparations. Most recently, insulin lispro has been introduced. A rapid-acting insulin preparation, this insulin, which features reversal of proline and lysine at positions B28 and B29, remains in monomeric form, and is rapidly absorbed. Its action begins in 15 minutes and peaks in 2 to 3 hours. Because its duration of action is shorter than that of regular insulin, unexpected hypoglycemia hours after an injection is avoided. Insulin lispro is not yet approved for use in pregnancy, but it is a category B drug. While an early report raised some question regarding a possible association between insulin lispro and progression of retinopathy in pregnancy, recent experience suggests this is not the case.^{[173], [174]}

Insulin is generally administered in two to three injections. We prefer a three-injection regimen, although most patients present taking a combination of intermediate-acting and short-acting insulin before dinner and breakfast. As a general rule, the amount of intermediate-acting insulin will exceed the short-acting component by a 2:1 ratio. Patients usually receive two thirds their total dose with breakfast and the remaining third in the evening as a combined dose with dinner or split into components with short-acting insulin at dinner time and intermediate-acting insulin at bedtime in an effort to minimize periods of nocturnal hypoglycemia. These episodes frequently occur when the mother is in a relative fasting state while placental and fetal glucose consumption continue. Finally, some women may require a small dose of short-acting insulin before lunch, thus constituting a four-injection regimen.

There has now been considerable experience with open-loop CSII pump therapy during pregnancy. The pump is a battery-powered unit, which may be worn, like a pager, during most daily activities. These systems provide continuous short-acting insulin via a subcutaneous infusion. The basal infusion rate and bolus doses to cover meals are determined by frequent self-monitoring of blood glucose. The basal infusion rate is generally close to 1 unit/h.

Initiation of pump therapy requires a highly motivated patient and a knowledgeable health care team. Many pregnant patients will be able to start using a pump without hospitalization.^[175] Women must be educated regarding the strategy of continuous infusion and bolus doses. This requires that multiple blood glucose determinations be made to prevent periods of hyperand hypoglycemia. Glucose values will quickly become normalized with minimal amplitude of daily excursions in most patients.^[176]

Episodes of severe hypoglycemia are generally reduced with pump therapy.^[176] When they occur, these events are usually secondary to errors in dose selection or failure to adhere to the required diet. The risk of nocturnal hypoglycemia, which is increased in the pregnant state, is reduced by lowering the basal rate from late evening until early morning. The basal rate can be programmed to increase in the early morning hours to counteract the "dawn phenomenon."

The mechanics of the pump system are relatively simple. A fine-gauge butterfly needle device is attached by connecting tubing to the pump. This cannula is

reimplanted every 2 to 3 days at a different site, usually in the anterior abdominal wall. Short-acting insulin is stored in the pump syringe. Infusion occurs at a basal rate, which can be fixed or altered for a specific time of day and duration. As noted above, the basal rate can be programmed for a lower rate at night. The size of preprandial boluses is based on the composition of each meal or snack. Approximately 60 percent of the total daily insulin dose is usually given as the basal rate and the remainder as premeal boluses infused. The largest bolus (30 to 35 percent) is administered with breakfast, followed by 25 percent before lunch and dinner and 15 to 20 percent before snacks.

Patients without any pancreatic reserve may have rapid elevations of blood glucose if there is pump failure or intercurrent infection. For this reason, many clinicians recommend that patients using a pump check their glucose level at 2 to 3 A.M. to detect hyperglycemia resulting from pump failure. Since the advent of buffered insulin, insulin aggregation leading to occlusion of the Silastic infusion tubing is uncommon.

Increasing numbers of patients are using pumps, in large part because they provide greater flexibility in lifestyle. However, the benefits and risks associated with the use of the pump in pregnancy have not been well studied. In the largest prospective, randomized investigation, Coustan and colleagues randomized 22 pregnant patients to intensive conventional therapy with multiple injections versus pump therapy.^[175] There were no differences between the two treatment groups

1101

with respect to outpatient mean glucose levels, glycosylated hemoglobin levels, or glycemic excursions. Gabbe et al. recently reported a large retrospective cohort study of women who began pump therapy during gestation as compared to a group treated with multiple insulin injections. Patients using the pump, many with insulin lispro, had fewer hypoglycemic reactions and comparable glucose control and pregnancy outcomes. Most continued using the pump after delivery, and their control was significantly better than that of patients on multiple injections.^[176]

Diet therapy is critical to successful regulation of maternal diabetes. A program consisting of three meals and several snacks is used for most patients. Dietary composition should be 50 to 60 percent carbohydrate, 20 percent protein, and 25 to 30 percent fat with less than 10 percent saturated fats, up to 10 percent polyunsaturated fatty acids, and the remainder derived from monosaturated sources.^[177] Caloric intake is established based on prepregnancy weight and weight gain during gestation. Weight reduction is not advised. Patients should consume approximately 35 kcal/kg ideal body weight. Obese women may be managed with an intake as low as 1,600 cal/day, although if ketonuria develops, this allowance may be increased.

The presence of maternal vasculopathy should be thoroughly assessed early in pregnancy. The patient should be evaluated by an ophthalmologist familiar with diabetic retinopathy. Ophthalmologic examinations are performed during each trimester and repeated more often if retinopathy is detected. Baseline renal function is established by assaying a 24-hour urine collection for creatinine clearance and protein. An electrocardiogram, thyroid function studies, and a urine culture are also obtained.

Most patients are followed with outpatient visits at 1- to 2-week intervals. At each visit, control is assessed and adjustments in insulin dosage and diet are made. However, patients should be instructed to call at any time if periods of hypoglycemia (<50 mg/dl) or hyperglycemia (>200 mg/dl) occur. The increased risk of hypoglycemia in pregnant individuals may be related to defective glucose counterregulatory hormone mechanisms.^[108] Both epinephrine and glucagon appear to be suppressed in pregnant diabetic women during hypoglycemia.^[28],^[129] For these reasons, family members should be instructed on how and when to administer a glucagon injection for the treatment of severe reactions.

KETOACIDOSIS

With the implementation of antenatal care, programs stressing strict metabolic control of blood glucose levels for type 1 and type 2 diabetic women, diabetic ketoacidosis (DKA) has fortunately become a less common occurrence. Kilvert and colleagues reported 11 cases of ketoacidosis in 635 insulin-treated pregnancies between 1971 and 1990. One fetal loss and one spontaneous miscarriage complicated the pregnancies affected by DKA. ^[178]

Diabetic ketoacidosis can occur in the newly diagnosed diabetic patient, and the hormonal milieu of pregnancy may become the background for this phenomenon. As pregnancy is a state of relative insulin resistance marked by enhanced lipolysis and ketogenesis, diabetic ketoacidosis may develop in a pregnant woman with glucose levels barely exceeding 200 mg/dl (11.1 mmol/L). Thus, DKA may be diagnosed during pregnancy with minimal hyperglycemia accompanied by a fall in plasma bicarbonate and a pH value less than 7.30. Serum acetone is positive at a 1:2 dilution.

Early recognition of signs and symptoms of DKA will improve both maternal and fetal outcome. As in the nonpregnant state, clinical signs of volume depletion follow the symptoms of hyperglycemia, which include polydipsia and polyuria. Malaise, headache, nausea, and vomiting are common complaints. Occasionally, diabetic ketoacidosis may present in an undiagnosed diabetic woman receiving -mimetic agents to arrest preterm labor. Because of the risk of hyperglycemia and diabetic ketoacidosis in diabetic women receiving intravenous medications such as a terbutaline, magnesium sulfate has become the preferred tocolytic for cases of preterm labor in these cases. Administration of antenatal corticosteroids to accelerate fetal lung maturation can cause significant maternal hyperglycemia and precipitate DKA. These patients must be closely followed in an acute care setting for at least 48 to 72 hours after corticosteroids have been given. An intravenous insulin infusion will usually be required and is adjusted on the basis of frequent capillary glucose measurements.

Once the diagnosis of DKA is established and the patient is stabilized, she should be transported to a facility where tertiary care in both perinatology and neonatology is available. Therapy hinges on the meticulous correction of metabolic and fluid abnormalities. An attempt at treatment of any underlying cause for ketoacidosis, such as infection, should be instituted as well (see the box "Management of DKA during Pregnancy"). Diabetic ketoacidosis does represent a substantial risk for fetal compromise. However, successful fetal resuscitation will often accompany correction of maternal acidosis. Every effort should therefore be made to correct maternal condition before intervening and delivering a preterm infant.

Management of DKA during Pregnancy

1. Laboratory assessment:
Obtain arterial blood gases to document degree of acidosis present; measure glucose, ketones, electrolytes, at 1- to 2-hour intervals.
2. Insulin:
Low-dose, intravenous (IV)
 - Loading dose: 0.20.4 units/kg
 - Maintenance: 2.010.0 units/h
3. Fluids:
Isotonic NaCl
 - Total replacement in first 12 h = 46 L
 - 1 L in first hour
 - 5001,000 ml/h for 24 h
 - 250 ml/h until 80% replaced
4. Glucose:
Begin 5% D/NS* when plasma level reaches 250 mg/dl (14 mmol/L)
5. Potassium:
If initially normal or reduced, an infusion rate up to 15 to 20 mEq/h may be required; if elevated, wait until levels decline into the normal range, then add to IV solution in a concentration of 2030 mEq/L
6. Bicarbonate:
Add one ampule (44 mEq) to 1 L of 0.45 NS if pH is <7.10

* D/NS, dextrose in normal saline.

-fetoprotein (MSAFP) at 16 weeks' gestation is often used in association with a detailed ultrasound study during the second trimester in an attempt to detect neural tube defects and other anomalies. Normal values of MSAFP for diabetic women are lower than in the nondiabetic population.^[189] A lower threshold for the upper limit of normal may thus be preferable in pregnancies complicated by diabetes mellitus in order to help detect spina bifida and other major malformations that are increased in this population.

Fetal echocardiography is performed at 20 to 22 weeks' gestation for the investigation of possible cardiac anomalies. Using such an approach, Greene and Benacerraf detected 18 of 32 malformations in a series

TABLE 32-7 -- ANTEPARTUM FETAL SURVEILLANCE IN HIGH-RISK PREGESTATIONAL DIABETES MELLITUS*

Study	
Ultrasonography at 4 to 6-week intervals	Yes
Maternal assessment of fetal activity, daily at 28 weeks	Yes
Nonstress test (NST)	Minimum twice weekly
Contraction stress test or biophysical profile if NST nonreactive L/S, lung profile at 37/38 weeks	Yes

* High-risk pregestational diabetes mellitus: poor control (macrosomia, hydramnios), vasculopathy (classes D, F, R), prior stillbirth.

of 432 diabetic pregnancies.^[190] The specificity was in excess of 99 percent and the negative predictive value was 97 percent. Spina bifida was identified in all cases; however, ventricular septal defects, limb abnormalities, and facial clefts were missed. A review of the prenatal diagnosis experience in 289 diabetic women in The Ohio State University Diabetes in Pregnancy Program revealed 29 anomalies in which 12 were cardiac, 14 were noncardiac, and 3 were combined.^[86] Twelve of 15 (80 percent) cardiac and 10 of 17 (59 percent) noncardiac lesions were identified prenatally. When considering cardiac defects alone, we could not identify a glycosylated hemoglobin cut-off for these anomalies. Therefore, we believe detailed cardiac imaging should be offered to all women with pregestational diabetes mellitus to assist in the detection of cardiac lesions, especially those of the great vessels and cardiac septum.

Ultrasound examinations should be repeated at 4- to 6-week intervals to assess fetal growth. The detection of fetal macrosomia, the leading risk factor for shoulder dystocia, is important in the selection of patients who are best delivered by cesarean section. An increased rate of cephalopelvic disproportion and shoulder dystocia accompanied by significant risk of traumatic birth injury and asphyxia have been consistently associated with the vaginal delivery of large infants. The risk of such complications rises exponentially when birth weight exceeds 4 kg and is greater for the fetus of a diabetic mother when compared to a fetus with similar weight whose mother does not have diabetes.^[191] Sonographic measurements of the fetal abdominal circumference have proved most helpful in predicting fetal macrosomia.^[192] The abdomen is likely to be large because of increased glycogen deposition in the fetal liver and subcutaneous fat deposition. Using serial sonographic examinations, accelerated abdominal growth can be identified by 32 weeks' gestation.^[193]

TIMING AND MODE OF DELIVERY

Delivery should be delayed until fetal maturation has taken place, provided that the patient's diabetes is well controlled and antepartum surveillance remains normal. In our practice, elective induction of labor is often planned at 38 to 40 weeks' gestation in well-controlled patients without vascular disease. Patients with vascular disease are delivered prior to term only if hypertension worsens or fetal growth restriction mandates early delivery. Before elective delivery prior to 39 weeks' gestation, an amniocentesis may be performed to document fetal pulmonary maturity. There is much evidence that tests of fetal lung maturity have the same predictive value in diabetic pregnancies as they do in the normal population. ^[124]

The presence of the acidic phospholipid phosphatidylglycerol (PG) is the final marker of fetal pulmonary maturation. Several authors have suggested that fetal hyperinsulinemia may be associated with delayed appearance of PG and an increased incidence of RDS. Landon et al. ^[108] have correlated the appearance of PG in amniotic fluid with maternal glycemic control during gestation. RDS may occur in the IDM with a mature lecithin/sphingomyelin ratio or fetal lung maturity index but absent PG. It follows that the clinician must be familiar with the laboratory analysis of amniotic fluid in his or her institution and the neonatal outcome associated with the results of fetal lung maturity testing.

When antepartum testing suggests fetal compromise, delivery must be considered. If amniotic fluid analysis yields a mature test result, delivery should be accomplished promptly. In the presence of presumed lung immaturity, the decision to proceed with delivery should be based on confirmation of deteriorating fetal condition by several abnormal tests. For example, if the NST as well as the BPP indicates fetal compromise, delivery is indicated. Finally, there remain several maternal indications for delivery including preeclampsia, worsening renal function, or deteriorating vision secondary to proliferative retinopathy.

The route of delivery for the diabetic patient remains controversial. Cousins, ^[194] in reviewing over 1,600 (White Class B, C, D, R) patients in the literature between 1965 and 1985, noted a cesarean section rate of approximately 45 percent. This figure is likely to represent the practice trends of most obstetricians and perinatologists in the United States. ^[182] Delivery by cesarean section usually is favored when fetal distress has been suggested by antepartum heart rate monitoring. If a patient reaches 38 weeks' gestation with a mature fetal lung profile and is at significant risk for intrauterine demise because of poor control or a history of a prior stillbirth, an elective delivery is planned.

The increased rate of shoulder dystocia and brachial plexus injury in the offspring of diabetic women has prompted adoption of early induction strategies as well as selection of patients for cesarean section based on ultrasound estimation of fetal size. Kjos and colleagues demonstrated that induction at 38 weeks in a population of GDM women was associated with a lower frequency of large-for-gestational age infants and shoulder dystocia without an increased cesarean rate. ^[195] This is in contrast to studies of nondiabetic women in which suspected macrosomia is apparently associated with an increased cesarean rate. ^[196] In a sophisticated decision tree analysis of cost effectiveness, Rouse and colleagues found that whereas elective cesarean delivery for macrosomia to prevent permanent brachial plexus injury

TABLE 32-8 -- RATE OF SHOULDER DYSTOCIA RELATED TO BIRTH WEIGHT AND DIABETIC STATUS

Birth Weight (g)	Without Diabetes (%)	With Diabetes (%)
<4,000	0.11.1	0.63.7
4,000-4,449	1.110.0	4.923.1
>4,500	4.122.6	20.050.0

Adapted from ACOG Practice Patterns No. 7, October 1997.

was prohibitively expensive in the nondiabetic woman at a cost of several million dollars per injury prevented, 489 cesarean sections at a cost per avoided birth injury of \$880,000 per case for diabetic pregnancies with an estimated fetal size greater than 4,000 g seemed to be at least tenable. ^[197]

During labor, continuous fetal heart rate monitoring is mandatory. Labor is allowed to progress as long as normal rates of cervical dilatation and descent are documented. Acker et al. ^[198] have reported that the overall risk for shoulder dystocia in the macrosomic IDM is greater than for the large, normal infant. In their series of diabetic women, the risk for shoulder dystocia with a fetal weight greater than 4,000 g was approximately 30 percent. Somewhat less impressive yet significantly greater frequencies of shoulder dystocia for delivery of macrosomic IDMs versus non-IDMs have been reported by Nesbitt and colleagues ^[199] (Table 32-8). Despite attempts to select patients with obvious fetal macrosomia for elective cesarean delivery, arrest of dilatation or descent despite adequate labor should alert the physician to the possibility of cephalopelvic disproportion. About 25 percent of macrosomic infants (>4,000 g) delivered after a prolonged second stage will have shoulder dystocia. ^[199] It follows that cesarean delivery should be considered in a patient who demonstrates significant protracted labor or failure of descent.

GLUCOREGULATION DURING LABOR AND DELIVERY

As neonatal hypoglycemia is in part related to maternal glucose levels during labor, it is important to maintain maternal plasma glucose levels within the physiologic normal range. The patient is given nothing by mouth after midnight of the evening before induction or elective cesarean delivery. The usual bedtime dose of insulin is administered or, for women receiving pump therapy, the infusion is continued overnight. Upon arrival to labor and delivery early in the morning, the patient's capillary glucose level is assessed with a bedside meter. Continuous infusion of both insulin and glucose are then administered based on maternal glucose levels ([see the box "Insulin Management during Labor and Delivery"](#)). Ten units of regular insulin may be added to 1,000 ml of solution containing 5 percent dextrose. An infusion rate of 100 to 125 ml/h (1 unit/h) will, in most cases, result in good glucose control. Insulin may also be infused from a syringe pump at a dose of 0.25 to 2.0 units/h, and adjusted to maintain normal glucose values. Glucose levels are recorded hourly, and the infusion rate is adjusted accordingly. Jovanovic and Peterson have noted that well-controlled patients will often be euglycemic once active labor begins and will then require glucose at an infusion rate of 2.5 mg/kg/min. ^[200] It may be necessary to increase the insulin infusion during the second stage of labor with increased catecholamine secretion.

When cesarean delivery is to be performed, it should be scheduled for early morning. This simplifies intrapartum glucose control and allows the neonatal team to prepare for the care of the newborn. The patient is given nothing by mouth, and her usual morning insulin dose is withheld. If her surgery is not performed early in the day, one third to one half of the patient's intermediate-acting dose of insulin may be administered. Regional anesthesia is preferred because an awake patient permits earlier detection of hypoglycemia. Following surgery, glucose levels are monitored every 2 hours and an intravenous solution of 5 percent dextrose is administered.

Insulin Management during Labor and Delivery

Usual dose of intermediate-acting insulin is given at bedtime.
Morning dose of insulin is withheld.
Intravenous infusion of normal saline is begun.
Once active labor begins or glucose levels fall below 70 mg/dl, the infusion is changed from saline to 5% dextrose and delivered at a rate of 2.5 mg/kg/min.
Glucose levels are checked hourly using a portable meter allowing for adjustment in the infusion rate.
Regular (short-acting) insulin is administered by intravenous infusion if glucose levels exceed 140 mg/dl.

Adapted from Jovanovic L, Peterson CM: Management of the pregnant, insulin-dependent diabetic woman. Diabetes Care 3: 63, 1980.

After delivery, insulin requirements are usually significantly lower than were pregnancy or prepregnancy needs. The objective of "tight control" used in the antepartum period is relaxed for the first 24 to 48 hours. Patients delivered vaginally, who are able to eat a regular diet, are given one third to one half of their end-of-pregnancy dose of NPH insulin and short-acting insulin the morning of the first postpartum day. Frequent glucose determinations are used to guide insulin dosage. Most patients are stabilized on this regimen within a few days after delivery.

Women with diabetes are encouraged to breast-feed. The additional 500 kcal required daily are given as approximately 100 g of carbohydrate and 20 g of protein. ^[201] The insulin dose may be somewhat lower in lactating diabetic women. Hypoglycemia appears to be common in the first week following delivery and immediately after nursing.

MANAGEMENT OF THE PATIENT WITH GESTATIONAL DIABETES

The mainstay of treatment of GDM is nutritional counseling and dietary intervention. The optimal diet should provide caloric and nutrient needs to sustain pregnancy without resulting in significant postprandial hyperglycemia. ^[202] Women with GDM generally do not need hospitalization for dietary instruction and management. Once the diagnosis is established, patients are begun on a dietary program of 2,000 to 2,500 kcal daily. ^[202] This represents approximately 35 kcal/kg present pregnancy weight. Jovanovic-Peterson and Peterson have noted that such a diet composed of 50 to 60 percent carbohydrate will cause excessive weight gain and postprandial hyperglycemia, and will require insulin therapy in 50 percent of patients. ^[203] For this reason, several groups have studied the use of calorie-restricted diets. Algert and colleagues^[204] have reported that obese women with GDM may be managed on as little as 1,700 to 1,800 kcal/day with less weight gain and no apparent reduction in fetal size. Magee et al.^[205] designed a study to evaluate strict caloric restriction as a treatment for obese subjects with GDM. They randomized patients to a 2,400 kcal/day diet compared to a 1,200 kcal/day group. Average glucose levels and fasting insulin were reduced in the hypocaloric group. However, fasting glucose levels and postchallenge glucose levels were not significantly different. Significant ketonuria did develop in the restricted group, which may have a detrimental effect on fetal neurologic development. ^[206] The authors thus went on to study a 1,800-kcal diet, which improved glycemia and did not increase serum ketone levels. ^[207] Similar results have been reported by Peterson and Jovanovic-Peterson, who recommend 30 kcal/kg present pregnant weight for normal weight women, 24 kcal/kg for overweight women, and 12 kcal/kg for morbidly obese women. ^[208] These authors indicate that mild caloric restriction with modification of the carbohydrate component may be advised in obese GDM women. ^[209]

Once the patient with GDM is placed on an appropriate diet, surveillance of blood glucose levels is necessary to be certain that glycemic control has been established. At a minimum, practitioners have performed weekly assessment of fasting or postprandial glucose levels or both at clinic or office visits. Some clinicians prefer to have patients perform daily self-blood glucose monitoring, which in two retrospective studies has been associated with a decline in macrosomia at the expense of nearly half of all women requiring insulin therapy. ^[210], ^[211] A practical approach may be to provide women with GDM with a glucose meter; however, if after a few weeks, both fasting and postprandial measurements are within the normal range, the frequency of testing can be reduced accordingly.

Whereas the ACOG has recommended that fasting plasma glucose levels be maintained below 105 mg/dl and 2-hour postprandial values be less than 120 mg/dl, therapeutic thresholds of fasting below 95 mg/dl and 1-hour postprandial below 140 mg/dl as well as 2-hour postprandial below 120 mg/dl have been suggested by the Fourth International Workshop-Conference. ^[212] If a patient repetitively exceeds these thresholds, then insulin therapy is suggested. The use of the above cutoffs for initiating insulin are based on data regarding increased perinatal morbidity when such values are exceeded in women with preexisting diabetes. Currently, there are no data from controlled trials to identify ideal glycemic targets for prevention of fetal risk for women with GDM.

Langer and colleagues^[213] have critically evaluated thresholds for insulin therapy in GDM and concluded that to evaluate the effect of therapy, appropriate endpoints should include fetal macrosomia or large-for-gestational-age (LGA) infants, and neonatal metabolic complications. Langer and colleagues ^[213] evaluated insulin secretion patterns in women with GDM and non-GDM during an oral glucose tolerance test. Patients with fasting plasma glucose below 95 mg/dl had significantly greater insulin production than those with a glucose level greater than or equal to 95 mg/dl. To test whether the assignment to insulin therapy for a patient with a fasting value of 95 mg/dl or higher was appropriate, Langer et al. ^[213] compared rates of delivery of LGA infants among women with GDM grouped according to their fasting plasma glucose levels and whether diet or diet and insulin were used. He found that patients with a fasting glucose between 96 and 105 mg/dl had a greater incidence of LGA infants (28.6 percent) when receiving diet therapy alone versus obese

women with GDM receiving both diet and insulin. Whereas Langer and co-workers ^[211] have documented a relationship between maternal glycemia and macrosomia in GDM, which would establish guidelines for insulin therapy, some authors have suggested that estimation of glycemia alone may be sufficient to optimally prescribe insulin therapy in these cases.

Buchanan and colleagues have reviewed the utility of fetal ultrasound measurements to guide insulin therapy in women with GDM. ^[214] In their study of diet-treated GDM, ultrasound performed at 29 to 33 weeks was used to identify pregnancies with fetuses having a large abdominal circumference (>75th percentile). These cases were then randomized to diet versus diet and insulin treatment. The insulin-treated group ultimately had a frequency of LGA infants of 13 percent, which was far below the 45 percent present in the diet-treated group. The cost-effectiveness of this approach needs to be compared to administration of insulin to women with fasting hyperglycemia on diet therapy, since approximately two thirds of women require insulin therapy for a large fetal abdominal circumference (on ultrasound examination) in this range of maternal glycemia.

In addition to aggressive insulin therapy and hypocaloric diet regimens, exercise has recently been studied as an alternative primary treatment for GDM. Such an approach is beneficial for nonpregnant type 2 diabetic patients in whom physical training increases insulin sensitivity. Fasting and postprandial insulin concentrations and glucose excursions are lowered in both obese and physically fit individuals who exercise. This effect apparently is sustained up to 5 to 7 days after the last training session. Three 20-minute aerobic exercise sessions weekly are recommended. Brisk walking is ideal.

Bung and colleagues^[215] conducted a prospective study of the utility of exercise in the treatment of GDM. These authors randomized 41 women with GDM who manifested elevated fasting glucose levels, which would normally require insulin therapy. In the final analysis, 17 women completed a supervised bicycle ergometry training program compared with 17 women receiving insulin treatment. No statistical differences were observed in weekly blood glucose determinations between study groups. All fetal heart rate patterns were reactive before and after exercise. Thus, exercise programs for the treatment of GDM appear to be safe and may obviate the need for insulin therapy in some individuals.

Most recently, Langer and colleagues^[216] have suggested that oral hypoglycemic therapy may be a suitable alternative to insulin treatment in women with GDM. ^[216] These investigators randomized 404 women to insulin versus glyburide and reported similar improvement in glycemia with both regimens. Most importantly, the frequency of macrosomia and neonatal hypoglycemia was similar in the two study groups. Further studies will be necessary to establish the safety of this regimen.

Patients with GDM who are well controlled are at low risk for an intrauterine death. For this reason, we do not routinely institute antepartum fetal heart rate testing in uncomplicated diet-controlled GDM patients unless the patient has a hypertensive disorder, history of a prior stillbirth, or suspected macrosomia. ^[217] Women in these categories as well as those who require insulin treatment of GDM undergo twice-weekly heart rate testing at 32 weeks' gestation. Women with uncomplicated GDM do undergo fetal heart rate testing at 40 weeks' gestation. Using such a protocol at The Ohio State University Hospital Diabetes in Pregnancy Program, only two intrauterine deaths in over 1,500 cases of uncomplicated GDM have been observed in the last 12 years. Thus, it appears that the third-trimester stillbirth rate in these patients is no higher than that of the general obstetric population. A study of 389 women with GDM documented an antepartum stillbirth rate of 7.7 per 1,000, which was not significantly different from the rate of 4.8 per 1,000 observed in nondiabetic low-risk patients. ^[218] In this study, because 7 percent of fetuses were delivered for a low biophysical profile score, the benefit of testing all GDM pregnancies was raised. In the absence of a large prospective study comparing outcomes in monitored and nonmonitored GDM women without other risk factors, it is not possible to determine if any benefit exists to antepartum fetal surveillance in this apparently low-risk

population.

Because many obstetricians have extrapolated the increased risk for stillbirth in pregestational diabetic women to those with GDM, a remarkable number of these pregnancies are subject to scheduled delivery at term. If glycemic control is suboptimal, or maternal hypertension or a previous stillbirth exists, such an approach seems warranted. As with antepartum fetal testing, should elective induction be the standard approach for uncomplicated GDM pregnancies? Lurie and co-workers [\[219\]](#) have in part addressed this issue by retrospectively comparing the outcomes of 124 GDM women delivered beyond 40 weeks' gestation compared with the same number of GDM women delivered before their expected date of confinement. Antepartum fetal surveillance was not routinely begun until 40 weeks' gestation. No significant differences in perinatal outcome, cesarean delivery rates, or shoulder dystocia were found between study groups. A vaginal delivery rate of 75.8 percent was achieved in GDM women delivering beyond 40 weeks' gestation. These authors concluded that elective induction before 40 weeks' gestation should be avoided and every attempt should be made to allow women with GDM, both diet- and insulin-treated, to proceed to spontaneous labor. In contrast, a follow-up prospective study from the same institution of 96 insulin-requiring women with GDM

demonstrated that induction at 38 to 39 weeks was associated with a shoulder dystocia rate of 1.4 percent versus 10.2 percent in historic controls. [\[220\]](#)

Kjos and colleagues [\[195\]](#) have conducted a prospective randomized trial of active induction of labor at 38 weeks' gestation versus expectant management in a series which included 187 insulin-requiring women with GDM. The cesarean delivery rate was not significantly different in the expectant-management group (31 percent) from the active-induction group (25 percent). However, an increased prevalence of LGA infants (23 percent vs. 10 percent) was observed in the expectant management group. Moreover, the frequency of shoulder dystocia was 3 percent in this group, with no cases reported in those undergoing induction at 38 weeks' gestation. These data led the authors to conclude that elective delivery be considered in insulin-requiring patients with GDM because it does not increase the risk for macrosomia, shoulder dystocia, and cesarean delivery, and lowers the risk for fetal death. In patients managed expectantly, careful monitoring of fetal growth should be performed because of an apparent increasing risk for macrosomia with advancing gestational age in this population.

COUNSELING THE DIABETIC PATIENT

Anomalies of the cardiac, renal, and central nervous systems arise during the first 7 weeks of gestation, a time when it is most unusual for patients to seek prenatal care. Therefore, the management and counseling of women with diabetes in the reproductive age group should begin prior to conception. Unfortunately, it has been estimated that less than 20 percent of diabetic women in the United States obtain prepregnancy counseling. ^[182]

A reduced rate of major congenital malformation in patients optimally managed before conception is observed with special diabetes clinics (Table 32-9). In

TABLE 32-9 -- COMPARATIVE RATES OF MAJOR MALFORMATIONS IN OFFSPRING OF DIABETIC WOMEN RECEIVING PRECONCEPTIONAL COUNSELING

Study	With Preconceptional Counseling	Without Preconceptional Counseling
Fuhrmann et al. ^[222]	1/128 (0.8%)	22/292 (7.5%)
Steel and Duncan ^[237]	2/143 (1.4%)	10/96 (10.4%)
Kitzmilller et al. ^[224]	1/84 (1.2%)	12/110 (10.9%)
Whillhoite et al. ^[228]	1/62 (1.6%)	8/123 (6.5%)

Copenhagen, the rate of malformations fell from 19.4 percent to 8.5 percent in Class D and F patients who attended a prepregnancy clinic. ^[221] Fuhrmann et al. ^[222] found that intensive treatment begun prior to conception in 307 East German diabetic women reduced the malformation rate to 1 percent. Nearly 90 percent of women in this study maintained mean glucose levels less than 100 mg/dl (5.6 mmol/L). In contrast, the incidence of anomalies in the offspring of 593 diabetic women who registered for care after 8 weeks' gestation was 8.0 percent (47 of 593). Only 205 of those women had mean daily glucose levels of less than 100 mg/dl (5.6 mmol/L). Mills et al. ^[89] have reported that diabetic women registered prior to pregnancy had fewer infants with anomalies when compared to late registrants (4.9 percent vs. 9.0 percent). While the incidence of 4.9 percent is higher than that in a normal control population (2 percent), normalization of glycemia was not established in the early entry group.

Kitzmilller and colleagues studied 84 women with pregestational diabetes who were recruited for preconception education and management during a 7-year period. ^[224] A group of 110 pregnancy diabetic women presenting in the first trimester without preconceptional counseling served as controls in this study. One anomaly (1.2 percent) occurred in the preconception group versus 12 (10.9 percent) malformations in the control population.

Glycosylated hemoglobin levels obtained during the first trimester may be used to counsel diabetic women regarding the risk for an anomalous infant. In a retrospective study of 116 women at the Joslin Clinic, Miller and colleagues ^[223] observed that elevated hemoglobin A_{1c} concentrations early in pregnancy correlated with an increased incidence of malformations. In 58 patients with elevated glycosylated hemoglobin levels, 13 (22 percent) malformed infants were noted. This is in contrast to a 3.4 percent incidence of major malformations in 58 women whose glycosylated hemoglobin levels were in the normal range. Their findings were confirmed by Ylinen et al., ^[225] who measured glycosylated hemoglobin before the 15th week of gestation in 142 pregnancies. In pregnancies complicated by fetal malformations, mean values were significantly higher than in pregnancies without malformations. In the subgroup of patients with glycosylated hemoglobin values greater than 10 percent (normal, <8 percent), fetal malformations were present in 6 of 17 cases. Overall, the risk of a major fetal anomaly may be as high as 1 in 4 or 1 in 5 when the glycosylated hemoglobin level is several percent above normal values. Greene ^[226] has reported that 14 of 35 pregnancies with a glycosylated hemoglobin exceeding 12.8 percent were complicated by major malformations. In his series from the Joslin Clinic, the risk for major anomalies did not become evident until glycosylated hemoglobin values exceed 6 SD above the mean. In contrast to the studies cited above is the Diabetes

in Early Pregnancy (DIEP) study, in which malformation rates in IDMs were not correlated with first-trimester maternal glycosylated hemoglobin levels. ^[88] The authors suggested that more sensitive measures are needed to identify teratogenic mechanisms or that not all malformations can be prevented by good glycemic control. Further review of these data, which included glycosylated hemoglobin levels only in the early entry patients, demonstrates that these women were a relatively homogeneous group with respect to glycemic control; 93 percent had glycosylated hemoglobin levels less than 7 SD below the mean, a level of control that barely increases the risk for anomalies according to Greene's data. ^[226] Regardless of the glycosylated hemoglobin value obtained, all patients require a careful program of surveillance, as outlined earlier, to detect fetal malformations. The risk for spontaneous abortion also appears to be increased with marked elevations in glycosylated hemoglobin. However, for diabetic women in good control, there appears to be no greater likelihood of miscarriage. ^[227]

With the increasing evidence that poor control is responsible for the congenital malformations seen in pregnancies complicated by diabetes, it is apparent that preconception counseling involving the patient and her family should be instituted. ^[224], ^[228] Physicians who care for young women with diabetes must be aware of the importance of such counseling. At this time, the non-pregnant patient may learn techniques for self-glucose monitoring as well as the need for proper dietary management. Folic acid dietary supplementation at a dose of at least 0.4 mg daily should be prescribed, as there is increasing evidence that this vitamin may reduce the frequency of neural tube defects, although it has not specifically been studied in the diabetic population. ^[229], ^[230] During counseling, questions may be answered regarding risk factors for complications and the plan for general management of diabetes in pregnancy. Planning for pregnancy should optimally be accomplished over several months. Glycosylated hemoglobin measurements are performed to aid in the timing of conception. As a conservative recommendation, the patient should attempt to achieve a glycosylated hemoglobin level within 2 SD of the mean for the reference laboratory. ^[231]

CONTRACEPTION

There is no evidence that diabetes mellitus impairs fertility. Family planning is thus an important consideration for the diabetic woman. A careful history and complete gynecologic examination and counseling are required before selecting a method of contraception. Barrier methods continue to be a safe and inexpensive method of birth control. The diaphragm, used correctly with a spermicide, has a failure rate of less than 10 percent. Because there are no inherent risks to the diaphragm and other barrier methods, these have become the preferred interim method of contraception for women with diabetes. The intrauterine device may also be used by diabetic women without an increased risk of infection. ^[232]

Combined oral contraceptives (OCs) are the most effective reversible method of contraception, with failure rates generally less than 1 percent. There is, however, continued controversy regarding their use in the diabetic woman. The serious side effects of pill use, including thromboembolic disease and myocardial infarction, may be increased in diabetic women using combined OCs. In a retrospective study, Steel and Duncan ^[233] observed five cardiovascular complications in 136 diabetic women using primarily low-dose pills. Three patients had cerebrovascular accidents, one had a myocardial infarction, and one an axillary vein thrombosis. In a recent retrospective case-control study, despite diabetes increasing the risk for cerebral thromboembolism five-fold compared with controls, this risk was not enhanced by use of combined oral contraceptives. ^[234]

In Steel and Duncan's report, several women exhibited rapid progression of retinopathy. Klein and colleagues ^[235] studied OC use in a cross-sectional study of 384 type 1 diabetic women and reported no association between OCs and progression of vascular complications. For physicians who prescribe low-dose OCs to diabetic women, their use should probably be restricted to patients without serious vascular complications or additional risk factors such as a strong family history of myocardial disease. In these women, a monophasic preparation (progestin only) may be considered. In women receiving oral contraceptives, the lowest dose of estrogen and progesterone should be employed. Patients should have blood pressure monitoring after the first cycle and quarterly with baseline and follow-up lipid levels as well.

Women using the OCs may demonstrate increased resistance to insulin as a result of a diminished concentration of insulin receptors. ^[236] Despite the fact that carbohydrate metabolism may be affected by the progestin component of the pill, disturbances in diabetic control are actually uncommon with its use. In Steel and Duncan's study, ^[237] 81 percent of patients using the pill did not require a change in insulin dose. Triphasic OCs may also be used safely in former GDM women without other risk factors. Skouby et al. ^[238] have demonstrated that normal glucose tolerance and lipid levels can be expected in nonobese former GDM women followed after 6 months of therapy. Kjos and colleagues ^[239] performed a prospective randomized study of 230 women with recent GDM. OC users were randomized to low-dose norethindrone or levonorgestrel preparations in combination with ethinyl estradiol. The rate of

subsequent diabetes in OC users was 15 to 20 percent, after 1-year follow-up. This rate was not significantly different from non-OC users (17 percent). Importantly, no adverse effects on total cholesterol, LDL, HDL, or triglycerides were found with OC use.

At present, there is little information available concerning long-acting progestins in women with diabetes or previous GDM. A statistically significant, yet clinically limited deterioration in carbohydrate tolerance has been reported in healthy depot medroxyprogesterone acetate (Depo-Provera; DMPA) users. ^[240] A decrease in serum triglyceride and HDL cholesterol levels, but not total cholesterol or LDL cholesterol has also been demonstrated with Depo-Provera. ^[241] Similarly, the subdermal implant, Norplant, which releases levonorgestrel, has been associated with elevated glucose and insulin levels in the nondiabetic population. ^[242] For these reasons, neither DMPA nor Norplant are recommended as first-line methods of contraception for women with diabetes. The progestin-only oral contraceptive would be preferred, as it does not produce significant metabolic effects in diabetic women. Kjos et al. have reported that progestin-only OCs administered to breast-feeding Hispanic women with prior gestational diabetes may accelerate the progression to type 2 diabetes. ^[243]

Key Points

Pregnancy has been characterized as a diabetogenic state because of increased postprandial glucose levels in a late gestation.

Both hepatic and peripheral (tissue) insulin sensitivity are reduced in normal pregnancy. As a result, a progressive increase in insulin secretion follows a glucose challenge.

In women with gestational diabetes, the hormonal milieu of pregnancy may represent an unmasking of a susceptibility to the development of type 2 diabetes mellitus.

According to the Pedersen hypothesis, maternal hyperglycemia results in fetal hyperglycemia and hyperinsulinemia, resulting in excessive fetal growth.

Physiologic maternal glycemic control is associated with a reduced risk for fetal macrosomia.

Congenital malformations occur with a two to sixfold increased rate in offspring of type 1 and type 2 diabetic women compared with the normal population.

Impaired glycemic control and the associated derangement in maternal metabolism appear to contribute to abnormal embryogenesis.

Women with Class F (nephropathy) diabetes have an increased risk for preeclampsia and preterm delivery which correlates with their degree of renal impairment.

Diabetic retinopathy may worsen during pregnancy, yet for women optimally treated with laser photocoagulation *prior* to pregnancy, significant deterioration of vision is uncommon.

Screening for GDM is generally performed between 24-28 weeks gestation. Screening strategies include universal screening or limiting screening to women over age 25 with risk factors for developing type 2 diabetes mellitus.

Treatment of the insulin-dependent woman during pregnancy requires intensive therapy consisting of frequent self blood glucose monitoring and aggressive insulin dosing by multiple injections or continuous subcutaneous infusion (insulin pump).

The cornerstone of treatment for GDM is dietary therapy. Insulin or glyburide are reserved for individuals who manifest significant fasting hyperglycemia or postprandial glucose elevations despite dietary intervention.

Antepartum fetal assessment for both pregestational and GDM pregnancies is based on the degree of risk believed to be present in each case. Glycemic control, prior obstetric history, and the presence of vascular disease or hypertension are important considerations.

Delivery should be delayed until fetal maturation has occurred, provided that diabetes is well controlled and fetal surveillance remains normal. The mode of delivery for the suspected large fetus remains controversial. In cases of suspected macrosomia, a low threshold for cesarean section has been recommended to prevent traumatic delivery.

Women with type 1 and type 2 diabetes mellitus should seek prepregnancy consultation. Efforts to improve glycemic control prior to conception have been associated with a significant reduction in the rate of congenital malformations in the offspring of such women.

Chapter 33 - Endocrine Diseases in Pregnancy

Jorge H. Mestman

Endocrine diseases, with the exception of diabetes mellitus and those affecting the thyroid gland, are not frequently seen in pregnancy; furthermore, they are rarely diagnosed for the first time during gestation, since in many cases they also affect the hypothalamic-pituitary-ovarian axis, causing infertility. They present a challenge to the physician, not only because they may complicate the maternal course during gestation, but because they may also affect the growth and development of the fetus. The obstetrician should be aware of the symptoms and signs of the particular disease, the effect of pregnancy on the interpretation of endocrine tests, and the transfer of hormones and medications across the placenta with the potential complications for the fetus and neonate. In this chapter, we present a brief description of the disease, its etiology, the interpretation of functional endocrine tests, appropriate therapy, and the potential effects of both the disease and drug therapy on the conceptus. It is imperative that a team approach be used in the management of these conditions; the close cooperation of the obstetrician, endocrinologist, and anesthesiologist will offer the patient the best maternal and perinatal outcomes.

PITUITARY DISEASES

The pituitary gland enlarges during gestation, but the growth does not have clinical repercussions, unless a pathologic process is present. The enlargement is due to hyperplasia of the lactotroph cells, producers of prolactin (PRL).^[1] Normal hormonal changes with progression of pregnancy will be discussed in relation to a specific disease.

Anterior Pituitary Insufficiency

Hypopituitarism is defined as a constellation of signs and symptoms resulting from a partial or total deficiency of hormones secreted by the pituitary gland. The pathologic lesion may be localized in the pituitary gland itself or in the hypothalamus: if the hypothalamus is involved, there will be a decrease in the secretion of hypothalamic releasing hormones. The most common etiologies of anterior pituitary insufficiency include destruction of the anterior pituitary gland by tumors, infarction (postpartum necrosis, or Sheehan's syndrome), an autoimmune process (lymphocytic hypophysitis), infiltrative lesions (tuberculosis, sarcoidosis), pituitary apoplexy,^[2] idiopathic disease (Simmonds' disease), the empty sella syndrome, previous pituitary surgery, and radiotherapy to the pituitary gland. Recently, several reports of hypopituitarism as a result of mutations in the genes that encode the transcription factors for the differentiation of anterior pituitary cells have been published.^[3],^[4] As a result of these mutations, both sporadic and familial congenital deficiencies of single or multiple hormones have been described. Mass lesions in the hypothalamus, history of radiation to the hypothalamic area, infiltrative lesions, head trauma, and infections account for some of the causes of partial or total hypopituitarism. Diabetes insipidus (DI) is usually present when the lesion is in the hypothalamic region. In a study of 172 adults with hypopituitarism, the disorder was due to a pituitary tumor or the consequence of the tumor in almost 80 percent, whereas 13 percent had extrapituitary disease, with sarcoidosis in 1 percent and Sheehan's syndrome in 0.5 percent.^[5]

Sheehan's syndrome or postpartum pituitary necrosis due to severe blood loss during delivery has been considered the most common cause of panhypopituitarism in women of childbearing age. The pathogenesis is not

clear, although Sheehan in his original description did associate it with severe postpartum hemorrhage.^[6] The classic clinical presentation of Sheehan's syndrome is severe bleeding during delivery or immediately postpartum in about 90 percent of patients; in more than 10 percent of patients no catastrophic event is elicited. In some cases, acute adrenal insufficiency with hypotension and shock results; in most cases, however, a more insidious onset occurs with lack of lactation following delivery, amenorrhea, loss of pubic and axillary hair or failure of pubic hair to grow back following cesarean delivery, anorexia and nausea, lethargy, weakness, and weight loss. The disease may be recognized in the few days or weeks following delivery or many years after the original event.^[7] On physical examination, the findings depend on the severity and duration of the disease. Commonly, the skin has a waxy character with fine wrinkles about the eyes and mouth. There is some periorbital edema, and a decrease in pigmentation is often seen. Axillary and pubic hair becomes increasingly sparse. Atrophy of the breast tissue may be present. Even in those patients losing weight, cachexia is not a feature of the disease. Postural hypotension is not uncommon, patients complaining of dizziness on arising in the morning or when getting up from a sitting position. Normocytic anemia is common. Serum electrolytes may be within normal limits, unless severe vomiting is present. Most of the gastrointestinal and postural hypotension symptoms are due to secondary adrenal insufficiency, although the serum potassium remains normal because aldosterone production by the adrenal gland is not affected. This constellation of symptoms does not occur in every patient, and it is not unusual for the full-blown picture to take 10 to 20 years to develop. Occasionally, the diagnosis is made when the patient develops acute adrenal insufficiency secondary to a stressful situation such as infection, trauma, or surgery.

The diagnosis is confirmed by the use of appropriate tests to investigate each of the pituitary hormones. Baseline or random determination of serum pituitary hormone concentrations is of little value, and dynamic tests to evaluate hypothalamic-pituitary hormonal reserve must be used. The most practical tests are presented [in Table 33-1](#). However, their use in pregnancy is limited because, in most cases, the response is blunted.

Partial pituitary insufficiency is common. In a review of anterior pituitary function in patients with pituitary apoplexy due to different causes, growth hormone deficiency was common and occurred in almost 90 percent of patients; adrenocorticotropic hormone (ACTH) deficiency in about 66 percent, hypothyroidism caused by thyroid-stimulating hormone (TSH) deficiency in about 42 percent, and hypogonadism in 65 percent, whereas the incidence of diabetes insipidus was less than 5 percent.^[8]

Several reports of successful pregnancies following the diagnosis of Sheehan's syndrome have been reported.^[9]^[10]^[11] Placental function is not altered in patients with pituitary insufficiency. Although several patients conceived after treatment with gonadotropin, others have conceived spontaneously, an indication of partial pituitary failure. The outcome of pregnancy in women with Sheehan's syndrome is good in those receiving

TABLE 33-1 -- TESTS OF ANTERIOR PITUITARY HORMONE RESERVE

Hormone	Basal Levels	Test	Normal Response	Response In Pregnancy
GH	Suppressed	L-Dopa 500 mg, GH levels at 0, 1, 2 h	by 10 ng/dl	Blunted
		Insulin hypoglycemia 0.1 U regular IV/kg		
		GH at 0, 20, 60, 90 min	by 10 ng/dl	Blunted
ACTH	Small rise	Insulin hypoglycemia (see above)	by 10 g/dl	Blunted
		Cortisol at 0, 20, 60, 90 min		
		Metirapone 750 mg every 4 h X 6	urinary 17-KGS	Blunted
			serum substance S	
TSH	First trimester: may be suppressed; second and third trimester normal	TRH 500 g IV 0, 30, 50 min	by 5 l/ml	First may be blunted; second & third nl or increased

Prolactin	Increased	TRH (see above); prolactin 0, 30, 60 min	X 2 baseline	Exaggerated
LH-FSH	Suppressed	LHRH IU 500 g IV; LH + FSH 0, 30, 60 min	X 2 baseline	Blunted

GH, growth hormone; ACTH, corticotropin; TSH, thyrotropin-stimulating hormone; TRH, thyrotropin-releasing hormone; LH, luteinizing hormone; FSH, follicle stimulating hormone; LHRH, luteinizing hormone-releasing hormone; 17-KGS, 17 ketogenic steroids; S, 11-desoxycortisol; IV, intravenous.

proper replacement therapy. In one review, 87 percent had live births and 13 percent had spontaneous abortions.^[9]

When anterior pituitary insufficiency develops for the first time in pregnancy or early postpartum, the clinical manifestations may be related to local signs and symptoms due to acute expansion of the pituitary gland or by those related to specific hormone deficiencies. Acute enlargement of the pituitary gland could be the result of acute edema of a known or unknown pituitary lesion or bleeding into a preexisting pituitary tumor. Severe, deep, midline headaches and nausea, vomiting, and visual disturbances are common. Symptoms of an acute endocrine deficiency are mainly related to reduced cortisol secretion: protracted hypoglycemia responding to glucocorticoid therapy, nausea, vomiting, and hypotension.^{[12] [13] [14]}

Lymphocytic hypophysitis, first described in 1962 by Goudie and Pinkerton,^[15] is being recognized with increasing frequency as a cause of partial or total hypopituitarism.^{[16] [17] [18]} It is considered to have an autoimmune pathogenesis and occurs mainly in women during pregnancy or in the postpartum period. Association with other autoimmune endocrine disorders (thyroiditis, gastritis, and adrenalitis) has been reported.^[15],^[19] Sheehan^[6] reported lymphocytic infiltration of the pituitary gland in some women with postpartum pituitary insufficiency. The clinical presentation is characterized by headaches and visual disturbances related to pressure from the expanding lesion mimicking a pituitary tumor or symptoms and signs of hypopituitarism such as hypoglycemia, hypotension, nausea, and vomiting. It may also present in the postpartum period as pituitary insufficiency, similar to Sheehan's syndrome without the history of profound bleeding.^[20] Lymphocytic hypophysitis may be precipitated by acute infections and labor. Asa and associates^[19] reported two patients with severe headache, nausea, vomiting, and impaired vision, one of whom required pituitary surgery at 6 months' gestation, because of an enlarging pituitary mass. Light and electron microscopic studies of the pituitary gland were consistent with lymphoid hypophysitis. The authors found another eight cases of proven lymphocytic hypophysitis, five seen on postmortem examination, and three on biopsy. In five patients, the diagnosis was made during the postpartum period, and in four patients there was evidence of other autoimmune endocrine disease. In some of the reported cases, endocrine manifestations related to pituitary insufficiency manifested for the first time in the postpartum period. Postpartum thyroiditis with reversible ACTH deficiency was described by Bevan et al.^[19] Hyperprolactinemia, partial pituitary insufficiency, with or without a pituitary mass, has been reported in the postpartum period.^[21],^[22] When available, the pathologic specimen showed significant lymphocytic infiltration. The differential diagnosis between pituitary tumor and lymphocytic hypophysitis can be made only by histologic examination; indeed, in some cases surgery was performed in pregnancy with the preoperative diagnosis of pituitary tumor.

Over 100 cases of lymphocytic hypophysitis have been described in the English literature and were recently reviewed by Gagneja et al.^[18] In most cases, the diagnosis was made on clinical grounds with a few confirmed by histologic examination. Spontaneous regression of the pituitary mass with recovery of endocrine function has been reported.^[23],^[24] Two patients became pregnant after the initial episode and had an uneventful delivery.^[18],^[25] Based on the above information, in the presence of a clinical diagnosis of lymphocytic hypophysitis and absence of visual field defects, surgical therapy may be safely withheld, with periodic reassessment of endocrine function and the size of the lesion. In the majority of cases reported, gonadotropin function has been spared, suggesting a possibility of future spontaneous pregnancies. The most frequent associations are ACTH and prolactin defects and the presence of autoimmune thyroid disease.

Patients with partial or total hypopituitarism who become pregnant spontaneously or after treatment with gonadotropin may carry a normal pregnancy with successful neonatal outcome. In women on glucocorticoid replacement therapy, no increase in the dose is needed; the usual amount of hydrocortisone in patients with pituitary insufficiency is between 20 and 30 mg/day, two thirds of the total amount in the morning and one third in the evening. Occasionally, the dose of hydrocortisone may be decreased by one third of the total dose owing to the potentiation of hydrocortisone effect during pregnancy by estrogen.^[26] This potentiation does not occur when synthetic corticosteroids such as prednisone and dexamethasone are used. The equivalent amount of prednisone is 5.0 to 7.5 mg daily and of dexamethasone 0.5 to 0.75 mg daily (Table 33-2). Aldosterone secretion is preserved, since its adrenal secretion is independent from ACTH. Therefore, in contrast to primary adrenal insufficiency, there is no need for mineralocorticoid replacement therapy. In the presence of thyroid deficiency, the amount of L-thyroxine may need to be increased from early pregnancy; the usual replacement dose is between 0.075 and 0.15 mg daily. The amount should be adjusted to keep the free thyroxine in the upper third of normal; in patients with secondary hypothyroidism, such as in women with hypopituitarism, serum TSH cannot be followed as a marker for proper thyroxine replacement as is the case in primary hypothyroidism.

Acute adrenal insufficiency is an emergency and should be managed with intravenous glucocorticoids, 200 to 300 mg of hydrocortisone in 24 hours or equivalent

doses of synthetic corticosteroids. Aggressive intravenous fluid therapy with 5 percent dextrose/normal saline should be started immediately (see section Addison's Disease below).

Pregnancy in cases of isolated growth hormone deficiency has been reported.^[27] Lactation was unimpaired, placental function studies were normal, and intrauterine growth was also normal.

Prolactinomas

Serum prolactin normally increases early in pregnancy, reaching values close to 140 ng/ml by the end of pregnancy.^[28] Prolactinoma is the most common pituitary tumor diagnosed in women of childbearing age. Pituitary tumors are divided according to their size, into microadenomas, less than 10 mm in diameter, and

macroadenomas; the latter are further classified according to suprasellar extension and invasion of adjacent structures. Serum prolactin concentrations correlate fairly well with the size of the tumor. Hyperprolactinemia may be diagnosed in the absence of an enlargement of the pituitary gland, known as idiopathic hyperprolactinemia. Hyperprolactinemia decreases gonadotropin-releasing hormone (GnRH) secretion, accounting for the infertility seen in these patients. However, high levels of serum prolactin in the presence of normal menses, normal fertility, and absence of a pituitary lesion have been reported.^[29],^[30] The syndrome is due to the presence of large amounts of "big-big prolactin," that normally accounts for less than 10 percent of the total serum prolactin. Pregnancy outcome is excellent for both mother and infant.

Once the diagnosis of prolactinoma is confirmed, several types of therapy are available, the choice depending on tumor size, radiologic classification, local symptoms, and the patient's age and desire for pregnancy.^[31]

Radiation therapy as the initial and only therapy is seldom indicated.^[32] Radiation therapy is employed following surgery in those patients with a residual lesion in order to prevent recurrences.

Surgical treatment, mainly transsphenoidal adenectomy, has been effective as the sole form of therapy in restoring ovulation in patients with small tumors. The cure rate, that is, normalization of serum prolactin, is in the range of 60 to 70 percent.^[33] However, the recurrence rate is between 25 and 40 percent. The cure rate is significantly lower for macroadenomas. Feigenbaum et al.^[34] followed over 400 patients for a mean of 9.2 years after surgery for prolactinoma. Hyperprolactinemia recurred in 47 percent of all patients. The best results were obtained in those patients with microadenomas and with serum prolactin levels 1 day after surgery of less than 5 ng/ml.

Medical therapy with bromocriptine, a dopamine-receptor agonist, has been effective in producing ovulation in 80 to 90 percent of hyperprolactinemic women.^[35] Most patients respond to doses between 2.5 and 5 mg/day, although occasionally a dose of 7.5 mg/day or more is needed. Bromocriptine is effective not only in normalizing prolactin levels but also in reducing the size of the tumor.^[36],^[37] In women desiring a pregnancy, it is advisable to use mechanical contraception in the first few months of bromocriptine therapy, until normal menses have been established. In patients who have side effects such as nausea and vomiting, an oral bromocriptine tablet may be administered vaginally with normalization of prolactin levels.^[38]

In patients with large tumors on bromocriptine therapy, the drug should be given for at least 1 year, since recurrence of tumors of this size has been reported when the drug is stopped before the completion of the first year of treatment.^[39],^[40]

Once conception takes place, bromocriptine should

be discontinued and the patient followed closely. For those women whose initial prolactin levels are over 200 ng/ml, or who have abnormal magnetic resonance imaging (MRI) scans with suprasellar extension, bromocriptine therapy during pregnancy should be continued.^[39],^[40] Although the experience is limited to approximately 100 women who have used bromocriptine throughout gestation, no abnormalities have been noted in the infants, except for one with an undescended testicle and one with a talipes deformity.^[31]

Cabergoline, a dopamine agonist with long duration of action, has been used in a few patients with a prolactinoma. It is as effective as bromocriptine in lowering prolactin levels, reducing the size of the tumor, and inducing ovulation. Its advantages include its long duration of action, with a dose taken every 3 or 4 days, and less side effects than bromocriptine.^[41],^[42] The weekly dose is between 0.5 and 3 mg. The incidence of spontaneous abortion, preterm delivery, and congenital malformation is similar to that in the general population.^[43] However, the number of pregnancies treated with cabergoline is much lower than with bromocriptine; therefore, bromocriptine should be the drug of choice for women seeking conception.

Complications during pregnancy are directly related to tumor size.^[7],^[31],^[44]^[45]^[46]^[47]^[48] In patients with microadenomas, following induction of ovulation with bromocriptine, the reported incidence of headaches and visual field disturbances is between 1 and 4 percent. The incidence is close to 35 percent for patients with macroadenomas. However, if the pituitary macroadenoma is treated before pregnancy with either surgery or radiotherapy, the complication rate is about 4 percent. Complications may occur with equal frequency at any stage of pregnancy. Therefore, the management of patients with prolactinomas or any type of pituitary tumor in pregnancy depends on the size of the tumor and previous therapy. For patients with microadenomas, visual fields are indicated only if there are signs and symptoms of tumor enlargement; if the visual fields are abnormal, then an MRI scan of the pituitary gland is obtained. In the presence of any objective evidence of tumor enlargement, bromocriptine is resumed and continued throughout pregnancy at a dose of up to 20 mg/day. If after a few days there is no improvement, dexamethasone 4 mg every 6 hours is indicated. Surgery is performed in those complicated cases not responding to the above therapies.

The determination of serum prolactin during gestation is not helpful in evaluating tumor growth. With a few exceptions, serum prolactin levels in women with prepregnancy hyperprolactinemia remained unchanged during pregnancy. In one study, serum prolactin levels remained stable in the majority of patients with prepregnancy baseline prolactin levels of over 60 ng/ml.^[49] However, in those patients with prolactin levels of less than 60 ng/ml, the mean level doubled at the end of pregnancy and returned to pretreatment levels at the end of lactation.

Potential perinatal complications due to the use of bromocriptine have been reported^[46] abortion rates (11.1 percent), multiple pregnancy rates (1.2 percent), and prematurity rates (10.1 percent) are similar to those seen in the infertile population. Early reports of cervical incompetence have not been confirmed. The congenital malformation rate of 3.5 percent for major and minor lesions is comparable to the rate of 2.7 percent reported in a control group. Although bromocriptine crosses the placenta, no abnormalities in mental and physical development were detected in a group of 64 children, age 6 months to 9 years, whose mothers took bromocriptine at some time during gestation.^[45]

Breast-feeding is not contraindicated in mothers with prolactinoma. There is no increase in prolactin secretion after suckling, and the mean value of prolactin is not increased compared with that of pregnancy.^[50] A concern about seizures and strokes in the puerperium of women taking bromocriptine was not confirmed by a well-controlled study.^[51]

Following delivery, women should be followed carefully for assessment of tumor growth. In patients with microadenomas, prolactin levels are measured a few months after delivery; drug therapy is reinstated in the presence of persistent hyperprolactinemia. An MRI scan should be repeated in cases of macroadenomas soon after delivery, to detect any change in the size of the tumor.^[52]

Management of patients who wish to conceive is summarized in [Table 33-3](#).^[31],^[47] Although a serum prolactin level of less than 100 ng/ml and a normal radiologic examination before pregnancy are predictors of low complication rates, exceptions have been reported. It is suggested that treatment with bromocriptine be

TABLE 33-3 -- MANAGEMENT OF WOMEN WITH HYPERPROLACTINEMIA BEFORE CONCEPTION

Tumor	Management	Pregnancy Follow-up
No tumor	Bromocriptine	Visual field (?)
Microadenoma	Bromocriptine or surgery	Visual field every trimester
Macroadenoma	(A) Surgery + bromocriptine	Visual field monthly
	(B) Radiotherapy + bromocriptine	Visual field monthly

* Therapy for 1 year before conception.

continued for at least 12 months before conception, as it seems to reduce the risk of tumor enlargement during pregnancy. ^[40], ^[48]

Acromegaly

Acromegaly is a chronic disease caused in the vast majority of cases by hypersecretion of growth hormone by the adenohypophysis. It is almost always associated with a benign pituitary tumor and is characterized by slow and progressive enlargement of the extremities. Facial changes are typical, but they develop so gradually that neither the family nor the patient recognizes the changes. As in other endocrine disorders, comparison of the patient's photographs taken over many years may be the only clue to the presence and progression of the disease. Symptoms may be due to local expansion of the tumor, with headaches and visual field disturbances, or due to the somatic effect of chronic excess growth hormone secretion, such as hyperhidrosis, weight gain, arthralgias, and acroparesthesia (carpal tunnel syndrome). Most women with acromegaly suffer from menstrual irregularities. Galactorrhea with hyperprolactinemia is a common finding, and therefore infertility is common. The diagnosis is confirmed by an elevation in plasma growth hormone levels and/or elevations in insulin-like growth factor I (IGF-I). The latter is now considered the test of choice in nonpregnant women.

The diagnosis of acromegaly during pregnancy is difficult to confirm, since the conventional radioimmunoassay for growth hormone (GH) does not distinguish normal pituitary GH from the variant produced by the placenta, ^[53] unless a special radioimmunoassay (RIA) is used. The placental variant is secreted continuously rather than in a pulsatile pattern as is pituitary GH, binds to GH receptors, and functions as a GH agonist. ^[54] After the first trimester of pregnancy, the placental GH variant is the major component of circulating GH. Using specific RIAs for the placental GH variant, to separate both hormones, the highly pulsatile secretion of pituitary GH seen in acromegaly may help establish the diagnosis. GH release after thyrotropin-releasing hormone (TRH) injection is observed in most patients with acromegaly; however, the placental GH variant is unresponsive. ^[54] IGF-I values are less useful in the diagnosis, as they are elevated during normal pregnancy.

Patients with acromegaly rarely ovulate spontaneously. However, with the advent of new medical therapy, successful pregnancies have been reported with increased frequency. In 1954, Abelow and co-workers ^[55] reported 35 cases; they followed 2 acromegalic women and reviewed 33 reported cases with active disease. With few exceptions, infant outcome was normal. In one case, the infant was born with acromegalic features; during the neonatal period, growth was above average, but subsequently a normal growth pattern returned. ^[56] Unfortunately, no neonatal GH determinations were obtained. The lack of acromegalic features in newborns is in accord with the demonstration by King and colleagues that GH does not cross the placental barrier. ^[57] Herman-Bonert et al. ^[58] described 24 pregnancies in acromegalic women, and individual cases were reviewed by Neal in a recent report of one of his own cases. ^[59]

During pregnancy, women with active acromegaly are at potential risk for developing gestational diabetes, worsening of impaired glucose metabolism, and enlargement of the pituitary tumor. It is estimated that overt diabetes mellitus will develop in 10 to 20 percent, impaired glucose tolerance in 30 percent, and hypertension in 25 to 35 percent. Carpal tunnel syndrome symptoms may worsen during gestation. Patients with acromegaly usually have cardiomegaly shown on routine chest x-ray. Coronary artery disease and a specific cardiomyopathy have been reported. ^[60]

Therapy of acromegaly in nonpregnant patients includes surgery and/or radiation, or medical therapy using the somatostatin analogues. ^[61], ^[62] Bromocriptine was used with relative success until new agents, octreotide and lanreotide, became available. These somatostatin analogues inhibit the production of GH, as well as glucagon and insulin. Because a complete cure is not always achieved with surgery and/or radiation, chronic therapy with somatostatin analogues has proven effective in normalizing serum GH and IGF-I levels. The dose of octreotide is 300 to 1,500 g in three divided doses by subcutaneous injection. Long-acting somatostatin analogs, octreotide LAR (octreotide acetate for injectable suspension) and slow-release lanreotide (lanreotide SR), have been introduced. ^[63] Both preparations are administered intramuscularly at intervals of either 28 days (octreotide LAR) or 10 to 14 days (lanreotide SR). The goal of therapy is to achieve a serum GH level of less than 1.0 ng/ml with the new sensitive assays and normalization of IGF-I. The dose is adjusted according to the result of GH and IGF-I levels done every 3 months. Normalization of IGF-I has been achieved in about 70 percent of patients treated for periods over 6 months. The two preparations are well tolerated, although cholelithiasis may develop in 20 percent of patients.

Few cases of pregnancy in acromegalic women treated with bromocriptine have been reported. ^[64] ^[65] ^[66] ^[67] In each case, pregnancy occurred in spite of persistent elevation in GH levels. Pregnancies occurred when prolactin levels returned to normal following drug therapy.

Eight cases have been reported of successful pregnancy in acromegalic women treated with octreotide. ^[58], ^[59], ^[68], ^[69] Octreotide has been reported to cross the placenta by passive diffusion without producing adverse

effects in the fetus. ^[70] In most cases, octreotide was discontinued at the time of pregnancy diagnosis. However, in two cases the drug was continued throughout pregnancy. As in cases of prolactinoma, it is advisable to perform visual field examinations each trimester or as clinically indicated with severe headache or visual disturbances. MRI is reserved for those cases developing abnormal visual fields. If an enlargement of the pituitary tumor is detected, reinstitution of medical therapy and close follow-up is recommended.

Diabetes Insipidus

Women with isolated DI antedating pregnancy, and with normal anterior pituitary function, carry their pregnancies uneventfully and infant outcome is normal.

Shortly after conception, plasma osmolality decreases by about 9 to 10 mOsm/kg and remains low throughout pregnancy. Despite this decrease in plasma osmolality, basal levels of serum arginine vasopressin (AVP), the antidiuretic hormone, are similar to those seen in nonpregnant women. ^[71] It has been suggested that in pregnancy there is a resetting of the "thirst osmostat" with a decrease in the osmotic threshold for antidiuretic hormone release by 8 to 10 mOsm/kg. The ability to concentrate the urine remains unchanged. ^[72] The placenta produces vasopressinase, a cysteine aminopeptidase enzyme that degrades AVP. As the result of the increased production of the enzyme vasopressinase in the last part of pregnancy, a 1,000-fold increase between the 4th and 38th weeks of gestation, there is a threefold increase in endogenous AVP during pregnancy. ^[73] This rapid degradation of AVP may uncover latent forms of DI, and could explain the lack of response to injectable vasopressin, but a normal response to desmopressin, a drug that is not metabolized by vasopressinase. ^[74]

Diabetes insipidus is characterized clinically by polyuria (over 3 L/24 h) and polydipsia due to a deficiency of antidiuretic hormone (central or neurogenic diabetes insipidus), or to peripheral resistance to the action of the hormone at the level of the renal tubules (nephrogenic diabetes insipidus). Lesions at the level of the hypothalamus or pituitary gland are usually the cause of central diabetes insipidus. These include invasion of the neurohypophysis by tumors, metastatic lesions, including breast cancer, granulomas, infections, skull trauma, and following hypophysectomy. In 50 percent of cases, however, DI is considered idiopathic, probably on an autoimmune basis. It has recently been shown that many of the idiopathic cases are due to lymphocytic inflammation of the posterior pituitary gland, sometimes with partial involvement of the anterior pituitary gland. ^[75] MRI study shows thickening of the pituitary stalk, enlargement of the neurohypophysis, and normal appearance of the adenohypophysis. The term lymphocytic infundibulohypophysitis (LIH) has been suggested for this clinical entity. ^[76] Nephrogenic diabetes insipidus is a hereditary disorder affecting males; therefore, symptomatic women carriers are extremely rare. Psychogenic diabetes insipidus, rarely reported in pregnancy, ^[77] is differentiated from the other forms by the results of the water deprivation test.

The clinical presentation of idiopathic central DI is generally acute, with polyuria and polydipsia developing in a few days. Patients usually remember the day their symptoms began, they prefer to drink cold water, and their urinary output varies between 4 and 15 L in 24 hours.

The diagnosis of DI is confirmed by the results of the water deprivation test. ^[78] (see the box "Steps in the Water Deprivation Test"). The test separates patients into five groups: (1) normal, (2) complete central DI, (3) partial central DI, (4) nephrogenic DI, and (5) compulsive water drinking. The test is started early in the morning; the patient's weight, pulse, and blood pressure are obtained along with baseline determinations of serum and urine osmolality, and determination of plasma vasopressin levels. Thereafter, urine osmolality is obtained with each voided specimen. The test is terminated when the patient loses 3 percent of body weight or when urinary osmolality shows no increment in two successive specimens. At the end of the test, serum osmolality and vasopressin levels are measured. Patients with

in urinary osmolality, but plasma osmolality does increase due to dehydration. Plasma vasopressin levels are low in central DI; they are inappropriately high in the nephrogenic type. Injection of aqueous vasopressin 5 U subcutaneously at the end of the test separates central DI from nephrogenic DI in the vast majority of cases. L-Deamino-8-arginine vasopressin (desmopressin, [dDAVP], a synthetic analog of vasopressin resistant to vasopressinase) is preferable in pregnancy, a dose of 10 g given intranasally. In central DI, there is a decrease in urinary output and an increase in urinary osmolality. No changes are seen in the nephrogenic type. Patients with primary polydipsia or psychogenic DI respond with some increase in urine osmolality to the administration of dDAVP, but the increase is not as great as with patients who have central DI. In emergency situations, with acute onset of symptoms, such as cases of acute fatty liver of pregnancy or preeclampsia, treatment cannot be delayed, and diagnostic tests to assess the etiology of DI are limited to the determination of serum vasopressin, urinary, and plasma osmolality, with the dynamic test of water deprivation postponed until recovery from the acute injury.

Steps in the Water Deprivation Test

(Not Available)

From Mestman JH: Endocrine diseases in pregnancy. In Sciarra JJ (ed): Gynecology and Obstetrics. Philadelphia, Lippincott-Raven, 1997, p 7, with permission.

In patients with newly diagnosed central DI, a complete evaluation to define the cause of the disease is imperative. Radiologic examination of the hypothalamic-pituitary area and hormonal studies for assessment of anterior pituitary function should be obtained. Long-term follow-up is indicated, as hypothalamic dysfunction may appear with time.^[79]

Labor and delivery proceed normally in patients with DI, although an occasional patient with uterine atony has been reported. Plasma oxytocin concentrations have been reported as normal, with normal pulsatile release during labor and lactation.

DI during pregnancy may occur in different clinical settings^[80] (1) pregestational DI; (2) presenting for the first time in pregnancy and persisting thereafter; (3) transient, occurring during gestation or in the immediate postpartum period, associated with preeclampsia, liver disease, or HELLP (hemolysis, elevated liver enzymes, and low platelet count) syndrome; (4) transient, recurrent in pregnancy, patients with latent DI, manifesting only in pregnancy because of the increase in the placental vasopressinase; (5) postpartum DI in patients with acute pituitary insufficiency such as Sheehan's syndrome or hypophysitis; and (6) an unusual transient form of DI resistant both to vasopressin and dDAVP administration.

Hime and Richardson^[81] reviewed 67 cases of DI in pregnancy, 1 case per 66,000 deliveries. Worsening of the symptoms occurred in over 50 percent of cases, spontaneous improvement in 20 percent, and no changes in the remainder. Labor progressed normally in the majority of cases, with few patients requiring induction of labor or cesarean section.

A form of transient vasopressin-resistant DI has been reported in the last trimester of pregnancy.^[74],^[82] It is associated with preeclampsia, acute fatty liver of pregnancy, or HELLP syndrome, and responds to desmopressin but not AVP. DI was reported in a group of women in the last weeks of pregnancy associated with acute fatty liver. The presentation was characterized by nausea, vomiting, polyuria, and preeclampsia.^[83] Diabetes insipidus resolved in the first weeks after delivery.

In the transient recurrent form of DI, relative deficiency of antidiuretic hormone (ADH) is manifested in pregnancy, because of the inability to increase the secretion of ADH in the presence of high levels of placenta vasopressinase. It could represent the development of the full clinical picture of DI in patients with a latent form of the disease.^[84] ^[85] ^[86]

DI may present for the first time in the postpartum period, usually associated with partial anterior pituitary deficiency; the etiologies include lymphocytic hypophysitis or Sheehan's syndrome.^[87], ^[88]

Desmopressin is the drug of choice in the treatment of DI. Pitressin tannate in oil or water has been the standard drug of choice for many years and is still used occasionally. The antidiuretic effects of dDAVP last from 8 to 24 hours. dDAVP is available in three forms, nasal insufflation, parenteral and, most recently, tablet form. The usual dose of the nasal spray is 10 to 25 g once or twice daily as needed to control polyuria. In the presence of rhinitis or other conditions that would interfere with absorption, or in the postoperative period, the parenteral form is used. Two to 4 g is injected subcutaneously or intravenously and repeated every 12 to 24 hours, according to the control of symptoms, particularly nocturia, urinary osmolality, and 24-hour urinary output. Occasionally, lower extremity edema may result from an excessive dosage. Plasma electrolytes, fluid intake, and urinary output should be followed closely to avoid water intoxication. In patients with long-standing DI, complications are rare, the dosage of drug is stable, and electrolyte abnormalities are infrequent. There has been considerable experience with dDAVP in pregnancy.^[89] The prepregnancy dose does not need to be modified in most cases. There are no adverse fetal effects, and the drug is safe in lactating mothers. In the rare case of nephrogenic DI, thiazide diuretics^[90] are the only drugs that may be used, since nonsteroidal anti-inflammatory drugs are not recommended in pregnancy.

PARATHYROID DISEASES

Parathyroid diseases, uncommon in pregnancy, may produce significant perinatal and maternal morbidity and mortality if not diagnosed and properly managed. After

1125

a brief review of calcium homeostasis during pregnancy, primary hyperparathyroidism, hypoparathyroidism, and osteoporosis are discussed. Several reviews on these topics have recently been published. ^[91] ^[92] ^[93]

Calcium Homeostasis during Pregnancy

Two hormones, parathyroid hormone (PTH) and 1,25-dihydroxyvitamin D, (1,25[OH]₂D₃) are responsible for maintaining calcium homeostasis. Approximately 50 percent of serum calcium is protein bound (mostly to albumin), 10 percent is complexed to anions, and 40 percent circulates free as ionized calcium. During pregnancy, there is an active transfer of maternal calcium to the fetus. A full-term infant requires 25 to 30 g of calcium during the course of pregnancy for new bone mineralization.

Total serum calcium during gestation is 8 percent below postpartum levels. ^[94] The upper limit of normal is 9.5 mg/dl. This decrease in total serum calcium is due to the physiologic hypoalbuminemia secondary to the normal expansion of the intravascular volume observed early in pregnancy. Ionized calcium levels, however, remain unchanged throughout gestation. Serum phosphate and renal tubular reabsorption of phosphorus also remain normal throughout pregnancy. Maternal serum PTH levels, when measured by a sensitive assay that accurately measures the levels of intact PTH, are slightly decreased in the second half of pregnancy.

Blood levels of 1,25(OH)₂D₃ (calcitriol), increase early in gestation as a result of stimulation of renal 1-hydroxylase activity by estrogen, placental lactogen, and PTH, as well as synthesis of calcitriol by the placenta. ^[95] Both free and total 1,25(OH)₂D₃ are increased in pregnancy, the total because of an increase in vitamin D-binding protein. ^[96] Twenty-four-hour urinary calcium excretion also increases with each trimester of gestation and falls in the postpartum period, ^[97] ^[98] reflecting the increased intestinal calcium absorption induced by higher levels of 1,25-hydroxyvitamin D during gestation. Pregnancy-induced hypertension is characterized by decreased urinary calcium excretion probably explained by a decrease in serum 1,25-vitamin D serum levels. ^[99]

Parathyroid hormone-related protein (PTHrP), a peptide responsible for the hypercalcemia found in many malignant tumors, increases in early pregnancy. Hirota et al. ^[100] measured PTHrP in each trimester of human pregnancy, in umbilical venous blood and postpartum. A steady increase in plasma values was observed throughout pregnancy, with a peak in the third trimester and high values in cord blood. The plasma concentration in the postpartum period was directly related to the degree of breast-feeding. The source of maternal serum PTHrP is unknown, and both fetal and maternal sites have been postulated. PTHrP is secreted by breast tissue and may be involved in the transfer of calcium into milk. ^[101] PTHrP plays a role in placental calcium transport in sheep, ^[102] but its importance in human maternal physiology is less clear.

Serum calcitonin levels are higher during pregnancy and in the postpartum period, when compared with nonpregnant controls. In 20 percent of patients, the values exceed the normal nonpregnant range. ^[103] The origin of calcitonin is thyroidal C cells, breast, and placenta. Its role in pregnancy has not been elucidated, although it may protect the maternal skeleton from excessive resorption of calcium. ^[91]

Osteocalcin is a bone-specific protein released by osteoblasts into the circulation proportional to the rate of new bone formation. It is slightly decreased during the second trimester of pregnancy, with an increase in the postpartum period. ^[95] ^[104] Markers of bone resorption increase during pregnancy, reaching values in the last trimester of pregnancy up to twice normal. These changes are consistent with the increase in bone turnover at the time of maximal transfer of maternal calcium to the fetus.

Following delivery, urinary calcium excretion is reduced; ionized serum calcium remains within normal limits; and total calcium, 1,25-hydroxyvitamin D, and serum PTH return to prepregnancy levels. Early concern of calcium loss in lactating mothers, with the development of osteopenia, has not been confirmed; and calcium supplementation during breast-feeding appears to be unnecessary. The alteration in calcium and bone metabolism that accompanies human lactation represents a physiologic response that is independent of calcium intake. ^[92] ^[105]

Hyperparathyroidism

Primary hyperparathyroidism (PHP) is an uncommon disease in women of childbearing age. The incidence of the disease in pregnancy is unknown, but it is definitely rare; and most of the reported cases have been single ones complemented with a review of the literature. Over 150 cases have been reported in the English literature and have been recently reviewed. ^[106] Since the introduction of routine automated techniques in clinical medicine, the majority of patients with PHP are asymptomatic and their serum calcium elevation are mild. There are few clinical indications for ordering a serum calcium level in pregnancy.

The first case of PHP during pregnancy was reported in 1931. ^[107] Shortly thereafter, the first case of neonatal hypocalcemia causing tetany in a mother with undiagnosed hypercalcemia due to hyperparathyroidism was described by Friderichsen. ^[108] The most common cause of PHP in pregnancy is a single parathyroid adenoma, present in about 80 percent of all cases. Primary hyperplasia of the four parathyroid glands accounts for about 15 percent of the cases reported, 3 percent are due to multiple adenomas, and only four cases due to

1126

parathyroid carcinoma have been reported in the English literature. ^[109] In 1962, Ludwig ^[110] reviewed the literature on the subject, describing 21 women with 40 pregnancies. The incidence of fetal wastage was 27.5 percent. Neonatal tetany due to hypocalcemia representing the first indication of maternal hyperparathyroidism occurred in 19 percent of these cases. In 1972, Johnstone and co-workers ^[111] confirmed a perinatal mortality of 25 percent with a high incidence of neonatal hypocalcemia. Most of the patients reported in early years had significant metabolic complications of hyperparathyroidism, the two most common being renal and bone disease. In contrast to the previous high neonatal morbidity and mortality Kelly, ^[112] reviewing the literature from 1976 to 1990, found only 2 perinatal deaths (5 percent) among 37 infants born of hyperparathyroid mothers. Two additional cases of perinatal deaths were reported in mothers with hypercalcemic crisis. ^[113] ^[114]

Today, in the nonpregnant state, almost 70 percent of patients are asymptomatic, and the diagnosis is made through the routine use of biochemical screening. ^[115] In

pregnancy, since routine calcium determinations are not performed, manifestations of the disease are present in almost 70 percent of the diagnosed patients. In a review of 70 pregnant women, gastrointestinal symptoms such as nausea, vomiting, and anorexia were present in 36 percent of patients, whereas 34 percent presented with weakness and fatigue. In 26 percent, mental symptoms including headaches, lethargy, agitation, emotional lability, confusion, and inappropriate behavior were reported. Nephrolithiasis was detected in 36 percent, bone disease in 19 percent, acute pancreatitis in 13 percent, and hypertension in 10 percent. Only 24 percent of these patients were asymptomatic.^[116]

Parathyroid cancer is a rare cause of hyperparathyroidism, with four cases documented in pregnancy. Serum calcium levels are significantly higher than in other causes of PHP.^[109], ^[117] ^[118] ^[119] Perinatal mortality and morbidity were significant. Hypercalcemia with values above 13 mg/dl in the presence of a palpable neck mass should raise a strong suspicion of parathyroid carcinoma. On the contrary, in the presence of mild hypercalcemia and a neck mass, the most common cause of the neck lesion is a thyroid nodule. One other clinical feature of parathyroid carcinoma is poor response to the usual clinical therapeutic measures such as intensive hydration and loop diuretics. Surgery is the only effective therapy.

Hyperparathyroidism should be considered in the differential diagnosis of acute pancreatitis during pregnancy. Acute pancreatitis has been reported in 13 percent of women with primary hyperparathyroidism. The incidence in nonpregnant hyperparathyroid women is about 1.5 percent, and is less than 1 percent in normal pregnancy.^[120] This complication is associated with significant neonatal and maternal morbidity. It is more common in the primipara than in women who have had multiple pregnancies. Acute pancreatitis with PHP is mostly likely to occur during the last trimester of pregnancy or the postpartum period, but has also been reported in the first trimester of pregnancy, mimicking hyperemesis gravidarum. Indeed, in two cases hyperthyroidism was also present, which most likely represents the syndrome of transient hyperthyroidism of hyperemesis gravidarum (see section Thyroid Diseases, below). Serum calcium should be obtained in any pregnant woman with persistent significant nausea, vomiting, and abdominal pain.

Hyperparathyroid crisis, a serious complication of PHP, has been reported during gestation and the postpartum period, and is characterized by severe nausea and vomiting, generalized weakness, changes in mental status, and severe dehydration. Hypertension may be present and should be differentiated from preeclampsia. The serum calcium is frequently over 14 mg/dl; hypokalemia and elevation in serum creatinine are routinely seen. If not recognized and treated promptly, hyperparathyroid crisis may progress to uremia, coma, and death. Of the 12 cases reported in the literature, 4 occurred in the postpartum period. Patients presented with severe nausea, vomiting, and elevation in serum creatinine due to dehydration. Serum calcium levels over 20 mg/dl were reported in three cases,^[106] ^[121] ^[122] and three patients died.^[121], ^[123], ^[124] Six cases have been associated with pancreatitis. Four fetal deaths have also been reported.

Bone disease in patients with PHP is now unusual. However, in early series, it was a common complication.^[111] Radiologic evaluation of the bones showed diffuse demineralization, subperiosteal resorption of the phalanges and, in severe cases, single or multiple cystic lesions and generalized osteoporosis. A 27-year-old woman was described with generalized musculoskeletal pain and radiographic evidence of advanced bone disease at 34 weeks' gestation.^[125]

The two most common causes of neonatal morbidity are prematurity and neonatal hypocalcemia, the latter related to levels of maternal hypercalcemia. In early reports it was frequently the only clue of maternal hyperparathyroidism. It develops between the 2nd and 14th day of life and last for a few days.^[109], ^[111]

The diagnosis of PHP is based on persistent hypercalcemia in the presence of increased serum PTH levels.^[126] A persistent serum calcium value over 9.5 mg/dl is suspicious of hypercalcemia. Serum phosphorus is decreased in about 50 percent of pregnant women with PHP. A determination of 24-hour urinary calcium excretion is helpful in the diagnosis, since most women with PHP have an increase in urinary calcium excretion, above the usual hypercalciuria of normal pregnancy. Urinary calcium excretion is low or low normal in the syndrome of familial hypocalciuric hypercalcemia (FHH), another cause of hypercalcemia that needs to be included in the differential diagnosis. The serum alkaline

1127

phosphatase level may be increased in PHP. However, it is also increased in normal pregnancy. High-resolution ultrasonography of the neck is not useful, since it seldom differentiates a parathyroid lesion from thyroid nodular disease. Parathyroid imaging studies are contraindicated in pregnancy.

Causes of Hypercalcemia in Pregnancy and the Puerperium

(Not Available)

From Mestman JH: Endocrine diseases in pregnancy. *In* Sciarra JJ (ed): Gynecology and Obstetrics. Philadelphia, Lippincott-Raven, 1997, p 11, with permission.

Differential Diagnosis of Hypercalcemia

Although most young women with hypercalcemia have PHP, other unusual causes should be ruled out, mainly endocrine disorders, vitamin D or A overdose, the use of thiazide diuretics, or granulomatous diseases (see the box "Causes of Hypercalcemia in Pregnancy and the Puerperium") (Box Not Available). A brief discussion of three uncommon syndromes associated with hypercalcemia during pregnancy follows.

1. Familial hypocalciuric hypercalcemia (FHH) is an autosomal dominant condition with a high penetrance for hypercalcemia. The disorder is associated with an inactivating mutation in the gene for the calcium-sensor receptor.^[127] The main function of the receptor is in the regulation of calcium balance via changes in the parathyroid and kidneys. Mild hypercalcemia, slight elevation in serum PTH, mild hypermagnesemia, and low urinary calcium excretion are the typical findings. There is moderate hyperplasia of the four parathyroid glands. Total parathyroidectomy is seldom indicated due to the benign course of the disease.^[128] Infants born to mothers with FHH may present with different clinical manifestations. First, asymptomatic hypercalcemia can develop in an affected offspring if the mother is a carrier for FHH. In a second situation, severe neonatal hypocalcemia can occur in a mother with FHH syndrome. Although neonatal hypocalcemia could be severe, neonatal parathyroid function returns to normal a few weeks after delivery. In the third situation, severe neonatal hypercalcemia, also called neonatal severe hyperparathyroidism,^[129] occurs in infants homozygous for the FHH gene defect. Some infants require parathyroidectomy soon after birth.
2. Postpartum hypercalcemia may occur in women with treated hypoparathyroidism.^[130], ^[131] The mechanism for hypercalcemia is not well understood. Nausea and vomiting develop a few days after delivery, dehydration ensues, and other manifestations of hypercalcemia develop, mainly mental changes. Serum calcium may be significantly elevated. Patients with treated hypoparathyroidism should be followed postpartum with serum calcium determinations, and vitamin D should be discontinued if hypercalcemia occurs. In severe cases, intravenous fluids and glucocorticoid therapy are required^[132] (Fig. 33-1).
3. A few cases of hypercalcemia, mediated by PTHrP, during pregnancy and in the postpartum period have been reported.^[133], ^[134] In one case, hypercalcemia developed in two successive pregnancies. In the second pregnancy, serum PTHrP levels were elevated three times normal and the infant was born with mild hypercalcemia that returned to normal within 24 hours after delivery.^[133] In the other case,^[134] a 25-year-old woman had massive bilateral breast enlargement at 24 weeks' gestation. Her serum calcium level was 14.3 mg/dl, but her serum PTH level was undetectable. She underwent bilateral mastectomy during pregnancy. The immunohistochemical studies demonstrated PTHrP antigenic activity in breast tissue.

Therapy

Surgery is the only effective treatment for PHP. A novel oral agent that acts directly on the calcium sensor is being investigated. It has not been approved for clinical use.^[135] Surgery is a safe procedure when performed by a surgeon with extensive experience in neck surgery. Complications

1128

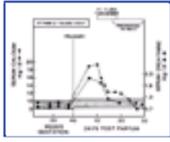

Figure 33-1 Serum calcium (closed circles) and creatinine (closed squares) levels during pregnancy and 1 month after delivery in a woman with hypoparathyroidism who was treated with vitamin D and calcium. IV, intravenously administered; stippled area, normal range.

due to surgery, particularly in the presence of a single lesion, are low and the cure rate is excellent. In nonpregnant individuals without symptoms or complications and with a serum calcium below 12 mg/dl, the conservative approach is an alternative therapeutic choice.

Guidelines for the management of PHP in nonpregnant individuals have been suggested.^[136] The proper management of PHP in pregnancy has not been uniformly agreed upon. For asymptomatic pregnant women in whom serum calcium is below 11 mg/dl, close follow-up with proper hydration and avoidance of medications that could elevate calcium such as thiazide diuretics is reasonable, although there are no studies in the literature supporting this or any other approach. Since most of the neonatal complications have been reported in patients with symptomatic disease, a surgical approach is indicated in these patients, as well as those with complications such as nephrolithiasis and bone disease and those with persistent hypercalcemia (>11 mg/dl). It is preferable to perform the surgery in the second trimester of pregnancy. In the series reported by Carella and Gossain,^[116] 38 women underwent parathyroidectomy during pregnancy, 7 during the first trimester and the other 18 in the second trimester. In the total group of 25, there was only 1 fetal loss. In 12 women in whom surgery was performed during the third trimester of pregnancy, the incidence of perinatal complications was 58 percent.

For women with PHP first diagnosed after 28 weeks' gestation, the optimal treatment strategy is unclear, and the decision in such a situation should be based on general patient condition, severity of hypercalcemia, and other complicating circumstances.

Medical therapy is reserved for those patients with significant hypercalcemia that are not surgical candidates. Oral phosphate therapy of 1.5 to 2.5 g/day has been shown to be effective in controlling hypercalcemia.^[137] Side effects of oral phosphate therapy include nausea, vomiting, and hypokalemia. These problems can be easily avoided by decreasing the dose of the medication. In patients in whom surgery is not advisable, it is important to prevent elevations in serum calcium. Good hydration, early treatment of urinary tract infections, and avoiding medications known to cause elevations in serum calcium such as vitamin D, vitamin A, aminophylline, and thiazide diuretics are all important. Serum calcium should be determined on a regular basis.

In patients undergoing surgical treatment, hypocalcemia, albeit transient, may occur after surgery in some cases. Serum calcium should be checked every 6 hours, and if the patient develops hypocalcemic symptoms, intravenous calcium in the form of calcium gluconate, 10 to 20 ml of a 10 percent solution, should be given over a period of 5 to 10 minutes. Intermittent infusions may be repeated or calcium gluconate can be diluted in 5 percent dextrose or isotonic saline and infused continuously at 1 mg/kg body weight per hour. In patients with bone disease, postsurgical hypocalcemia may be profound, and aggressive treatment is needed. These patients may benefit from vitamin D supplementation in the form of calcitriol 0.25 to 0.5 g/day for a few days before operative intervention.^[138]

Hypoparathyroidism

The most common etiology of hypoparathyroidism is damage to or removal of the parathyroid glands in the course of surgery for thyroid gland pathology. The incidence of permanent hypoparathyroidism following thyroid surgery has been estimated to be between 0.2 and 3.5 percent. In many cases, hypocalcemia in the immediate postoperative period is only transitory. Idiopathic hypoparathyroidism is a much less common cause of the disease, frequently associated with other autoimmune endocrinopathies, as part of the polyglandular autoimmune syndrome type 1. Antibodies directed against parathyroid calcium-sensing receptor have been detected in 56 percent of patients with idiopathic hypoparathyroidism.^[139]

The requirement for calcium supplementation and vitamin D may decrease in some but not all women with hypoparathyroidism during the second half of pregnancy and lactation. In a few cases, hypocalcemic symptoms ameliorate with progression of pregnancy. The explanation for the above findings is not clear. It may be related to the increased intestinal absorption of calcium and/or the production of vitamin D by the placenta.

Clinical clues for the diagnosis of hypoparathyroidism

1129

include a previous history of thyroid surgery, and clinical, radiologic, and laboratory information. Typical symptoms of hypocalcemia are numbness and tingling of the fingers and toes and around the lips. Patients may complain of carpopedal spasm, laryngeal stridor, and dyspnea. Convulsions may be a manifestation of severe hypocalcemia. Symptoms of irritability, emotional lability, impairment of memory, and depression are common. On physical examination, patients with idiopathic hypoparathyroidism demonstrate changes in the teeth, skin, nails, and hair as well as papilledema and cataracts. Chvostek's sign, a twitch of the facial muscles, notably those of the upper lip, when a sharp tap is given over the facial nerve, is seen in many patients with hypocalcemia. Chvostek's sign has also been described in 10 percent of normal adults. Trousseau's sign is another sign of hypocalcemia. It is the induction of carpopedal spasm by reducing the circulation in the arm with a blood pressure cuff. The constriction should be maintained above the systolic blood pressure for 2 minutes before the test is considered negative.

The diagnosis of hypoparathyroidism is confirmed by the presence of persistent low serum calcium and high serum phosphate levels. Plasma alkaline phosphatase is usually normal. The differential diagnosis of hypocalcemia includes rickets, osteomalacia, and hypomagnesemia.

Marked hypocalcemia may occur in severely ill patients. The etiology is unclear, and a return to normal serum calcium is the rule following the recovery from the acute event.^[140]

In 1942, Anderson and Musselman^[141] published a review of the literature on hypoparathyroidism and tetany in pregnancy, collecting 240 cases. Twenty-six of the cases were due to postthyroid surgery, and 140 were the so-called idiopathic type. It is likely that in some of these cases tetany was not due to hypoparathyroidism. Therapeutic abortion was recommended because of the high fetal and maternal mortality. Other reports have confirmed that hypoparathyroidism, if not properly treated, may increase perinatal loss, including spontaneous abortions, stillbirths, and neonatal deaths.^{[142], [143]} Radiologic bone changes may be present in the newborn as a consequence of intrauterine hyperparathyroidism. They are characterized by generalized skeletal demineralization, subperiosteal bone resorption, bowing of the long bones, osteitis fibrosa cystica, and rib and limb deformities. Loughead et al.^[144] described 16 infants of hypoparathyroid mothers. Secondary hyperparathyroidism in the infants resolved by 1 month of age.

Vitamin D deficiency in the mother has been associated with decreased fetal growth. Maternal serum calcium may be normal or slightly decreased. Brunvand et al.^[145] followed 30 Pakistani women during pregnancy, 13 with elevated serum PTH levels at the time of delivery, and 29 with serum levels of 25-hydroxyvitamin D below normal. There was a positive correlation between serum maternal ionized calcium levels and the crown-heel length of the newborn. The authors suggested that vitamin D deficiency could interfere with fetal growth through an effect on maternal calcium homeostasis.

Treatment of hypoparathyroidism in pregnancy does not differ from the nonpregnant state, including a normal high-calcium diet and vitamin D supplementation. The normal calcium supplementation of pregnancy is about 1.2 g/day. Vitamin D requirements may decrease in some patients by the second half of gestation. Calcitriol 1 to 3 g/day is used almost routinely in most patients affected with hypoparathyroidism.^{[132], [146], [147]} Calcitriol must be given in single or divided doses, since its half-life is much shorter than vitamin D. If vitamin D is used, the dose is in the range of 50,000 to 150,000 IU/day. The importance of compliance with medications should be strongly emphasized, particularly when calcitriol is prescribed, in view of its short half-life. The major problem in the treatment of hypoparathyroidism is the recurrence of hypercalcemia and hypocalcemia. Therefore, serum calcium determinations should be performed at regular intervals. The most common symptoms of vitamin D intoxication are nausea, constipation, fatigue, headaches, and in more severe cases, vomiting and dehydration. It is important to assess serum calcium and phosphorous during pregnancy, particularly in the postpartum period, to detect the early onset of hypercalcemia (see above).^{[137], [148]}

Lactation in mothers taking vitamin D may be contraindicated, because a metabolite of vitamin D, 25-hydroxyvitamin D, has been detected in breast milk in high concentration in a mother taking 50,000 IU of vitamin D daily.^[149] Regardless of the form of vitamin D prescribed, serum calcium determinations should be done in the postpartum period, particularly in breast-feeding mothers.

Pseudohypoparathyroidism

Pseudohypoparathyroidism encompasses several different disorders having as a common feature varying degrees of target organ resistance to PTH. Somatic changes are present in some forms of the syndrome, including short stature, obesity, round face, brachydactyly, and mental retardation, with brain calcifications. This variant is known as Albright's syndrome of type 1a. Most patients suffer from hypocalcemia, due to a derangement of renal 1-hydroxylase and production of calcitriol. A few cases have been reported during pregnancy. Spontaneous normocalcemia occurred in two patients during four pregnancies. The authors provided evidence of placental synthesis of calcitriol to account for the normocalcemia. In both patients, serum PTH, which was significantly increased before pregnancy,

1130

was reduced by 50 percent during gestation. Serum cord calcium, phosphorus, and calcitriol concentrations were within normal limits. ^[150], ^[151] These infants are at risk for intrauterine fetal hyperparathyroidism, perhaps because of the relative maternal hypocalcemia during pregnancy. ^[152]

Osteoporosis

The condition of idiopathic osteoporosis related to pregnancy was recognized in the 1950s. ^[153] In the last few years, there has been an increased interest in several clinical aspects of osteoporosis in pregnancy and lactation. ^[154] ^[155] ^[156] In general, osteoporosis is suspected in pregnancy when the patient presents with severe, persistent back or hip pain and radiologic examination shows signs of osteopenia. Studies measuring calcitrophic hormones and biochemical markers of bone reabsorption in each trimester in pregnancy and in the postpartum period showed a slight decrease in bone mass in the third trimester, ^[157] followed by recovery within the first 6 months postpartum. In a study of a group of white, upper middle class, postmenopausal women, there was no association between the number of pregnancies and lactation as predictors of decreased bone mineral density. ^[158]

Osteoporosis may be diagnosed during pregnancy or in the postpartum period. Whether these are two different syndromes or represent the same clinical entity is unclear, since the symptoms may begin during pregnancy, but the diagnosis is made for the first time after delivery. Osteoporosis diagnosed during pregnancy may be localized in the hip(s) or lumbar spine or both. Pain in one hip or back pain is the presenting symptom in most cases, usually in the second half of gestation. Spontaneous recovery is the usual course a few months postpartum. ^[159] A case has been reported of onset in the first trimester with recovery following abortion. ^[160]

Although osteoporosis has been diagnosed during pregnancy, pregnancy unmasks rather than causes low bone mass. As suggested by Rizzoli and Bonjour and others, ^[161], ^[162] postural changes during pregnancy, including increased lordosis, when superimposed on a small and transient decrease in bone mass, may lead to pain and even fractures. In a study of 24 women with symptoms of bone pain for many years, 18 of them complained of back pain, 5 complained of hip pain, and 1 complained of ankle pain in late pregnancy or up to 8 months after delivery. ^[163] Radiologic examination of the spine showed vertebral deformities in 17. Bone mass was measured in 21, and 7 women had evidence of osteoporosis and 13 were osteopenic. The authors conclude that bone mass was probably low before pregnancy and that a transient and slight decrease in bone mass during pregnancy could have weakened the bone further. Radiologic examination of the localized painful area and studies of bone density following delivery are indicated. In some cases, a short course of calcitonin or bisphosphonate therapy plus calcium supplementation may be needed.

The impact of lactation on the progression of osteoporosis is controversial. The study by Kritz-Silverstein et al. revealed that lactation by itself was not a determinant of bone mineral density. ^[164] Although one investigation reported that lactation for more than 8 months was associated with greater bone mineral at both the femoral neck and shaft, ^[165] another study found that nursing for longer than 9 months produced a greater decrease in bone mass than observed during the first 6- to 9-month period of nursing. ^[166] Given this controversy, the health care provider must decide if cessation of lactation is advisable in the management of osteoporosis.

Heparin-associated osteoporosis has been reported in several cases during pregnancy. ^[167] It may be related to the total dose of heparin. Treatment with calcium supplementation or calcitriol, although not proven, may be helpful in those patients receiving heparin therapy. Barbour et al. ^[168] followed 14 pregnant women requiring heparin therapy. Five of the 14 cases experienced a 10 percent decrease from baseline proximal femur bone density measurements as compared with none in a matched control group. They concluded that heparin adversely affected bone density in about one third of exposed patients.

ADRENAL DISEASES

Adrenal Gland Physiology

The adrenal gland secretes three main hormones: cortisol, aldosterone, and dehydroepiandrosterone (DHEA) and dehydroepiandrosterone-sulfate (DHEA-S) and some estrogen. Cortisol is present in the circulation bound to a specific binding protein, corticosteroid-binding globulin (CBG) or transcortin, bound to albumin, and in a free or biologically active form. In the nonpregnant woman, 70 to 80 percent is bound to CBG and only 10 to 15 percent remains in the free or unbound fraction. In pregnancy, there is an increase in plasma levels of CBG, and by the end of the third trimester the serum levels of CBG have doubled from prepregnancy levels. At the same time, there is an increase in free or unbound cortisol, its serum concentration increasing by the first trimester of gestation. ^[167], ^[168]

Aldosterone is the most potent mineralocorticoid secreted by the adrenal cortex. The daily secretion rate in nonpregnant women is about 50 to 250 g on a normal sodium intake. Its secretion is controlled by the

1131

renin-angiotensin system, by serum potassium levels, and to a lesser degree by ACTH. The aldosterone secretion rate and plasma concentration increase during pregnancy, with the first changes occurring as early as 2 weeks after conception. ^[169]

The adrenal cortex secretes hormones with weak androgenic properties: DHEA and DHEA-S. DHEA production rate is increased during pregnancy. It is aromatized to estradiol and estrone by the term placenta and contributes up to 9 percent of circulating estradiol. ^[170]

Cushing's Syndrome

Cushing's syndrome is a result of chronic tissue exposure to excessive amounts of glucocorticoids. Cushing's syndrome may be classified as ACTH dependent and ACTH nondependent (see the box "Classification of Cushing's Syndrome" (Box Not Available)). ACTH-dependent Cushing's syndrome is due to excessive or inappropriate secretion of ACTH by a pituitary tumor or hyperplasia, or by an ectopic tumor producing ACTH or ACTH-releasing hormone. ACTH-nondependent Cushing's syndrome is due to an intrinsic disorder of the adrenal gland, such as a benign or malignant tumor, or is iatrogenic, secondary to pharmacologic doses of glucocorticoids used in the treatment of systemic medical diseases. Women are nine times more likely than men to develop Cushing's syndrome, with a higher incidence between 20 and 40 years of age. In women of childbearing age, the most common cause of Cushing's syndrome is bilateral adrenal hyperplasia, accounting for 75 percent of all cases; 20 percent of cases are caused by an adrenal tumor, most commonly a single adenoma, whereas a few cases result from bilateral nodular adrenal hyperplasia and ectopic ACTH production. In pregnancy, however, adrenal adenomas account for over 50 percent of Cushing's syndrome. ^[171] ^[172] ^[173] Adrenal carcinoma is rare, although it appears to be more common in pregnancy. Although ectopic ACTH syndrome is unusual in young women, an occasional case has been reported in pregnancy. ^[174]

Classification of Cushing's Syndrome

(Not Available)

From Mestman JH: Endocrine diseases in pregnancy. In Sciarra JJ (ed): Gynecology and Obstetrics. Philadelphia, Lippincott-Raven, 1997, p 15, with permission.

Cushing's syndrome is characterized clinically by a protracted progression of symptoms, manifested by muscle weakness, personality changes, oligo- or amenorrhea, hirsutism, weight gain, and back pain due to osteoporosis. An increased incidence of thromboembolism also has been reported. One of the first common manifestations in women is oligomenorrhea, which progresses to amenorrhea; hence, pregnancy in women with Cushing's syndrome is unusual. Anovulation may be due to suppression of pituitary gonadotropin by high levels of glucocorticoids and/or high androgen levels.

On physical examination, hypertension, truncal obesity, fat deposition in the supraclavicular areas and upper dorsal spine areas (buffalo hump), moon face, atrophy of the skin that is easily bruised, and purple striae (over the abdomen, axillae, and hip areas) are common features. Weakness, due to muscular atrophy, can be marked, particularly in the quadriceps muscles, the patient being unable to rise from a deep knee bend without assistance. Headaches and visual field disturbances due to a large pituitary tumor are rare. Kidney stones due to hypercalciuria are reported to occur in 15 to 20 percent of patients. Hirsutism, sometimes of the lanugo type, is common. The severity of virilization depends on the amount of androgen produced by the adrenal lesion. In patients with an adrenal adenoma, the secretion of androgens is low, whereas it is moderately high in patients with bilateral adrenal hyperplasia. Masculinization is rare and when it occurs is due to an adrenal carcinoma producing large amounts of androgens.

An increase in hematocrit, leukocytosis with relative lymphopenia, and eosinopenia are usually seen. An abnormal glucose tolerance test has been reported in over 50 percent of patients, and frank diabetes in 20 to 30 percent. Mild hypokalemia with metabolic alkalosis is common. Radiologic examination of the chest may show an enlarged mediastinum secondary to fat deposition. Osteoporosis is also observed.

The clinical diagnosis may present difficulty during pregnancy because characteristically similar striae, weight gain, and hypertension are seen in both conditions. ^[175] Comparisons of close-up photographs from earlier years are helpful in detecting subtle changes. Some clinical features such as severe hypertension in the second trimester, significant hyperglycemia, mental changes, and muscle weakness may alert the physician to this rare disorder. Proper use and interpretation of tests assessing the hypothalamic-pituitary-adrenal axis function confirm the diagnosis.

A persistent elevation in urinary-free cortisol is the best indicator of excessive production by the adrenal gland(s). It should be kept in mind, however, that a slight elevation does occur in normal pregnancy. Mean urinary free cortisol levels of 127 g/day (range, 68 to 252g/day) as compared with nonpregnant levels of 37 g/day (range, 11 to 83) have been reported in pregnancy.^[176] Plasma cortisol increases three fold from the first to the third trimester of pregnancy, and random determinations of plasma cortisol are of little help in establishing this diagnosis, because values are normal in many patients with Cushing's syndrome. Furthermore, plasma cortisol is normally elevated due to an increase in CBG. The overnight dexamethasone suppression test, although an excellent screening test in nonpregnant patients, is of limited value during gestation. Lack of diurnal variation of serum cortisol is suggestive of the disease, but in order to properly assess the result of the test, specimens should be obtained between 7 A.M. and 9 A.M. in the morning and late in the evening, preferably at midnight.^[177] In view of the normal elevation in serum cortisol, the criteria for evening levels is a decrease to less than 50 percent of morning levels.^[178],^[179]

In pregnancy, the determination of free cortisol in a 24-hour urine specimen is the best screening test to rule out Cushing's syndrome. At least two collections of 24 hours are needed before proceeding to further diagnostic tests. Concomitant determination of urinary creatinine is necessary to ensure a complete urine collection. Once the diagnosis of Cushing's syndrome is confirmed, the etiology should be investigated. As noted above, the most common causes in pregnancy are adrenal hyperplasia and adrenal adenomas.

Plasma ACTH levels are helpful when interpreted in the light of urinary cortisol values. They are better if obtained in early morning (7 to 9 A.M.). A high-normal or elevated value in the presence of high urinary cortisol is suggestive of ACTH-dependent Cushing's syndrome (Cushing's disease). Low ACTH values are consistent with a unilateral adrenal tumor.

Further delineation of the pathologic cause is carried out with the use of the dexamethasone suppression test. Urinary cortisol is measured prior to and during 2 days, first with a small dose (0.5 mg every 6 hours) and then with a high dose of oral dexamethasone (2 mg every 6 hours). In normal pregnancy, urinary cortisol is suppressed to less than 55 nmol/24 h.^[173] Patients with Cushing's syndrome, regardless of the cause, fail to suppress urinary cortisol excretion with the small doses (0.5 mg every 6 hours). On the high-dose dexamethasone regimen, patients with bilateral adrenal hyperplasia show a 50 percent or greater fall in urinary free cortisol, whereas there is no suppression in those patients with an adrenal tumor.

Intravenous administration of corticotropin-releasing hormone (CRH) with the determination of plasma ACTH and cortisol is used as an adjunctive test in establishing the etiology of Cushing's syndrome.^[180],^[181] Plasma ACTH does not increase following the administration of CRH when the cause is an adrenal tumor or ectopic ACTH production. An increase in plasma ACTH of greater than 50 percent or serum cortisol of greater than 20 percent from baseline values has a 95 percent specificity and almost 90 percent sensitivity in the diagnosis of Cushing's disease.

In cases in which the diagnosis is not confirmed by the above tests, or when more specific localization of the pituitary lesion is desired in preparation for surgery, inferior petrosal sinus blood sampling is obtained for measuring both cortisol and ACTH. Venous blood is obtained by catheterization through the femoral vein. Comparison of central versus peripheral levels of ACTH allows for the separation between an ectopic source of ACTH from a pituitary lesion. In pregnancy, the jugular vein has been used instead of the femoral vein, in order to avoid excessive radiation exposure to the fetus. Although the procedure was successful in confirming the pituitary origin of Cushing's disease, it did not localize the site of the lesion.^[182]

Once the diagnosis of Cushing's syndrome is confirmed by these hormonal tests, imaging of the pituitary or adrenal gland will demonstrate the presence of a lesion in the majority of cases. In pregnancy, MRI is the preferred method of imaging for both the adrenal and pituitary glands, because of the lack of radiation exposure for the fetus. In patients with Cushing's disease, MRI of the pituitary gland may identify a tumor or diffuse hyperplasia, diagnoses sometimes difficult to confirm because of the enlargement of the pituitary gland occurring during normal pregnancy. Imaging by itself without the validation of biochemical tests should be discouraged, since nonfunctional tumors or "incidentalomas" have been reported in at least 10 percent of a so-called normal population.^[183],^[184]

Cushing's syndrome, itself an uncommon disorder, is rarely seen during pregnancy. Just over 100 cases have been reported in the English literature, most of them isolated reports. Several reviews have been published.^[171]^[172]^[173] During pregnancy or in the postpartum period, spontaneous exacerbation^[185]^[186]^[187] or amelioration^[188]^[189]^[190]^[191] of symptoms have been described. Wallace et al.^[192] presented a patient with recurrent Cushing's syndrome in three successive pregnancies. In this woman with "pregnancy induced Cushing's syndrome," hormonal and clinical features normalized postpartum. There was a lack of urinary cortisol suppression with the administration of dexamethasone. Although the authors were unable to detect any direct adrenal stimulation in vitro and in vivo from extracts of the placenta or maternal serum, the clinical course is suggestive of a stimulator originating in the fetoplacental unit. Estrogen-dependent

nodular adrenal hyperplasia was the apparent cause in one woman. In another report with spontaneous resolution after delivery, the presence of gastric inhibitory polypeptide receptors was the cause of ACTH-independent Cushing's syndrome.^[193]

Maternal and perinatal morbidity and mortality are significant in Cushing's syndrome. Arterial hypertension occurs in over 70 percent of cases,^[171] overt diabetes in 30 percent, preeclampsia in 7 percent, and congestive heart failure in 7 percent. Maternal death has been reported in 4 percent of cases due to congestive heart failure in the postpartum period and sepsis.^[174],^[194] Fetal wastage, including abortions, stillbirths, and neonatal deaths, approaches 30 percent. Prematurity has been reported in 52 percent of infants and intrauterine growth restriction in 25 percent.

The modality of treatment depends on the severity of the disease, the etiology, the gestational age at the time of diagnosis, and a frank discussion of potential benefits and risks of therapy with the patient and her family. There is some evidence that treatment during pregnancy improves fetal outcome. Buescher^[173] reviewed 105 pregnancies in women with Cushing's disease and confirmed the high incidence of prematurity and a perinatal mortality of 12.4 percent, equally divided between neonatal and intrauterine deaths. Comparing a subgroup of 32 patients treated during pregnancy against 73 untreated women, the perinatal mortality was 6.3 percent in the former and 15.1 percent in the untreated group. However, there was no difference in the incidence of premature birth or intrauterine growth restriction. In another series, the outcome of pregnancy was significantly better in patients who underwent a bilateral adrenalectomy for hyperplasia or unilateral adrenalectomy for adenoma during pregnancy.^[195]

Transsphenoidal pituitary surgery has been performed in several patients during pregnancy.^[182],^[197]^[198]^[199]^[200] In one case, surgery was done at 22 weeks' gestation, and the patient was delivered at 30 weeks' gestation because of severe hypertension.^[198] In two other patients, transsphenoidal surgery was performed in the second trimester, with a healthy infant delivered at 38 weeks' gestation in one case^[197] and an intrauterine death at 33 weeks of pregnancy in another.^[182]

Drugs such as metyrapone and particularly ketoconazole are used to treat Cushing's syndrome when surgery has failed, while awaiting the effect of radiation therapy to the pituitary gland, or in preparation for surgery. These medications have shown beneficial effects in some pregnant patients.^[175],^[191],^[193],^[196],^[200],^[201],^[203]^[204]^[205] Metyrapone acts primarily to inhibit steroid 11-hydroxylation, thereby decreasing the secretion of cortisol by the adrenal glands. Its main use is as a diagnostic tool to assess ACTH reserve. In one case,^[200] metyrapone in doses between 250 and 1,000 mg daily was given from 29 weeks' gestation until the spontaneous onset of labor at 36 weeks' gestation. The patient improved, and fetal growth and well-being were satisfactory. The newborn showed no signs of adrenal insufficiency.

Several cases of Nelson's syndrome (pituitary tumor with skin pigmentation following bilateral adrenalectomy for Cushing's disease) have been reported during pregnancy with good infant outcome.^[206],^[207] Because ACTH does not cross the placenta, the fetal adrenal glands are not affected.

In summary, the etiology and gestational age may determine management of Cushing's syndrome in pregnancy. In the first two trimesters, adrenal surgery is indicated in the presence of an adrenal tumor; if MRI localizes the lesion in the pituitary gland, transsphenoidal surgery may be attempted in specialized centers. For patients in the third trimester, or those in whom the source of hypercortisolism cannot be localized, drug therapy with ketoconazole or metyrapone should be considered. Drug therapy during embryogenesis, however, should be used with great caution in view of the possible teratogenicity of these drugs, particularly ketoconazole.

Addison's Disease

Addison's disease, or primary adrenal insufficiency, results from the total destruction of the adrenal cortex, with deficiency of glucocorticoids (cortisol), mineralocorticoid (aldosterone), and the weak androgen dehydroepiandrosterone. When adrenal insufficiency is caused by a deficiency of pituitary ACTH (secondary adrenal insufficiency), aldosterone and adrenal androgen secretions are preserved. Autoimmune disease is the most common cause of primary adrenal insufficiency, accounting for about 70 percent of all cases. Other causes include granulomatous diseases, particularly tuberculosis, surgical bilateral adrenalectomy for systemic diseases, bilateral metastatic carcinoma, bilateral adrenal bleeding during anticoagulant therapy, as well as fungal infections and acquired immunodeficiency syndrome (AIDS). Severe systemic infections by meningococcus (Waterhouse-Friderichsen syndrome) may present as acute adrenal insufficiency characterized by vascular collapse and petechial hemorrhage in the skin and mucosa.

Secondary adrenal insufficiency occurs as a result of pituitary insufficiency, mainly through chronic suppression of pituitary ACTH in patients receiving corticosteroid therapy for various periods of time. In this situation, symptoms of adrenal insufficiency are manifested during periods of stress. It takes an average of 8 months for the hypothalamic-ACTH-adrenal axis to recover completely following the discontinuation of corticosteroid therapy. ^[209]

The most common symptoms of chronic primary adrenal insufficiency are weakness, fatigue, nausea and eventually vomiting early on awakening, and weight

1134

loss. Characteristically, these patients feel relatively well in the morning and experience increased fatigue and asthenia during the progression of the day. Blood pressure is low, and patients may complain of postural hypotension. Although pigmentation of the skin and mucosa is characteristically described in Addison's disease, it is not seen in all patients. The pigmentation is seen in body creases, such as palms of the hands, knuckles, knees, and elbows; in scars; and in the genital, gingival margin, and buccal mucosa. Vitiligo may be found in 10 to 15 percent of patients with Addison's disease. These lesions have been ascribed to autoimmune destruction of the melanocyte and occur in hyperpigmented areas. Gonadal function is disturbed, and in women, axillary and pubic hair may be reduced because of lack of adrenal androgens. Adrenal crisis, a medical emergency, is characterized by severe hypotension, nausea, vomiting, diarrhea, and severe dehydration. Patients may present with elevated body temperature, although infection is not always demonstrated.

Laboratory findings typically include mild anemia, hyponatremia, hyperkalemia, and increased serum blood urea nitrogen. However, in a significant number of patients, serum electrolytes remain within normal limits. Hypercalcemia may be seen during the acute phase of adrenal insufficiency. Hypoglycemia presents in the fasting state and during adrenal crisis.

Lack of cortisol response to ACTH administration or elevated plasma ACTH levels in the presence of a low serum cortisol concentration, or both, ^[209] confirm the diagnosis. Baseline or random serum cortisol levels are low in most patients with Addison's disease. However, normal cortisol levels do not rule out the disease, as cortisol levels are normally elevated due to the increased CBG. In nonpregnant patients, a serum cortisol value of less than 3 g/dl provides presumptive evidence of adrenal insufficiency, whereas a value of less than 10 g/dl suggests the diagnosis. ^[210] Basal values for diagnosing adrenal insufficiency in pregnancy have not been established. The diagnosis of adrenal insufficiency must be confirmed by dynamic tests, namely, the serum cortisol response to the administration of ACTH. There are several ways to perform ACTH stimulation tests:

Short ACTH Stimulation Test: This is the simplest available test to rule out the presence of Addison's disease. It can be performed at any time of the day. For the test, synthetic ACTH (124) (cosyntropin), 0.25 g, is given as a rapid intravenous bolus and plasma cortisol is measured before and 30, 60, and 120 minutes after cosyntropin administration. ^[211] A peak cortisol response of 18 g/dl over the baseline values rules out Addison's disease and almost all cases of secondary adrenal insufficiency, the exception being recent onset of secondary adrenal failure. In these cases, a low-dose, 1-g cosyntropin intravenous dose may detect patients with a mild form of secondary adrenal insufficiency. ^[212] However, a suboptimal or complete lack of response to ACTH administration does not confirm the diagnosis, and a more prolonged ACTH stimulation test is needed. ^[213]

Long ACTH Stimulation Test: There are several modifications of the original test; ACTH in the form of cosyntropin, 0.25 mg in 500 ml 5 percent dextrose in normal saline is given every 12 hours for 48 hours, and serum cortisol is measured before and every 12 hours. A serum plasma cortisol of over 30 g/dl rules out the presence of primary adrenal insufficiency. To prevent acute adrenal crisis in symptomatic patients, dexamethasone, 0.5 mg, is added to the continuous ACTH infusion. In patients already on glucocorticoid replacement therapy, dexamethasone is substituted at least 24 hours before and during the test. This dose of corticosteroid does not interfere with the determination of serum cortisol and provides enough glucocorticoid activity to correct the patient's symptoms. The 48-hour continuous ACTH infusion can accurately distinguish between primary and secondary adrenal insufficiency. With the former, there is no increase in cortisol values; in the latter situation, serum cortisol levels increase after the first 24 hours of the test.

Plasma ACTH Determination: High serum ACTH and low cortisol levels are the hallmark of primary adrenal insufficiency. Normal ACTH values early in the morning are between 20 and 150 pg/ml. Baseline cortisol values less than 10 g/dl and ACTH levels of greater than 250 pg/ml are diagnostic of primary adrenal insufficiency.

Patients with primary adrenal insufficiency require treatment for the remainder of their lives with occasional exceptions. Cortisone or hydrocortisone is the treatment of choice, in doses of 15 to 30 mg/day, with two thirds of the dose being given in the morning and one third in the evening. In most patients, a mineralocorticoid is added in the form of fluorohydrocortisone; the dosage varies from 0.05 to 0.2 mg daily. Although cortisol is the natural hormone produced by the adrenal gland and is the drug of choice, other synthetic glucocorticoids may be used. Prednisone and prednisolone are less expensive and more available than cortisone, and either may be used in doses of 3 to 5 mg in the morning and 1 to 3 mg in the evening. Dexamethasone (Decadron) is not recommended, because of its prolonged action (more than 24 hours).

Patient education is imperative to prevent medical catastrophes. Patients should wear visible identification with their diagnosis, therapy, and physician phone number. They should know that their dosage of corticosteroids

1135

should be doubled in cases of moderate stress, and they should have available an injectable form of glucocorticoid in case of vomiting. Available injectable preparations include dexamethasone 4 mg/ml, or hydrocortisone 100 mg/ml, for intramuscular injections.

Adrenal crisis is a medical emergency requiring immediate treatment. Dehydration is treated with intravenous fluids in the form of normal saline and glucose; 100 mg of hydrocortisone should be injected as a bolus intravenously. An additional 200 mg should be given during the first 24 hours. Appropriate therapy for hypotension should be instituted. In most cases, infection is responsible, and a careful search for the cause of the acute crisis should be made.

In patients with known adrenal insufficiency or on corticosteroid therapy undergoing elective surgery, cortisol should be given in total doses of 200 to 300 mg during the day of surgery. Many regimens have been proposed for the management of patients. However, we recommend cortisol, 100 mg intravenously every 8 hours, in continuous infusion for the first 24 hours and then decreased by 50 mg/day until the patient is able to take oral medications. The infusion should be started early on the morning of surgery. In most cases, by the fourth or fifth postoperative day the patient is able to return to her routine preoperative daily dosage. Because the amount of cortisol administered has adequate mineralocorticoid action, no mineralocorticoid supplementation is needed during this time. Daily determinations of serum electrolytes and glucose should be obtained to rule out hypokalemia and hyperglycemia resulting from the high dose of glucocorticoids. It has also been suggested that an injection of cortisone acetate, 50 to 100 mg intramuscularly, be given the day before surgery. The same regimen is applied to patients having received corticosteroid therapy in the past and having discontinued it within the last 12 months. An additional scheme is to use cortisone acetate, 50 mg intramuscularly, every 6 hours for the first day, every 8 hours during the second day, and every 12 hours for the fourth day after a surgical procedure. During surgery, 100 mg of hydrocortisone is added to the intravenous solution.

Women with Addison's disease have few complications during pregnancy. Early reports have indicated no increase in miscarriage rate, prematurity, or intrauterine death. ^[214] ^[215] ^[216] The amount of glucocorticoid needed does not increase during pregnancy. The dose may actually be reduced as a result of the potentiation of hydrocortisone's biological action by estrogen. ^[26] The requirement for glucocorticoid increases during the stress of labor. A booster dose of hydrocortisone 100 mg or

equivalent amounts of synthetic preparations are given at the beginning of labor (see Table 33-2). Mineralocorticoid requirements remain the same throughout pregnancy.

Acute adrenal insufficiency developing in pregnancy or the puerperium is rare, and in most cases is secondary to an acute deficiency of pituitary ACTH such as in the reported cases of pituitary lymphocytic hypophysitis or bleeding into a pituitary tumor. The classic presentation is protracted hypoglycemia resistant to glucose administration but responding to glucocorticoid administration.^[14]

Neonatal adrenal insufficiency is rare in infants of mothers receiving corticosteroid therapy. In a review of 260 pregnancies during which steroids were given to the mother for variable periods, only one infant was believed to have adrenal corticosteroid insufficiency.^[217]

Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia (CAH)^[218] is a hereditary disorder involving both adrenal glands. It is produced by a number of defects of corticosteroid biosynthesis that result in reduced production of cortisol, a secondary increase in ACTH secretion, which is then responsible for adrenal hyperplasia and accumulation of hormonal precursors. Defects of several enzymes related to the cytochrome P-450 group of oxidases can produce different clinical pictures (Fig. 33-2).

The 21-hydroxylation defect (CYP21A2) is most common, with impaired conversion of 17-hydroxyprogesterone to 11-deoxycortisol. This abnormality is found in more than 90 percent of patients with CAH. It is transmitted as an autosomal recessive disorder involving a gene on the short arm of chromosome 6 and affects approximately 1 of every 14,200 live births.^[219],^[220] In the Caucasian population, the incidence of the mild non-classic forms of the disorder have been estimated to be between 1 in 100 to 1 in 1,000.^[221],^[222] In Caucasian women with clinical evidence of excessive androgen production, the incidence is about 2 percent, and is even slightly higher in Jewish women of European origin.^[223]

The clinical manifestations depend on the severity of the abnormality in the 21-hydroxylase genes. The two classic presentations of CYP21A2 deficiency are a simple virilizing form presenting as genital ambiguity, and a sodium-wasting form, recognized at the time of delivery or soon thereafter. In the former, the 21-hydroxylase enzymatic activity is low but detectable; while in the salt-wasting form there is no enzymatic activity. The third form of the disease, nonclassic or late-onset CYP21A2 deficiency, is mild and is detected in childhood or adulthood, with manifestations of hirsutism and menstrual irregularities. These patients have 20 to 60 percent of normal enzymatic activity.^[224]

Female infants affected by the disease have pseudohermaphroditism, while affected males have normal sexual development. Clitoral enlargement, labial fusion, and formation of a urogenital sinus are due to the

1136

Figure 33-2 Adrenal steroid biosynthesis pathway.

effects of androgen excess in utero. Infants with the severe form of salt wasting, affecting more than two thirds of infants with this enzymatic defect, present with dehydration, hypovolemia, hypotension, hyponatremia, and hyperkalemia.

The diagnosis is based on the clinical picture and high serum 17-hydroxyprogesterone (17-OHP) levels. In addition, serum testosterone, progesterone, and DHEA-S levels are also elevated. In the salt-wasting type, low aldosterone and high renin levels are typically found. In patients with the nonclassic form or late-onset disease, serum 17-OHP levels are over 200 ng/dl in the basal state during the follicular phase of the menstrual cycle, and have an exaggerated response to the administration of ACTH, with values over 1,500 ng/dl.

Other types of defects include the 11-hydroxylation (CYP11B1) deficiency and, more rarely, a defect of the 3-hydroxysteroid-dehydrogenase enzyme.

The goal of treatment is to prevent adrenal insufficiency, to provide salt-retaining corticosteroids in cases of the salt-losing variety, to suppress androgen secretion to prevent virilization, and to normalize growth and later reproductive function. This is achieved with doses of hydrocortisone between 25 and 75 mg/day or 10 to 25 mg/m²/day, divided in two or three doses.^[225] Dexamethasone with a longer half-life is preferred by some authors in doses of 0.25 to 0.75 mg/day.^[226] Parameters of adequate glucocorticoid dosage are assessed by the determination of plasma 17-OHP, androstenedione (A), and testosterone (T); growth curve velocity; and the rate of skeletal maturation. Adult patients with the salt-losing variety also require mineralocorticoid therapy in the form of Florinef (fludrocortisone) 0.05 to 0.3 mg/day. The dose is adjusted to normalize plasma renin activity. The pediatric dose is 70 /m²/day. No adjustment is needed in pregnancy.^[227] A free testosterone determination is the best test to assess glucocorticoid therapy during gestation.^[227] However, the techniques for the determination of free testosterone have not been universally refined at the present time. The fetal outcome may be normal. In spite of the lack of suppression of maternal androgens, placental aromatase activity has a protective effect not only on the fetal genitalia but also in preventing the effect of androgens on the fetal brain.^[228]

Reproductive function may be impaired, particularly in those women with the salt-wasting form. The causes of a low rate of conception are multiple and have been discussed in a recent article.^[229] In addition to anatomic vaginal problems, poor compliance with medications and other factors such as bisexuality or homosexuality, and decreased interest in sexual activity play an important role.

Klingensmith and co-workers^[230] reported a group of 18 women, 10 years of age or older with CAH followed over many years. Initiation of menstruation was delayed in all of these patients when compared with the general population. Eight patients were treated for the first time after age 20 years, and none were able to conceive. Of 20 patients in whom treatment was started between ages 6 and 20 years, 64 percent who were sexually active had at least one pregnancy. For patients treated before age 6, the pregnancy rate was about 60 percent. The amount of cortisone needed was between 30 and 56 mg/m² in 24 hours, and the levels of urinary 17-ketosteroids were between 2.5 and 5.3 mg/day. All women were maintained during pregnancy on the prepregnancy dose of steroids. Of the 13 pregnancies, 9 were viable and only 1 resulted in an infant born with multiple congenital malformations. That mother had systemic lupus erythematosus and was treated with large doses of salicylate. All of the mothers underwent cesarean section, and there was only one case of a premature infant with mild residual cerebral palsy. No patient in this study had an infant with CAH. Overall, the fertility rate was low, and first-trimester abortions were common.^[227],^[230],^[231],^[232]

Prenatal evaluation of the partner of a woman, who

1137

has the disease or is a carrier, is needed to assess possible fetal risk. The partner has 1 to 6 percent chance of being a carrier of the disease. Determination of plasma 17-OHP at baseline and following the administration of ACTH allows the detection of the partner's heterozygous state in most cases.^[218] Fetuses are considered "potentially affected" if (1) both parents are heterozygous, (2) both parents are homozygous, or (3) one parent is homozygous and the other heterozygous.

Prenatal diagnosis of CAH due to 21-hydroxylase deficiency is possible with detection of elevated amniotic fluid 17-OHP and adrenal androgen concentrations or with linkage analysis and HLA typing of cultured amniotic fluid cells. However, because these tests cannot be completed before 16 to 17 weeks' gestation, any preventive therapy should be given before the results of the tests become available, as masculinization of the female fetus occurs between 10 and 16 weeks' gestation.^[233]

Chorionic villus biopsy at 8 to 10 weeks' gestation allows the earliest and most accurate prenatal diagnosis.^[219] Early treatment, as soon as pregnancy is recognized, may prevent the development of masculinization of external genitalia in the affected female fetus. Dexamethasone is the drug of choice, since it crosses the placenta most readily and suppresses fetal adrenal androgen synthesis, reducing masculinization. Potentially affected mothers should be treated until fetal sex is known. Overall, this treatment is effective in about two thirds of patients.^[234] The dose of dexamethasone is between 1.0 and 1.5 mg daily from early in pregnancy until delivery (20 g/kg maternal weight). Maternal estriol levels are an accurate index of fetal adrenal function and genital development,^[235] while amniotic fluid steroid

levels have shown an inconsistent correlation with fetal masculinization. Pang et al. [236] reported maternal side effects of this therapy including cushingoid facial features; facial hirsutism; excessive weight gain; and permanent striae, hypertension, and gestational diabetes. The authors recommend that patients be made aware of potential side effects, that women receiving this treatment be closely monitored, and that the dose of dexamethasone be reduced during the second half of pregnancy, to reduce side effects.

Follow-up of 84 newborns whose mothers were treated with dexamethasone showed normal birth weight, birth length, and head circumference compared with untreated fetuses. In 43 neonates of mothers treated with dexamethasone, [237] 15 had congenital adrenal hyperplasia and 28 were unaffected. Five unaffected and three affected had postnatal failure to thrive and psychomotor developmental delay.

11-Hydroxylase (CYP11B1) deficiency is common in the Middle East, but rare in European populations, with a rate of only in 100,000 live births. It accounts for 8 percent of all cases of CAH. [238] The production of cortisol is reduced, with an excessive production of 11-deoxycortisol, 11-deoxycorticosterone, and adrenal androgens. [218] It is transmitted as an autosomal recessive disorder, caused by mutations of the CYP11B1 gene on the long arm of chromosome 8. The clinical manifestations may be present at birth, in children, or as a late-onset form. [239]

In the neonate, ambiguous genitalia in the female and penile enlargement are the clinical presentations. [240] In childhood, the disease may present as sexual precocity, early puberty in boys, or acne in men. Hirsutism, acne, and menstrual irregularities are the manifestations in puberty or young women. Hypertension and hypokalemia are the most common form of presentation along with virilization. The diagnosis may be made for the first time in adolescence or adulthood, when the patient presents with infertility, or oligomenorrhea, hirsutism, and short stature. Hypertension in the late-onset form is uncommon.

Laboratory findings include high serum levels of 11-deoxycortisol, 11-deoxycorticosterone, DHEA-S, androstenedione, and testosterone. In the late-onset form of the disease, ACTH stimulation is needed, since in most cases basal serum levels of 11-deoxycortisol are within normal limits.

Treatment with glucocorticoid normalizes infertility, and successful pregnancies have been reported. [241] Prenatal treatment may be effective in preventing the development of ambiguous genitalia. In one case, dexamethasone in doses of 20 g/kg/day was started in the fifth week of gestation in a woman with two previous daughters affected by CYP11B1 deficiency. At 10 weeks' gestation, karyotyping by chorionic villus sampling showed the fetus to be female, and treatment was continued throughout pregnancy. The newborn female was normal without evidence of abnormal external genitalia. [242]

Primary Aldosteronism

Described by Conn in 1955, hypertension and hypokalemia due to excessive production of aldosterone by the adrenal gland(s) characterizes primary aldosteronism. [243] A single adrenal adenoma is the most common etiology, accounting for over 70 percent of cases: 20 to 30 percent of patients suffer from bilateral adrenal hyperplasia or multiple microadenomas.

Primary hyperaldosteronism is an uncommon cause of hypertension representing less than 0.5 percent of all etiologies. Serum potassium is decreased in more than 90 percent of the cases. Headaches and muscle weakness are frequently present. Severe hypokalemia may produce polyuria and nocturia resistant to the action of vasopressin.

Metabolic alkalosis with hypochloremia, an elevation in serum bicarbonate, and a serum sodium at the upper

limits of normal are commonly seen. Urinary potassium excretion is elevated and inappropriate to the serum potassium levels. Renal function is within normal limits, and the pH of the urine is neutral or alkaline.

The diagnosis is suspected in those patients having hypertension and hypokalemia. All other causes of hypokalemia, particularly ingestion of diuretics, must be ruled out. High levels of urinary potassium in the presence of hypokalemia are very suggestive of primary hyperaldosteronism. The diagnosis is confirmed by (1) an elevation in serum or urinary aldosterone, (2) suppressed levels of plasma renin, (3) lack of plasma renin elevation with the administration of a potent diuretic such as furosemide or in the upright posture, and (4) failure of serum aldosterone level to be suppressed by the administration of 200 g of 9-fludrocortisone twice a day for 3 days. [244] It is important to normalize serum potassium levels before performing the above tests.

In pregnant patients with primary aldosteronism, the excretion of urinary potassium is lower than in nonpregnant patients with this disorder. The increased levels of progesterone in the pregnant patient blocks the action of aldosterone. In normal pregnancies, there is an increase in aldosterone secretion and plasma aldosterone levels, with a peak at 36 weeks' gestation at levels eightfold to tenfold higher than in nonpregnant women. This elevation in plasma aldosterone is normally suppressed in pregnancy by administration of 9-fludrocortisone. [245] Plasma renin levels increase early in gestation, reaching a peak at 12 weeks and then remain elevated throughout pregnancy.

Few cases of primary hyperaldosteronism have been reported in pregnancy. Aldosterone levels were elevated, and plasma renin was suppressed. [246] [247] [248] [249] [250] [251] [252] Spontaneous remission occurred in one woman during pregnancy. [247] A case of unexplained virilization in the fetus has been reported. [248]

Treatment is based on the cause of aldosteronism. An MRI scan of the abdomen is effective in localizing the adrenal lesion. In most cases reported in pregnancy, a single adrenal tumor was the etiology, making adrenalectomy the treatment of choice. Several cases have been reported in which adrenalectomy was performed in the second trimester. In cases of bilateral adrenal hyperplasia, medical treatment with spironolactone is effective. [252] However, their use in pregnancy is not recommended, since this drug may cause feminization of a male fetus. Oral medications, with the exception of spiro lactone, are not effective in controlling hypertension or reversing hypokalemia. Calcium channel blockers may have a place in these difficult cases. [253]

Pheochromocytoma

Pheochromocytoma is a rare syndrome accounting for about 0.5 percent of all cases of newly diagnosed hypertension. It occurs with equal frequency in both sexes and is more common in the third and fourth decades of life. A single adrenal adenoma is the cause in 80 percent of all cases. Approximately 15 percent are multiple adenomas, and 10 to 12 percent are malignant. In patients with a strong family history of pheochromocytoma, involvement of both adrenals is commonly seen, associated with the syndrome of multiple endocrine neoplasia type II (MEN types IIa and IIb), with Von Hippel-Lindau syndrome, in association with medullary carcinoma of the thyroid and in association with parathyroid adenoma (Sipple's syndrome). Five percent of patients with neurofibromatosis are also affected with pheochromocytoma. [254] In fewer than 10 percent of cases, the chromaffin tumors initiate from outside the adrenal gland in the organ of Zuckerkandl [255] and the bladder wall [256] they are known as paragangliomas.

The classic symptoms of pheochromocytoma are episodic headaches, sweating, and tachycardia. Hypertension may be persistent or paroxysmal; in about half of patients, arterial hypertension is paroxysmal. Other common symptoms include nervousness, tremor, weakness, psychiatric disorders, anxiety, abdominal pain, and warm flashes. Weight loss is seen in some patients, with symptoms suggesting hyperthyroidism. Indeed, in the past, when basal metabolic rate (BMR) was determined as a diagnostic test for hyperthyroidism, it was frequently elevated in patients with a pheochromocytoma. In pregnancy, itself a normal hypermetabolic state, many of the symptoms of pheochromocytoma may be confused with those of a normal gestation. This disorder may present a real diagnostic challenge to the physician. [257] Induction of anesthesia, examination of the abdomen, or changes in the patient's position can precipitate paroxysmal attacks.

As with many other endocrine diseases, pheochromocytoma associated with pregnancy is uncommon. However, when present it poses a life-threatening situation for mother and fetus. In 1969, Fox and co-workers [258] described one case and reviewed 89 others published in the literature. In 1982, Schenker and Granat [259] reviewed 112 pregnancies in 89 patients with pheochromocytoma. In 22, the diagnosis was made for the first time during pregnancy. Both of these articles emphasized the poor prognosis for mother and fetus. The maternal mortality rate was 48 percent and the fetal mortality rate 54 percent when the disease remained undiagnosed during pregnancy. Most of the maternal mortality occurred within 72 hours after delivery. The causes of maternal death included cerebrovascular accidents, cardiac arrhythmia, shock, and acute pulmonary edema. Only 1 of 26 patients died when the diagnosis was made before delivery. In 17 cases, the symptoms remitted between pregnancies, and in two thirds of all cases it occurred in multiparous women. Hypertension, paroxysmal or sustained, was present in 82 percent of the

TABLE 33-4 -- SYMPTOMS OF PHEOCHROMOCYTOMA IN PREGNANCY

(Not Available)

From Mestman JH: Endocrine diseases in pregnancy. In Sciarra JJ (ed): Gynecology and Obstetrics. Philadelphia, Lippincott-Raven, 1997, p 24, with permission.

percent, anxiety in 15 percent, and convulsions in 10 percent. In several cases, sudden shock appeared spontaneously or was induced by anesthesia or vaginal delivery without previous symptoms (Table 33-4) (Table Not Available). Of 67 patients with pheochromocytoma in whom the disease remained undiagnosed during pregnancy, preeclampsia was diagnosed in 29 (43 percent) and essential hypertension in 11 (16.4 percent). Clues for the diagnosis are paroxysmal hypertension, diaphoresis, palpitations, a gestational age less than 20 weeks, significant blood pressure changes from supine to recumbent position, postural hypotension, and aggravation of the blood pressure in patients given α -blockers. The differential diagnosis from pregnancy-induced hypertension (PIH) could be difficult, particularly in the presence of proteinuria.

In 1989, fetal wastage was reviewed in 162 pregnancies.^[269] Fetal loss was observed in 53 percent, spontaneous abortion in 12 percent, intrauterine death in 23 percent, and neonatal or intrapartum death in 18 percent. Both maternal and fetal morbidity and mortality have greatly improved in the last three decades, since therapy with α -adrenergic receptor blocking agents was routinely introduced in the management of the disease.

The demonstration of elevated levels of catecholamines or their metabolites norepinephrine and epinephrine, their methylated metabolites normetanephrine and metanephrine, and the methylated deaminated metabolite vanillyl mandelic acid (VMA) confirms the diagnosis of pheochromocytoma. An elevation in VMA or metanephrines in a 24-hour urine specimen is suggestive of the diagnosis. Unfortunately, no one test is considered the best. Some authors prefer a determination of urinary metanephrine, since it is less likely to be altered by drugs or foods.^[281] All abnormal values should be confirmed by a second 24-hour collection. The following recommendations have been suggested for the proper interpretation of urinary catecholamine and their metabolites:

1. Overnight or 24-hour urine collections are preferable to random ones. An overnight urine collection, however, has been reported to be as accurate as a 24-hour collection and is more convenient.^[262] Urinary creatinine should be measured in each 24-hour collection to determine if the collection is complete.
2. It is preferable to collect the urine with the patient at rest, on no medications, and without recent exposure to radiographic contrast media. Among medications for hypertension, diuretics, adrenergic blocking agents, and hydralazine do not interfere with the assays appreciably.
3. Urine collection must be acidified (pH < 3.0) and kept cold during and after collection.
4. The diagnostic information is greater in patients with paroxysmal symptoms if a 24-hour collection is done when they experience the crisis.

Total urinary free catecholamines are elevated in most patients with pheochromocytoma. Normally, total catecholamine excretion is between 100 and 150 g/day, similar to the nonpregnant state. However, it may be slightly elevated in preeclampsia^[263] and also in stressed, working, normal, pregnant women.^[264] Specific quantitation of epinephrine and norepinephrine may assist in the localization of a lesion. Increased epinephrine excretion in excess of 50 g/day suggests an adrenal lesion. Excessive secretion of norepinephrine is suspicious, but not diagnostic of an extra-adrenal tumor. False-positive elevations may occur in patients taking methyl dopa, labetalol, or aminophylline; undergoing strenuous exercise; or in the presence of increased intracranial pressure, hypoglycemia, or clonidine withdrawal.

Plasma levels of catecholamines may be measured, particularly during a paroxysmal episode. It is important to adhere strictly to the technique of blood collection. Values may fluctuate under routine stressful situations, such as exercise, venipuncture, or anxiety. It is recommended that the patient rest in the sitting position in a quiet environment for half an hour before blood is drawn. Blood is obtained through an indwelling catheter. The plasma should be centrifuged and the serum stored at -80°C until assayed.^[265] A value above 2,000 pg/ml is diagnostic of pheochromocytoma.

In cases in which the diagnosis is in doubt, the clonidine suppression test may be used, with the caution that, in some cases, it may cause severe hypotension. For the test, 0.3 mg of oral clonidine is administered, with plasma catecholamine determinations before and 3 hours after. A normal response is a total catecholamine concentration of less than 500 pg/ml (3.0 nmol/L). Because of the risk of severe hypotension, the test should not be done in the presence of normal catecholamine concentrations, in patients taking other medications such as methyl dopa, α -blockers, antidepressants, or diuretics, or in hypovolemic patients.^[266]

As soon as the diagnosis is confirmed, α -adrenergic

blocking agents should be started.^[267],^[268] The drug most frequently used is phenoxybenzamine (Dibenzylamine). The starting dose is 10 mg daily, with increases of 10 mg every 2 to 3 days until blood pressure and symptoms are controlled. The usual blocking dose is 1.0 mg/kg body weight per day. The dose may require adjustment because the drug has a half-life of approximately 24 hours, and hence it is cumulative. The usual dose of phenoxybenzamine is 40 to 80 mg/day.^[267] A 2-week course of an α -adrenergic receptor blocker is the cornerstone of preoperative management.^[269]

β -Blockers are added to the regimen when tachycardia develops following administration of an α -adrenergic blocking agent.^[254] Propranolol 10 mg 3 to 4 times a day is useful in maintaining the pulse rate between 80 and 100 beats/min.^[269] Labetalol should not be used, since it has α - and β -blocking properties in a ratio of 1:5. The danger of excess β -blockade with precipitation of a hypertensive crisis limits its usefulness.^[269] Hypertensive crises are treated with intravenous phentolamine in doses of 1 to 5 mg. Intravenous therapy also may be used in cases of unstable hypertension in preparation for surgery.^[270] A course of 10 and 14 days of β -blockade and α -adrenergic blockers is the usual therapy in preparation for surgery. Indicators of acceptable control include a blood pressure less than 165/90 mm Hg; orthostatic hypotension present, but with standing blood pressure greater than 90/45 mm Hg; no changes in the electrocardiogram (ECG) for the last 2 weeks (no ST-segment or T-wave abnormalities); and less than one premature ventricular contraction every 5 minutes.^[271]

Surgical intervention is the treatment of choice. Tumor localization in 47 cases in pregnancy showed 25 percent of them in the right adrenal gland, 17 percent in the left, 17 percent bilateral, and 32 percent intra-abdominal extra-adrenal.^[269] Localization of the tumor is imperative and is achieved in most cases with modern radiologic techniques. In pregnancy, the use of the computed axial tomographic (CAT) scan, arteriography, and selected venous catheterization is contraindicated for obvious reasons. MRI is useful in localizing and diagnosing adrenal lesions and, in pregnancy, is the method of choice for localization of the tumor. The major advantages are lack of ionizing radiation, lack of contrast dye, and the ability to distinguish pheochromocytoma from other adrenal lesions with the high-intensity signal emitted in T2-weighted images. Ultrasonography is of little value; pressure exerted by the sonogram probe has been reported as the causative agent in a paroxysmal attack.^[272]

When the diagnosis is made during the first trimester, elective termination of pregnancy followed by tumor excision is recommended by some, whereas others^[264],^[273] recommend selective tumor resection without interruption of pregnancy. However, the incidence of spontaneous abortion occurring after surgery is high.

During the last two trimesters of pregnancy, medical treatment is preferred, with removal of the tumor at the time of delivery by cesarean section.^[264],^[274] The best results are obtained when the pregnancy has advanced to viability, the fetus is delivered by cesarean section, and tumor exploration is done immediately after delivery. Cesarean section rather than vaginal delivery is strongly recommended as the safest procedure both for mother and for the fetus.^[259] Fetal mortality has been reduced to 17 percent when the diagnosis was made in the first two trimesters of pregnancy. When the diagnosis is made in the third trimester, administration of an α -adrenergic blocking agent may eliminate fetal mortality, compared with fetal deaths of 42 percent in the group that did not receive α -adrenergic blocking agent. No maternal mortality has been reported in those patients treated with an α -adrenergic blocking agent.

Stenstrom and co-workers^[275] reviewed 29 cases from the literature and added 3 of their own. In this series, the pheochromocytoma was diagnosed antepartum and treated with α -adrenergic receptor blockade. Fourteen patients underwent treatment of short duration, between 4 and 21 days, six underwent treatment from 46 to 91 days, and in nine cases the duration was unknown. The investigators recommended use of elective tumor resection in the first trimester, and medical treatment

followed by cesarean section and tumor removal when the diagnosis was made after the first trimester. Fetal mortality in the treated cases was 19 percent compared with 50 percent in those without the benefit of -adrenergic receptor blockade treatment. Laparoscopic adrenal surgery has been successful in pregnancy. ^[276], ^[277] An anesthesiologist should be consulted and become closely involved in the management of patients with pheochromocytoma. ^[278], ^[279]

Syndromes Due to Excessive Production of Androgens

Virilization in pregnancy is exceedingly rare (see the box "Causes of Fetal and Maternal Virilization in Pregnancy") (Box Not Available) . ^[280], ^[281] When signs of hyperandrogenism appear for the first time in pregnancy, a complete investigation is warranted because of the possibility, albeit low, of a malignant lesion as the cause of the excess androgen production. A medical history may reveal drugs responsible for hirsutism, the time of onset of the symptoms and signs, a similar history in previous pregnancies, the degree of virilization, and the presence of systemic symptoms. Virilization of the newborn does not always depend on the concentration of maternal androgens.

Drugs producing maternal hyperandrogenism, hirsutism, and even virilization in pregnancy, are those with the highest risk for fetal virilization. Progestins given before the 13th week of gestation for the treatment of habitual abortion has been responsible for labial fusion in a group of infants born to mothers treated with this drug ^[282] (see Chapter 9) . Male fetuses are not affected. Oral

contraceptives or exposure to progestins after the completion of external genital development between 7 and 12 weeks of gestation do not produce virilization in the fetus.

Causes of Fetal and Maternal Virilization in Pregnancy

(Not Available)

From Mestman JH: Endocrine diseases in pregnancy. In Sciarra JJ (ed): Gynecology and Obstetrics. Philadelphia, Lippincott-Raven, 1997, p 25, with permission.

The most common cause of hirsutism and virilization in pregnancy is a luteoma of pregnancy, ^[283] ^[284] ^[285] a benign human chorionic gonadotropin-dependent ovarian tumor that develops during pregnancy. It is a solid mass, consisting of hyperplastic lutein cells, is bilateral in 50 percent of cases, and is usually 6 to 10 cm in diameter. Luteomas disappear after delivery. Virilization occurs in about 25 to 40 percent of such patients due to high levels of testosterone and androstenedione. Patients develop hirsutism, acne, deepening of the voice, and clitoral enlargement, beginning early in the second trimester. Fetal virilization is seen in 65 percent of female newborns. Cord serum androgen concentrations have been measured in few infants. ^[285], ^[286] Those born with virilization have higher concentrations of testosterone in cord blood. In the case reported by Thomas and coworkers, chorionic gonadotropin stimulation 8 months postpartum resulted in increased urinary excretion of 17-ketosteroids and ovarian enlargement in a patient with a history of virilization in prior pregnancies. ^[283]

The other common cause of hyperandrogenism in pregnancy is hyperractio luteinalis, an entity of benign hyperplastic luteinization of ovarian thecal cells believed to develop as the consequence of an abnormal ovarian response to human chorionic gonadotropin (hCG). The ovaries are involved bilaterally, with multiple amber-colored cysts. As in the case of luteomas, virilization regresses after delivery but may recur in future pregnancies. ^[287], ^[288] Virilization has been reported in 25 percent of women. Serum testosterone and androstenedione concentrations are significantly elevated, but virilization has not been reported in the female fetus. ^[289]

Other causes of virilization are rare and are listed in the box "Causes of Fetal and Maternal Virilization in Pregnancy." A solid, unilateral lesion on ultrasound is suspicious of malignancy. The chances of malignancy in the presence of an ovarian tumor in a virilized woman are close to 50 percent. In such a case, laparotomy or laparoscopy should be considered.

An unusual case of maternal virilization due to placental aromatase deficiency has been reported. ^[290] The infant was virilized at birth.

THYROID DISEASES

Thyroid disorders in pregnancy present a unique opportunity for health care professionals to use a similar "team approach" that has successfully improved the care of diabetic women. Because of changes in thyroid economy occurring early in pregnancy, it is imperative to advise women with chronic thyroid diseases to plan their pregnancies and contact their health care professionals as soon as the diagnosis of pregnancy is made. Autoimmune thyroid disease occurs five to eight times more often in women than in men, and its course could be affected by the immunologic changes occurring in pregnancy and in the postpartum period. ^[291] ^[292] ^[293]

In early pregnancy, the maternal thyroid gland is challenged with an increased demand for thyroid hormone secretion, due mainly to three different factors: (1) the increase in thyroxine-binding globulin (TBG) due to the effect of estrogen on the liver, (2) the stimulatory effect of hCG on the TSH thyroid receptor, and (3) the supply of iodine available to the thyroid gland. This last factor is of importance in areas of iodine deficiency. In the United States, the iodine content in the diet, although decreased in the last decades, appears to be sufficient for pregnancy needs. ^[294] The normal thyroid gland is able to compensate for these demands by increasing the secretion of thyroid hormones and maintaining the serum levels of free hormones within normal limits. However, in those situations in which there is a subtle pathologic abnormality of the thyroid gland, such as chronic autoimmune thyroiditis, the normal increase in the production of thyroid hormones is not met. As a consequence, the pregnant woman could develop

1142

biochemical markers of hypothyroidism (i.e., an elevation in serum TSH, and an increase in the size of the thyroid gland).

Active secretion of thyroid hormones by the fetal thyroid gland commences at about 18 weeks' gestation, although iodine uptake occurs between 10 and 14 weeks. ^[297] Transfer of thyroxine from the mother to the embryo occurs from early pregnancy. Maternal thyroxine has been demonstrated in coelomic fluid at 6 weeks ^[298] and in the fetal brain at 9 weeks. ^[299] This maternal transfer continues until delivery, but only in significant amounts in the presence of fetal hypothyroidism. ^[300] Recently, thyroid hormone receptor gene expression has been shown in human fetal brain by 8 weeks' gestation, supporting the important role of maternal thyroid hormone during the first trimester of human pregnancy in fetal brain development. ^[301] Recent studies, that need to be confirmed, suggest that mild maternal thyroid deficiency in the first trimester could result in long-term neuropsychological damage to the offspring. ^[295] ^[296]

The levels of maternal thyroid hormone concentrations, both total thyroxine (TT_4) and total triiodothyronine (TT_3) increase from early pregnancy as the result of an elevation in TBG and a reduced peripheral TBG degradation rate. ^[302] TBG reaches a plateau by 20 weeks' gestation and remains unchanged until delivery. In spite of these acute changes in total hormone concentration, the serum free fractions of both T_4 and T_3 remain within normal limits, unless there is a decreased supply of iodine to the mother or in the presence of abnormalities of the thyroid gland. ^[291]

Human chorionic gonadotropin is a weak thyroid stimulator, acting on the thyroid TSH receptor. It is estimated that a 10,000 IU/L increment in circulating hCG corresponds to a mean T_4 increment in serum of 0.1 ng/dl, and in turn to a lowering of TSH of 0.1 mU/L. In situations in which there is a high production of hCG, such as in cases of multiple pregnancies, hydatidiform mole, and hyperemesis gravidarum (HG), serum T_4 concentrations rise to levels seen in thyrotoxicosis with a transient suppression in serum TSH values. Low TSH values may be seen in 15 percent of uncomplicated pregnancies, returning to normal with progression of pregnancy. ^[303]

Thyroid Function Tests

In spite of the limitations in the interpretation of serum TSH in the first trimester, measurement of serum TSH is the most practical, simple, and economic screening test for thyroid dysfunction. A high TSH value is consistent with the diagnosis of primary hypothyroidism, whereas a suppressed one, with few exceptions, is suggestive of hyperthyroidism (Fig. 33-3). In the presence of an abnormal serum TSH value, the determination of FT_4 or its equivalent free thyroxine index ($FT_4 I$), is obtained for the assessment of thyroid function. A low TSH value and high concentrations of FT_4 or $FT_4 I$ is diagnostic of hyperthyroidism. There are special situations in which hyperthyroidism may be present in the presence of normal concentrations of FT_4 . In such cases, a serum FT_3 or $FT_3 I$ determination should be obtained. High values are diagnostic of hyperthyroidism,

Figure 33-3 Algorithm for the diagnosis of thyroid disease. If there is clinical suspicion of secondary hypothyroidism, a determination of $FT_4 I$ is indicated. In this situation, the serum TSH is normal in the presence of low $FT_4 I$. $FT_4 I$, free thyroxine index or its equivalent, free thyroxine; $FT_3 I$, free triiodothyronine index or its equivalent, free triiodothyronine; TSH, thyroid-stimulating hormone.

1143

the so-called T_3 -toxicosis syndrome, sometimes seen in patients with an autonomous or "hot" thyroid nodule. Therefore, the use of a limited number of thyroid function tests (TFTs), properly ordered and interpreted, will allow the physician to assess thyroid function, and make the proper therapeutic decisions. ^[304]

Indications for Maternal Determination of TSI or TRAB

(Not Available)

From Mestman JH: Endocrine diseases in pregnancy. In Sciarra JJ (ed): Gynecology and Obstetrics. Philadelphia, Lippincott-Raven, 1997, p 27, with permission.

The determination of TSH receptor antibodies (TSHRAB or TRAb) is indicated in very special circumstances (see the box "Indications for Maternal Determination of TSI or TRAb") (Box Not Available), in order to predict the possibility of fetal or neonatal thyroid dysfunction. These antibodies are immunoglobulins, usually of the IgG subclass, having different functional activity: stimulating (in most patients with Graves' disease) or blocking (in some patients with Hashimoto's thyroiditis, particularly in those without goiter) the TSH receptor of the thyroid gland. They do cross the placental barrier and may affect fetal thyroid function. The determination of TSHRABs is commercially available using binding assays. These assays do not discriminate between stimulating or blocking antibodies. However, a specific bioassay is commercially available for the determination of stimulating antibodies (thyroid-stimulating immunoglobulins [TSIs]). Antibodies in the serum of patients with Graves' disease indicate a stimulating effect, and in the serum of patients with chronic or Hashimoto's thyroiditis suggest blocking or inhibitory effect. TSIs, formerly known as long-acting thyroid-stimulating antibody (LATS), when present in high concentrations in the maternal serum may cause fetal or neonatal hyperthyroidism.^[305] Thyroid-blocking antibodies (TRBAb) in high titers in the mother may produce neonatal hypothyroidism, a condition that is transient due to the short half-life of these antibodies.^[306] Both antibodies may be present in patients with Graves' disease, and could explain the spontaneous improvement or aggravation of the disease with progression of pregnancy and in the postpartum period, respectively. The chances for the offspring to be affected by these maternal antibodies are very low (up to 2 percent of mothers with autoimmune thyroid disease). However, if mothers with high titers are not properly identified, the consequences for the infant could be irreversible neurologic and metabolic sequelae. Titers of these antibodies decrease with the progression of pregnancy. This could explain, in the case of Graves' disease, the tendency to spontaneous clinical improvement and the decrease in antithyroid drug requirement in the second half of pregnancy. A value of TSHRAB three to five times greater than normal is considered predictive of neonatal or fetal thyroid dysfunction.

Goiter is commonly seen in pregnancy in areas of iodine deficiency. However, in the United States and other areas of the world with sufficient iodine intake, the thyroid gland does not clinically increase in size during pregnancy. Therefore, the detection of a goiter in pregnancy is an abnormal finding that needs careful evaluation. The most common cause of diffuse goiter is chronic autoimmune thyroiditis or Hashimoto's thyroiditis. Most patients are euthyroid and the diagnosis is made by the determination of thyroid antibodies, mainly thyroid peroxidase (TPO). Antibody concentration decreases during pregnancy, and increases in the postpartum period. High values in the first trimester of pregnancy are predictors of the syndrome of postpartum thyroid dysfunction.^[307]

The indications for requesting TFTs are represented in the box "Indications for Thyroid Testing in Pregnancy." Whether routine thyroid screening in pregnant women is necessary remains a controversial issue, to be decided in the next few years, it is hoped, when more scientific information becomes available on the relationship of abnormal thyroid function early in pregnancy and neuropsychological and metabolic development of the offspring.

<p>Indications for Thyroid Testing in Pregnancy</p> <p>(Not Available)</p> <p><i>From Mestman JH: Thyroid diseases in pregnancy other than Graves' disease and postpartum thyroid dysfunction. Endocrinologist 9:924, 1999, with permission.</i></p>

Prepregnancy Counseling

The physician may be faced with different clinical situations when counseling a woman contemplating pregnancy. With the advent of available information in the electronic media, it is important for the health care professional to offer the patient and her family objective and scientific data, supported by medical literature published in recognized peer-reviewed medical journals. The clinical situations may be summarized as follows:

1. **Hyperthyroidism under treatment:** A choice of the three classic therapeutic options for hyperthyroidism treatment should be given: (1) long-term antithyroid drug therapy, (2) radioactive ¹³¹I ablation, and (3) near total thyroidectomy. Potential side effects of antithyroid drugs on the fetus should be discussed. If the patient opts for ablation therapy, there is no long-term effect of ¹³¹I given to the future mother on the offspring. However, it is customary to wait 6 months after the therapeutic dose is administered before pregnancy is contemplated. Surgery is another option, selected by some physicians and patients concerned about the potential side effects of antithyroid drugs or radioactive treatment. Regardless of the form of therapy chosen, it is important for the patient to be euthyroid at the time of conception. In a large series of hyperthyroid pregnant women, a doubling in congenital malformations was reported when hyperthyroidism was not controlled in the first trimester of pregnancy as compared with women who were euthyroid early in gestation.^[308]
2. **Previous ablation treatment for Graves' disease:** Two points are important: (1) the dose of thyroid replacement therapy needs to be increased in most women soon after conception^[309], ^[310] and (2) in spite of euthyroidism, high maternal titers for TSI may be present, with the fetus being at risk of developing hyperthyroidism despite the mother being euthyroid.^[311] Close follow-up during pregnancy and communication between the obstetrician and endocrinologist are essential.
3. **Previous treatment with ¹³¹I for thyroid carcinoma:** Pregnancy does not affect the natural history of women previously treated for thyroid cancer. Spontaneous miscarriages have been reported to be as high as 40 percent in the first year after radiation treatment as compared with 18 percent in women who have received no radiation.^[312] Therefore, it appears reasonable for patients with thyroid carcinoma to wait 1 year after completion of radioactive treatment before conception. Adjustment of the thyroid dose should be done early in pregnancy and in each trimester; serum TSH should be kept in the low normal range or undetectable.
4. **Treated hypothyroidism:** Women under treatment with thyroid hormone may require higher doses soon after conception.^[309], ^[310], ^[313] As shown by Kaplan,^[314] the amount of thyroid requirement increases according to the etiology of hypothyroidism. As soon as the diagnosis of pregnancy is made, thyroid tests should be performed, and thyroid doses adjusted accordingly. Following delivery, the dose should be reduced to prepregnancy levels. Common medications may affect the absorption of L-thyroxine, such as ferrous sulfate^[314] and calcium,^[315] among others. Patients should take L-thyroxine at least 2 hours apart from other medications.
5. **Euthyroid chronic thyroiditis:** Patients with Hashimoto's thyroiditis are at greater risk of spontaneous abortions and the development of postpartum thyroiditis.^[316], ^[317] Thyroid tests are indicated in early pregnancy to detect elevations in TSH and assess the need for treatment with thyroid hormones or to adjust the dose in patients already on thyroid therapy.

Maternal Placental Fetal Interactions

Studies in the last two decades have shown an important role of maternal thyroid hormones in embryogenesis.^[318] It is accepted that maternal thyroxine crosses the placenta in the first half of pregnancy at the time when the fetal thyroid gland is not functional. Several studies have suggested an adverse effect on the intellectual development of children of mothers with mild thyroid deficiency in the first 20 weeks of gestation.^[295], ^[296]

Maternal TSH does not cross the placenta. TRH does cross the placental barrier, but its physiologic significance is unknown. TRH has been given to mothers to accelerate fetal lung maturation in premature infants.^[319]

Methimazole (MM) and propylthiouracil (PTU), drugs used for the treatment of hyperthyroidism, cross the placenta, and if given in inappropriate doses may produce fetal goiter and hypothyroidism.^[320] Preparations containing iodine given in large doses or for prolonged periods of time are contraindicated in pregnancy, since accumulation by the fetal thyroid may induce goiter and hypothyroidism.^[321]

Hyperthyroidism

Hyperthyroidism is diagnosed in pregnancy in about 0.1 to 0.4 percent of patients.^[322], ^[323] Classically, it has been stated that Graves' disease is the most common

cause of hyperthyroxinemia in pregnancy, with other etiologies being uncommon (see the box "Etiologies of Hyperthyroidism in Pregnancy"). As will be discussed subsequently, transient hyperthyroidism due to inappropriate secretion or action of hCG is becoming recognized as the most common cause of hyperthyroidism in pregnancy. [324], [325] In our experience, single toxic adenoma and multinodular toxic goiter are found in less than 10 percent of cases. Subacute thyroiditis is rarely seen during gestation.

Etiologies of Hyperthyroidism in Pregnancy	
Graves' disease	
Nodular thyroid disease	
Subacute thyroiditis	
Iatrogenic	
Hyperemesis gravidarum	
Molar disease	
Rare:	
Iodine induced	
TSH-producing pituitary tumor	

Transient Hyperthyroidism of Hyperemesis Gravidarum

This disorder is characterized by severe nausea and vomiting, with onset between 4 to 8 weeks' gestation, requiring frequent visits to the emergency room and sometimes repeated hospitalizations for intravenous hydration. Weight loss of at least 5 kg, ketonuria, abnormal liver function tests, and hypokalemia are common findings, depending on the severity of vomiting and dehydration. Free thyroxine levels are elevated, sometimes up to four to six times the normal values, whereas FT₃ is elevated in up to 40 percent of affected women, values not as high as serum FT₄. The T₃/T₄ ratio is less than 20, as compared with Graves hyperthyroidism, where the ratio is over 20. Serum TSH measured by a sensitive assay is consistently suppressed. [324] [325] [326] [327] [328] In spite of the significant biochemical hyperthyroidism, signs and symptoms of hypermetabolism are mild or absent. Patients may complain of mild palpitations and heat intolerance, but perspiration, proximal muscle weakness, and frequent bowel movements are rare. On physical examination, ophthalmopathy and goiter are absent, a mild tremor of the outstretched fingers is occasionally seen, and tachycardia may be present due in part to dehydration. Significant in the medical history is the lack of hyperthyroid symptoms before conception, since patients with Graves' disease diagnosed for the first time during gestation give the history of hypermetabolic symptoms several months before pregnancy. Spontaneous normalization of hyperthyroxinemia parallels the improvement in vomiting and weight gain, with most of the cases resolving spontaneously between 14 and 20 weeks' gestation, although persistence of hyperthyroidism beyond 20 weeks' gestation has been reported in 15 to 25 percent of cases. [326], [327] Suppressed serum TSH may lag for a few more weeks after normalization of free thyroid hormone levels (Fig. 33-4). Antithyroid medications are not needed. In one series in which antithyroid medication was used, pregnancy outcome was not significantly different from a similar group of patients receiving no therapy. [326] Furthermore, a case has been reported in which normalization of serum thyroid levels with antithyroid medications did not resolve severe vomiting that was controlled only after first-trimester termination of pregnancy. [329] Occasionally, severe vomiting and hyperthyroidism may require parenteral nutrition.

The degree of thyroid abnormalities is directly related to the severity of vomiting and weight loss. In 67 patients studied by Goodwin et al. [324], [330] liver and electrolyte abnormalities were routinely found in women with more symptomatology, including severe vomiting, weight loss of at least 5 kg, and significant dehydration. They also presented with more significant elevations in free thyroxine levels and suppression of serum TSH values. Those with a lesser degree of hyperemesis had a less severe disorder of thyroid function. Transient hyperthyroidism due to hyperemesis gravidarum should be suspected in women who present in the first few weeks after conception with the sudden onset of severe nausea and vomiting and thyroid tests in the hyperthyroid range. These patients do not complain of hypermetabolic symptoms antedating pregnancy, goiter is not detected by palpation, and symptoms or signs of tissue thyrotoxicosis are mild or absent. In addition, thyroid anti-TPO antibodies, markers of autoimmune thyroid disease, are negative. The differential diagnosis may also be difficult, as vomiting may also be a presenting symptom of hyperthyroidism of Graves' disease. [331]

The cause for the elevations of thyroid hormones in

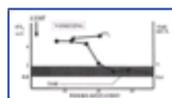

Figure 33-4 Clinical course of transient hyperthyroidism of hyperemesis gravidarum. LNMP, last normal menstrual period; FT₄, free thyroxine; TSH, thyroid-stimulating hormone.

patients with hyperemesis gravidarum remains controversial. [329], [332] Most likely, high levels of hCG, a known stimulator of the TSH receptor, play an important role, as well as prolongation in its biologic activity as seen in twin pregnancies. [333] There is a significant, albeit weak correlation between the degree of thyroid stimulation and total hCG levels in normal women and those with hyperemesis. [330] It seems likely, however, that certain hCG fractions may be more important than the total hCG as thyroid stimulators. The thyroid-stimulating activity of hCG in early pregnancy and in molar gestations correlates best with the percentage of basic, partially desialated hCG in serum. [325] A case has been reported in a mother and daughter with recurrent hyperemesis, in whom hCG levels were not elevated. Both were heterozygous for a missense mutation in the extracellular domain of the thyrotropin receptor. The mutant receptor was more sensitive than the wild-type receptor to hCG, thus accounting for the occurrence of hyperthyroidism despite the presence of normal hCG levels. [334]

The diagnosis of transient hyperthyroidism of hyperemesis gravidarum should be considered in women with severe vomiting, no clinical manifestations of Graves' disease, and biochemical evidence of hyperthyroidism in early pregnancy. Vomiting should be persistent and severe with a significant weight loss, since most women with morning sickness of pregnancy have normal thyroid function tests. [335] The syndrome may repeat in future pregnancies.

Gestational trophoblastic diseases, partial and complete hydatidiform moles, and choriocarcinoma are other causes of hyperthyroidism early in pregnancy. [334] Patients may present without symptoms in spite of chemical hyperthyroidism, or with various degrees of severity, including congestive heart failure. Evacuation of the mole eliminates the source of the excessive hCG and reverses the clinical and biochemical features of hyperthyroidism. Treatment with α -adrenergic blocking agents is effective in controlling the symptoms. Sodium iopanoate has been used to reduce the release of hormones by the thyroid gland and block peripheral conversion of T₄ to T₃.

Graves' Disease

The natural course of hyperthyroidism due to Graves' disease in pregnancy is characterized by an exacerbation of symptoms in the first trimester and during the

postpartum period and an amelioration of symptoms in the second half of pregnancy. Stimulation of the thyroid gland by hCG in the first trimester has been suggested as the cause of exacerbation.^[336] Immunologic responses caused by changes in lymphocyte subsets could explain spontaneous improvement in the second half of pregnancy and recurrences in the postpartum period.^[337] Kung

and Jones,^[338] in a study comparing Graves' disease in pregnant and nonpregnant women, postulated that the amelioration of symptoms seen with progression of pregnancy was due to a decrease in the titers of TSHRAB with stimulating activity and an increase in TSHRBAB with thyroid-blocking activity. The reverse was true in the postpartum period, when aggravation of Graves' hyperthyroidism usually occurs.

When hyperthyroidism is properly managed throughout pregnancy, the outcome for mother and fetus is good; however, maternal and neonatal complications for untreated or poorly controlled mothers are significantly increased (Table 33-5).^[339]^[340]^[341]^[342]

In the vast majority of patients in whom the diagnosis is made for the first time during pregnancy, hyperthyroid symptoms antedate conception. The clinical diagnosis of thyrotoxicosis may present difficulties during gestation, since many symptoms and signs are commonly seen in normal pregnancy, such as mild palpitations, heart rate between 90 and 100 beats/min, mild heat intolerance, shortness of breath on exercise, and warm skin. There are some clinical clues that increase the likelihood of the diagnosis of hyperthyroidism: presence of goiter, ophthalmopathy, proximal muscle weakness, tachycardia with a pulse rate over 100 beats/min, and weight loss or inability to gain weight in spite of a good appetite. Occasionally, the patient may be seen for the first time in congestive heart failure, and the etiologic diagnosis is difficult, since many of the physical findings are suggestive of cardiac valvular disease, particularly mitral insufficiency or stenosis. Hyperthyroidism under poor control is frequently complicated by preeclampsia. The physician should suspect hyperthyroidism in the presence of systolic hypertension with an inappropriately low diastolic blood pressure and a wide pulse pressure, also seen in other conditions such as aortic insufficiency.

Classic symptoms of hyperthyroidism include nervousness, increased sweating, increased appetite, heat

intolerance, insomnia, proximal muscle weakness, irritability, changes in personality, frequent bowel movements, decreased tolerance to exercise (sometimes manifested as shortness of breath), eye irritation, frequent lacrimation, pruritus, and weight loss. Not all symptoms are present in a given patient. The physician should be aware of subtle complaints, particularly in the presence of weight loss or inability to gain weight. As mentioned above, in the first trimester of pregnancy the differential diagnosis from transient hyperthyroidism of hyperemesis gravidarum presents a real challenge for the health care professional.

On physical examination, the thyroid gland is enlarged in almost every patient with Graves' disease. Indeed, the absence of a goiter makes the diagnosis unlikely. The gland is diffusely enlarged, between two and six times the normal size, varies from soft to firm, sometimes being irregular to palpation, and with one lobe being more prominent than the other one. A thrill may be felt or a bruit may be heard, indications of a hyperdynamic circulation. Examination of the eyes may reveal obvious ophthalmopathy, but in the majority of cases exophthalmos is absent or mild, with one eye slightly more prominent than the other. Extraocular movements may be impaired on careful eye examination. Stare is common, as well as injection or edema of the conjunctiva. Pretibial myxedema is rare, seen in less than 10 percent of women. A hyperdynamic heart with a loud systolic murmur are common findings. Proximal muscle weakness, fine tremor of the outstretched fingers, and hyperkinetic symptoms are seen frequently. The skin is warm and moist, and palmar erythema is accentuated.

Free thyroxine determination or the calculation of the free thyroxine index (using total thyroxine levels and a test for assessment of TBG, such as resin T₃ uptake) are standard tests in most clinical laboratories, with the result available in 24 to 48 hours. Almost every patient with Graves' disease will have an elevated FT₄ concentration. A suppressed TSH value in the presence of a high FT₄ or FT₄ index confirms the diagnosis of hyperthyroidism.^[304] It must be kept in mind, however, that a suppressed serum TSH is present in about 15 percent of normal pregnant women in the first trimester of pregnancy.^[291] In some unusual situations, the serum FT₄ may be at the upper limit of normal or be slightly elevated, in which case the determination of FT₃ and the FT₃ index will confirm the diagnosis of hyperthyroidism. Thyroid peroxidase antibodies (anti-TPO) or thyroid antimicrosomal antibodies, markers of thyroid autoimmune disease, are elevated in most patients with Graves' disease; its determination is indicated in patients in whom the etiology of the hyperthyroidism is in doubt.

Significant maternal and perinatal morbidity and mortality were reported in early studies of pregnancies complicated by hyperthyroidism.^[343]^[344] In the last 20 years, however, there has been a significant decrease in the incidence of maternal and fetal complications directly related to improved control of maternal hyperthyroidism.^[340]^[342]^[345]^[346]^[347]^[348] The most common maternal complication is PIH. In women with uncontrolled hyperthyroidism, the risk of severe preeclampsia was five times greater than in those patients with controlled disease.^[342] Other complications include preterm delivery, placental abruption, and miscarriage. Congestive heart failure may occur in women untreated or treated for a short period of time in the presence of PIH or operative delivery.^[349]^[350] Left ventricular dysfunction is usually detected by echocardiography in women with cardiovascular manifestations. Although these changes are reversible, they may persist for several weeks after achieving a euthyroid state. In one study,^[351] reduction in peripheral vascular resistance and higher cardiac output were still present in spite of normalization of thyroxine levels. This is an important finding with significant clinical implications. Left ventricular decompensation in hyperthyroid pregnant women may develop in the presence of superimposed preeclampsia, at the time of delivery or with intercurrent complications such as anemia or infection. We have seen congestive heart failure in the first half of pregnancy in women with longstanding hyperthyroidism. It is likely that the aggravation of hyperthyroidism seen in the first part of pregnancy played an important role in the development of this complication. Careful monitoring of fluid administration is imperative in these situations. Thyroid storm has been rarely reported in pregnancy.^[352]^[353]

Fetal and neonatal complications are also related to maternal control of hyperthyroidism. Intrauterine growth restriction (IUGR), prematurity, stillbirth, and neonatal morbidity are the most common complications. Millar et al.^[342] demonstrated that hyperthyroidism uncontrolled during the entire gestation was associated with a ninefold greater incidence of low-birth-weight infants as compared with the control population. It was almost 2.5 times greater in those whose hyperthyroidism was treated during pregnancy and became euthyroid at some time during gestation. In those mothers achieving a euthyroid state before or early in pregnancy, the incidence of low-birth-weight infants was no different from that in the control population. Mitzuda et al.^[341] correlated the risk of delivering a small-for-gestational-age (SGA) infant with the presence of maternal thyrotoxicosis lasting more than 30 weeks of pregnancy, a duration of Graves' disease for most of 10 years, and onset of Graves' disease before age 20. Momotani and Ito^[348] reported an incidence of spontaneous abortions (25.7 percent) and premature delivery (14.9 percent) in mothers hyperthyroid at the time of conception, as compared with 12.8 percent and 9.5 percent, respectively, in euthyroid mothers.

Treatment of hyperthyroidism is essential to prevent maternal, fetal, and neonatal complications (Table 33-5). The goal of treatment is normalization of thyroid tests as soon as possible and to maintain euthyroidism with the minimum amount of antithyroid medication. Excessive amounts of antithyroid drugs crossing the placenta may affect the fetal thyroid, with the development of hypothyroidism with or without goiter. Patients should be monitored at regular intervals and the dose of their medications adjusted to keep the FT₄ in the upper one third of the range of normal.^[349] For this purpose, thyroid tests should be performed every 2 weeks at the

beginning of treatment and every 2 to 4 weeks when euthyroidism is achieved. Patients with small goiters, a short duration of symptoms, and on minimal amounts of antithyroid medication will be able to discontinue antithyroid drugs by 34 weeks' gestation or beyond. It is not recommended to discontinue antithyroid therapy before 32 weeks' gestation, since in our experience relapses may occur in a significant number of patients.^[354] In this country, the two antithyroid drugs available are PTU and methimazole (Tapazole). Both drugs are effective in controlling symptoms. To our knowledge, no studies have shown PTU to be superior to methimazole, both drugs having similar placental transfer kinetics.^[355] Furthermore, when the efficacies of both drugs have been compared, euthyroidism was achieved with equivalent amounts of drugs and in the same period of time.^[356] Neonatal outcomes were no different in both groups. Aplasia cutis, an unusual scalp lesion, occurred in a small group of patients taking methimazole,^[358] but this is not a contraindication for its use in pregnancy. Isolated cases of esophageal atresia and choanal atresia were also reported with the use of methimazole, although the casual relationship was never proven.^[361]

The initial recommended dose of PTU is 100 to 450 mg/day, and methimazole 10 to 40 mg/day divided in two daily doses.^[364] Methimazole is preferable in the outpatient setting, since it is given once or twice daily, allowing for improvement in patient compliance. PTU, due to its shorter half-life, should be given every 8 hours. In our experience, 10 mg of methimazole twice a day or 100 to 150 mg of PTU three times a day is an effective initial dose in most patients. Those with large goiters and longer duration of the disease may need larger doses at initiation of therapy. In patients with minimum symptoms, an initial dose of 10 mg of Tapazole daily or PTU 50 mg two or three times a day may be initiated. In most patients, clinical improvement is seen in 2 to 6 weeks, and improvement in thyroid tests occurs within the first 2 weeks of therapy, with normalization to chemical euthyroidism in 3 to 7 weeks.^[356] Resistance to drug therapy is unusual, most likely due to poor patient compliance.^[365] Once clinical improvement occurs, mainly weight gain and reduction in tachycardia, the dose of antithyroid medication may be

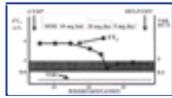

Figure 33-5 Management of hyperthyroidism. TSH, thyroid-stimulating hormone; FT₄, free thyroxine; LNMP, last normal menstrual period; MMI, methimazole.

reduced by half of the initial dose. The daily dose is adjusted every few weeks according to the clinical response and the results of thyroid tests. Serum TSH remains suppressed despite the normalization of thyroid hormone levels (Fig. 33-5). Normalization of serum TSH is an indicator to reduce the dose of medication. We do not recommend adding thyroxine to antithyroid drug therapy in the management of Graves' disease in pregnancy. If there is an exacerbation of symptoms or worsening of the thyroid tests, the amount of antithyroid medication is doubled. The main concern of maternal drug therapy is the potential side effect on the fetus; mainly, goiter and hypothyroidism. In most studies this has been prevented by using doses no greater than 200 mg PTU or 20 mg methimazole in the last few weeks of gestation.^[366] However, small elevations in serum TSH in the neonate have been reported even with lower doses of antithyroid medication.^[367] Furthermore, in one study, cord blood FT₄ values were not correlated to the antithyroid dose at term.^[345]

Side effects of antithyroid drugs occur in 3 to 5 percent of treated patients.^[368] The most common complications of both drugs are pruritus and skin rash. They usually resolve by switching to the other antithyroid medication. In general, the rash occurs 2 to 6 weeks after initiation of therapy. Since pruritus may be an initial symptom of hyperthyroidism, it is customary to ask the patient during the first visit if she is bothered by this. Other complications that are much less common are migratory polyarthritis, a lupus-like syndrome, and cholestatic jaundice. Agranulocytosis, a serious but unusual complication, has been reported in 1 in 300 patients receiving the drug.^[369] It is manifested by fever, malaise, gingivitis, and sore throat. Agranulocytosis occurs in the first 12 weeks of therapy and appears to be related to the dose of medication.^[370] Women should be made aware of the symptoms at the time the prescription is given, and advised to discontinue the drug and obtain a leukocyte count at once. Although some have recommended routine blood counts in patients on antithyroid therapy, it is not indicated, since granulocytopenia

or agranulocytosis may appear without warning symptoms.

-Adrenergic blocking agents (propranolol 20 to 40 mg every 6 hours or atenolol 25 to 50 mg/day) are very effective in controlling hyperdynamic symptoms and are indicated for the first few weeks in symptomatic patients.^[322] One situation in which -adrenergic blocking agents may be very effective is in the treatment of severe hyperthyroidism during labor. In a case reported with both mother and fetus affected, labetalol was infused at a rate of 2 mg/min, controlling maternal and fetal tachycardia within 45 minutes.^[371]

Subtotal thyroidectomy in pregnancy is effective in managing the disease; nowadays, indications for surgical treatment are few: allergy to antithyroid drugs,^[372] very large goiters, patient preference, and the exceptional case of resistance to drug therapy.

¹³¹I therapy is contraindicated in pregnancy since, when given after 10 weeks' gestation, it produces fetal hypothyroidism.^[373] A pregnancy test is mandatory in any woman of childbearing age before a therapeutic dose of ¹³¹I is administered.^[374]

Iodine crosses the placenta. If given in large amounts and for prolonged periods, it may produce a fetal goiter and hypothyroidism.^[321] Therefore, its use is not recommended in pregnancy. However, iodine has been used in small amounts, 6 to 40 mg/day in a group of pregnant Japanese women with mild hyperthyroidism.^[375] Elevation in serum TSH was observed in 2 of 35 newborns, and the mothers were slightly hyperthyroid at the time of delivery. In spite of this observation, iodine therapy is not routinely indicated in the treatment of hyperthyroidism in pregnancy.

Excessive amounts of antithyroid drugs have induced fetal hypothyroidism and goiter. The diagnosis of goiter is made by ultrasonography, which shows hyperextension of the neck and a neck mass. Few cases of hypothyroidism have been confirmed by measuring serum thyroxine and TSH in fetal blood obtained by cordocentesis.^[377] Treatment with intra-amniotic injection of L-thyroxine has resulted in resolution of the goiter.

Breast-feeding should be permitted if the daily dose of PTU or methimazole is less than 150 to 200 mg/day, respectively. It is prudent to give the total dose in divided doses after each feeding. The infant should be followed with thyroid function tests.^[378] In a very provocative study, PTU was given to lactating hyperthyroid mothers whose infants were born with elevated serum TSH levels. Infant TSH levels normalized even with continuation of PTU therapy by the mothers.^[379] In another study, thyroid tests were done at regular intervals in breast-fed infants of mothers taking up to 20 mg of methimazole daily, showing no evidence of hypothyroidism.^[380]

Assessment of fetal well-being with the use of ultrasonography, the nonstress test, and a biophysical profile is indicated for cases in poor metabolic control, in the presence of fetal tachycardia and/or intrauterine growth restriction, in pregnancies complicated by PIH or any other obstetrical or medical complications.

Treatment of Thyroid Storm

Thyroid storm is a clinical diagnosis based on severe signs of thyrotoxicosis, with significant hyperpyrexia (>103°F), and neuropsychiatric symptoms that are essential for the clinical diagnosis. Tachycardia with a pulse rate exceeding 140 beats/min is not uncommon, and congestive heart failure is a frequent complication. Gastrointestinal symptoms such as nausea and vomiting, accompanied by liver compromise, have been reported. Laboratory tests show the classic hyperthyroid changes, although the actual elevation in FT₄ values does not help in the diagnosis.

Management includes the following:

1. Admission to the intensive care unit for supportive therapy such as fluids and correction of electrolyte abnormalities, oxygen therapy as needed, and control of hyperpyrexia. Acetaminophen is the drug of choice, since aspirin may increase free thyroid hormones.
2. Management of congestive heart failure, which may require large doses of digoxin.
3. Proper antibiotic therapy in case of infection.
4. -Blocker therapy to control hyperadrenergic symptoms such as propranolol 60 to 80 mg every 4 hours orally or 1 mg/min intravenously. Esmolol, a short-acting -acting antagonist given intravenously with a loading dose of 250 to 500 g/kg of body weight followed by continuous infusion at 50 to 100 g/kg/min may be used.
5. Methimazole 30 mg or PTU 300 mg every 6 hours (if unable to take oral medications a nasogastric tube may be needed); thionamides block the synthesis of thyroid hormones in a few hours.
6. One hour after the administration of thionamides, iodine is administered in the form of Lugol's solution, 10 drops three times a day or, if available, sodium iodide, given intravenously 1 g every 12 hours.

7. Glucocorticoids are also helpful, since they reduce the peripheral conversion of serum T₄ to T₃ in the form of hydrocortisone every 8 hours or equivalent amounts of other glucocorticoids.

In summary, thyroid storm is a life-threatening condition, requiring early recognition and aggressive therapy in an intensive unit care setting.

Neonatal Hyperthyroidism

Neonatal hyperthyroidism is infrequent, with an incidence of less than 1 percent of infants born to mothers

1150

with Graves' disease, therefore affecting 1 in 50,000 neonates. In the vast majority of cases, the disease is caused by the transfer of maternal immunoglobulin antibodies to the fetus. These stimulating thyroid antibodies to the TSH receptor (TSIs), when present in high concentrations in maternal serum, cross the placental barrier, stimulate the fetal thyroid gland, and may produce fetal or neonatal hyperthyroidism.^[381] When the mother is treated with antithyroid medications, the fetus benefits from maternal therapy, remaining euthyroid during pregnancy. However, the protective effect of the antithyroid drug is lost after delivery, and neonatal hyperthyroidism may develop within a few days after birth. High titers of TSI receptor antibodies, a three- to fivefold increase over baseline, in the third trimester of pregnancy are predictors of neonatal hyperthyroidism.^[341] If neonatal hyperthyroidism is not recognized and treated properly; neonatal mortality could be as high as 30 percent. Since the half-life of the antibodies is only a few weeks, complete resolution of neonatal hyperthyroidism is the rule.^[382]

A few cases of familial neonatal Graves' disease^[383] have been reported; the pathogenesis is not clearly understood. This condition may persist for several years.

Sporadic cases of neonatal hyperthyroidism without evidence of the presence of circulating TSI in mother or infant have recently been published.^[384],^[385] Activation of mutations in the TSH receptor molecule are the cause of this entity. It is inherited as an autosomal dominant trait and, in contrast to Graves' neonatal hyperthyroidism, the condition persists indefinitely. Treatment with antithyroid medications followed by thyroid ablation therapy will eventually be needed.

Fetal Hyperthyroidism

In mothers with a history of Graves' disease previously treated with ablation therapy, either surgery or ¹³¹I, concentrations of TSI may remain elevated, in spite of maternal euthyroidism. The concentration of these IgG immunoglobulins is low early in normal pregnancy, reaching a level in the fetus similar to that of the mother around 30 weeks' gestation. Therefore, the symptoms of fetal hyperthyroidism are not evident until 22 to 24 weeks of gestation. When TSI levels are present in high concentrations, fetal hyperthyroidism may result, characterized by fetal tachycardia, IUGR, oligohydramnios, and occasionally a goiter identified on ultrasonography by hyperextension of the fetal neck.^[311],^[386]^[387]^[388] The diagnosis may be confirmed by measuring thyroid hormone levels in cord blood obtained by cordocentesis.^[389],^[390] Heckel et al.^[311] reviewed nine cases of fetal hyperthyroidism treated by maternal administration of antithyroid medications. Fetal tachycardia was the most frequent sign, whereas oligohydramnios and IUGR were reported in only two cases. Fetal goiter was detected by ultrasonography in three cases. Treatment consisted of antithyroid medication given to the mother, PTU 100 to 400 mg/day or methimazole 10 to 20 mg/day. The dose is guided by the improvement and resolution of fetal tachycardia and normalization of fetal growth, both of which are indicators of good therapeutic response. Serial cordocentesis for the determination of thyroid hormone concentrations has also been used to monitor drug therapy.^[391] The procedure should be reserved for centers with technical expertise in its use, since the complication rate is around 1 percent.^[392]

In summary, the diagnosis of fetal hyperthyroidism should be suspected in the presence of fetal tachycardia with or without fetal goiter in mothers with a history of Graves' disease treated by ablation therapy and with high titers of serum TSI antibodies. The diagnosis can be confirmed by the determination of fetal thyroid hormones by cordocentesis.^[392]^[393]^[394]

Hypothyroidism

Hypothyroidism in pregnancy is rarely diagnosed. Only a few series of patients have been reported.^[395]^[396]^[397] However, subclinical hypothyroidism is more often encountered. Mild elevations in serum TSH are frequently detected in hypothyroid women on thyroid therapy soon after conception because of the increased demand for thyroid hormones in the first weeks of gestation.^[309],^[310],^[398] The incidence of hypothyroidism, defined as any elevation in serum TSH above normal values, is between 0.19 and 2.5 percent.^[399]^[400]^[401]^[402]^[403] In the above-mentioned studies, serum TSH was measured in the first half of pregnancy. The two most common etiologies of primary hypothyroidism are autoimmune thyroiditis (Hashimoto's thyroiditis) and postthyroid ablation therapy, surgical or ¹³¹I treatment. Original studies reported a high incidence of congenital malformations, perinatal mortality, and impaired mental and somatic development in infants of hypothyroid women.^[404] In contrast, recent reports showed no increase in the incidence of congenital malformations, and perinatal mortality is only slightly elevated.^[395]^[396]^[397]

Regardless of the etiology, primary hypothyroidism is classified as subclinical hypothyroidism (normal FT₄ and elevated TSH) and overt hypothyroidism (low FT₄ and elevated TSH). The spectrum of women with hypothyroidism in pregnancy includes (1) women with subclinical and overt hypothyroidism diagnosed for the first time during pregnancy; (2) hypothyroid women who discontinue thyroid therapy at the time of conception because of poor medical advice or because of the misconception that thyroid medications affect the fetus; (3) those women on thyroid therapy requiring larger doses in pregnancy; (4) those women previously diagnosed but not compliant with their medication; (5) hyperthyroid

1151

patients on excessive amounts of antithyroid drug therapy; and (6) some patients on lithium or amiodarone therapy, as both drugs may impact thyroid function, particularly in women affected by chronic thyroiditis.^[405],^[406]

The vast majority of patients with subclinical hypothyroidism are asymptomatic. Patients with overt hypothyroidism may complain of tiredness, cold intolerance, fatigue, muscle cramps, constipation, and deepening of the voice. On physical examination, the skin is dry and cold, deep tendon reflexes are delayed, and bradycardia may be detected as well as periorbital edema. A goiter is present in almost 80 percent of patients with chronic thyroiditis. The characteristic of the goiter is a diffuse enlargement, about two to three times the normal size, firm to palpation, painless, and with a rubbery consistency. In the other 20 percent, no goiter is found (atrophic thyroiditis, also known as primary myxedema or chronic thyroiditis without goiter).

The diagnosis of hypothyroidism is confirmed by the determination of serum TSH and FT₄ or FT₄I. The degree of severity of the clinical symptoms varies with the chemical thyroid abnormalities, although there is not always good correlation between clinical and chemical parameters. Serum thyroid antibodies (thyroid peroxidase antibodies [anti-TPO] formerly known as antimicrosomal antibodies [AMAs]), are elevated in patients with autoimmune thyroiditis. The titer of antibodies does not correlate with the size of the goiter or the clinical severity of hypothyroidism. In our series,^[397] the mean TSH value at the time of diagnosis of overt hypothyroidism was 89.7 ± 86.2 mU/ml (normal, 0.4 to 5.0), with a mean FT₄I of 2.1 ± 1.5 (normal, 4.5 to 12). In the group with subclinical hypothyroidism, the mean serum TSH value was 28.4 ± 47.1 mU/mL with a mean FT₄I of 8.7 ± 3.6.

As in the case of hyperthyroidism, the most common complication in hypothyroid pregnant women is PIH, with an incidence of 21 percent in 60 patients with overt hypothyroidism (Table 33-6) (Table Not Available). Low birth weight was reported in 16.6 percent of infants. In one series,^[397] 2 of 12 women with subclinical hypothyroidism developed postpartum hemorrhage. In our recent series of 23 women that conceived while being hypothyroid and completed their pregnancy in our institution, 10 presented with subclinical and 13 with overt hypothyroidism. In 13 of 23, the diagnosis of hypothyroidism was made for the first time during pregnancy, and the other 10 women had discontinued thyroid medication at least 3 months before conception. The incidence of complications was much less than in previous reports. No problems were seen in those women achieving euthyroidism before 24 weeks' gestation. The results of this study suggest that achieving euthyroidism early in pregnancy prevents late complications, even in women with severe hypothyroidism. The mean serum TSH in the overt hyperthyroid patients at presentation (16.1 weeks) was 90.4 IU/ml and the FT₄I was 1.4 (normal, 4.512).^[407]

The impact of maternal hypothyroidism on the intellectual development of the offspring has been the subject of four studies, including two recent studies, one from this

country and the other from Belgium.^[295], ^[296], ^[408], ^[409] In the study by Haddow et al.,^[295] children born of mothers with mild elevations of serum TSH, measured between 16 and 18 weeks' gestation, were studied at age 7 to 9. They reported a 4-point decrease in IQ score on the Wechsler Intelligence Scale for Children. Pop et al.^[296] detected a lower Baylor Psychomotor Developmental Index at 10 months of age in a small group of children the mothers of whom had low FT₄ but normal TSH at 12 weeks' gestation. In another study from Japan, Lui et al.^[409] examined a group of eight children at age 4 and 10. IQs were compared in these children, whose mothers were hypothyroid in the first trimester, with their siblings. In the latter group, the mothers were euthyroid throughout gestation. There was no difference in the IQs of both groups of children. Mann et al.^[408] had reported lower IQs in children from a group of mothers considered

TABLE 33-6 -- MATERNAL AND NEONATAL COMPLICATIONS OF HYPOTHYROIDISM IN PREGNANCY

(Not Available)

1152

hypothyroxinemic in pregnancy (serum TSH was not available at the time of the study). When they were studied at age 7, 5 of 21 (24 percent) had an IQ of less than 80, as compared with 10 percent of control children. These preliminary studies appear to support earlier animal research^[410] showing the importance of maternal transfer of thyroxine in the first trimester of pregnancy, at a time when the fetal thyroid had not yet developed. From a practical point of view, these studies emphasize the importance of adjusting the dose of thyroxine in women under treatment for hypothyroidism soon after conception. Although we do not now support universal screening for hypothyroidism, we do recommend determination of thyroid tests early in pregnancy in those women at high risk for developing hypothyroidism (see the box "Indications for Thyroid Testing in Pregnancy" (Box Not Available)).

Levothyroxine, or L-thyroxine, is the drug of choice for the treatment of hypothyroidism. In view of the complications mentioned above, it is important to normalize thyroid tests as soon as possible. An initial dose of 0.150 mg of levothyroxine is well tolerated by the majority of young hypothyroid patients. In those with severe hypothyroidism, there is a delay in the normalization of serum TSH, but normal serum FT₄ values are achieved in the first two weeks of therapy. The maintenance dose required for most patients is between 0.125 and 0.250 mg of levothyroxine per day. Higher doses may be required for patients after total thyroidectomy for thyroid carcinoma, since the goal in these cases is suppression of serum TSH.^[313]

Patients on thyroid therapy before conception should have their TSH checked on their first visit and the amount of levothyroxine adjusted accordingly. The serum TSH should be repeated between 20 and 24 weeks and 28 and 32 weeks. Immediately after delivery, they should return to prepregnancy dosage. Interference in the absorption of thyroxine was discussed previously.^[314], ^[315]

Single Nodule of the Thyroid Gland

It is estimated that nodular thyroid disease is clinically detectable in 10 percent of pregnant women. In most cases, it is discovered during the first routine clinical examination or detected by the patient herself. The chances for a single or solitary thyroid nodule to be malignant are between 5 and 10 percent,^[411] depending on risk factors such as previous radiation therapy to the upper body, rapid growth of a painless nodule, patient age, and family history of thyroid cancer. Papillary carcinoma accounts for almost 75 to 80 percent of malignant tumors, and follicular neoplasm for 15 to 20 percent; a few percent are represented by medullary thyroid carcinoma. Undifferentiated thyroid carcinoma is extremely rare in people under 50 years of age. There is a paucity of information in the literature regarding the management and timing of the work-up in the presence of thyroid nodularity.^[412] ^[413] ^[414] ^[415] ^[416] It is generally agreed that elective surgery should be avoided in the first trimester and after 24 weeks' gestation because of the potential risks of spontaneous abortion and premature delivery, respectively. In a selective group of patients operated on during or in the few months after delivery, the incidence of thyroid cancer was reported to be near 40 percent.^[415], ^[416] In both studies, fine-needle aspiration biopsy of the thyroid nodule was obtained before surgery, with findings consistent with papillary carcinoma or highly suspicious lesions.

Careful examination of the neck enables the physician to define and characterize the thyroid lesion. In addition to the size of the nodule, the consistency, tenderness, fixation to the skin, and presence of metastasis should be noted. A hard, painless nodule, measuring more than 2 cm in diameter, is suspicious of malignancy. High-resolution real-time ultrasound is very helpful in defining the size of the lesion, characterizing the dominant one, and identifying microcalcifications suspicious for either papillary or medullary thyroid carcinoma. Fine-needle aspiration biopsy is routinely used for diagnostic purposes.

In a recent retrospective study, a conservative approach to the management of a single thyroid nodule was recommended.^[417] In this study, 61 women were pregnant at the time of the diagnosis of a differentiated thyroid carcinoma. The diagnosis was papillary cancer in 87 percent of them and follicular cancer in 13 percent. Fourteen women were operated on during pregnancy, whereas the other 47 women underwent surgical treatment 1 to 84 months after delivery. The outcome was compared with a group of 598 nonpregnant women matched for age. The median follow-up was 22.4 years as compared with 19.5 years in the nonpregnant group. Treatment and outcome were similar in both groups, those operated on during pregnancy and those in whom thyroidectomy was performed postpartum. The authors concluded that both diagnostic studies and initial therapy might be delayed until after delivery in most patients.

In the presence of a single thyroid nodule detected on physical examination, the following approach is recommended in our institution (Fig. 33-6)^[416]

1. *Serum TSH*: a suppressed serum TSH may indicate the presence of an autonomous nodule, which rarely is malignant.^[418] In such cases, FT₄ and FT₃ are measured to rule out hyperthyroidism. It should be kept in mind that in normal first-trimester pregnancies, serum TSH level may be transiently low or undetected.^[303]
2. If the serum TSH is within normal limits, the next step is *ultrasonography*, which will distinguish a

1153

solid from a cystic lesion. In addition, it may show a multinodular gland not detected by palpation.

3. In the presence of a *solid lesion less than 2 cm or cystic lesion less than 4 cm* in diameter, observation with or without thyroxine suppression therapy is recommended. If clinically indicated, such as presence of cervical adenopathy or an increase in the size of the lesion with progression of pregnancy, fine-needle aspiration biopsy (FNAB) of the lesion is considered. It is important to point out the rarity of enlargement of these small nodules in the course of a few months of follow-up.
4. In patients with a *solid or mixed lesion on ultrasound greater than 2 cm or a cystic nodule greater than 4 cm*, the diagnostic approach differs according to gestational age: (a) *Before 20 weeks' gestation*, FNAB is done. The most important component of the FNAB is the cytopathologist's interpretation. A specific diagnosis is required: malignant, benign, follicular lesion, or inadequate specimen. In the latter, a repeat FNAB is recommended. (b) *For lesions diagnosed after 24 weeks' gestation*, FNAB may be postponed until after delivery, unless there is a strong suspicion of malignancy. Suppressive therapy with thyroxine to prevent further growth of the lesion, although considered controversial by some,^[411] is the recommendation by our group. If there is further growth of the lesion in spite of suppressive therapy, FNAB is recommended. (c) *For lesions diagnosed between 20 and 24 weeks' gestation*, the decision to wait until after delivery or to complete the work-up is made by the patient and her physician. The patient's anxiety and fear of having a potential malignant lesion should be considered when advice is given. Most malignant lesions of the thyroid gland are slow growing, and the long-term prognosis is good in the majority of patients.
5. *If the lesion is papillary carcinoma*, surgery is recommended before 24 weeks' gestation, although long-term follow-up of patients diagnosed in pregnancy indicates that postponement of surgery until after delivery does not affect morbidity or mortality.^[417]
6. *For follicular lesions*, the decision about surgery is a personal one, since the chance for the lesion to be malignant is only between 15 and 20 percent. A similar approach is followed with Hürthle cell lesions.

Figure 33-6 Evaluation of single thyroid nodules in pregnancy.

The above protocol has been used in our institution for many years. In view of a recent publication discussed previously, [417] it is imperative for the physician to discuss the different therapeutic options with the patient and her family. If the lesion is diagnosed before

24 weeks' gestation, they should be informed of the recent data showing no deleterious effect in postponing therapy until after delivery. The anxiety of the patient and her family, and their wishes should be considered in making the final decision. The long-term prognosis of most thyroid cancers is exceptionally good, but patients should be followed for many years. General principles of care include the determination of serum thyroglobulin before surgery and at regular intervals thereafter; the decision to use radioactive iodine, which is indicated for completeness of thyroid ablation; and the importance of thyroid suppression therapy to keep the serum TSH suppressed in order to prevent possible recurrence of the lesion. [419]

Chronic Autoimmune Thyroiditis (Hashimoto's Thyroiditis)

Chronic or Hashimoto's thyroiditis [420] is an inflammatory disorder of the thyroid gland, the incidence depending on the definition of the entity. For example, in a long-term follow-up study in the Whickham survey, [421] there was an incidence in women of 3.5 cases per 1,000 per year, as contrasted with an incidence in men of 0.8 case per 1,000 per year. The prevalence increases with age. In most cases, there is a family history of thyroid disease, with 18 percent of relatives affected in one study [422] and 33 percent of siblings in another. [423] Chronic autoimmune thyroid disease is more common in women with other autoimmune diseases, particularly type 1 diabetes. [424] The classic clinic picture is characterized by the presence of a goiter, moderate in size, bilateral in most cases, with one lobe larger than the other, firm, rubbery consistency, and moving freely on swallowing. It is painless, although rapid growth of the gland may elicit some tenderness on palpation.

On presentation, most patients have no symptoms. The discovery of the goiter is made on routine physical examination, or detected by the patient or a family member. Occasionally, the patient may complain of mild to severe hypothyroid symptoms. The diagnosis may be suggested by a hyperechoic pattern on ultrasound of the thyroid. [425] The diagnosis is confirmed by the presence of thyroid autoantibodies (anti-TPO or antithyroglobulin autoantibodies). The actual antibody titer is not correlated with the size of the goiter, symptoms, or severity of the disease. From a practical point of view, there is no need to perform a determination of antithyroglobulin antibodies, since it does not add new information, increases the cost, and is not as sensitive as a determination of TPO autoantibodies. A serum TSH should be ordered to rule out thyroid dysfunction. If the serum TSH is elevated, a serum FT₄ will define if the patient suffers from subclinical or clinical hypothyroidism (see section Hypothyroidism, above). In some cases, goiter is not detected (atrophic thyroiditis or primary myxedema). Patients with euthyroid chronic thyroiditis may develop hypothyroidism over time. The odds ratio was 8 over 20 years in those women with a normal serum TSH and positive antibodies. [421]

The importance of diagnosing chronic thyroiditis in women of childbearing age relates to the potential consequences in pregnancy and the postpartum period. Women with chronic thyroiditis are at higher risk for spontaneous abortion, development of hypothyroidism for the first time in pregnancy, and postpartum thyroiditis.

Several investigators [426] [427] [428] have reported an association between thyroid autoantibodies and spontaneous miscarriages. Ongoing studies are evaluating the association of thyroid autoantibodies in women with recurrent spontaneous recurrent abortion. [429] Determination of serum TSH and anti-TPO antibodies should be performed in women with recurrent miscarriages. In the presence of normal TSH values, whether thyroid therapy is beneficial in preventing fetal loss in future pregnancies is not being systematically evaluated, although anecdotal information suggests a beneficial effect.

Women with chronic thyroiditis known to be euthyroid should be evaluated early in pregnancy, since some of them may develop hypothyroidism. Most euthyroid women will remain euthyroid throughout gestation, although there is a report suggesting an increased incidence of premature delivery in this group. [430]

In a subset of women with chronic thyroiditis, particularly those without a goiter (atrophic form), antibodies to the TSH receptor with blocking capabilities are present (TSHRBAbs). [431] These antibodies cross the placenta, and in high titers may block the action of TSH in the fetal thyroid, causing transient congenital hypothyroidism. [432] [433] The neonatal disease resolves spontaneously over 3 to 6 months as the maternal antibody is degraded. [434] In a population of 1,614,166 patients screened in New York, 9 mothers and their infants out of 788 infants with suspected congenital hypothyroidism had these antibodies. [435] Therefore, in mothers who have given birth to infants with congenital hypothyroidism, thyroid tests including TSHRBAbs should be determined. In one study from Belgium, infants of euthyroid mothers with positive anti-TPO antibodies were evaluated for intellectual performance. A mild deficit was detected. [436] The significance of these findings needs to be confirmed by other long-term studies.

As will be discussed in the following section, the presence of thyroid antibodies, particularly high titers in the first trimester of pregnancy, predicts the development of the syndrome of postpartum thyroiditis.

Postpartum Thyroid Dysfunction

Thyroid dysfunction, hyper- and hypothyroidism, is recognized with increasing frequency in the 12 months following delivery, or following spontaneous or medically

induced abortions. Most of the cases are due to intrinsic thyroid disease, with a few due to hypothalamic or pituitary lesions (see the box "Postpartum Thyroid Dysfunction") (Box Not Available) . Patients with autoimmune thyroid disease, chronic thyroiditis, and Graves' disease are most frequently affected.

Postpartum Thyroid Dysfunction

(Not Available)

From Mestman JH: Endocrine diseases in pregnancy. In Sciarra JJ (ed): Gynecology and Obstetrics. Philadelphia, Lippincott-Raven, 1997, p 34, with permission.

Postpartum thyroiditis (PPT), a variant of Hashimoto's or chronic thyroiditis, is the most common cause of thyroid dysfunction in the postpartum period. The prevalence is between 5 and 10 percent of all women, [430] [437] [438] [439] [440] with the exception of women with type 1 diabetes, where the incidence is close to 30 percent. [441] The clinical diagnosis is not always obvious and the clinician should be concerned about nonspecific symptoms such as tiredness, fatigue, depression, palpitations, and irritability in women following the birth of their child or a miscarriage or abortion. Fatigue is the most common complaint. [437] In some cases, the clinical symptoms resemble the syndrome of postpartum depression. Indeed, thyroid antibodies have been found more frequently in euthyroid women with postpartum depression, but this is still a controversial issue. [442] Since the clinical symptoms are mild, and many times are confused with the usual tiredness of women in the months following delivery, an argument can be made for routine screening in the postpartum period. This controversial issue has been recently reviewed. [443] It is the author's opinion that a careful history and physical examination will allow the physician to decide if thyroid tests are indicated in a given situation. Recognizing the mild degree of the symptoms, the presence of a goiter, history of similar symptoms in previous pregnancies, family history of thyroid disease, and type 1 diabetes mellitus, among other features, will prompt the health care professional to order serum TSH with anti-TPO antibodies. Those patients at risk should be evaluated in the first year postpartum because of the different manifestations of the disease.

Postpartum thyroiditis may also develop in women with negative antibodies. In a study from The Netherlands, the authors suggested two forms of PPT: an autoimmune form, which is most common and eventually will develop into chronic hypothyroidism, and a nonautoimmune form, without antibodies, that appears to be

transient without progressing to permanent hypothyroidism.^[444]

The clinical course is not uniform in the majority of patients. In about one third of the cases, mild symptoms of hyperthyroidism develop between 2 and 4 months postpartum. On physical examination, a goiter is felt in the majority of cases, firm and nontender to palpation. Tachycardia may be detected. The goiter may be discovered for the first time, or the patient may have noticed an increase in the size of a previously diagnosed goiter. Thyroid tests are in the hyperthyroid range and thyroid antibodies, anti-TPO antibody titers, are elevated in most cases. Spontaneously, without specific therapy, hypothyroidism develops in a few months, with spontaneous recovery and return to a euthyroid state by 7 to 12 months following delivery. Antibody titers have a tendency to increase during this process, and a change in the size of the goiter is usually noted. In a few patients, permanent hypothyroidism may develop. About 50 percent of patients, however, will develop permanent hypothyroidism within 5 years of the diagnosis of PPT.^[445], ^[446]

In one third of patients, the course of PPT is different, characterized by an initial episode of hypothyroidism between 3 and 7 months postpartum without the initial hyperthyroid phase. In the other one third of patients, the initial episode of hyperthyroidism is followed by a return to normal thyroid function. It has been suggested that some ultrasonographic changes of the thyroid gland, such as hypoechogenicity, are typical of PPT and may aid in the diagnosis of the syndrome.^[447]

Postpartum thyroid dysfunction may also occur in patients with a known history of Graves' disease. It is common for women with Graves' disease to have an exacerbation of their symptoms in the first 2 months postpartum.^[448] The symptoms of hyperthyroidism are more severe than those in patients with PPT. They may present with ophthalmopathy and the hypermetabolic findings. Therapy with antithyroid medications is needed in these cases. On the other hand, patients with Graves' disease may have a bout of hyperthyroidism secondary to a concomitant episode of PPT.^[449], ^[450] The differential diagnosis in this situation is important, since the treatment is different. If not contraindicated, as in breast-feeding mothers, a 4- or 24-hour thyroid radioactive iodine uptake (RAIU) is helpful. It will be very low in patients with PPT, whereas it is high normal or elevated in patients with recurrent hyperthyroidism

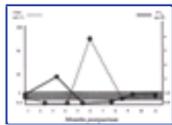

Figure 33-7 Clinical course of postpartum thyroiditis.

due to Graves' disease. When it is due to recurrent Graves' disease, treatment with antithyroid medications is indicated, or the physician may advise ablation therapy with ^[131]

Therefore, PPT is characterized by symptoms of thyroid dysfunction, that present in four different forms: (1) an episode of hyperthyroidism (2 to 4 months), followed by hypothyroidism (4 to 6 months) and reverting to euthyroidism (after the seventh month); (2) an episode of hyperthyroidism (3 to 4 months) reverting to euthyroidism; (3) an episode of hypothyroidism (4 to 6 months) reverting to a euthyroid state; and (4) permanent hypothyroidism after the hypothyroid phase (Fig. 33-7). However, there are exceptions to these chronologic phases. It is recommended that a diagnosis of PPT be considered for any thyroid abnormality occurring within 1 year after delivery or miscarriages.

Since most cases of postpartum thyroid dysfunction recover spontaneously, treatment is indicated for symptomatic patients. In the presence of hyperthyroid symptoms, -adrenergic-blocking drugs (propranolol 20 to 40 mg every 6 hours or atenolol 25 to 50 mg every 24 hours) are effective in controlling the symptoms. Anti-thyroid medications are not effective, because the hyperthyroxinemia is secondary to the release of thyroid hormones due to the acute injury to the gland (destructive hyperthyroidism). There is no new hormone production, and therefore medications that work by blocking new thyroid hormone formation are ineffective. For hypothyroid symptoms, small amounts of levothyroxine 0.050 mg/day will control symptoms, allowing for a spontaneous recovery of thyroid function after discontinuation of the drug.

There are some features that may predict the development of PPT: presence of a goiter and high titers of thyroid antibodies in the first half of pregnancy, episodes of PPT in previous pregnancies, hypothyroidism antedating pregnancy,^[451] and a strong family history of autoimmune thyroid disease.^[452] Women with type 1 diabetes mellitus are at high risk for developing PPT. PPT may recur in future pregnancies, with a recurrence rate between 30 and 70 percent.^[453] ^[454] ^[455] PPT has been reported to be associated with other autoimmune endocrine disorders, such as adrenal insufficiency and lymphocytic hypophysitis.^[19], ^[456]

Key Points

Hypopituitarism may present de novo in the second half of pregnancy, in the immediate postpartum period, or less commonly late postpartum. Severe hypoglycemia, responsive only to glucocorticoid therapy, is a characteristic feature. Lymphocytic hypophysitis with a normal or enlarged sella turcica on MRI appears to be the most common etiology.

Idiopathic diabetes insipidus may manifest for the first time in pregnancy in patients with subclinical disease, or may occur as a complication of acute liver failure. An increase in polyuria and nocturia in a pregnant woman with normal serum glucose should alert the physician of such a diagnostic possibility.

Cushing's disease is rare in pregnancy. The cause of Cushing's syndrome in pregnancy is the presence of an adrenal tumor in 50 percent of cases, versus 15 to 20 percent in nonpregnant patients.

Hyperparathyroidism is almost always asymptomatic. Surgery is indicated in symptomatic patients and those with serum calcium levels over 11 mg/dl. The management of asymptomatic patients with levels of less than 11 mg/dl is unsettled.

Hyperthyroidism due to Graves' disease needs to be differentiated in the first trimester of pregnancy from the syndrome of transient hyperthyroidism of hyperemesis gravidarum.

Transient hyperthyroidism of hyperemesis gravidarum is the most common cause of hyperthyroxinemia in pregnancy; the cause is high or inappropriate levels of hCG.

Both methimazole and PTU are used for the management of Graves' hyperthyroidism. The dosage should be adjusted frequently, aiming to

use the minimum amount of drug that will keep the FT₄ at the upper limits of normal.

Breast-feeding is not contraindicated in women on either methimazole or PTU, provided that the maximum daily dose is 200 mg of PTU and 20 mg of Tapazole.

Hypothyroid women should have their thyroid tests checked early in pregnancy. An increase in dosage is needed in over 50 percent of patients.

Postpartum thyroiditis affects between 5 and 10 percent of all women in the postpartum period. Women with chronic thyroiditis are at higher risk of developing the syndrome.

When significant hirsutism with or without virilization occurs de novo in pregnancy, a complete endocrine evaluation should be carried out. The most common cause is a luteoma of pregnancy.

Rare causes of hypertension in pregnancy include pheochromocytoma, Cushing's disease, and primary aldosteronism.

Chapter 34 - Hematologic Complications of Pregnancy

Philip Samuels

PREGNANCY-ASSOCIATED THROMBOCYTOPENIA

The widespread use of automated blood counts has led to the increased diagnosis of thrombocytopenia coexisting with pregnancy. Affecting approximately 4 percent of pregnancies, thrombocytopenia is the most frequent hematologic complication of pregnancy resulting in consultation. Hospital laboratories vary on their lower limit of a normal platelet count, but it is usually between 135,000 and 150,000/mm³. Platelet counts generally fall slightly, due to hemodilution and increased destruction, as gestation progresses. Platelet counts, however, should not fall below the normal range. In pregnancy, the vast majority of cases of mild to moderate thrombocytopenia are caused by gestational thrombocytopenia.^[1] This form of thrombocytopenia has little chance of causing maternal or neonatal complications.^[2] The obstetrician, however, is obliged to rule out other forms of thrombocytopenia that are associated with severe maternal or perinatal morbidity. The common and rare causes of thrombocytopenia in the gravida at term are shown [in the box "Causes of Thrombocytopenia During Pregnancy."](#) Until the late 1980s, it was assumed that all patients with an unexplained low platelet count carried a diagnosis of immune thrombocytopenic purpura (ITP), a recognized cause of neonatal thrombocytopenia. Unfortunately, traditional platelet antibody testing cannot distinguish among ITP, thrombocytopenia accompanying preeclampsia, and gestational thrombocytopenia.^[3], ^[4] Yet, the distinction between these disorders is important because each of these diagnoses carries distinct maternal and neonatal implications.

Gestational Thrombocytopenia

Patients with gestational thrombocytopenia usually present with mild (platelet count = 100,000 to 149,000/mm³) to moderate (platelet count = 50,000 to 99,000/mm³) thrombocytopenia.^[5] These patients usually require no therapy, and the fetus appears to be at little, if any, risk of being born with profound thrombocytopenia (platelet count <50,000/mm³) or a bleeding diathesis. This distinct entity was first suggested but not specifically defined in a study published in 1986 by Hart et al.^[6] In this study, 28 of 116 pregnant women (24 percent) who were evaluated prospectively during an 8-month period in 1983 had platelet counts less than 150,000/mm³ at least once during pregnancy. In all 17 patients who were followed after delivery, platelet counts returned to normal. Platelet-associated IgG (a positive direct test) was present in 79 percent of these 28 women, and 61 percent had serum antiplatelet IgG (a positive indirect test). None of these women had positive antibodies after delivery. Hart et al.^[6] were actually describing gestational thrombocytopenia before the condition had been recognized as a distinct entity. They, furthermore, were the first to demonstrate that conventional platelet antibody testing cannot distinguish gestational thrombocytopenia from ITP.^[6] Samuels et al.^[3] also investigated 74 mothers with gestational thrombocytopenia. Forty-six (62 percent) of these patients had circulating antiplatelet IgG in their plasma (a positive indirect test); these women gave birth to two neonates with thrombocytopenia, both having platelet counts above 50,000/mm³. Burrows and Kelton^[5], ^[7], ^[8] have further shown, in several large series, that there is little risk to the mother or neonate in cases of gestational thrombocytopenia. In one study no mother or

infant, in a group of 334 women with gestational thrombocytopenia, experienced bleeding complications.^[9] In their earlier study of 1,357 healthy, pregnant women, 112 (8.3 percent) had platelet counts less than 150,000/mm³.^[5] The lowest platelet count was 97,000/mm³. The incidence of thrombocytopenia (platelet count <150,000/mm³) in the infants of these 112 women was 4.3 percent, not statistically significantly different from infants born to healthy pregnant women without thrombocytopenia (1.5 percent). None of these infants had platelet counts less than 100,000/mm³. Indeed, the works by Samuels et al.^[3] and Burrows and Kelton^[5], ^[7] have convincingly demonstrated that gestational thrombocytopenia is an entity distinct from ITP.

Causes of Thrombocytopenia During Pregnancy

Common causes

- Gestational thrombocytopenia
- Severe preeclampsia
- HELLP syndrome
- Immune thrombocytopenic purpura
- Disseminated intravascular coagulation

Rare causes

- Lupus anticoagulant/antiphospholipid antibody syndrome
- Systemic lupus erythematosus
- Thrombotic thrombocytopenic purpura
- Hemolytic uremic syndrome
- Type 2b von Willebrand's syndrome
- Folic acid deficiency
- Human immunodeficiency virus infection
- Hematologic malignancies
- May-Hegglin syndrome (congenital thrombocytopenia)

The decrease in platelet count, occurring in gestational thrombocytopenia, is not merely due to dilution of platelets with increasing blood volume. It appears to be due to an acceleration of the normal increase in platelet destruction that occurs during pregnancy.^[1] This is demonstrated by the fact that the mean platelet volume (MPV) is increased in patients with gestational thrombocytopenia. The increase in platelet-associated IgG seen in these patients may merely reflect immune complexes adhering to the platelet surface rather than specific antiplatelet antibodies. Pregnant women who have gestational thrombocytopenia do not require any special therapy during the puerperium unless their platelet counts fall below 20,000/mm³ or if there is clinical bleeding. These complications, however, are rare, and it is difficult to determine whether these patients, with profound thrombocytopenia, have gestational thrombocytopenia or new onset of immune thrombocytopenic purpura.

Immune Thrombocytopenic Purpura

Although it only affects 1 to 3 per 1,000 pregnancies, ITP has received much attention in the obstetrics literature because of the potential for profound neonatal thrombocytopenia in infants born to mothers with this condition.

In 1954, Peterson and Larson^[9] were the first to recognize that profound thrombocytopenia (platelet count <50,000/mm³) may develop in infants born to women with ITP. A subsequent report confirmed this observation.^[10] In 1973, Territo et al.^[11] made the first effort to predict which infants were at increased risk of being born with profound thrombocytopenia. They demonstrated, in a small number of patients, that fetuses born to mothers with platelet counts less than 100,000/mm³ were at highest risk. Many larger studies have since shown that this arbitrary cut-off, while generally true, is not useful in individual cases. Subsequently, a number of efforts have been made to use noninvasive parameters to assess the risk of severe neonatal thrombocytopenia, including the use of maternal glucocorticoids, whether or not the mother had undergone splenectomy, and the presence of maternal antiplatelet antibodies. None of these, however, has shown the desired positive or negative predictive values.^{[12] [13] [14] [15] [16]}

In general, pregnancy has not been determined to cause ITP or to change its severity. Other studies, however, have demonstrated that in individual patients ITP exacerbations often occur during pregnancy and improve postpartum.^{[3] , [17] , [18]} Harrington et al.^[19] were the first to demonstrate that this disorder was humorally mediated. Shulman et al.^[20] showed that the mediator of this disorder was IgG. These findings were confirmed when Cines and Schreiber^[21] developed the first platelet antiglobulin test, a radioimmunoassay, in 1979. This test is now mostly performed by enzyme-linked immunosorbent assay (ELISA) or flow cytometry. New assays have shown that these autoantibodies may be directed against specific platelet surface glycoproteins, including the IIb/IIIa and Ib/IX complexes.^[22] After the platelets are coated with antibody they are removed from circulation by binding to the Fc receptors of macrophages in the reticuloendothelial system, especially the spleen. Approximately 90 percent of women with ITP will have platelet-associated IgG.^[23] Unfortunately, this is not specific for ITP, as studies have shown that these tests are also positive in women with gestational thrombocytopenia and preeclampsia.^{[3] , [4]} Studies concerning the use of antibodies to specific epitopes on platelet surface glycoproteins are ongoing, and these tests eventually may be useful to distinguish among the various disorders.

To make the issue more confusing, the pathogenesis of ITP in children and adults usually differs. Childhood ITP usually follows a viral infection and clinically presents with petechiae and bleeding.^[23] This form of ITP is generally self-limited and disappears over time. Adults, conversely, have milder bleeding and easy bruisability and are often diagnosed after a prolonged period of subtle symptoms. Adult ITP usually runs a chronic course, and long-term therapy is often eventually needed. Many pregnancies occur in women in their late teens and early twenties. In these women, with a history of ITP, it may be difficult to ascertain whether the patient has childhood ITP or adult ITP. Also, no study has shown whether the risk of neonatal thrombocytopenia is similar in both forms of ITP.

ITP is different from other causes of thrombocytopenia in pregnancy because of the aforementioned risk of profound neonatal thrombocytopenia. This has further been confounded by the fact that before 1990 it was assumed that all patients with unexplained thrombocytopenia during gestation had ITP. It was only after 1990 that gestational thrombocytopenia became recognized as a distinct entity.^{[2] , [3]} This, therefore, has confounded studies because cases of gestational thrombocytopenia have diluted many studies, making it difficult to determine the true incidence of neonatal thrombocytopenia in women with ITP.

[Table 34-1](#) lists several studies in which all patients had true ITP and delineates the rates of profound neonatal thrombocytopenia. Even these carefully performed studies show wide ranges in the rates of profound neonatal thrombocytopenia.

In 1980, Scott et al.^[24] were the first to institute direct fetal platelet determination in a series of women with ITP by utilizing fetal scalp sampling. This procedure, however, requires operator skill, an engaged fetal vertex, a dilated cervix, ruptured membranes, and the ability to obtain a pure sample of fetal blood without any contamination with maternal blood or amniotic fluid. The procedure has proven to be technically difficult in the hands of many practicing obstetricians who do not perform fetal scalp sampling on a regular basis. In many cases, amniotic fluid in the vagina contaminates the specimen. Amniotic fluid contains procoagulants, which cause fetal platelet clumping and spurious thrombocytopenia.

With the development and increased use of ultrasound-guided cordocentesis in the mid-1980s, accurate in utero sampling of fetal platelets has become feasible. Some authors advocate routine use of this technique in mothers with ITP. [25] [26] [27] Some maternal-fetal specialists believe that there is minimal risk involved with the cordocentesis. Ghidini and colleagues, [28] however, reviewed cordocentesis complications at medical centers where more than 100 procedures had been performed. They found a 1.4 percent risk of perinatal death in low-risk fetuses at more than 28 weeks' gestation undergoing the procedure. The complication rate may be appreciably higher when larger numbers of severely thrombocytopenic neonates have been studied. Bleeding may occur in up to 41 percent of cases, but most stop in less than 60 seconds. Complication rates will probably fall as experience increases and imaging, including color Doppler, improves. However, cordocentesis is expensive when including the price of the procedure, the physician consultation fee, the ultrasound guidance, and the fetal monitoring that must accompany the procedure. Indeed, the risks, associated costs, and low yield with which profoundly thrombocytopenic infants are identified do not justify the routine use of cordocentesis in all thrombocytopenic mothers.

The major reason why invasive testing has identified so few thrombocytopenic neonates is that many women with gestational thrombocytopenia were included in these series. Gestational thrombocytopenia, previously cited as the most common cause of thrombocytopenia in the third trimester, was not recognized until 1986. It was first alluded to by Hart et al. [6] In 1990, Burrows and Kelton, [8] as well as Samuels et al. [9] firmly established thrombocytopenia as an entity distinct from ITP. In the latter study, Samuels et al. [9] showed that roughly 50 percent of women referred to two major medical centers over 10 years with presumptive ITP actually had gestational thrombocytopenia. It is likely that the

inclusion of large numbers of women with gestational thrombocytopenia in recent studies of maternal "ITP" has led to the spurious impression that the natural history of ITP has changed.

In a meta-analysis by Burrows and Kelton, [29] a 14.6 percent incidence of profound thrombocytopenia in infants born to mothers with ITP was reported. This meta-analysis did not, however, take into account that many of the studies included did not exclude patients with gestational thrombocytopenia. Therefore, the risks of profound thrombocytopenia may very well be greater than this reported incidence. These authors, also, reported a neonatal morbidity rate of 24 per 1,000 with few serious complications. This may only be low for the reasons mentioned above.

Samuels et al. [9] reported a neonatal morbidity rate of 278 per 1,000 infants born to mothers with true ITP. The sample size, however, was too small to determine if mode of delivery or degree of neonatal thrombocytopenia made an impact on this morbidity. This rate may be overly high, as these were patients referred to two large tertiary care centers. Nonetheless, this study does point out that ITP does not always carry a benign course for the neonate. The neonatal morbidities included intraventricular hemorrhage, hemopericardium, gastrointestinal bleeding, and extensive cutaneous manifestations of bleeding. [9] Regardless of the complication rates in profoundly thrombocytopenic fetuses, cordocentesis is rarely indicated in patients with ITP.

Thrombotic Thrombocytopenic Purpura and Hemolytic Uremic Syndrome

These two conditions are characterized by microangiopathic hemolytic anemia and severe thrombocytopenia. Pregnancy does not predispose a patient to these conditions, but these conditions should be considered when evaluating the gravida with severe thrombocytopenia. Thrombotic thrombocytopenic purpura (TTP) is characterized by a pentad of findings, which are shown in the box "Pentad of Findings in TTP." [30] [31] The complete pentad only occurs in approximately 40 percent of patients, but approximately 75 percent present with a triad of microangiopathic hemolytic anemia, thrombocytopenia, and neurologic changes. [32] Pathologically, these patients have thrombotic occlusion of arterioles and capillaries. [33] These occur in multiple organs, and there is no specific clinical manifestation for the disease. The clinical picture will reflect the organs that are involved. The pathophysiology of TTP remains elusive, but diffuse endothelial damage and impaired fibrinolytic activity are hallmarks of this disorder. [33] Weiner [34] has published the most extensive literature review concerning TTP. In this series of 45 patients, 40 developed the disease antepartum, with 58 percent occurring before 24 weeks' gestation. The mean gestational age at onset of symptoms was 23.5 weeks.

Pentad of Findings in Thrombotic Thrombocytopenic Purpura (TTP)*

- Microangiopathic hemolytic anemia
- Thrombocytopenia
- Neurologic abnormalities: confusion, headache, paresis, visual hallucinations, seizures
- Fever
- Renal dysfunction

* The classic pentad is only found in 40% of patients.
These three findings are present in 74% of patients. [33]

This finding may be helpful when trying to distinguish TTP from other causes of thrombocytopenia and microangiopathic hemolytic anemia occurring during gestation. In Weiner's review, the fetal and maternal mortality rates were 80 and 44 percent, respectively. [34] These mortality rates are overly pessimistic, as this series included many patients who contracted the disease before plasma infusion/exchange therapy was used for treating TTP. This disorder may be confused with rarely occurring early-onset severe preeclampsia. In preeclampsia, antithrombin III levels are frequently low, and this is not the case with TTP. [35] This test, therefore, may be a useful discriminator between these two disorders.

Although the hemolytic uremic syndrome (HUS) has many features in common with TTP, it usually has its onset in the postpartum period. Patients with HUS display a triad of microangiopathic hemolytic anemia, acute nephropathy, and thrombocytopenia. HUS is rare in adults, and the thrombocytopenia is usually milder than that seen in TTP, with only 50 percent of patients having a platelet count less than 100,000/mm³ at time of diagnosis. The thrombocytopenia worsens as the disease progresses. [36] A major difference between TTP and HUS is that 15 to 25 percent of patients with the latter develop chronic renal disease. [31] HUS often follows infections with verotoxin-producing enteric bacteria. [37] Cyclosporine therapy, cytotoxic drugs, and oral contraceptives may predispose adults to develop HUS. [38] [39] [40] The majority of cases of HUS occurring in pregnancy develop at least 2 days after delivery. [31] [33] In fact, in one series, only 9 of 62 cases (6.9 percent) of pregnancy-associated HUS occurred antepartum. [34] Four of those nine developed symptoms on the day of delivery. The mean time from delivery to development of

HUS in patients in this series was 26.6 days. Maternal mortality may exceed 50 percent in postpartum HUS.

EVALUATION OF THROMBOCYTOPENIA DURING PREGNANCY AND THE PUERPERIUM

Before deciding on a course to follow in treating the patient with thrombocytopenia, the obstetrician must evaluate the patient and attempt to ascertain the etiology of her low platelet count. Important management decisions are dependent on arriving at an accurate diagnosis. A complete medical history, although time consuming, is critically important. It is essential to learn whether the patient has previously had a depressed platelet count or bleeding diathesis. It is also important to know whether these clinical conditions occur coincidentally with pregnancy. A complete medication history should be elicited, as certain medications, such as heparin, can result in profound maternal thrombocytopenia. The obstetric history should focus on whether there have been any maternal or neonatal bleeding problems in the past. Excessive bleeding from an episiotomy site or cesarean delivery incision site, a need for blood component therapy, easy bruising, or bleeding from intravenous sites during labor should alert the physician to the possibility of thrombocytopenia in the previous pregnancy. The obstetrician should also question whether the infant had any bleeding diathesis or if there was any problem following a circumcision. The obstetrician should also ask pertinent questions to determine whether severe preeclampsia or HELLP (Hemolysis, Elevated Liver Enzymes, Low Platelets) syndrome is the cause of her thrombocytopenia. The treatment of preeclampsia and HELLP is not discussed in this chapter, as they are covered elsewhere ([see Chapter 28](#)). Importantly, all thrombocytopenic pregnant women should be carefully evaluated for the presence of risk factors for human immunodeficiency virus (HIV) infection, as this infection can cause an ITP-like syndrome.

An accurate assessment of the gestational age should also be carried out. This is important, as some of the etiologies of thrombocytopenia in pregnancy are dependent on the gestational age. A thorough physical examination of the patient should also be performed. The physician should look for the presence of ecchymoses or petechiae. Blood pressure should be determined to ascertain whether the patient has impending preeclampsia. If the patient is developing HELLP syndrome, scleral icterus may be present. The eye grounds should be examined for evidence of arteriolar spasm or hemorrhage.

It is imperative that a peripheral blood smear be examined by an experienced hematologist or pathologist whenever a case of pregnancy-associated thrombocytopenia is diagnosed. This individual must determine if microangiopathic hemolysis is present. This will help in establishing a diagnosis. This specialist can also rule out platelet clumping, which will result in a factitious thrombocytopenia. Other laboratory evaluation should be performed as necessary to rule out preeclampsia and/or HELLP syndrome, as well as disseminated intravascular coagulopathy. If a diagnosis of ITP is entertained, appropriate platelet antibody testing should be performed.

After determining the etiology of thrombocytopenia, the physician can better determine whether imminent delivery is necessary, if the thrombocytopenia should be treated before initiating delivery, or if the low platelet count should be ignored.

THErapy OF THROMBOCYTOPENIA DURING PREGNANCY

Gestational Thrombocytopenia

Gestational thrombocytopenia, the most common form encountered in the third trimester, requires no special therapy. The most important therapeutic issue is to refrain from therapies and testing that may lead to unnecessary intervention or iatrogenic preterm delivery. In patients with mild to moderate thrombocytopenia and no antenatal or antecedent history of thrombocytopenia, the patient should be treated like a normal pregnant patient. If the maternal platelet count drops below $50,000/\text{mm}^3$, the patient may still have gestational thrombocytopenia, but there are not enough data on mothers with counts this low to determine if there are any maternal or fetal risks. These patients, therefore, should be treated as if they have de novo ITP. Although approximately 4 percent of patients have gestational thrombocytopenia, less than 1 percent of uncomplicated pregnant women will have gestational thrombocytopenia with platelet counts less than $100,000/\text{mm}^3$.^[8]

Immune Thrombocytopenic Purpura

Treatment of the gravida with ITP during pregnancy and the puerperium requires attention to both mother and fetus. As in other cases of thrombocytopenia, maternal therapy only needs to be instituted if there is evidence of a bleeding diathesis or to prevent a bleeding complication if surgery is anticipated. Again, there is usually no spontaneous bleeding unless the platelet count falls below $20,000/\text{mm}^3$. Surgical bleeding does not usually occur until the platelet count is less than $50,000/\text{mm}^3$. The conventional forms of raising a platelet count in the patient with ITP include glucocorticoid

1174

therapy, intravenous gammaglobulins, platelet transfusions, and splenectomy.

If the patient is having a bleeding diathesis or if the platelet count is below $20,000/\text{mm}^3$, there is usually a need to raise the platelet count in a relatively short period of time. Although oral glucocorticoids can be used, intravenous glucocorticoids may work more rapidly. Any steroid that has a glucocorticoid effect can be used. However, hematologists have the most experience with methylprednisolone. It can be given intravenously, and it has very little mineralocorticoid effect. It is important to avoid steroids with strong mineralocorticoid effects because these agents can disturb electrolyte balance, cause fluid retention, and result in hypertension. The usual dose of methylprednisolone is 1.0 to 1.5 mg/kg of *total body weight* intravenously daily in divided doses. It usually takes about 2 days to see a response, but it may take up to 10 days to see a maximum response. Even though it does have very little mineralocorticoid effect, there is some present. Because of the large dose that is being administered, it is important to follow the patient's electrolytes. There is little chance methylprednisolone will cause neonatal adrenal suppression because very little crosses the placenta. It is metabolized by placental 11 α -ol-dehydrogenase to an inactive 11-keto metabolite.

After the platelet count has risen satisfactorily using intravenous methylprednisolone, the patient can be switched to oral prednisone. The usual dose is 60 to 100 mg/day. It can be given in a single dose, but there is less gastrointestinal upset with divided doses. The physician can rapidly taper the dose to 30 or 40 mg/day, but slowly thereafter. Since the patient did have a very low platelet count before (or otherwise she would not be undergoing therapy), the physician should titrate the dose to keep the platelet count around $100,000/\text{mm}^3$. If the physician begins therapy with oral prednisone, the usual initial daily dose is 1 mg/kg total body weight. The response rate to glucocorticoids is about 70 percent. It is important to realize that if the patient has been taking glucocorticoids for a period of at least 2 to 3 weeks, she may have adrenal suppression and should undergo increased doses of steroids during labor and delivery in order to avoid an adrenal crisis. Tapering should be slowly thereafter. Also, if the patient has been on glucocorticoids for some time, she may experience significant side effects, including fluid retention, hirsutism, acne, striae, poor wound healing, and monilia vaginitis. In rare circumstances, patients on long-term steroids during gestation can develop osteoporosis or cataract formation. The chance of any fetal or neonatal side effects from the glucocorticoids, however, is remote.

Although glucocorticoids are the mainstays of treating maternal thrombocytopenia, up to 30 percent of patients will not respond to these medications. In this instance, the next medication to use is intravenous immunoglobulin. This agent probably works by binding to the Fc receptors on reticuloendothelial cells and preventing destruction of platelets. It may also adhere to receptors on platelets and prevent antiplatelet antibodies from binding to these sites. The usual dose is 0.4 g/kg/day for 3 to 5 days. However, it may be necessary to use as much as 1 g/kg/day. The response usually begins in 2 to 3 days and usually peaks in 5 days. An alternate regimen is to give 1 g/kg once and observe the patient. Often this single dose will result in an adequate increase in platelets. The length of this response is variable, and the timing of the dose is extremely important. If the obstetrician wants a peak platelet count for delivery, he or she should institute therapy about 5 to 8 days before the planned delivery.

Intravenous immunoglobulin is a blood product, but its method of preparation makes it safe for use. Plasma is thawed and pooled. After the cryoprecipitate is removed, it undergoes Cohn-Oncley cold ethanol fractionation.^[41] This inactivates viruses.^[42] Furthermore, the liquid form is incubated for 21 days at pH 4.25. This removes and inactivates both enveloped and nonenveloped model viruses,^[43] ^[44] including HIV, hepatitis C virus, hepatitis B virus, cytomegalovirus virus, Epstein-Barr virus, and herpes simplex virus. It has also been tested against RNA and DNA nonenveloped viruses.^[45] ^[46] A recent review of the literature uncovered no cases of viral transmission with the liquid formula of immunoglobulin that had been incubated at pH 4.25. Although intravenous immunoglobulin is very expensive, it should be used before contemplating splenectomy, as some patients with ITP will experience remission after delivery.^[47]

In midtrimester, splenectomy can also be used to raise the maternal platelet count. This procedure is reserved for those who do not respond to medical management, with the platelet count remaining below $20,000/\text{mm}^3$. It can be performed postpartum if the patient does not respond to medical management. In extremely emergent cases of life-threatening bleeding or nonresponse, splenectomy can be safely performed at the time of cesarean section after extending a midline incision cephalad.

Platelet transfusions are indicated when there is clinically significant bleeding and while awaiting other therapies to become effective. Platelets can be given if the maternal platelet count is less than $50,000/\text{mm}^3$ during splenectomy, or during cesarean delivery if clinical bleeding is evident. They can be used before a vaginal delivery if the mother's platelet count is less than $20,000/\text{mm}^3$. Each "pack" of platelets will increase the platelet count by approximately $10,000/\text{mm}^3$. The half-life of these platelets is extremely short because the same antibodies and reticuloendothelial cell clearance rates that affect the mother's endogenous platelets will also affect the transfused platelets. However, if these

1175

platelets are transfused at the time the skin incision is made, it will allow enough hemostasis to carry out the surgical procedure.

If the patient with profound thrombocytopenia undergoes cesarean delivery, certain surgical precautions should be taken. The obstetrician should use electrocautery liberally. The bladder flap may be left open in order to avoid hematoma formation. If the parietal peritoneum is closed, subfascial drains are helpful if hemostasis is imperfect.

Although treating maternal thrombocytopenia is fairly straightforward, the need for evaluation of the fetal platelet count and how this information should alter patient management remain controversial. Although papers by Cooke^[49] and Burrows and Kelton^[29] have attempted to show that there is no risk in delivering a profoundly thrombocytopenic fetus vaginally, these meta-analyses are only generalizations. There is no one series large enough from which to draw adequate conclusions concerning mode of delivery of the profoundly thrombocytopenic fetus. There are no randomized studies concerning delivery of these patients. It is not our purpose to recommend a mode of delivery for the profoundly thrombocytopenic fetus, but to outline which fetuses are at risk of being born with thrombocytopenia and to allow the obstetrician to make decisions concerning delivery after discussion with the patient. As previously shown ([Table 34-1](#)), anywhere from 5 to 38 percent of infants born to mothers with ITP will have platelet counts less than 50,000/mm³. Several studies have tried to determine if administering glucocorticoids to the mother may have an effect on raising the fetal platelet count in utero. ^[12], ^[13], ^[15]

Although the study by Karapatkin et al.^[19] was promising, other studies have not corroborated these findings. Furthermore, studies have shown that splenectomy has no bearing on neonatal platelet counts. The study by Samuels et al.^[9] showed that 19.2 percent of ITP patients undergoing no therapy gave birth to profoundly thrombocytopenic infants compared with 22.7 percent of those receiving prednisone alone, 23 percent of those who had undergone a splenectomy and received prednisone, and 17.8 percent of those having undergone only splenectomy. The rate of profound neonatal thrombocytopenia was not significantly different among any of these groups. Even if there is not a difference in perinatal morbidity between vaginal and cesarean delivery, there are advantages of knowing whether a fetus is at risk of being born with a platelet count less than 50,000/mm³. The use of scalp electrodes and vacuum extractors are examples of interventions that may be avoided in the profoundly thrombocytopenic fetus. A prolonged second stage of labor in the nulliparous patient who is carrying a severely thrombocytopenic fetus should probably be avoided. Furthermore, because of the potential neonatal morbidity, it might be safest if the profoundly thrombocytopenic infant were delivered in a tertiary care setting. In the study by Samuels et al.,^[9] there were cases of severe gastrointestinal bleeding, hemopericardium, intraventricular hemorrhage, and severe cutaneous manifestations of bleeding in infants born to mothers with ITP.

The only method currently available to determine the fetal platelet count accurately before the onset of labor (cordocentesis) is both expensive and invasive. Furthermore, it carries an inherent risk of an adverse fetal outcome. Fear of an adverse outcome in the setting of a neonate with an unknown platelet count has led obstetricians to overutilize this invasive testing as well as surgical deliveries. There is almost no place for cordocentesis in the patient with ITP.

In summary, the treatment of thrombocytopenia during gestation is dependent on the etiology. The obstetrician need not act on the mother's platelet count unless it is below 20,000/mm³, or if it is below 50,000/mm³ with evidence of clinical bleeding or if surgery is anticipated. In these cases, the treatment will depend upon the diagnosis. Furthermore, whether delivery needs to be expedited or can be delayed is also dependent on the etiology of thrombocytopenia. The fetal/neonatal platelet count need only be considered if the mother carries a true diagnosis of ITP or, in the case of presumed gestational thrombocytopenia, when the platelet count is less than 75,000/mm³, as this may actually be de novo ITP. The key to managing these patients is to arrive at an accurate etiology for the thrombocytopenia and to approach the patient and her fetus rationally.

MANAGEMENT OF THROMBOTIC THROMBOCYTOPENIC PURPURA AND HEMOLYTIC UREMIC SYNDROME

Before the use of plasma exchange, maternal and fetal outcomes in cases complicated by TTP were uniformly poor.^[34] The first cases treated with plasma exchange for TTP during pregnancy were reported in 1984.^[54] One report described a patient who had previous fetal deaths from chronic TTP and experienced a successful pregnancy when treated with aspirin, dipyridamol, and plasma infusion.^[51] There are no large series of patients with TTP in pregnancy. It does appear, however, through case reports, that the prognosis has improved greatly with plasma infusion and plasma exchange.

HUS has been much more difficult to treat. Only a few case reports have appeared. Supportive therapy remains the mainstay of these treatments.^[34], ^[50] Dialysis is

1176

often necessary with close attention to fluid management. Platelet function inhibitors have also been used in two cases during pregnancy.^[52], ^[53] Plasma infusion and plasma exchange can be attempted, but the results have not been as good as in cases of TTP.^[54] Vincristine has been used with some success in nonpregnant patients but has not been tried with pregnancy, and prostacyclin infusion has been effective in children but has not been used during pregnancy.^[53], ^[55]

Gabbe: Obstetrics - Normal and Problem Pregnancies, 4th ed. , Copyright © 2002 Churchill Livingstone, Inc.

NEONATAL ALLOIMMUNE THROMBOCYTOPENIA

In neonatal alloimmune thrombocytopenia, a rare disorder, the mother lacks a specific platelet antigen and develops antibodies to this antigen. The disease is somewhat analogous to Rh isoimmunization, but involves platelets. If the fetus inherits this antigen from its father, maternal antibody can cross the placenta, resulting in severe neonatal thrombocytopenia. The mother, however, will have a normal platelet count. Deaver and co-investigators ^[56] reviewed 58 cases of neonatal alloimmune thrombocytopenia. The overall mortality rate was 9 percent, and the total incidence of suspected intracranial hemorrhage was 28 percent. The mortality rate was 24 percent for the firstborn infant and only 5 percent for subsequent offspring. The improved outcome in the latter group appeared to be related to more frequent utilization of cesarean delivery and to earlier use of corticosteroids in these children because obstetricians and pediatricians were expecting the disease. ^[56] The most common antibodies noted in these patients are anti-PLA 1 and BAK antibodies. ^[57] Transfusion of maternal platelets into the neonate also improved outcome in these cases. After birth or in utero the child can be transfused with the mother's platelets, since she lacks the antigen that would lead to platelet destruction by circulating antibodies. Bussel and colleagues ^[58] have demonstrated that the antenatal use of intravenous immunoglobulin may help to prevent thrombocytopenia in infants at risk for neonatal alloimmune thrombocytopenia. These investigators administered 1 g/kg per week to at-risk mothers and observed no toxicity. The concomitant use of glucocorticoids has not necessarily been shown to boost the effect of the intravenous immunoglobulin. ^[59] Because of the frequency with which very low platelet counts are encountered in these fetuses, there is a risk of fetal exsanguination with cordocentesis. ^[60] These patients should be cared for in a tertiary care center with experience caring for mothers and infants with this rare disorder.

IRON DEFICIENCY ANEMIA

During a singleton pregnancy, maternal plasma volume gradually expands by approximately 50 percent (1,000 ml). The total red blood cell (RBC) mass also increases, but only by approximately 300 ml (25 percent), and this starts later in pregnancy.^[61] It is not surprising, therefore, that hemoglobin and hematocrit levels usually fall during gestation. These changes are not necessarily pathologic but usually represent a physiologic alteration of pregnancy. By 6 weeks postpartum, in the absence of excessive blood loss during the puerperium, hemoglobin and hematocrit levels have returned to normal.

Most researchers and clinicians diagnose anemia as a hemoglobin less than 11 g/dl or a hematocrit less than 32 percent. Using these criteria, 50 percent of pregnant woman are anemic. The incidence of anemia changes, depending on the population studied. It is unfortunate that this problem is often ignored, as most textbooks are published in industrialized nations, where anemia does not result in major morbidity and mortality. Yet, in the majority of the world, iron deficiency is an overwhelming problem. It does not receive the recognition it needs. It is not one of the "exciting subjects" that warrants significant federal funding in the United States. Yet, worldwide there are many maternal mortalities because of blood loss in women who are already anemic. The arbitrary cutoff for hemoglobin/hematocrit may need to be adjusted. Beaton suggests that these numbers should be adjusted downward and different targets should be established for different times in pregnancy.^[62] Causes of anemia in pregnancy are shown [in the box "Causes of Anemia During Pregnancy."](#)

This is important because as pregnancy progresses, hemoglobin levels are often in the range of 10 to 10.5 g/dl in the late second and early third trimesters. These patients, if iron stores are present, do regain their normal hemoglobin/hematocrit postpartum. Approximately 75 percent of anemias that occur during pregnancy are secondary to iron deficiency.^[61] Ho and co-investigators^[63] performed elaborate hematologic evaluations of 221 term gravidas in Taiwan. None of the studied patients received an added iron preparation during gestation. Of the previously nonanemic patients, 10.4 percent developed clinical anemia after a full-term delivery. Of these 23 patients, 11 (47.8 percent) developed florid iron deficiency anemia, and another 11 developed moderate iron depletion.^[63] The other anemic patients in the group had folate deficiency. Of the 198 nonanemic gravidas at term, 46.5 percent showed evidence of iron depletion even though they had a normal hematocrit.^[63]

To distinguish the normal physiologic changes of pregnancy from those of pathologic iron deficiency, one

must understand the normal iron requirements of pregnancy ([Table 34-2](#)) and the proper use of hematologic laboratory parameters. In adult women, iron stores are located in the bone marrow, liver, and spleen in the form of ferritin. Ferritin constitutes approximately 25 percent (500 mg) of the 2 g of iron stores found in the normal woman. Approximately 65 percent of stored iron is in circulating RBCs.^[61], ^[64] ^[65] ^[66] If the dietary iron intake is poor, the interval between pregnancies is short, or the delivery is complicated by hemorrhage, iron deficiency anemia readily and rapidly develops.

Causes of Anemia During Pregnancy	
Common causes	85% of anemias
	Physiologic anemia
	Iron deficiency
Uncommon causes	
	Folic acid deficiency
	Hemoglobinopathies
	Sickle cell disease
	Hemoglobin SC
	-Thalassemia minor
Rare causes	
	Hemoglobinopathies
	-Thalassemia major
	-Thalassemia
	Vitamin B ₁₂ deficiency
	Syndromes of chronic hemolysis
	Hereditary spherocytosis
	Paroxysmal nocturnal hemoglobinuria
	Hematologic malignancy
	Gastrointestinal bleeding

The first pathologic change to occur in iron deficiency anemia is the depletion of bone marrow, liver, and spleen iron stores. The serum iron level falls, as does the percentage saturation of transferrin. The total iron-binding capacity rises, as this is a reflection of unbound transferrin. A falling hemoglobin and hematocrit follow. Microcytic hypochromic RBCs are released into the circulation. If iron deficiency is combined with folate deficiency, normocytic and normochromic RBCs are observed on the peripheral blood smear.

Care must be taken when using laboratory parameters to establish the diagnosis of iron deficiency anemia during gestation. A serum iron concentration less than 60 mg/dl with less than 16 percent saturation of transferrin is suggestive of iron deficiency. An increase in iron-binding capacity, however, is not reliable, as 15 percent of pregnant women without iron deficiency will show an increase in this parameter.^[67] Serum ferritin levels normally decrease mildly during pregnancy. A significantly reduced ferritin concentration is also indicative of iron deficiency anemia and is the best parameter with which to judge the degree of iron deficiency. Ferritin levels, however, can change 25 percent from one day to the next.^[68] Harthoorn-Lasthuizen et al. examined erythrocyte zinc protoporphyrin testing in pregnancy.^[69] They found that serum ferritin levels did not predict the development of iron deficient erythropoiesis. However, erythrocyte zinc protoporphyrin measurements did help determine which patients were developing iron deficiency before they developed frank anemia. These patients will benefit from iron therapy.^[69] Van den Broek et al. felt that the erythrocyte zinc protoporphyrin level was not particularly helpful and that a serum ferritin of less than 30 g/L is more than adequate to determine iron deficiency.^[70] If a patient has been iron deficient for an extended period of time, her serum iron level can rise before she has depleted her iron stores. Also, if she takes a few iron pills before her prenatal visit, her serum iron level can rise to normal while her ferritin is still low. The ferritin level, at least, will indicate the total status of her iron stores.

Ahluwalia^[71] feels that measuring serum transferrin receptors can give a better index of true iron status. Ferritin can be elevated in acute and chronic infections and transferrin receptors do not change in response to an infection. This is important in countries where chronic infection is common in pregnant women. Also, receptor concentrations are not confounded by the hemodynamic changes of pregnancy. This test is not yet readily available but may help us in the future to detect iron-deficient patients.^[71] When hematologic parameters remain confusing, bone marrow aspiration usually provides the definitive diagnosis. The procedure, however, is rarely necessary.

Whether all women should receive prophylactic iron during pregnancy remains controversial. Long^[72] believes that physiology is responsible for much of the decrease in hematocrit and, unless the patient is symptomatic or the hematocrit is very low, iron supplementation is unnecessary. Millman et al.^[73] in reviewing the Cochrane database, found that 20 percent of fertile women have iron stores greater than 500 mg, which is the required minimum for pregnancy. They also noted that 40 percent of women have iron stores between 100 and 500 mg, and 40 percent have virtually no iron stores. This shows that the majority of individuals do need some iron supplementation.^[73]

TABLE 34-2 -- IRON REQUIREMENTS FOR PREGNANCY AND THE PUERPERIUM

Increased red blood cell mass	450 mg
Fetus and placenta	360 mg
Vaginal delivery	190 mg
Lactation	1 mg/day

1178

TABLE 34-3 -- ELEMENTAL IRON AVAILABLE FROM COMMON GENETIC IRON PREPARATIONS

Preparation	Elemental Iron (mg)
Ferrous gluconate, 325 mg	3739
Ferrous sulfate, 325 mg	6065
Ferrous fumarate, 325 mg	107

In pregnancy, iron absorption from the duodenum increases, providing 1.3 to 2.6 mg of elemental iron daily.^[74],^[75] Iron is absorbed in the duodenum, and an acid environment helps this absorption. Therefore, the frequent use of antacid medications, commonly used by many patients, decreases the absorption of iron. Vitamin C, in addition to the iron, may increase the acid environment of the stomach and increase absorption. In patients who do not show clear signs of iron deficiency, it is uncertain whether prophylactic iron, in addition to what is in prenatal vitamins, leads to an increased hemoglobin concentration at term. Iron prophylaxis, however, is safe. With the exception of dyspepsia and constipation, side effects are few. One 325-mg tablet of ferrous sulfate daily provides adequate prophylaxis. It contains 60 mg of elemental iron, 10 percent of which is absorbed. If the iron is not needed, it will not be absorbed and will be excreted in the feces. The standard generic iron tablets and the amount of elemental iron they provide are listed [in Table 34-3](#).

In iron-deficient patients, one iron tablet three times daily is recommended. I cannot ascertain the scientific source of this recommendation. Most individuals can absorb as much iron as they need taking iron twice daily. It should be taken 30 minutes before meals to allow maximum absorption. However, when taken in this manner, dyspepsia and nausea are more common. Therapy, therefore, must be individualized to maximize patient compliance.

Zavaleta et al. examined the use of zinc in addition to iron, since it is thought that zinc may help with hematopoiesis. They found that zinc, in addition to iron, did not increase the hemoglobin concentration in patients.^[76] Young et al. studied the effectiveness of weekly iron supplementation as opposed to daily iron supplementation.^[77] They found that weekly iron supplementation was almost as effective as daily supplementation in raising the hemoglobin concentration in iron-deficient patients. This approach can be used in patients with less than optimal compliance.

For those patients who are noncompliant or are unable to take oral iron and are severely anemic, intravenous iron can be given. Singh et al.^[78] found that parenteral iron can be safely given and significantly raises the hematocrit in patients. It also raises the serum ferritin. There were no adverse effects in their study of patients.^[78] Hallak et al.^[79] looked at the safety and efficacy of parenteral iron administration. They administered parenteral iron to 26 patients. Only one patient developed signs of mild allergy during the test dose and was excluded from the study. The remaining 21 pregnant patients completed the course of therapy and received a mean of 1,000 mg of elemental iron. Their hemoglobin increased an average of 1.6 g/dl from the beginning to the end of therapy and rose another 0.8 g/dl during the following 2 weeks. Ferritin levels increased from 2.9 ng/ml at the beginning of therapy to 122.8 ng/ml by the end of therapy.^[79] Ferritin levels only decreased to a mean of 109.4 ng/ml 2 weeks later. Only mild transient side effects were noted. The authors concluded that parenteral iron therapy is safe during pregnancy.^[79]

Iron dextran comes in a concentration of 50 mg/ml. It can be given intramuscularly or intravenously. Intramuscular injection is very painful. Parenteral iron is indicated in those who cannot or will not take oral iron therapy and are not anemic enough to require transfusion. In fact, by building iron stores in the patients before delivery, we may be able to prevent a need for transfusion postpartum in the severely anemic patient. Unfortunately, iron dextran can cause anaphylaxis, which is caused by dissociation of the iron component and carbohydrate component. The reaction may be immediate or delayed. Therefore, a 0.5-ml test should be given and epinephrine should be readily available. This anaphylaxis usually occurs within several minutes but may take 2 days to develop. The dosage for iron dextran therapy is shown [in the box "Iron Dextran Administration."](#)

It is still not certain whether anemia results in an increased risk for poor pregnancy outcome. In a literature review, Scholl and Hediger^[80] concluded that anemia diagnosed in early pregnancy is associated with preterm delivery and low birth weight. In this study, women with iron deficiency anemia had twice the risk of preterm delivery and thrice the risk of delivering a low-birth-weight infant.^[80] Preterm labor, however, is a multifactorial problem, and there were many confounders in this study.

Iron Dextran Administration

$$\text{Dose(ml)} = 0.0442 (\text{Desired hgb} - \text{Observed hgb}) \times \text{LBW} + (0.26 \times \text{LBW})$$

hgb, hemoglobin; LBW, Lean body weight.

Yip^[81] reviewed the literature concerning pregnancy outcome with anemia. He found through epidemiologic studies that there is an association between moderate anemia and poor perinatal outcome, yet he was unable to determine whether this relationship was causal. ^[81] Sifakis and Pharmakides^[82] observed that hemoglobin concentrations less than 6 g/dl are associated with preterm birth, spontaneous abortion, low birth weight, and fetal deaths. Nevertheless, a mild to moderate anemia did not appear to have any significant effect on fetal outcome. ^[82] Hemminki and Starfield^[83] reviewed controlled trials, concluding that routine iron administration did not decrease preterm labor or raise birth weight. Conversely, Stephansson et al. found an increased risk of stillbirth and growth-restricted infants in women with hemoglobin concentrations greater than 14.6 g/dl at their first prenatal visit. ^[84]

In summary, iron deficiency is very prevalent in the general pregnant population. In developing nations, it is alarmingly common and is a major cause of maternal morbidity and mortality. Routine iron administration should be used unless it is certain that the patient is iron replete. Iron prophylaxis can be taken as 1 iron tablet daily, or as one study showed, can be given on a weekly basis. There appears to be an association between poor pregnancy outcome and maternal anemia, especially severe anemia. It is uncertain, however, if this is a causal relationship.

FOLATE DEFICIENCY

Folic acid, a water-soluble vitamin, is found in green vegetables, peanuts, and liver. Folate stores are located primarily in the liver and are usually sufficient for 6 weeks. After 3 weeks of a diet deficient in folate, the serum folate level falls. Two weeks later, hypersegmentation of neutrophils occurs. After 17 weeks without folate ingestion, RBC folate levels drop. In the next week a megaloblastic bone marrow develops. During pregnancy, folate deficiency is the most common cause of megaloblastic anemia, as vitamin B₁₂ deficiency is extremely rare. The daily folate requirement in the nonpregnant state is approximately 50 g, but this rises three- to fourfold during gestation.^[85] Fetal demands increase the requirement, as does the decrease in the gastrointestinal absorption of folate during pregnancy.^[86]

Clinical megaloblastic anemia seldom occurs before the third trimester of pregnancy. If the patient is at risk for folate deficiency or has mild anemia, an attempt should be made to detect this disorder before megaloblastosis occurs. Serum folate and RBC folate levels are the best tests for folate deficiency.^[87]

Folate deficiency rarely occurs in the fetus and is not a cause of significant perinatal morbidity. There is some evidence that fetuses that are homozygous for the C677T variant of the gene encoding for 5, 10-methylene tetrahydrofolate reductase have a 20 percent lower folate level and may be at risk for a neural tube defect.^[88] Because infants born to pregestational diabetic mothers have an increased incidence of neural tube defects, Kaplan et al.^[89] studied 31 pregnant diabetics and 54 controls to determine if there are aberrations in folate metabolism in patients with diabetes. They found that there were no differences in how ingested folate is processed in the diabetic pregnant patient.^[89] Maternal morbidity, however, may result from the anemia, especially if the patient additionally suffers significant blood loss during the puerperium. Prenatal vitamins that require physician prescription contain 1 mg of folic acid. Most nonprescription prenatal vitamins contain 0.8 mg of folic acid. These amounts are more than adequate to prevent and treat folate deficiency. Women with significant hemoglobinopathies, patients ingesting anticonvulsant medications, women carrying a multiple gestation, and women with frequent conception may require more than 1 mg supplemental folate daily. If the patient is folic acid deficient, her reticulocyte count will be depressed. Within 3 days after the administration of sufficient folic acid, reticulocytosis usually occurs. In fact, folic acid deficiency should be considered when a patient has unexplained thrombocytopenia. (Leukopenia and thrombocytopenia, which accompany megaloblastosis, are rapidly reversed.) The hematocrit level may rise as much as 1 percent per day after 1 week of folate replacement.

Vollset et al.^[90] performed a retrospective analysis of 14,492 pregnancies in 5,883 women in Norway to determine if elevated homocysteine levels were associated with pregnancy complications. An elevated homocysteine level is often found with depressed folate levels. They compared those in the upper quartile homocysteine levels with those in the lower quartile. They noted a 32 percent (odds ratio: 1.32) higher risk for preeclampsia, 38 percent (odds ratio: 1.38) higher risk for prematurity, and a 10 percent (odds ratio: 2.01) higher risk for very low birth weight. All trends were statistically significant, but the limitations inherent in retrospective epidemiologic studies apply here.^[90] Nelen et al.^[91] found a relation between recurrent early pregnancy loss and genetic-related disturbances in folate and homocysteine metabolism.

Iron deficiency is frequently concomitant with folic acid deficiency. If a patient with folate deficiency does not develop a significant reticulocytosis within 1 week after administration of sufficient replacement therapy, appropriate tests for iron deficiency should be performed.

HEMOGLOBINOPATHIES

Since the last edition of this text, there has not been much change in the care of pregnant patients with sickle cell disease. The majority of research has focused on prenatal diagnosis of hemoglobinopathies.

Hemoglobin is a tetrameric protein composed of two pairs of polypeptide chains with a heme group attached to each chain.^[92] The normal adult hemoglobin A₁ comprises 95 percent of hemoglobin. It consists of two α -chains and two β -chains. The remaining 5 percent of hemoglobin usually consists of hemoglobin A₂ (containing two α -chains and two δ -chains) and/or hemoglobin F (with two α -chains and two γ -chains). In the fetus, hemoglobin F (fetal hemoglobin) declines during the third trimester of pregnancy, reaching its permanent nadir several months after birth. Hemoglobinopathies arise when there is a change in the structure of a peptide chain or a defect in the ability to synthesize a specific polypeptide chain. The patterns of inheritance are often straightforward. The prevalences of the most common hemoglobinopathies are listed in Table 34-4.

Hemoglobin S

Hemoglobin S, an aberrant hemoglobin, is present in patients with sickle cell disease (hemoglobin SS) and sickle cell trait (hemoglobin AS). A single substitution of valine for glutamic acid at the sixth position in the β -polypeptide chain causes a significant change in the physical characteristics of this hemoglobin. At low oxygen tensions, RBCs containing hemoglobin S assume a sickle shape. Sludging in small vessels occurs, resulting in microinfarction of the affected organs. Sick cells have a life span of 5 to 10 days, compared with 120 days for a normal RBC. Sickling is triggered by hypoxia, acidosis, or dehydration. Infants with sickle cell anemia show no signs of the disease until the concentration of hemoglobin F falls to adult levels. Some patients do not experience symptoms until adolescence.

TABLE 34-4 -- FREQUENCY OF COMMON HEMOGLOBINOPATHIES IN AFRICAN-AMERICAN ADULTS IN THE UNITED STATES

Hemoglobin Type	Frequency
Hemoglobin AS	1 in 12
Hemoglobin SS	1 in 708
Hemoglobin AC	1 in 41
Hemoglobin CC	1 in 4,790
Hemoglobin SC	1 in 757
Hemoglobin S/-thalassemia	1 in 1,672

Approximately 1 of 12 African-American adults in the United States is heterozygous for hemoglobin S and, therefore, has sickle cell trait (hemoglobin AS) and carries the affected gene. These individuals generally have 35 to 45 percent hemoglobin S and are asymptomatic. The child of two individuals with sickle cell trait has a 50 percent probability of inheriting the trait and a 25 percent probability of actually having sickle cell disease. One of every 625 African-American children born in the United States is homozygous for hemoglobin S, and the frequency of sickle cell disease among adult African-Americans is 1 in 708.^[93] I recommend that all at-risk patients undergo hemoglobin electrophoresis. Although it is more expensive, it will identify all patients with aberrant hemoglobin types. Chasen et al.^[94] disagree with this protocol. By looking at RBC indices and sickle solubility testing, they saved \$18 per patient. Using this testing, they missed only 4 of 36 carriers of a hemoglobinopathy.^[95] I do not recommend this. In many practices, ancillary personnel often initially review and file laboratory test results. The interpretation of RBC indices is often confusing to the nonphysician.

The traditional teaching is that women with sickle cell trait are not at increased risk for maternal and perinatal morbidity. A study by Larrabee and Monga^[96] question this. In their study, 162 women with hemoglobin AS had a 24.7 percent incidence of preeclampsia compared with 10.3 percent of controls. Furthermore, the mean birth weight of infants born to women with hemoglobin AS was 3,082 g compared with 3,369 g for controls ($p < 0.0001$). The rate of endometritis was 12.3 percent for sickle trait patients compared with 5.1 percent for controls ($p < 0.001$) despite similar rates for cesarean delivery.^[97] This study indicates that our surveillance should be higher in patients with hemoglobin AS.

If a patient has hemoglobin AS, the spouse should be tested, and if both are carriers of a hemoglobinopathy, prenatal diagnosis should be offered. Prenatal diagnosis can be performed by DNA analysis with the polymerase chain reaction (PCR) and Southern blotting.^[96],^[97] PCR amplification of DNA fragments can allow a more rapid laboratory diagnosis. Hemoglobin S can also be identified by hemoglobin electrophoresis and DNA analysis of fetal blood.^[98] Wang et al.^[99] reported on 500 prenatal diagnoses of sickle cell disease, 196 utilizing only Southern blotting and 304 utilizing PCR. PCR greatly shortened the time interval from sampling to diagnosis and resulted in an overall fourfold increase in diagnoses. They showed that a diagnosis made prior to 20 weeks' gestation increased the likelihood that the patient would elect pregnancy termination.^[99] The odds ratio of termination in cases with earlier relative to later diagnosis was 4.7.

Painful vaso-occlusive episodes involving multiple organs are the clinical hallmark of sickle cell anemia. The

most common sites for these episodes are the extremities, joints, and abdomen. Vaso-occlusive episodes can also occur in the lung, resulting in pulmonary infarction. Analgesia, oxygen, and hydration are the clinical foundations for treating these painful crises.

Sickle cell disease can affect virtually all organ systems. Osteomyelitis is common, and osteomyelitis caused by *Salmonella* is found almost exclusively in these patients. The risk of pyelonephritis is increased. Sickling may also occur in the renal medulla, where oxygen tension is reduced, resulting in papillary necrosis. These patients also exhibit renal tubular dysfunction and hyposthenuria. Because of chronic hemolysis and decreased RBC survival, patients with sickle cell anemia often demonstrate some degree of jaundice. Biliary stasis commonly occurs during crises, and cholelithiasis is seen in about 30 percent of cases.^[100],^[101] Because of chronic anemia, high-output cardiac failure can occur. Left ventricular hypertrophy and cardiomegaly are not uncommon.

Many pregnancies complicated by sickle cell anemia are associated with poor perinatal outcomes. The rate of spontaneous abortion may be as high as 25 percent.^[102]^[103]^[104] Perinatal mortality rates of up to 40 percent were reported in the past, but the current estimate is approximately 15 percent.^[103]^[104]^[105]^[106]^[107]^[108] Powars and co-workers^[109] studied 156 pregnancies in 79 women with sickle cell anemia. In this group, the perinatal mortality rate was 52.7 percent before 1972 and 22.7 percent after that time. In a report by Seoud and co-workers,^[110] the perinatal mortality rate was 10.5 percent. Much of this poor perinatal outcome is related to preterm birth. Approximately 30 percent of infants born to mothers with sickle cell disease have birth weights below 2,500 g.^[108] In the Seoud et al.^[110] report, the mean birth weight was 2,443 g.^[110] In a multicenter study, Smith et al.^[111] reported that 21 percent of infants born to mothers with sickle cell disease were small for gestational age. It has been hypothesized that sickling in the uterine vessels may lead to decreased fetal oxygenation and intrauterine growth restriction.^[112] Classic teaching is that increased levels of hemoglobin F in the mother spared her from increased painful crises during pregnancy and may also have a protective effect on the neonate. In a study by Anyaegbunam and colleagues,^[113] hemoglobin F levels, however, were inversely correlated with birth weight percentile. In contrast, Morris et al.^[114] studied 270 singleton pregnancies in 175 women with sickle cell disease. The overall fetal wastage rate was 32.2 percent. Mothers with high hemoglobin F levels had a significantly lower perinatal mortality rate. This finding may have real clinical significance for obstetricians in the future. Ohne-Frempong and Smith-Whitley^[115] reviewed the use of hydroxyurea in children with sickle cell disease. This drug reduces the incidence of painful crises and increases hemoglobin F concentration.^[115] The safety of this drug in pregnancy has not been established. Further studies of its use in sickle cell disease are underway.

Stillbirth rates of 8 to 10 percent have been described in patients with sickle cell anemia.^[103] These fetal deaths happen not only during crises but also unexpectedly. Careful antepartum fetal testing must therefore be utilized, including serial ultrasonography to assess fetal growth. In another study, Anyaegbunam and co-workers^[116] studied Doppler flow velocimetry in patients with hemoglobinopathies. They showed abnormal systolic/diastolic ratios for the uterine or umbilical arteries in 88 percent of patients with hemoglobin SS compared with 7 percent with hemoglobin AS and 4 percent with hemoglobin AA. However, only 8 patients with hemoglobin SS were studied compared with 40 patients with hemoglobin AS and 48 women with hemoglobin AA.^[116] Howard et al. showed that maternal exchange transfusions did not change uteroplacental Doppler blood flow velocimetry in these patients.^[117] This demonstrates that although maternal well-being may be improved, there is no change in uteroplacental pathology.

Although maternal mortality is rare in patients with sickle cell anemia, maternal morbidity is great. Infections are common, occurring in 50 to 67 percent of women with hemoglobin SS. Most are urinary tract infections (UTIs), which can be detected by frequent urine cultures. Patients with hemoglobin AS are also at greater risk for a UTI and should be screened as well. Pulmonary infection and infarction are also common. Patients with sickle cell anemia should receive pneumococcal vaccine before pregnancy. Any infection demands prompt attention, because fever, dehydration, and acidosis will result in further sickling and painful crises. The incidence of pregnancy-induced hypertension is increased in patients with sickle cell anemia and may complicate almost one third of pregnancies in these patients.^[106]^[111] Painful crises also appear to be more common during gestation.^[118]^[119] This was not true, however, in one study.^[111]

The care of the pregnant patient with sickle cell anemia must be individualized and meticulous. These patients will benefit from care in a medical center experienced in treating the multitude of problems that can complicate such pregnancies. From early gestation, good dietary habits should be promoted. A folate supplement of at least 1 mg/day should be administered as soon as pregnancy is confirmed. Although hemoglobin and hematocrit levels are decreased, iron supplements need not be routinely given. Serum iron and ferritin levels should be checked monthly and iron supplementation started only when these levels are diminished. Abudu and co-workers^[120] found that serum ferritin values were significantly higher in pregnant women with hemoglobin SS disease than in those with hemoglobin AA. They concluded that the physiologic changes of

pregnancy in patients with hemoglobin SS did not result in an iron deficiency state and that the use of prophylactic iron supplementations in these patients appears unjustified. Aken'Ova et al. found that ferritin and iron levels decreased in pregnant patients with sickle cell disease in Nigeria.^[121] This points out that iron and ferritin levels should be checked during pregnancy. It must be emphasized that routine iron supplementation, even that in the prenatal vitamins, should not be given, as iron overload may lead to hemochromatosis.

The role of prophylactic transfusions in the gravida with sickle cell anemia is controversial. This therapy, which replaces the patient's sickle cells with normal RBCs, can both improve oxygen-carrying capacity and suppress the synthesis of sickle hemoglobin. A previous study showed a sevenfold reduction in perinatal mortality in patients receiving prophylactic transfusions.^[122] In the same group of patients, there was a significant decrease in fetal growth restriction and preterm births. Morrison and co-workers^[123] have also previously reported reduced perinatal wastage and maternal morbidity using a regimen of exchange transfusion. In contrast, workers at Johns Hopkins believe that meticulous prenatal care gives results as favorable as those obtained with prophylactic transfusion.^[102] Many patients in that series, however, did require transfusion for painful crises and anemia. Koshy and co-investigators^[124] followed 72 pregnant patients with sickle cell anemia, one half of whom received prophylactic transfusions and one half transfusions only for medical or obstetric emergencies. There was no significant difference in perinatal outcome between the offspring of mothers who received prophylactic transfusions and those who did not. Two risk factors were identified as harbingers of an unfavorable outcome: (1) the occurrence of a perinatal death in a previous pregnancy and (2) twins in the present pregnancy. Even though there was no difference in perinatal morbidity and mortality, prophylactic transfusion did appear to decrease significantly the incidence of painful crises. The investigators concluded that the omission of prophylactic RBC transfusion will not harm pregnant patients with sickle cell disease or their offspring.^[124]

Tuck and co-workers^[125] delineated the risks involved with exchange transfusion. In a study of 51 pregnancies transfused between 1978 and 1984, 22 percent developed atypical red cell antibodies and 14 percent had immediate minor transfusion reactions. These data showed no significant difference in maternal or fetal outcomes among patients who were transfused prophylactically and those who were not.^[125] Mahomed^[126] reviewed the Cochrane database and found there is not enough evidence to make any conclusions about the use of prophylactic RBC transfusion in patients with sickle cell disease. Many of the studies cited in this chapter did not show fetal benefits from exchange transfusion. They did not, however, attempt to quantify changes in maternal well-being. This needs to be carefully evaluated before stating that prophylactic transfusions should be eliminated from the care of the pregnant patient with sickle cell disease.

If one chooses to perform prophylactic transfusion, the goal is to maintain a percentage of hemoglobin A above 20 percent at all times and preferably above 40 percent, as well as to maintain the hematocrit above 25 percent. Morrison et al.^[123] recommend that prophylactic transfusion begin at 28 weeks' gestation. Buffy-coat-poor washed RBCs are used to reduce the risk of isosensitization. Other risks of transfusion therapy include hepatitis, acquired immunodeficiency syndrome (AIDS), transfusion reactions, and hemochromatosis. HIV antibody testing and new tests for hepatitis C have made transfusions much safer.

Either booster or exchange transfusions can be used. Exchange transfusions are preferable because they result in less stress on the cardiovascular system, thus decreasing the possibility of congestive heart failure. Exchange transfusions also raise the percentage of hemoglobin A more efficiently. If only booster transfusions are utilized, diuretics should probably be administered to prevent fluid overload. Exchange transfusion can easily be performed by the pheresis unit of the hospital. This is faster and safer than older techniques. The patient should be positioned on her left side during the procedure to maximize uterine blood flow.

Vaginal delivery is preferred for patients with sickle cell disease. Cesarean delivery should be reserved for obstetric indications. Patients should labor in the left lateral recumbent position and receive supplemental oxygen. Although adequate hydration should be maintained, fluid overload must be avoided. Conduction anesthesia is recommended, as it provides excellent pain relief and can be used for cesarean delivery, if necessary. [Figure 34-1](#) provides a schematic presentation for the care of patients with sickle cell anemia. It can be adapted to patients with other hemoglobinopathies.

Hemoglobin SC Disease

Hemoglobin C is another -chain variant in which lysine is substituted for glutamic acid in the sixth position. Clinically significant hemoglobin SC disease occurs in 1 in 833 African-American adults in the United States.^[93] Women with both S and C hemoglobin suffer less morbidity in pregnancy than do patients with only hemoglobin S.^[99]^[102]^[104] As in sickle cell disease, however, there is an increased incidence of early spontaneous abortion and pregnancy-induced hypertension.^[102]^[103]^[104]^[105]

Because patients with SC disease can have only mild symptoms, the hemoglobinopathy may remain undiagnosed until they suffer a crisis during pregnancy. These

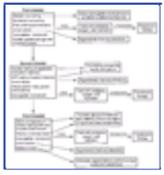

Figure 34-1 Schematic presentation of the care of patients with sickle cell anemia.

crises may be marked by sequestration of a large volume of RBCs in the spleen accompanied by a dramatic fall in hematocrit. ^[127], ^[128] Because these patients have increased splenic activity, they may be mildly thrombocytopenic throughout pregnancy. During gestation, patients with hemoglobin SC should receive the same program of prenatal care outlined for women with hemoglobin SS.

Thalassemia

Thalassemia results from a defect in the rate of globin chain synthesis. Any of the polypeptide chains can be affected. The disease may range from minimal suppression of synthesis of the affected chain to its complete absence. Either α - or β -thalassemia can occur. Heterozygous patients are often asymptomatic. Thalassemia can be detected by prenatal diagnosis. Wainscoat and co-workers ^[129] were able to offer prenatal diagnosis to 19 of 25 families with a potential for α -thalassemia using linkage analysis of restriction fragment length polymorphisms (RFLP). Cao and colleagues ^[130] reported their experience with prenatal diagnosis of α -thalassemia in 1,000 pregnancies followed at least 12 months after birth. Fetal blood sampling was carried out by placental aspiration, which yielded a sufficient amount of blood in 99 percent of cases. The fetal mortality rate associated with the fetal blood sampling, however, was 6.3 percent. With improvement in chorionic villous sampling and cordocentesis, prenatal diagnosis is now safe and the loss rate is much lower. Focharoen and co-workers ^[131] have been able to diagnose α -thalassemia in the second trimester by in vitro protein synthesis. They detect α -thalassemia by gene amplification in the first trimester.

Homozygous α -thalassemia results in the formation of tetramers of α -chains known as hemoglobin Bart. This hemoglobinopathy can result in hydrops fetalis. Ghosh

and co-investigators ^[132] reported their experience with 26 Chinese women who were at risk of giving birth to a fetus with homozygous α -thalassemia. Six of the 26 fetuses were affected. In two of the six cases, progressive fetal ascites appeared before 24 weeks' gestation. These pregnancies were terminated and the diagnoses confirmed. In the remaining four cases, there was evidence of intrauterine growth restriction by 28 weeks' gestation. At later gestational ages, an increase in the transverse cardiac diameter was seen in the affected fetuses. ^[132] Woo and colleagues ^[133] reported that umbilical artery velocimetry reveals a hyperdynamic circulatory state in fetuses that are hydropic because of α -thalassemia. In a study from Taiwan, Hsieh et al. ^[134] demonstrated that umbilical vein blood flow measurements can help to distinguish hydrops fetalis caused by hemoglobin Bart from hydrops fetalis having other causes. The umbilical vein diameter, blood velocity, and blood flow in fetuses with hemoglobin Bart were usually higher than those in fetuses with hydrops fetalis having other etiologies.

β -Thalassemia is the most common form of thalassemia. Patients with the heterozygous state are usually asymptomatic. They are detected by an increase in their level of hemoglobin A_2 . In the homozygous state, synthesis of hemoglobin A_1 may be completely suppressed. This condition is characterized by an increase in both hemoglobin F and hemoglobin A_2 . The homozygous state of β -thalassemia is known as thalassemia major, or Cooley's anemia. Patients with this disorder are transfusion dependent and have marked hepatosplenomegaly and bone changes secondary to increased hematopoiesis. These individuals usually die of infectious or cardiovascular complications before they reach childbearing age. Successful full-term pregnancies have been reported. ^[135] The few patients who do become pregnant generally exhibit severe anemia and congestive heart failure. Prenatal care is dependent on transfusion therapy similar to that used in the care of the patient with sickle cell disease.

Heterozygous β -thalassemia has different forms of expression. Patients with thalassemia minima have microcytosis but are asymptomatic. Those with thalassemia intermedia exhibit splenomegaly and significant anemia and may become transfusion dependent during pregnancy. Their anemia can be significant enough to produce high-output cardiac failure. ^[136] If these patients have not undergone splenectomy, they are at risk for a hypersplenic crisis. ^[137] Also, extramedullary hematopoiesis may impinge upon the spine, resulting in neurologic symptoms. ^[138]

These patients should be managed with a treatment program similar to that followed for patients with sickle cell disease. As in the case of sickle hemoglobinopathies, iron supplementation should only be given if necessary, as indiscriminate use of iron can lead to hemochromatosis. White and co-workers ^[139] have shown that patients with β -thalassemia usually have a much higher ferritin concentration than normal patients and those who are β -thalassemia carriers. In β -thalassemia carriers, the incidence of iron deficiency anemia is four times less common than it is in β -thalassemia carriers and normal patients. ^[139] Van der Weyden and co-workers ^[140] have convincingly shown that red cell ferritin and plasma ferritin can be used in combination to determine if a patient has a potential for iron overload. Although iron is not necessary, folic acid supplementation appears important in β -thalassemia carriers. Leung and co-investigators ^[141] showed that the daily administration of folate significantly increased the predelivery hemoglobin concentration in both nulliparous and multiparous patients.

As in the case of sickle cell disease, antepartum fetal evaluation is essential in patients with thalassemia who are anemic. Asymptomatic thalassemia carriers need no special testing. However, patients with thalassemia should undergo frequent ultrasonography to assess fetal growth, as well as nonstress testing to evaluate fetal well-being.

Occasionally, individuals will inherit two hemoglobinopathies, such as sickle cell thalassemia (hemoglobin S β thal). The prevalence of this disorder among adult blacks in the United States is 1 in 1,672. ^[142] The clinical course is variable. If minimal suppression of β -chains occurs, patients may be free of symptoms. However, with total suppression of β -chain synthesis, a clinical picture similar to that of sickle cell disease will develop. The course of these patients during pregnancy is quite variable, and their therapy must be individualized.

In summary, [Figure 34-2](#) presents a stepwise approach to the work-up of anemia and the diagnosis of the conditions discussed in this chapter.

Von Willebrand's Disease

Von Willebrand's disease (vWD) is the most common congenital bleeding disorder in humans, and up to 1 percent of the population may have some form of the disorder. ^[143] Type 1 is an autosomal dominant disorder, whereas type 3 and occasionally type 2 are autosomal recessive. ^[144] Von Willebrand's disease is related to quantitative and/or qualitative abnormalities of von Willebrand's factor (vWF). This multimeric glycoprotein serves as carrier protein of factor VIII, an essential co-factor of coagulation in plasma, and promotes platelet adhesion to the damaged vessel and platelet aggregation. Distinct abnormalities of vWF are responsible for the three types of vWD. Types 1 and 3 are characterized by a quantitative defect of vWF, whereas type 2, comprising subtypes 2A, 2B, 2M, and 2N, refers to molecular variants with a qualitative defect of vWF. The knowledge of the structure of the vWF gene and

Figure 34-2 Evaluation of anemia.

the use of PCR have led to the identification of the molecular basis of vWD in a significant number of patients. ^[145] In type 2B, the only clinical symptom in pregnancy may be thrombocytopenia. This diagnosis, therefore, should be considered in the gravida presenting with isolated thrombocytopenia during pregnancy. ^[146], ^[147]

The clinical severity of von Willebrand's disease is quite variable. Menorrhagia, easy bruising, gingival bleeding, and epistaxis are common. Menorrhagia is most severe in patients with type 2 and 3 vWD and most common in patients with type 1 disease.^[148] In a compilation of two studies, 17 percent of women presenting with severe menorrhagia had a form of vWD.^[148] Some patients may be entirely asymptomatic until they have severe bleeding after surgery or trauma.

Classically, the bleeding time is prolonged in patients with von Willebrand's disease as a result of diminished platelet aggregation. Occasionally, the activated partial thromboplastin time (APTT) will also be abnormal. In pregnancy, clotting factors including the factor VIII complex increase, and the patient's bleeding time may improve as gestation progresses.^[148], ^[149] This is especially true for type 1A von Willebrand's disease. In type 1B, the patient may not correct her bleeding time.^[150] In type 2B, the platelet count will decrease. There will, however, be an improvement in the von Willebrand's factor multimeric pattern.^[151] Heavy bleeding may be encountered in patients with von Willebrand's disease undergoing elective or spontaneous first-trimester abortion because the levels of factor VIII have not yet risen.^[152] Von Willebrand's disease does not appear to affect fetal growth or development. Postpartum hemorrhage may be a serious problem. The concentration of factor VIII C appears to determine the risk of hemorrhage. If the factor VIII C level is greater than 50 percent of normal and the patient has a normal bleeding time, she should not bleed excessively at vaginal delivery.^[150], ^[153] ^[154] ^[155] In a study by Kadir et al.,^[152] 18.5 percent of patients with vWD experienced a significant postpartum hemorrhage, and 6 to 31 patients required transfusion. The clinical course during labor is quite variable. In a study by Chediak and co-workers,^[156] bleeding complications were seen in six of eight (75 percent) pregnancies. Five of the newborns had von Willebrand's disease, one of whom was born with a scalp hematoma. Conti and associates,^[157] conversely, reported no bleeding complications during the puerperium in five women with von Willebrand's disease. Ieko and colleagues^[158] demonstrated that factor VIII concentrate could raise the platelet levels in patients with type 2B von Willebrand's disease. Ito et al. followed six women with type 1 vWD in 10 term pregnancies, 3 induced abortions, and 1 spontaneous abortion.^[159] They found that bleeding complications occurred within 1 week after term delivery and immediately after both spontaneous and induced abortions.

Cryoprecipitate was, for many years, the treatment of

choice, as it contains all forms of both factor VIII C and the ristocetin cofactor. In those not responding to desmopressin, plasma-derived factor VIII/von Willebrand's factor concentrates should be used.^[144] These concentrates can be treated with virucidal agents. The medium-purity and high-purity forms should be used, as they contain the most variety of multimers. Desmopressin (DDAVP) is the treatment of choice for type 1 von Willebrand's disease.^[160] It elicits the release of von Willebrand's factor from endothelial cells. Intranasal preparations of 300 µg are usually used. In emergent or preoperative situations, 0.3 µg/kg can be given intravenously over 30 minutes.^[144] It can rarely cause hyponatremia and fluid retention.

Bleeding during pregnancy is rare. Patients with classic type 1 von Willebrand's disease usually need no treatment with the increase in factor VIII levels during pregnancy. Those with a history of postpartum hemorrhage should be given an intravenous dose of desmopressin immediately after delivery, and the dose should be repeated 24 hours later. For those with type 2 and 3 disease, factor VIII/von Willebrand's factor concentrates are occasionally needed. Before a cesarean delivery, bleeding time should be measured. If it is prolonged, type 1 patients should be given desmopressin and type 2 or 3 patients should be given factor VIII/von Willebrand's factor concentrate.

HEREDITARY THROMBOPHILIAS

Venous thrombosis is the third most common vascular disease in the nation.^[161] Pregnant women are particularly susceptible to this disorder. Virchow's triad, which is taught to most medical students, consists of vessel injury, venous stasis, and hypercoagulability. In pregnancy, we encounter venous stasis caused by hormonally related relaxation of vascular smooth muscle as well as mechanical compression of pelvic veins leading to decreased venous return to the vena cava. There are also changes in clotting factors, as all factors except V, XI, and XIII increase during pregnancy. Furthermore, there is a decrease in fibrinolytic activity. Therefore, deep vein thrombosis (DVT), occurring in 0.4 per 1,000 pregnancies, is six times more frequent during gestation as in nonpregnant individuals. In pregnancy, deep venous thrombosis usually involves the deep femoral and pelvic veins. If inadequately treated, these thromboses may lead to chronic venous insufficiency and leg ulcerations. These debilitating conditions are a major cause of disability in America.^[162] If untreated, 24 percent of DVTs will result in pulmonary embolus, which occurs in 0.5 to 3.0 per 1,000 pregnancies. Without therapy, recurrent emboli will occur in 33.3 percent of patients. The mortality rate from a pulmonary embolus is 15 percent in patients who are not treated for DVT, whereas the mortality rate is only 0.7 percent if prompt anticoagulation therapy is initiated. Therefore, prompt diagnosis and treatment are paramount. The diagnosis and treatment of pulmonary embolus is covered in Chapter 30. The purpose of this section is to address the causes, prevention, and treatment of DVT during pregnancy.

Before 1993, deficiencies or aberrations in protein S, C, antithrombin III, plasminogen, and fibrinogen were thought to be the only inheritable blood disorders that gave an individual a proclivity toward DVT and was responsible for 5 to 10 percent of all DVTs.^[162] However, in 1993, activated protein C was added to the plasma of an individual with a pulmonary embolus, and the APTT was not prolonged.^[163] This finding, activated protein C resistance, revolutionized the search for other etiologies of DVT. It has since been found that activated protein C resistance is responsible, at least in part, for about 40 percent of DVTs, fivefold more than any other single cause.^[164]

How does activated protein C resistance lead to hypercoagulability? [Figure 34-3](#) pictorially demonstrates what is discussed in this paragraph. Complexes of activated factors IX and VIII as well as activated factors V and X bind to the platelet surface and allow the amplification of thrombin ([Fig. 34-3A](#)), which catalyzes the conversion of fibrinogen to fibrin (the clot). When thrombin reaches a critical concentration, it stimulates thrombomodulin, which activates protein C. This in turn inactivates these factor complexes, thus turning off the production of thrombin ([Fig. 34-3B](#)). In the case of activated protein C resistance, protein C fails to turn off thrombin production by the activated factor VX complex ([Fig. 34-3C](#)). Thrombin production, therefore, continues, leading to more conversion of fibrinogen to fibrin and thus a propensity toward clotting.

It has since been found that a single DNA point mutation at the activated protein C cleavage site on factor V, a substitution of arginine for glutamic acid at codon 506 (Arg506Gln), is responsible for 90 to 95 percent of activated protein C resistance.^[165] This is known as the factor V_{Leiden} mutation. It is inheritable and fairly common. Homozygous and heterozygous forms exist. Heterozygous patients have a 5- to 10-fold clotting diathesis over the general population. Homozygotes, however, have a 50- to 100-fold increased risk.^[166] It is unusual to find a homozygous patient that has not had thrombotic episodes prior to midlife. The frequency of this factor V_{Leiden} mutation varies with the population studied. The gene frequency in the United States is shown [in the box "Population Frequency of Factor V_{Leiden} in the United States."](#)

Higher plasma levels of homocysteine can lead to increased oxidation of homocysteine and the development

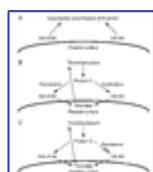

Figure 34-3 Activated protein C resistance and hypercoagulability. *A*, Binding of activated factors IX, VIII, V, and X to the platelet surface allows the amplification of thrombin, catalyzing the conversion of fibrinogen to fibrin. *B*, Stimulation of thrombomodulin leads to activation of protein C, which inactivates factor complexes and turns off the production of thrombin. *C*, In case of activated protein C resistance, protein C fails to turn off thrombin production by the activated factor VX complex.

of superoxide radicals, which can damage endothelial cells, causing thrombus formation. Increased levels of homocysteine can occur when the compound is not converted to its natural metabolites methionine and cystathionine. [Figure 34-4](#) demonstrates the metabolism of homocysteine. As shown in these diagrams, folic acid, pyridoxine (vitamin B₆), and cyanocobalamin (vitamin B₁₂) are co-enzymes in the metabolism in homocysteine. Deficiencies of these B vitamins can, therefore, result in an excess of plasma homocysteine by limiting its conversion to cystathionine and methionine. The most common cause of hyperhomocysteinemia, however, is caused by a mutation in the gene encoding for N⁵,N¹⁰-methylene tetrahydrofolate reductase, which is necessary for the metabolism of homocysteine to methionine ([Fig. 34-4B](#)). This mutation results in a thermolabile form of the enzyme that is less effective in the metabolism of homocysteine. The heterozygous state leads to a modest (if any) increase in homocysteine. The homozygous state, which is found in 9 percent of the general population, can cause significant increases in plasma homocysteine. Folic acid supplementation, even in individuals with normal serum folate levels, can lead to statistically significant reductions (up to 64.8 percent) in plasma homocysteine. Pyridoxine and vitamin B₁₂ should also be used in an attempt to lower plasma homocysteine levels before prescribing anticoagulant therapy to the asymptomatic patient with elevated plasma homocysteine levels.

Population Frequency of Factor V_{Leiden} in the United States

U.S. Caucasians	5.7%
African-Americans	1.2%
Hispanic-Americans	2.2%
Asian-Americans	0.45%
Native-Americans	1.25%

A mutation in the gene responsible for factor II (G20210A mutation) (prothrombin gene mutation) has also been identified. Individuals who are heterozygous for this gene mutation have an increased tendency toward thromboembolism, with an odds ratio of 2.8 to 3.8.^[167]

Individuals with these thrombophilic conditions do not always develop thromboses. There are also exogenous factors that predispose individuals to thrombotic events. These are listed [in the box "Nongenetic Synergistic Factors that May Predispose to Venous Thrombosis."](#) If an individual has an inheritable tendency toward thrombosis, these exogenous factors may tip the scale in favor of thrombus development. These three relatively recently discovered gene mutations that predispose an individual toward thrombosis can be tested using DNA techniques. These are reliable tests, and results are not affected by anticoagulation or the physiologic changes of pregnancy.

The prevalence of the factor V_{Leiden} mutation in an obstetric population in Utah studied by Dizon-Towson

Figure 34-4 A, Metabolism of homocysteine to cystathionine. B, Metabolism of homocysteine to methionine.

1188

was 3.4 percent, which is similar to the published rate for nonobstetric populations.^[168] Whereas less than 1 percent of patients without the mutation experienced a thromboembolic event during pregnancy, 28 percent of those with the factor V_{Leiden} mutation experienced such an event.^[168] Indeed, the factor V_{Leiden} mutation appears to be a significant cause of deep vein thrombosis during gestation, especially when a patient has a predisposing factor such as those listed [in the box "Nongenetic Synergistic Factors that May Predispose to Venous Thrombosis."](#)

Nongenetic Synergistic Factors that May Predispose to Venous Thrombosis

- Pregnancy
- Malignancy
- Chronic infection
- Diabetes mellitus
- Trauma (including surgery)
- Smoking
- Obesity
- Sedentary behavior (including bed rest for medical conditions)
- Oral contraceptives (probable)

Hereditary thrombophilias may be associated with other pregnancy complications, especially those that may have a vascular component. It is not the purpose of this chapter to discuss these in detail. Briefly, several studies have demonstrated a relationship between the presence of factor V_{Leiden} mutation and preeclampsia.^[169]^[170]^[171] These studies have not, however, demonstrated a causal role. Weiner-Megnagi and colleagues found that activated protein C resistance greatly increased the risk of placental abruption with an odds ratio of 8.16 ($p = 0.00125$).^[172] Ridker and co-workers found that factor V_{Leiden} was present in 8 to 9 percent of patients with recurrent spontaneous pregnancy loss compared with 3.7 percent of controls.^[173] Dizon-Towson reported that pregnancies with a fetus carrying the factor V_{Leiden} mutation were at increased risk for spontaneous abortion.^[174]

The most dramatic data have been reported by Kupferminc and colleagues.^[175] They determined the incidence of genetic thrombophilias in patients with severe preeclampsia, placental abruption, growth restriction, and stillbirth, pregnancy complications thought to have a strong vascular component. They found that 18 of 34 severe preeclamptic women had at least one of the three common gene mutations leading to thrombophilia. They also found at least one of these mutations in 12 of 20 abruptions, 22 of 44 pregnancies complicated by intrauterine growth restriction, and 5 of 12 still-births.^[175]

The treatment of thrombosis during pregnancy consists of heparin therapy. If the patient has an active thrombosis, heparin can be dosed by a weight-based or non-weight-based regimen. The important component of this therapy is to check the APTT every 4 to 6 hours until the results are consistently about twice the control value. Obstetricians are increasingly using low-molecular-weight heparins. They are much more expensive, but may cause decreased heparin-induced thrombocytopenia and osteopenia. Monitoring the APTT is not necessary. Therefore, this therapy is more convenient for the patient. We have had the greatest experience using enoxaparin. The therapeutic dose is 1 mg/kg twice daily. Therapeutic levels can be ascertained by intermittent monitoring of activated factor X levels, as the pharmacokinetics of these drugs have not been reliably established in pregnancy.

Much research is needed concerning prophylactic anticoagulation in patients with factor V_{Leiden} mutation, patients with the thermolabile form of N⁵,N¹⁰-methylene tetrahydrofolate reductase, and patients with the prothrombin gene mutation. Because family members of patients with thrombotic events are being tested, we are identifying many patients who carry one of these genetic thrombophilias who have never experienced a sentinel event. We do not know if these individuals warrant prophylactic heparin during pregnancy, a time of hypercoagulability. It is our current practice to look for other risk factors such as those listed [in the box "Nongenetic Synergistic Factors that May Predispose to Venous Thrombosis."](#) We then have a long discussion concerning risks and benefits of prophylactic anticoagulation with the patient before a joint decision is made.

Key Points

Four percent of pregnancies will be complicated by maternal platelet counts of less than $150,000/\text{mm}^3$. The vast majority of these patients will have gestational thrombocytopenia with a benign course and will need no intervention.

Surgical bleeding occurs if the platelet count falls below $50,000/\text{mm}^3$ and spontaneous bleeding occurs if the platelet count falls below $20,000/\text{mm}^3$.

Glucocorticoids are the first-line medication used to raise a low platelet count.

1189

Iron deficiency anemia is the most common cause of anemia in pregnancy and serum ferritin is the single best test to diagnose it.

If a patient with presumed iron deficiency does increase her reticulocyte count with iron therapy, she may also have a concomitant folic acid deficiency.

Patients pregnant with twins, those on anticonvulsant therapy, those with a hemoglobinopathy, and those who conceive frequently need supplemental folic acid during gestation.

Most hereditary hemoglobinopathies can be detected in utero and prenatal diagnosis should be offered to the patient early in pregnancy.

As in the nonpregnant patient, analgesia, hydration, and oxygen are the key factors in treating pregnant women with sickle cell crisis.

Patients with sickle cell disease are at high risk of having a fetus with growth restriction and adverse fetal outcomes. Therefore, they warrant frequent sonography and antepartum fetal evaluation.

Factor V_{Leiden} mutation occurs in up to 5 percent of the population and is responsible for a significant proportion of the thrombotic disease seen in pregnancy.

Chapter 35 - Collagen Vascular Diseases

Philip Samuels

With the exception of rheumatoid arthritis, autoimmune diseases are associated with an increased risk of poor pregnancy outcome. Many of these diseases have a predisposition for women in their childbearing years. In fact, autoimmune diseases are occasionally first diagnosed during gestation. Often patients with recurrent pregnancy complications show evidence of autoimmunity but without significant criteria to allow a specific diagnosis. ¹ These diseases are characterized by the production of autoantibodies/antibodies synthesized by an individual against a component of her own body. Increasingly sensitive and specific laboratory tests are being developed to aid in the diagnosis of these disorders ([Table 35-1](#)) and ([Table 35-2](#)).

SYSTEMIC LUPUS ERYTHEMATOSUS

Systemic lupus erythematosus (SLE) is a chronic disease with a great diversity of clinical and laboratory manifestations. Its onset is frequently insidious, and its diagnosis is often elusive and delayed. The course of SLE is characterized by chronic exacerbations and remissions. The prevalence of SLE is approximately 1 per 1,000 in the general population. The prevalence of the disease in women 15 to 64 years of age is estimated to be 1 per 700,^[2] but in black women of the same age group the prevalence is 1 per 245.^[3] The diagnosis of SLE is based on a patient meeting at least four of the diagnostic criteria accepted by the American Rheumatism Association ([see the box "Revised Criteria for the Classification of Systemic Lupus Erythematosus \[1982\]"](#)) .

Clinical Manifestations

Approximately 80 percent of patients with SLE demonstrate skin lesions. These may include the classic malar (butterfly) rash, alopecia, or discoid lesions that are often discolored. Photosensitivity is common. Arthralgias with some arthritis will be evident in 90 percent of patients. Nephritis and neurologic or psychiatric features are found in approximately 50 percent of cases. Because a patient can lose the majority of her renal function before she is symptomatic, renal pathology is often not diagnosed until other symptoms arise, which often delays the diagnosis of the disease.

The renal lesions of SLE include focal proliferative glomerulonephritis, membranous glomerulonephritis, mesangial nephritis, and diffuse proliferative glomerulonephritis. Patients with glomerulonephritis will excrete varying quantities of protein. The amount of proteinuria may range widely within the same individual, depending on disease activity. There are also diurnal variations; therefore, relying solely on a single voided specimen to determine the degree of proteinuria may be misleading. Those patients with focal and diffuse proliferative glomerulonephritis tend to have a worse long-term prognosis. Women with SLE may also present with seizures, peripheral neuropathy, or a psychotic episode. It is important to note that a recurrent fever of unknown etiology may also be the earliest manifestation of SLE.

Laboratory Diagnosis

More than 90 percent of patients with SLE will exhibit significant titers of antinuclear antibodies. In 80 to 90 percent of patients, an autoantibody directed against

1196

TABLE 35-1 -- AUTOANTIBODIES OF DIAGNOSTIC SIGNIFICANCE

Autoantibody	Associated Disease
Antinuclear antibodies (ANA)	Most collagen vascular diseases
Antineutrophil cytoplasmic antibodies (ANCA)	70%90% of patients with Wegner's granulomatosis, polyarteritis nodosa, crescentic glomerulonephritis
Anti-double-stranded DNA antibodies	80%90% of SLE patients
High-affinity anti-DNA antibodies	Lupus nephritis
Antihistone antibodies	30%60% of SLE patients, 95% of drug-induced lupus patients, 20% of rheumatoid arthritis patients
Antimitochondrial antibody	85%95% of patients with primary biliary cirrhosis, 25%30% of patients with chronic active hepatitis
Anti-Jo-1	Polymyositis, dermatomyositis
Anti-Ki	10% of SLE patients, especially with arthritis, pericarditis, and pulmonary hypertension
Anti-PM-1	Polymyositis
Antiscleroderma (SCL)-70 antibodies	20% of patients with scleroderma or progressive systemic sclerosis
Antiextractable nuclear antibodies (anti-Sm, anti-RNP, anti-SSA, anti-SSB)	SLE, Sjögren's syndrome, other collagen vascular diseases
Anti-RANA	Rheumatoid arthritis

double-stranded DNA will be detected. Anti-double-stranded DNA antibodies can be divided into subclasses. The high-affinity antibodies are seen more commonly in patients with renal involvement of their SLE, while the low-affinity antibodies are seen in milder forms of the disease. Extractable nuclear antibodies can be subdivided into antibodies against ribonuclear protein (anti-RNP, anti-SM), anti-SSA (Ro), and anti-SSB (La). The anti-SSA and -SSB antibodies are so named because they were initially identified in patients with Sjögren's syndrome. Anti-RNP antibodies are seen in 26 percent of patients with SLE; anti-SM antibodies are found in 28 percent of patients with SLE and can be correlated with renal involvement. Anti-SSA and anti-SSB antibodies, which are found in 25 and 12 percent of patients with SLE, respectively, have been associated with fetal and neonatal heart block. Anti-SSA antibodies are generally associated with manifestations of neonatal lupus. The extractable nuclear antibodies are usually seen in patients who have a speckled pattern of antinuclear antibodies.

Antihistone antibodies are seen in 30 to 60 percent of patients with SLE. They are seen in over 90 percent of patients with drug-induced lupus and are therefore useful in making this diagnosis. Anti-Ki antibodies are found in only 10 percent of patients with SLE, but correlate strongly with arthritis and with serious lupus systemic involvement such as pericarditis and pulmonary hypertension.

The Effects of Pregnancy on SLE

Pregnancy does not appear to affect or alter the long-term prognosis of patients with SLE.^[4] Several studies, however, have documented increased flares of SLE during pregnancy and particularly during the puerperium.^[4],^[5] It is difficult to compare and corroborate these studies, because there is no uniform definition of a lupus flare. Garsenstein et al.^[4] predicted that the probability of a flare was three times greater during the first half of pregnancy, 1.5 times greater in the second half, and six times greater in the puerperium.^[4] Meehan and Dorsey^[6] examined the effects of pregnancy on the course of SLE in patients receiving glucocorticoids or azathioprine

at conception. They found no statistically significant difference in the number of flares in pregnant women and nonpregnant controls when matched by disease duration and prior organ involvement. Lockshin^[7] and Lockshin et al.^[8] studied a variety of clinical markers of disease activity in 33 pregnancies in 28 women with SLE. They also demonstrated an absence of exacerbation during or after pregnancy. In a prospective study of 80 women, Lockshin^[9] showed that exacerbation occurred in less than 13 percent of pregnant patients. He concluded, therefore, that there is no

TABLE 35-2 -- ANTINUCLEAR ANTIBODY PATTERNS IN RHEUMATOLOGIC DISEASE

Pattern	Disease State
Homogeneous	SLE, drug-induced lupus, chronic active hepatitis, many collagen vascular diseases
Speckled	SLE, Sjögren's syndrome, mixed connective tissue disease, rheumatoid arthritis
Nucleolar	Progressive systemic sclerosis, scleroderma, Sjögren's syndrome, subcutaneous SLE, SLE
Centromere	Scleroderma, CREST syndrome

1197

need for prophylactic glucocorticoids in the gravid patient with SLE. Derksen and co-workers^[10] found that SLE patients who were in remission at the time of conception did not have any serious flares postpartum. In 82 percent of the 29 prospectively studied pregnancies, the disease remained quiescent throughout gestation.^[10]

Revised Criteria for the Classification of Systemic Lupus Erythematosus (1982)^{*}

- Malar rash
- Discoid rash
- Photosensitivity
- Oral ulcers
- Arthritis, nonerosive, involving two or more peripheral joints
- Serositis
 - Pleuritis
 - OR
 - Pericarditis
- Renal disorder
 - Persistent proteinuria >0.5 g/day
 - OR
 - Cellular casts
- Neurologic disorder
 - Seizures
 - OR
 - Psychosis
- Hematologic disorder
 - Hemolytic anemia with reticulocytosis
 - OR
 - Leukopenia, <4,000/mm³
 - OR
 - Lymphopenia, <1,500/mm³
 - OR
 - Thrombocytopenia, <100,000/mm³
- Immunologic disorder
 - Positive lupus erythematosus cell preparation
 - Antibody to native DNA
 - Anti-SM antibody
 - False-positive serologic test for syphilis
- Antinuclear antibodies in abnormal titers

Adapted from Tan EM, Cohen AS, Fries JF, et al: The 1982 revised criteria for the classification of systemic lupus erythematosus. Arthritis Rheum 25:1274, 1982.

^{*} Four criteria necessary for diagnosis.

Conversely, Mintz and colleagues^[11] showed an increase in SLE activity during pregnancy. This group studied 102 pregnancies in 75 women during a 10-year period. In this report, 59.7 percent of pregnancies that began with quiescent SLE experienced an exacerbation during pregnancy or the postpartum period. More than one half of these flares occurred in the first trimester and 20 percent during the puerperium. Most of the patients, however, readily responded to increased doses of glucocorticoids. Le Thi Huong and co-workers^[12] in Paris found similar findings. Of 75 patients with inactive lupus at conception, 27 relapsed in pregnancy and 7

experienced postpartum flares.^[12]

Although it remains debatable whether SLE is exacerbated by pregnancy, there is no dispute that there is a risk of major maternal morbidity and potentially of mortality in the gravida with SLE. Most maternal deaths occur during the puerperium as a result of pulmonary hemorrhage or lupus pneumonitis.^[13],^[14] Rubin and colleagues^[15] reported a case of pulmonary vasculitis resulting in pulmonary hypertension and death in a pregnant patient with SLE. Averbuch and co-workers^[16] reported a case of cardiac tamponade occurring in the postpartum period caused by SLE. Marabani and co-workers^[17] described a case of transverse myelitis during a pregnancy complicated by SLE. This complication responded quickly to steroids. In the study by Le Thi Huong et al.,^[12] two women had nephrotic syndrome postpartum requiring high doses of steroids. They died of opportunistic infection secondary to immune suppression.^[12] In our institution, we recently has a maternal death from SLE. The patient had a history of cocaine use and SLE. At the time of her admission, she had a negative toxicology screen but was experiencing lupus-related psychosis and had evidence of an old cerebral infarction on computed tomographic (CT) scan. Because of a low platelet count, general anesthesia was used for the ensuing cesarean delivery for fetal distress. She extended her cerebral infarction postoperatively and died. Gimovsky and associates^[18] reviewed 108 pregnancies in 39 women affected with SLE and found that morbidity was rare in the immediate postpartum period. However, there was increased morbidity and mortality in the first few years after delivery.^[19]

Most perinatologists advise their patients not to conceive during a time of increased lupus activity as this is associated with flares during pregnancy.^[19] Although this seems logical, the volume of the literature to support this assertion is small.^[20] The work by Mintz and colleagues^[11] does, however, seem to favor this assumption. In general, a patient's disease should be quiescent for 5 to 7 months before conception. This recommendation is based on work by Hayslett and Lynn,^[21] who observed that pregnancy outcome was good in 92 percent of women whose lupus had been in remission for at least 6 months prior to conception. This concept is also confirmed in the study of 35 pregnancies in 25 women observed by Derksen et al.^[19] between 1987 and 1993. This is also confirmed in two review articles by Reichlin^[22] and Julkunen.^[19]

Women with lupus nephritis must be aware that there is a small but significant risk of permanent deterioration of renal function during pregnancy. Fine and

1198

co-workers^[23] noted that in 9.6 percent of their patients renal function remained depressed for 3 to 12 months after delivery. Others have suggested that permanent renal deterioration during pregnancy is more frequent, perhaps as high as 50 percent.^[24],^[25] In these studies, however, sample sizes were small. Conversely, Hayslett and Lynn^[21] demonstrated no permanent change in renal function in pregnant patients with lupus nephritis. A summary of six studies reviewing 242 pregnancies in 156 patients revealed a 7.1 percent incidence of permanent renal dysfunction and a 30.2 percent incidence of transient renal dysfunction during gestation.^[25] In this review, transient deterioration usually occurred in the third trimester. Poor pregnancy outcome is associated with active lupus nephropathy,^[19] a serum creatinine level of at least 1.5 mg/dl, a BUN more than 50 mg/dl, and a creatinine clearance rate less than 50 ml/min.^[19],^[21],^[26]

A lupus flare and preeclampsia present a difficult differential diagnosis, because they have similar signs and symptoms.^[27] Both disorders often present with hypertension, edema, and proteinuria. To confound the issue, patients with lupus nephropathy are at an increased risk for developing superimposed preeclampsia during gestation. It is difficult, but very important, to make the distinction between these two phenomena. The treatment for preeclampsia is delivery, while the treatment for lupus nephritis is increased glucocorticoids and possibly azathioprine therapy. Buyon and co-workers^[28] found that serum complement levels (C3 and C4) are valuable in differentiating between heightened lupus activity and preeclampsia. In normal pregnancy, complement levels tend to rise. They are, therefore, high or normal in the SLE patient with pure preeclampsia. Conversely, these levels fall with an exacerbation of lupus. If a patient develops hypertension and proteinuria in the second trimester, it is imperative to distinguish between preeclampsia and a lupus flare. If the diagnosis of preeclampsia is made, mandatory obstetric intervention could result in neonatal death or major morbidity from prematurity, depending on the gestational age. If serologic and chemical testing cannot make the distinction between the two conditions, a renal biopsy rarely may be indicated. Unfortunately, it is often impossible to distinguish between a lupus flare and severe preeclampsia necessitating an extremely pre-term delivery.^[27]

The Effects of SLE on Pregnancy

Although fertility is not impaired, SLE can have an adverse effect on pregnancy outcome in each trimester.^[29] There is an increase in the spontaneous abortion rate, with the estimated incidence between 16 and 36 percent.^[11],^[18],^[30],^[31],^[32],^[33] The risk of miscarriage is not necessarily related to disease activity. Mintz and co-workers^[11] reported a 16 percent spontaneous abortion rate regardless of disease activity.

In a study by Julkunen and colleagues,^[34] patients with Sjögren's syndrome were compared with patients with SLE, and both were compared with controls. The relative risk of fetal loss was elevated in both patients with Sjögren's syndrome and SLE. Clinically significant intrauterine growth restriction was found more frequently in patients with SLE than in patients with Sjögren's syndrome.^[34] Le Thi Huong et al.^[12] examined 117 cases of SLE in pregnancy between 1987 and 1993. Twenty-eight infants were delivered full-term, while 48 were delivered prematurely. There were also 13 first-trimester losses, 2 second-trimester spontaneous abortions, and 3 third-trimester stillbirths, statistics above the expected rate of pregnancy loss. In this study, prematurity was related to a history of fetal loss, active SLE at onset of pregnancy, hypertension, and SLE requiring the patient to take at least 20 mg prednisone daily.^[12] Growth restriction correlated with hypertension, low complement levels, and absence of anti-SSA antibodies.

In the study of Derksen et al.^[19] of 35 pregnancies in 25 women, there were 8 first-trimester spontaneous abortions, no second-trimester losses, and 1 stillbirth. In a study by Ramsey-Goldman et al.,^[35] a previous poor pregnancy outcome was the best predictor of a poor outcome in the present pregnancy.

In a large retrospective study, Petri and Albritton^[36] reviewed 481 pregnancies in 203 women with SLE and used friends and family members without SLE as a control group. They found a 21 percent spontaneous abortion rate in women with SLE compared with 14 percent in friends and 8 percent in family members. Preterm delivery was found in 12 percent of lupus patients compared with 4 percent from each control group.^[36] Hypertension requiring therapy, Raynaud's phenomenon, and not finishing high school were found to be significantly correlated with preterm delivery.^[36]

In contrast to the study of Le Thi Huong et al.,^[12] Leu and Lan^[37] found anti-SSA antibodies were associated with growth restriction in pregnancies complicated by SLE. The presence of these antibodies, however, did not affect perinatal mortality. Kobayashi and co-workers studied 82 fetal outcomes in 55 women with SLE.^[31] Live births occurred in 66 of 82 patients. They found a 50 percent incidence of growth restriction in infants born to mothers with low complement levels. This rate was significantly greater than infants born to women with normal complement levels.^[31] Rahman and colleagues in Toronto^[38] researched 141 pregnancies in 73 women with SLE between 1970 and 1995. They observed a 23.8 percent rate of spontaneous abortion, 2.2 percent rate of stillbirth, and a 7.9 percent rate of intrauterine growth restriction (IUGR).^[38] They found that maternal renal disease was the only maternal predictor

1199

of fetal loss, and maternal hypertension was the only maternal predictor of pregnancy complications.^[38] In studying 60 pregnancies in 46 patients in Spain, Carmona et al. found a mean duration of SLE of 6.25 years.^[39] The rate of IUGR was 20.8 percent, had 18.9 percent of gravidas developed hypertension. Lupus flares occurred in 28.3 percent of patients postpartum.^[39] Aggarwal et al. found IUGR in 40 percent of the offspring of the SLE patients in their study.^[40]

Preterm birth is more frequent in women with SLE. Johnson et al.^[41] attempted to determine the etiology of this preterm birth. In their study of 66 women in 58 pregnancies, they found that 39 percent of those delivering prematurely had experienced preterm premature rupture of the membranes.^[41] This was not related to whether the patient was taking prednisone, the level of disease activity, or serologic studies. It appeared that rupture of the membranes was the single most frequent cause of preterm delivery in these patients. In Kleinman and colleagues review of 56 pregnancies spanning 19 years, the prematurity rate has 53 percent.^[39] Analyzing 60 pregnancies in 46 SLE patients over 11 years, the prematurity rate was 20.8 percent.^[39] This is increased, but not as dramatically as in the previously cited study.^[39] Aggarwal et al. found a mean gestational age at delivery of 35.9 weeks, about 2 weeks earlier than their control group.^[40]

Since the late 1980s, the lupus inhibitor and antiphospholipid antibodies have been the subject of concentrated research relating to recurrent miscarriage, infertility, and SLE. The diagnosis of the lupus inhibitor is often confusing. There is no single assay that is used to identify this phenomenon, and different assays have different sensitivities and specificities. Some clinicians and researchers rely solely on a prolongation of the activated partial thromboplastin time (aPTT) using platelet-poor

plasma. A sensitive reagent must be used. Otherwise there will be many false-negative results. Other commonly used tests include the tissue thromboplastin inhibition test (TTI), kaolin clotting time (KCT), dilute Russell viper venom time, platelet neutralization procedure, and the hexagonal antibody. This variety of tests makes it difficult for the critical reader to compare different studies concerning the role of the lupus inhibitor in pregnancy outcome. One must also look at the years during which the study was performed when drawing conclusions about the results.

There is confusion concerning the difference between anticardiolipin antibodies and antiphospholipid antibodies. Antiphospholipid antibodies encompass many phospholipids, of which cardiolipin is only one. Antiphospholipid testing performed in different clinical laboratories may give discrepant results. The testing is not very specific due to the inherent wide spectrum for the antibodies which are tested. Harris, one of the pioneers in testing for antiphospholipid antibodies, feels that using -2-glycoprotein 1 as an alternative antigen may enhance the specificity of the test.^[42] Ogasawara feels that -2-glycoprotein 1-dependent antiphospholipid antibodies may be helpful in identifying autoimmune causes for habitual spontaneous abortion.^[43]

The similarities and differences between the lupus inhibitor and anticardiolipin antibodies are also quite confusing. While many clinicians use the assays interchangeably, Rosove et al.^[44] showed that the correlation between the two is not perfect, and both assays should be performed in order to maximize sensitivity. According to Field et al., antiphospholipid antibodies and lupus inhibitors favor different primary antigens.^[45] The primary antigen for the lupus inhibitor appears to be prothrombin, while the primary antigen for antiphospholipid antibodies appears to be -2-glycoprotein 1.^[45] Munoz-Rodriguez and co-workers^[46] have shown in a study of 177 patients with SLE and/or antiphospholipid syndrome that antibodies against antithrombin seems to be an independent risk factor for thrombosis, with an odds ratio of 3.7 ($p = 0.01$).^[46]

Before concluding that the lupus inhibitor and anticardiolipin antibodies are a cause of poor pregnancy outcome, one must look at the prevalence of these phenomena in a normal pregnant population. Lockwood and co-workers,^[47] in a study of 737 low-risk pregnancies, were the first to address this issue. Two of the 737 patients (0.27 percent) had a lupus inhibitor documented by a prolonged aPTT that did not correct after mixing with normal plasma. Both patients experienced a pregnancy loss. Elevated titers of IgM or IgG anticardiolipin antibodies were found in 16 patients (2.2 percent). Twelve of these 16 patients experienced an adverse pregnancy outcome. This study suggests that, while these phenomena are not widespread, the presence of the lupus inhibitor and anticardiolipin antibodies can be related to poor pregnancy outcome and placental infarction.^[48], ^[49] Ogishima and co-investigators recently examined the placentas of 150 patients with SLE, lupus inhibitor, and antiphospholipid antibodies.^[50] They found the most extensive infarction and decidual vasculopathy in the placentas of patients who tested positive for both the lupus anticoagulant and antiphospholipid antibodies.^[50] As shown by Lubbe et al.^[51], ^[52] in New Zealand, Branch et al.^[53] in the United States, and Unander et al.^[54] in Sweden, the lupus inhibitor and anticardiolipin antibodies are associated with recurrent spontaneous abortions even when there is no other evidence of collagen vascular disease. Also, in the absence of SLE, anticardiolipin antibodies can be associated with an increased risk for early preeclampsia, intrauterine growth restriction (IUGR), and fetal death.^[53], ^[54] Druzin et al.^[55] and Lockshin and Druzin^[57] have observed that patients with elevated anticardiolipin antibodies who have SLE are at significant risk to develop fetal distress in the second trimester with subsequent fetal

1200

death. Kutteh et al.^[59] found that anticardiolipin antibodies were predictors of poor fetal outcome in patients with SLE. In their study, they found that the fetal loss rate was 39 percent in the patients with anticardiolipin antibodies and only 11 percent in those SLE patients without the antibodies.^[59] Julkunen and colleagues^[59] in Helsinki found that antiphospholipid antibodies were more sensitive in predicting fetal loss, but lupus inhibitor was more specific. Also, in this study, antiphospholipid antibodies did not correlate with prematurity or growth restriction.^[59] Birdsall et al.^[60] also found that antiphospholipid antibodies were present in 41 percent of women with recurrent miscarriage and 29 percent of women with a history of recent stillbirth. Their results were significant even in patients without signs suggestive of a collagen vascular disease.

Although treatment with heparin and aspirin has become the standard for treating lupus inhibitor and antiphospholipid antibodies, the precise population to be treated remains somewhat debatable. Furthermore, the type and dose of heparin has not been firmly established. Furthermore, the role of low-dose aspirin alone remains controversial.

Several studies report increased fetal survival and decreased morbidity and mortality in patients receiving prednisone in doses of 20 to 60 mg daily and low-dose aspirin.^[63], ^[64], ^[61] It appears that this regimen will normalize a prolonged aPTT or other coagulation assay, but will have little effect on the level of circulating antiphospholipid antibody. These investigations, however, have not been controlled for the gestational age at which therapy was initiated. There have been no studies comparing prednisone alone to prednisone and aspirin.

Lockshin and co-workers^[62] believe that prednisone may actually increase the incidence of fetal death in women with anticardiolipin antibodies. In their study of 21 women with a prior history of fetal death and a high titer of IgG anticardiolipin antibody, 11 were treated with prednisone. In the 11 treated women, 82 percent of the pregnancies ended in fetal death. In the untreated group, only 50 percent of pregnancies resulted in fetal death, a statistically significant difference. In patients treated with aspirin, there was no statistical difference in the outcomes of the groups. Based on these findings, Lockshin et al.^[62] concluded that prednisone may actually worsen fetal outcome of the current pregnancy. Karp et al.^[63] studied the outcomes of 27 pregnancies in 19 patients treated with prednisone and antiaggregants for the lupus inhibitor. There were only 13 successful outcomes, leading them to conclude that prednisone and antiaggregants may prevent second- and third-trimester losses but have only limited success in treating primary habitual abortion.^[63] Nonetheless, there are other data that do support the use of prednisone and low-dose aspirin in treating patients with the lupus inhibitor and the anticardiolipin antibody syndrome.^[54], ^[61], ^[64] Landy and co-workers^[65] followed 53 pregnancies complicated by lupus inhibitor or antiphospholipid antibodies. Thirty-three of these patients were treated with glucocorticoids and aspirin. They found that this therapy resulted in a 90.9 percent live-birth rate, higher than that achieved in patients only taking one medication. Geva et al. in Israel^[66] treated 52 consecutive autoimmune patients with repeated failure of in vitro fertilization embryo transfer with prednisone and aspirin and observed a success rate in excess of 70 percent.^[66]

Gatenby et al.^[67] showed a dramatic improvement in patients receiving only aspirin therapy for elevated anticardiolipin antibodies. In patients with elevated antibodies and SLE, the pregnancy wastage rate dropped from 88 to 55 percent. In those with elevated antibodies alone, the rate of loss fell from 79 to 25 percent.^[67] In their series, however, some of the patients were also receiving prednisone. Balasch and co-workers^[68] studied 65 consecutive women with two or more spontaneous miscarriages. Seven (10.7 percent) were found to have anticardiolipin antibodies. Four of the seven women (57.1 percent) carried to term after being treated with low-dose aspirin alone. While the number of patients treated with aspirin alone is small, it does appear that this therapy might be beneficial in patients who have anticardiolipin antibodies.

Because infarctions are often found in the placentas of patients with anticardiolipin antibodies, researchers have begun using heparin therapy in this group. Rosove was one of the first to embark on anticoagulant therapy for antiphospholipid antibodies.^[69] Rosove et al.^[69] initiated heparin therapy at a mean gestational age of 10.3 weeks in 14 women with adverse pregnancy outcomes. The daily dosage ranged from 10,000 to 36,000 units. Live births occurred in 14 of 15 pregnancies (93.3 percent) with a mean gestational age of 36.1 weeks and a mean birth weight percentile of 57.^[69] Heparin is now frequently used to treat patients with antiphospholipid antibodies. Low-dose heparin has less side effects than prednisone. Prednisone can be associated with increased striae, induction of gestational diabetes mellitus, poor wound healing, increased candidiasis, fluid retention, aseptic necrosis, cataracts, and other complications, especially when used in high doses. Branch et al.^[70] found equivalent fetal survival when using heparin and aspirin; prednisone and aspirin; or heparin, prednisone, and aspirin. The maternal side effects were much less with a regimen that incorporated only heparin and low-dose aspirin. These authors advocate using 10,000 to 20,000 units of heparin daily. This study included 82 pregnancies in 54 women. It showed that the diagnosis of SLE, a history of preeclampsia, a history of thrombosis, a false-positive test for syphilis, and the titer of IgG anticardiolipin antibody

1201

made no difference regarding outcome of the current pregnancy.^[70] The number of previous fetal deaths did correlate significantly with outcome in the current pregnancy. Heparin can result in heparin-induced thrombocytopenia, which can be life threatening. Danaparoid and r-hirudin (both heparinoids) have been used in such cases, as there is only a 10 to 20 percent cross-reactivity with heparin-associated antibodies.^[71] There has been a great increase in the use of low-molecular-weight heparin in patients with antiphospholipid antibodies. The cost is greater than unfractionated heparin, but there is less heparin-induced thrombocytopenia and there may be less osteopenia associated with low-molecular-weight heparin. Granger and Farquharson showed excellent results using both low-molecular-weight heparin and low-dose aspirin.^[72]

Intravenous immunoglobulin (IVIG) is currently being studied for use in treating patients with lupus inhibitor and/or antiphospholipid antibodies. Its mechanism of

action is not entirely understood, but it may bind to receptors, preventing the binding of these deleterious antibodies. The correct dosage and dosage interval have not been elucidated. Clark et al. reviewed 19 pregnancies in 15 patients in whom IVIG was added to standard therapy.^[73] There as a live birth rate of 84 percent, no growth restriction, and 75 percent delivered at or beyond 34 weeks' gestation. They felt that the cost was worthwhile if growth restriction and prematurity could be minimized.^[73] Kaaja et al.^[74] used high-dose immunoglobulin in conjunction with low-dose aspirin in four patients with good results. Somerset and co-workers^[75] and Gordon and Kilby^[76] also present evidence that IVIG is probably a useful adjuvant in the treatment of the antiphospholipid antibody syndrome in selected patients.

Anticardiolipin antibodies and the lupus inhibitor are associated with in vitro anticoagulation, but in vivo they are associated with thrombosis. These patients, therefore, are probably at some risk for thrombosis during gestation.^[54],^[77]^[78]^[79] Mizoguchi et al.^[78] described a 34-year-old woman with lupus inhibitor who had had six recurrent pregnancy losses without an intervening live birth. During her subsequent pregnancy, she developed multiple brain infarctions and hemiparesis. Rallings and co-workers^[79] reported a 28-year-old primigravida who developed an acute anteroseptal myocardial infarction and died during gestation. She had a past history of thromboembolism. The only serologic abnormality noted was an elevated level of IgG anticardiolipin antibody.

We currently individualize our therapy of patients with lupus inhibitor and antiphospholipid antibodies. We take the patient's history and laboratory results into account when making decisions regarding therapy. Unfortunately, patients are occasionally tested for this syndrome after only having one spontaneous abortion. If this patient has equivocal or weakly positive testing, we discourage therapy. For the patient whom we feel truly has this syndrome, we usually prescribe low-dose aspirin and heparin. Low-dose unfractionated heparin needs to be given twice daily. In these patients, low-molecular-weight heparin can probably be given once daily. The true key in treating these patients is to make certain they understand the potential side effects of the prescribed medication regimen and that they undergo the proper fetal and maternal surveillance throughout pregnancy.

Neonatal Manifestations of SLE

Complete congenital heart block, an infrequent complication of SLE, can be diagnosed prenatally. In the mid-trimester, a fetal heart rate of about 60 bpm with no baseline variability is indicative of congenital heart block. The patient should immediately undergo fetal echocardiography to rule out associated congenital cardiac malformations. Doppler studies can also locate the atrial ventricular disassociation. Fetal echocardiography can usually be carried out at 20 to 24 weeks' gestation and earlier in the asthenic patient. Affected fetuses usually show no evidence of congestive heart failure or hydrops, although occasionally this is observed. Therefore, fetuses with complete congenital heart block should be followed with serial ultrasonography every 1 to 2 weeks to ascertain if any evidence of anasarca has developed. Complete congenital heart block in the patient with SLE appears to be the result of immune complex deposition in fetal cardiac tissue as demonstrated by Litsey and co-workers.^[80] This process leads to endocardiofibroelastosis and fibrosis of the conduction system.^[81],^[82] Scott and colleagues^[83] identified the anti-SSA (Ro) antibody in 83 percent of mothers delivering infants with complete congenital heart block. Anti-SSB (La) antibodies were found in a smaller but significant number of these mothers. Scheib and Waxman^[84] have shown that these antibodies do bind to fetal cardiac tissue. They have described two successive pregnancies in a mother with anti-SSA antibody who gave birth to two antibody-positive children with complete congenital heart block. Derksen and Meilof^[85] found that the level of anti-SSA antibody did not correlate with the development of complete congenital heart block. Le Thi Huong and co-workers^[12] found manifestations of neonatal lupus in 3 of 22 infants whose mothers had anti-SSA antibody. Two had cutaneous manifestations and one had complete heart block. The titer of antibody did not appear to be related to the disease course. Conversely, Leu and Lan^[37] found that patients with high titer anti-SSA antibody had a greater chance of having a neonate with manifestations of lupus. Three of 257 women with this antibody gave birth to an infant with complete congenital heart block.^[37] All three had high antibody titers.

In most studies, mothers have had no symptoms of collagen vascular disease at the time of delivery. In the study of Vetter and Rashkad,^[86] a large proportion of these women later developed SLE. According to Esscher and Scott,^[87] the mother of a child born with complete congenital heart block has a 30 to 60 percent chance of developing a collagen vascular disease. Therefore, patients who deliver an infant with complete congenital heart block but who do not have SLE should have a careful clinical examination and undergo appropriate serologic tests on a routine basis. In future pregnancies, they should be treated as high-risk patients and undergo fetal echocardiography at the appropriate gestational age.

In the absence of structural cardiac anomalies, the neonatal mortality rate for infants born with complete congenital heart block is approximately 5 percent. In the studies of Vetter and Rashkad and Esscher and Scott^[86],^[87] the mortality rate was 20 to 30 percent if a structural abnormality was also found. Falcini et al.^[88] reported two cases of complete heart block and both mothers had anti-SSA/SSB antibodies. One child died of acute myocarditis at age 20 months. The other required cardiac surgery at age 10 years. Meng and Lockshin noted that childhood morbidity in children with anti-SSA/SSB heart block is high with 63 percent eventually requiring pacemakers.^[89] They also found that the recurrence rate for complete congenital heart block is 12 to 16 percent.^[86] Buyon and co-workers^[90] aggressively treated a fetus with presumptive fetal myocarditis and heart block in a mother with SLE. They administered high doses of dexamethasone and performed plasmapheresis three times weekly. The patient responded well to therapy, showing a significant decrease in the titer of anti-SSB antibody. The infant was delivered at 31 weeks, and the heart block persisted. Others are attempting to treat early heart block in utero with steroids to decrease maternal antibody production and plasmapheresis to remove antibodies. Plasmapheresis is not without inherent risks and the utility of this therapy is yet to be determined.

Infants born to mothers with SLE may exhibit erythematous skin lesions of the face, scalp, and upper thorax.^[12],^[91],^[92] These lesions usually disappear by 12 months of age. It appears that there is a higher incidence of anti-SSA antibodies in mothers giving birth to children with these skin lesions.^[91] Anti-SSA antibody, furthermore, may be associated with an increased risk of miscarriage, even in the patient without SLE.^[94]

Surveillance

Because of the increased risk of miscarriage, stillbirth, preterm delivery, and IUGR, the obstetrician caring for the patient with SLE should maintain close maternal and fetal surveillance. Any patient with a history of SLE should undergo preconceptual counseling and should have tests performed for the presence of the lupus inhibitor, anticardiolipin antibodies, anti-SSA (Ro) antibodies, anti-SSB (La) antibodies, and anti-double stranded DNA antibodies. As previously described, these findings are associated with a poorer pregnancy outcome. If indicated, therapy should be initiated after fully informing the patient of risks and benefits to both her and the fetus. If anti-SSA or anti-SSB antibodies are present, fetal echocardiography should be performed in the second trimester to rule out complete congenital heart block. Because of the risks of IUGR and preterm birth, accurate gestational dating is imperative in the patient with SLE. Patients should also have an examination of their urine sediment and a 24-hour urine collection for creatinine clearance and total protein excretion in early pregnancy to determine if there is any renal involvement of their SLE. Menstrual dating should be confirmed by ultrasonography at the first prenatal visit. At 18 to 20 weeks' gestation an additional ultrasound examination should be performed to confirm gestational age, ascertain appropriate fetal growth, and make certain that fetal anatomy is normal. IUGR in patients with SLE is usually asymmetric.^[12] Fine et al.,^[23] however, showed that symmetric IUGR can also occur. Because of the risk of IUGR and stillbirth, serial ultrasound examinations should be performed monthly after 20 weeks' gestation, with special attention to growth of the fetal abdomen, head, and femur.^[93] The obstetrician should also be attentive to the volume of amniotic fluid, as decreased amniotic fluid can be the harbinger of fetal compromise and stillbirth.

At 28 weeks' gestation, weekly antepartum fetal heart rate testing should be initiated using the nonstress test. Antepartum fetal heart rate testing has been shown to improve fetal outcome in patients with systemic lupus erythematosus.^[95] At 34 weeks, the frequency of testing should be increased to twice weekly. There are, however, no controlled studies showing that biweekly testing after 34 weeks improves perinatal outcome in the patient with SLE. Carroll^[96] has shown that Doppler blood flow velocimetry is useful in following the gravida with the lupus inhibitor. In that study, abnormal umbilical artery systolic/diastolic ratios were found in five of six women with the lupus inhibitor who delivered growth-restricted fetuses. Only two of these patients demonstrated abnormally elevated uterine artery systolic/diastolic ratios. Ariyuki et al.^[97] have demonstrated similar findings. Doppler may be a useful adjuvant in caring for the patient with SLE. Farine et al.^[98] in Toronto found absent or reversed end-diastolic flow velocity in the umbilical artery of 11 percent of 56 patients with SLE. These patients had a high rate of preeclampsia, growth restriction, and fetal distress.^[95]

Despite the sophisticated array of laboratory studies that are available to follow patients with SLE, the patient's clinical status remains of prime importance. There is no substitute for careful monitoring of maternal blood pressure and weight gain. These can be the earliest signs of superimposed preeclampsia, which is common in patients with SLE. They can also be the harbinger of a lupus flare.^[27],^[99] Twenty-four-hour urine collections for creatinine clearance and total protein excretion should be carried out every 1 to 2 months. Serum creatinine, BUN, and uric acid levels should be determined whenever these urine collections are performed. A rise in serum

uric acid can be a sign of impending preeclampsia. During a normal pregnancy, complement levels rise. A fall in the third or fourth components of complement (C3 or C4) or a fall in total hemolytic complement (CH50) has been associated with impending exacerbations of SLE. ^[100], ^[101] Devoe and Aloy^[102] found that a decrease in serum complement levels was also associated with a poor perinatal outcome. Because complement levels tend to rise during pregnancy, a single complement determination is of no value. A downward trend in complement levels, however, is significant, even though the level may fall within normal limits.

The timing of delivery is important and should be individualized. All too often, preterm delivery is performed merely to allay physician and patient anxiety. The obstetrician should strive for a vaginal delivery. If delivery is indicated near term and the patient's cervix is not favorable, cervical ripening agents may be employed. If the patient is taking glucocorticoids or if there is any evidence of lupus exacerbation, peripartum steroids should be administered parenterally. In the patient who undergoes cesarean delivery, intravenous steroids should be continued for 48 hours postoperatively, because adequate gastrointestinal absorption cannot be guaranteed until normal bowel function returns. Steroids should be tapered slowly and with great care in the postpartum period to prevent an exacerbation of SLE. ^[24], ^[103]

Drug Therapy for SLE During Pregnancy

Patients with SLE are often hesitant to take their prescribed medications during pregnancy for fear of fetal effects. Many obstetricians are also reluctant to prescribe these medications for similar reasons. It is important for the obstetrician to be aware of the benefits and risks of medications used to treat SLE. Pregnancy is accompanied by a 40 to 50 percent increase in intravascular volume and an increase in interstitial fluid. Any steroid that has mineralocorticoid activity exacerbates interstitial fluid retention. This additive effect can cause maternal discomfort. The obstetrician should therefore choose a steroid with minimal mineralocorticoid activity and maximum glucocorticoid activity. Steroids in combination with pregnancy may worsen acne and striae. Corticosteroid administration can also lead to gastrointestinal discomfort and ulceration. We therefore suggest that patients on chronic corticosteroid therapy use antacids after meals and at bedtime. Care should be taken, however, that antacid use does not interfere with the absorption of medications.

Chronic corticosteroid administration has been associated with bone demineralization and with an increased risk of hip fractures. For the gravida who is taking increased corticosteroids only during pregnancy, the actual risk is unknown. There is also a risk of cataract formation with long-term corticosteroid administration.

The induction of gestational diabetes from glucocorticoid administration is a distinct possibility. Approximately 3 percent of all pregnancies are complicated by gestational diabetes. ^[103] We perform 1-hour, 50-g oral glucose screening tests early and repeat them later in pregnancy in patients receiving long-term corticosteroids. We also test for diabetes later in gestation if there is any evidence of fetal macrosomia.

Pregnant women are often more concerned about the effects of the medication on their fetus than they are about the effects on themselves. The chronic ingestion of corticosteroids has not been associated with teratogenesis in humans. ^[104] An increase in the background incidence of cleft palate has been seen in rats and rabbits exposed to chronic corticosteroids but never in humans. ^[104] ^[105] ^[106] Neonatal adrenal suppression is a theoretical consideration in patients taking corticosteroids, but it has only rarely been reported. Nonetheless, the pediatrician should be informed when a mother has been taking corticosteroids antenatally.

Only a fraction of the steroids ingested by a pregnant woman reach the fetus. Prednisone, the most widely used glucocorticoid during gestation, is metabolized by the mother to its active form prednisolone. An 11--OH radical is responsible for prednisolone's physiologic activity. The placenta has an abundance of the metabolizing enzyme 11--ol dehydrogenase, which converts the active glucocorticoid to an inactive 11-keto metabolite. Depending on the study, only 10 to 50 percent of a dose of prednisone and only one sixth of a dose of hydrocortisone reach the fetus. ^[107] ^[108] ^[109] Levitz et al. ^[110] performed placental perfusion studies showing that steroids are rapidly cleared from the fetus. Beitins and co-workers ^[111] found that the maternal: fetal concentration gradient after intravenous administration of prednisolone was 10:1.

Dexamethasone and betamethasone cross the placenta more freely and for this reason are used to enhance fetal lung maturity. Blanford et al. ^[112] observed

1204

little conversion of dexamethasone or betamethasone to inactive forms. Work by Ballard et al. ^[107] and by Osathanondh et al. ^[109] demonstrate a maternal: fetal concentration gradient of 1:1 for dexamethasone and betamethasone.

To minimize potential fetal effects, prednisone should be the oral glucocorticoid of choice. ^[113] Both methylprednisolone and hydrocortisone are satisfactory for intravenous use when needed. Methylprednisolone has less mineralocorticoids effect and should create fewer maternal side effects.

Occasionally, azathioprine, a derivative of 6-mercaptopurine, will be required to control a patient's SLE. This medication readily crosses the placenta. In a study by Scott, ^[114] 64 to 93 percent of an administered dose appeared in fetal blood between 2.5 and 6 hours after intravenous administration. Azathioprine has not been shown to be teratogenic in humans, although congenital malformations have been observed in animal models. ^[115] Chronic azathioprine use during pregnancy has been associated with neonatal lymphopenia, lower serum IgG and IgM levels, and decreased thymic shadow on x-ray. ^[116] All of these changes have reversed with time. Scott ^[114], ^[117] reports an increased incidence of IUGR in infants born to mothers who took azathioprine during pregnancy. As yet, no long-term information is available on immunologic development and later infection rates in children who were exposed to this medication in utero. Before administering azathioprine during pregnancy, however, the benefits and risks should be weighed carefully. Antimalarials occasionally are needed in women with SLE. These drugs bind to cells in the developing fetal eye, but no studies have identified any long-term effects. They should be used cautiously and only when clearly indicated in the patient with SLE.

RHEUMATOID ARTHRITIS

Rheumatoid arthritis is an autoimmune disease with a prevalence of approximately 2 percent. Its crippling chronic form occurs in about 0.35 percent of the population.^[118] The onset of the disease is usually between the ages of 20 and 60 years, and women are two to three times more likely to be affected than are men.^[119]

Diagnosis

The diagnosis of rheumatoid arthritis is based on guidelines set forth by the American Rheumatism Association ([see the box "American Rheumatism Association Diagnostic Criteria for Rheumatoid Arthritis \[RA\]"](#)). A list of exclusions has also been devised to make the diagnosis more precise ([see the box "Exclusions from Rheumatoid Arthritis"](#)).

American Rheumatism Association Diagnostic Criteria for Rheumatoid Arthritis (RA)

- Morning stiffness
- Pain on motion or tenderness in at least one joint
- Soft tissue swelling in at least one joint
- Swelling in at least one other joint
- Simultaneous symmetric joint swelling
- Subcutaneous nodules
- Radiologic changes typical of rheumatoid arthritis
- Positive rheumatoid factor
- Poor mucin precipitate from synovial fluid
- Characteristic histologic changes in synovium
- Characteristic histologic changes in subcutaneous nodules
- A. Classic RA: 7 criteria
- B. Definite RA: 5 criteria
- C. Probable RA: 3 criteria
- D. Signs and symptoms must persist for at least 6 weeks
- E. No exclusions can be present

Adapted from Rodman GP, Schumacher HR: Appendix 2. In Primer on the Rheumatic Diseases, 9th ed. New York, Arthritis Foundation, 1988, p 207.

Clinical Manifestations

Articular involvement is the hallmark of rheumatoid arthritis. The most common finding is an erythematous, warm, swollen metacarpophalangeal joint. The proximal interphalangeal and wrist joints may also be involved. Less frequently, metatarsophalangeal and shoulder joints are affected. Over time, cartilage destruction and pannus formation occur.^[120] Carpal tunnel syndrome is often seen in patients with rheumatoid arthritis.^[121]

Extra-articular features of rheumatoid arthritis are found in patients with the most joint involvement and the highest titers of rheumatoid factor.^[122],^[123] Rheumatoid nodules, which occur in 20 percent of patients with rheumatoid arthritis, can appear in the heart and lungs and along any extremity.^[124] Pericarditis, myocarditis, and endocarditis are occasionally seen in patients with rheumatoid arthritis. Vasculitis may result secondary to immune complex deposition and may affect the skin, peripheral nerves, and blood vessels.^[125] Unlike

SLE, rheumatoid arthritis rarely involves the kidneys. It is important to note that after 10 years of disease more than 50 percent of patients are still able to work, and 15 percent will have a complete remission.^[126]

Exclusions From Rheumatoid Arthritis

Typical rash of systemic lupus erythematosus
Strongly positive lupus erythematosus cell preparation
Histologic evidence of periarteritis
Proximal muscle weakness consistent with dermatomyositis
Definite scleroderma
Clinical rheumatic fever
Clinical gouty arthritis
Tophi
Infectious arthritis
Tuberculous arthritis
Reiter syndrome
Clinical picture of shoulder-hand syndrome
Hypertrophic osteoarthropathy
Neuroarthropathy
Homogentisic aciduria
Sarcoidosis or positive Kveim test
Multiple myeloma
Erythema nodosum
Leukemia or lymphoma
Agammaglobulinemia

Adapted from Rodman GP, Schumacher HR: Appendix 2. In Primer on the Rheumatic Diseases, 9th ed. New York, Arthritis Foundation, 1988, p 207.

Pathophysiology

Rheumatoid arthritis is characterized by proliferation and inflammation of synovial membranes. The membranes characteristically show a dense collection of lymphocytes in a diffuse nodular pattern.^[127] T-cell function appears to be impaired, and there is an excessive number of T-suppressor cells.^[128] Immune complexes, which activate the complement cascade, have been demonstrated in the blood, synovial fluid, and synovial membranes of patients with rheumatoid arthritis.^[129], ^[130] There appears to be a genetic predisposition to rheumatoid arthritis. A strong association between the histocompatibility antigen HLA-DR4 and rheumatoid arthritis has been shown.^[131]

Laboratory Findings

Rheumatoid factors, IgM and IgG antibodies directed against the Fc fragment of IgG, are the hallmark laboratory finding of rheumatoid arthritis, but are not pathognomonic for this disorder. More severe disease is seen with higher titers of rheumatoid factor. Antinuclear antibodies are also found in approximately 20 percent of patients with rheumatoid arthritis.

Effects of Pregnancy on Rheumatoid Arthritis

Pope et al. determined that there is not an increase in infertility in women with rheumatoid arthritis.^[132] In 1938, Hench^[133] observed that many patients with rheumatoid arthritis experienced remissions during pregnancy. Persellin^[134] noted that in pregnant women with rheumatoid arthritis 74 percent underwent remission during the first trimester, 20 percent in the second trimester, and 5 percent in the third trimester. In this series, however, 90 percent of patients experienced a postpartum exacerbation of their disease. Approximately 25 percent of these flares occurred in the first 4 weeks postpartum.^[134] In a review, Klipple and Cecere^[135] reported that approximately 70 percent of patients with rheumatoid arthritis experienced substantial improvements in disease activity during pregnancy including extra-articular symptoms. Most of these patients no longer required medications. This remission, however, was short lived, with more than 90 percent of women relapsing within 6 to 8 months postpartum. Klipple and Cecere^[135] also found that in approximately 30 percent of patients with rheumatoid arthritis the course remained unchanged or worsened during gestation.

Quinn and colleagues^[136] studied 24 pregnant women with rheumatoid arthritis, 21 of whom had quiescent disease activity during pregnancy. Nineteen of these 21 women had significant flares during the puerperium. These researchers noted that IgM rheumatoid factor levels increased during these flares while pregnancy-associated α_2 -glycoprotein levels decreased. IgA rheumatoid factor was unaffected. These authors suggest that pregnancy-associated α_2 -glycoprotein may be responsible for modulating the improvement in clinical symptoms in rheumatoid arthritis patients during gestation.^[136] Nelson and colleagues^[137] investigated HLA antigens in patients with rheumatoid arthritis and their offspring, as this autoimmune disorder has a known HLA class II antigen association. They found that amelioration of rheumatoid arthritis during gestation is associated with a disparity in HLA class II antigens between mother and fetus. They think that the maternal immune response to paternal HLA antigens may play a role in the remission in this disease that is often seen during pregnancy.^[137] Lasink and co-workers^[138] looked at the

onset of rheumatoid arthritis in relation to pregnancy in 135 patients. They concluded that pregnancy may delay the clinical onset of disease in patients who will develop rheumatoid arthritis. Barrett et al. found an increase in relapse rate postpartum.^[139] They compared disease activity in 38 first-time breast-feeding mothers, 50 repeat breast-feeding mothers, and 49 non-breast-feeding mothers.^[140] They examined self-reported symptoms, joint counts (the number of involved joints), and C-reactive protein levels. They found that a postpartum flare may be induced by breast-feeding.^[140] Iijima et al. checked for the presence of rheumatoid factors in 2,547 healthy women.^[141] Only 2 (0.08 percent) of patients who could be followed developed rheumatoid arthritis within 12 months of delivery. One can conclude from

this study that pregnancy does not trigger the onset of rheumatoid arthritis. ^[141]

Effect of Rheumatoid Arthritis on Pregnancy

Rheumatoid arthritis appears to have no adverse effects on pregnancy. ^[139], ^[142], ^[143] Spector and Silman^[144] examined pregnancy outcomes in 195 women with rheumatoid arthritis and 462 controls. They found no increase in spontaneous abortions or stillbirths in patients with rheumatoid arthritis. They also concluded that a prior history of poor reproduction did not put the patient at risk for developing rheumatoid arthritis in the future. ^[144] A theoretical risk of uteroplacental insufficiency and IUGR does exist for patients with advanced extra-articular rheumatoid arthritis, and a case of IUGR attributed to vasculitis associated with severe disease has been described. ^[145]

To avoid pain and joint damage, care should be taken when positioning the patient with severe articular involvement on the delivery table. This is especially true if the patient has epidural or spinal anesthesia, because a joint can be damaged without the patient feeling pain. Obstetric anesthesiologists must also be cautious during rapid sequence induction of general anesthesia and intubation of patients with spinal involvement of rheumatoid arthritis. Subluxation of the atlanto-occipital joint is possible with devastating consequences. Popat et al. ^[146] describe these difficulties and the use of awake fiberoptic intubation in a patient with severe juvenile rheumatoid arthritis.

Effects of Medications Used to Treat Rheumatoid Arthritis

Nonsteroidal Anti-inflammatory Drugs

Acetylsalicylic acid (aspirin) was once the mainstay for the treatment of rheumatoid arthritis in pregnancy. The desired therapeutic blood level is 15 to 20 mg/dl. To achieve this the patient must take 3.6 to 4 g of acetylsalicylic acid daily in three divided doses. Because salicylism, tinnitus, and deafness usually occur at levels of approximately 25 mg/dl, salicylate levels should be monitored regularly. Salicylate used throughout pregnancy may be associated with a prolonged gestation, long labor, increased blood loss at delivery, and postpartum hemorrhage. ^[147], ^[148] These effects appear to be related to the inhibition of prostaglandin synthetase. ^[149] All nonsteroidals inhibit platelet aggregation. Inhibition by aspirin is irreversible while the effect on platelets by other nonsteroidals is reversible. The cyclooxygenase-2 inhibitors (cox-2) appear to have minimal, if any, effect on platelets.

There are many nonsteroidal anti-inflammatory agents currently available to treat rheumatoid arthritis. Physicians usually have their favorites, and the side-effect profiles differ somewhat, but not significantly. They have both analgesic and anti-inflammatory properties. There is considerable data available concerning indomethacin, as it is used as an adjuvant in the treatment of refractory preterm labor. Indomethacin, when used in late pregnancy, can cause premature closure of the fetal ductus arteriosus leading to pulmonary hypertension. Closure of the ductus arteriosus appears to be gestation-age dependent. These drugs, therefore, should be discontinued before 32 weeks' gestation if possible. Nonsteroidal anti-inflammatory agents can also cause changes in the fetal renal blood flow, resulting in oligohydramnios. It is unclear how long it takes these changes to occur. If at all possible, nonsteroidals should be avoided in the third trimester. Often, a short course of glucocorticoids can be used for symptoms in these patients. If, however, nonsteroidals must be used in late pregnancy, the amniotic fluid index must be carefully monitored.

Other Therapies

Penicillamine has been used successfully to treat rheumatoid arthritis in patients who are refractory to nonsteroidal agents. Penicillamine will reduce the titer of rheumatoid factor. Penicillamine freely crosses the placenta, and its use during pregnancy should be curtailed unless the benefits clearly outweigh the potential risks. Penicillamine has been successfully used in pregnancy without adverse effects. ^[150], ^[151] Antimalarials are also used in refractory patients. A review by Koren showed no adverse fetal effects, even with first-trimester exposure. ^[152]

SCLERODERMA AND PROGRESSIVE SYSTEMIC SCLEROSIS

Progressive systemic sclerosis (PSS) and scleroderma are related collagen vascular diseases. They affect females

1207

four times more frequently than males, with onset usually between the ages of 30 and 50 years. The reported incidence is about 5 new cases per 1 million population per year. *Scleroderma*, the term used to describe the disorder when it is localized to the skin, is characterized by tight and bound down skin, sclerodactyly, and Raynaud's phenomenon. Clinical signs may precede development of the overt disease by several years.

In PSS, there is systemic involvement, including the gastrointestinal viscera as well as pulmonary vascular and parenchymal changes. Pulmonary hypertension with resultant right-sided heart failure is often the fatal consequence of PSS. With cardiac involvement, left-sided heart failure is occasionally seen.

It is now thought that a microchimeric state resulting from persistent fetal cells from prior pregnancies contributes to the development of scleroderma. ^[153] Class II HLA compatibility is common in patients with scleroderma. ^[154] In one study, 70.2 percent of women with scleroderma had this HLA-II compatibility compared to 21 percent of controls. ^[155] Scleroderma may, therefore, be a form of chronic graft-versus-host disease caused by fetal cells that have crossed the placenta during pregnancy and have remained unrecognized by the host due to class II HLA compatibility. Subsequent activation of these cells by as yet unknown stimuli results in the development of the disease. ^[155]

Laboratory Manifestations

Speckled-pattern antinuclear antibodies are observed in about 50 percent of patients, and 40 percent will demonstrate a rheumatoid factor. Anti-Scl-70, an extractable nuclear antibody, appears in the serum of 40 percent of patients with scleroderma and PSS. It appears to be fairly specific for this disease. Anti-Jo-1 antibodies are also occasionally seen in patients with scleroderma.

Effects of Pregnancy on Scleroderma and PSS

Johnson and co-workers^[156] reported 18 cases of scleroderma and PSS complicating pregnancy. None of the women exhibited visceral involvement. In 39 percent of the patients, the disease showed no change or progressed at the same rate as prior to pregnancy. In an additional 39 percent the disease worsened, but no patient developed visceral involvement. In the remaining 22 percent some improvement was noted, but regression occurred after delivery. Several studies have described the onset of fatal renal involvement during pregnancy in patients with scleroderma and PSS. ^[157] ^[158] ^[159] ^[160] In these reports, it is unclear whether visceral involvement antedated the pregnancy. Altieri and Cameron^[161] reported a case of renal failure occurring in a pregnant woman with PSS. Partial recovery did follow the pregnancy. A successful pregnancy has been described in a patient with scleroderma complicated by renal disease and pulmonary hypertension who was treated with angiotensin-converting enzyme inhibitors. ^[162] The use of these agents during pregnancy is not recommended, but, because of the severity of the illness, they were used in this instance. Furthermore, Spiera et al. ^[163] reported a successful pregnancy in a patient with a previous hypertensive renal crisis caused by PSS. The patient was actually withdrawn from angiotensin-converting enzyme inhibitors when she became pregnant and had no renal complications during the pregnancy. ^[163] Jimenez^[164] described a group of Spanish patients with scleroderma. Some improved, but several experienced worsening of skin thickening during pregnancy. ^[164] In a large review, Maymon and Fejgin^[165] conducted a detailed literature search of scleroderma in pregnancy. Of 94 patients, 14 died during the course of pregnancy secondary to renal and cardiopulmonary involvement. It is important to note that this literature review covered many years. With more sophisticated maternal monitoring and therapy, the maternal mortality rate is probably much lower today.

Effects of Scleroderma on Pregnancy

Many theoretical complications exist, but few have been documented properly because of the rarity with which scleroderma and PSS coexist with pregnancy. Steen and Medsger^[166] report no increase in infertility in patients with scleroderma. Also, the miscarriage rate was no different than their control population. This is in contrast to a previous study by Silman and Black. ^[167] Preterm birth, premature rupture of membranes, and stillbirth seem to be more common in patients with scleroderma and PSS. ^[168] ^[169] Surviving infants show no evidence of scleroderma. ^[167] ^[170] Steen et al.^[171] examined pregnancy outcomes in 48 women with scleroderma and in two control groups matched for age and race. One control group contained normal patients and the other a group of women with rheumatoid arthritis. No difference was observed in the frequencies of miscarriage or perinatal death. Preterm births and infants with IUGR were found more frequently in patients with scleroderma and PSS. These data are favorable compared with those from the older literature reviewed by Maymon and Fejgin. ^[165] Steen and Medsger described pregnancy outcome between 1972 and 1986 in 214 women with scleroderma, 167 with rheumatoid arthritis, and 105 controls. ^[166] There were no significant differences in spontaneous abortion, preterm birth, growth restricted infants, or neonatal deaths amongst the three groups. ^[166]

Management During Pregnancy

If visceral involvement, especially pulmonary, cardiac, or renal, is documented, counseling should be undertaken

1208

before a patient attempts pregnancy. As previously mentioned, patients with renal involvement can carry to term, but gestation is often much more complicated. If scleroderma with only skin involvement exists, the patient may be followed expectantly. She should be aware that renal or cardiac involvement may be fatal. Steen suggests waiting until the disease stabilizes prior to conception. ^[172] A renal crisis with hypertension must be treated with angiotensin converting enzyme (ACE) inhibitors, even though these medications are usually contraindicated in pregnancy. ^[172] Anesthesia can be difficult in these patients, but several case reports have described how regional and general anesthesia can be safely employed in patients with scleroderma/progressive systemic sclerosis. ^[173] ^[174] ^[175]

MYASTHENIA GRAVIS

Although its prevalence is 1 per 25,000 in the general population, myasthenia gravis frequently coexists with pregnancy.^[176] Women are twice as frequently affected as men and have an earlier onset of the disease, with a peak incidence occurring between the ages of 20 and 30 years. Even though 60 percent of patients with myasthenia gravis have enlargement of the thymus, only 8 percent have a malignant thymoma.^[177] Thymectomy improves symptoms in up to two thirds of patients, but most still need additional medical therapy.^[178] If the patient presents for prepregnancy counseling and is symptomatic despite large doses of medication, thymectomy should be undertaken before attempting pregnancy. Myasthenia gravis in pregnancy has been extensively studied by Plauché.^[179] In a review of 314 pregnancies in 217 patients with myasthenia, he found no change in the myasthenic status throughout pregnancy, the puerperium, or the postpartum period in 31.5 percent of patients. In that review, exacerbations occurred in 40.8 percent of patients during pregnancy, including 30.6 percent during the puerperium. Another 28 percent showed a remission of their myasthenia during gestation.^[179] Historically, there is a 25 to 60 percent preterm birth rate among patients with myasthenia gravis.^[180],^[181] These are retrospective studies covering more than 40 years. With modern surveillance and therapy for preterm labor, this rate has probably decreased. Anti-acetylcholinesterase agents, which are used to treat myasthenia gravis, have an oxytocic action. It has been postulated that this could be the explanation for preterm labor observed in patients with myasthenia gravis.^[182]

A team approach is necessary for proper treatment of the patient with myasthenia gravis. The neurologist and rheumatologist are not always familiar with the medications used by the obstetrician in treating complications of pregnancy. Conversely, because of the infrequency with which obstetricians see myasthenia gravis, they may be unfamiliar with the interactions between these medications and the disease.

Magnesium sulfate, for example, is absolutely contraindicated in the myasthenic patient. It further interferes with the neuromuscular blockade that is characteristic of the disease.^[183] According to Castillo and Engbaek,^[183] magnesium reduces the stimulating effect of acetylcholine on the muscle. It affects the amplitude of the end-plate potential without affecting the muscle's resting potential. Cohen and co-workers^[184] reported a near maternal death from administration of magnesium to a myasthenic patient. Catanzarite and co-investigators^[182] described a respiratory arrest in a myasthenic patient with preterm labor who was treated with ritodrine and dexamethasone. They thought that the respiratory arrest was due to glucocorticoids. Although glucocorticoids generally ameliorate myasthenic symptoms, they may initially result in increased weakness in 25 to 80 percent of patients. Catanzarite and colleagues^[182] proposed that this paradoxical effect, coupled with the hypokalemia caused by the ritodrine, led to the crisis.

Patient Management

Most patients with myasthenia gravis will be taking acetylcholinesterase inhibitors when they become pregnant. These medications are generally safe during gestation. The most commonly used medication, pyridostigmine, does not readily cross the placenta. Dosage adjustments, however, are frequently necessary because of the physiologic changes in vascular volume, renal blood flow, and hepatic function during pregnancy. Because myasthenia gravis is a disease of striated muscle, the smooth muscle of the uterus is generally not affected. The first stage of labor progresses at a normal pace. The second stage of labor involves voluntary pushing and the use of skeletal and pelvic girdle musculature.^[185] These maternal expulsive efforts may be impaired because of the myasthenia gravis, and the obstetrician must be prepared to perform an operative vaginal delivery. Cesarean delivery should be reserved for obstetric indications. Patients are apt to undergo myasthenic crisis during labor, and the oral medications normally used have variable gastrointestinal absorption during this time. The obstetrician should therefore be prepared to use parenteral acetylcholinesterase inhibitors during labor and must be able to differentiate between an overdose of these medications and a myasthenic crisis.

Anesthesia and analgesia during labor present special challenges for the patient with myasthenia gravis. Although they are extremely sensitive to narcotics, patients with myasthenia gravis may be given these medications

if carefully monitored.^[186] Epidural anesthesia decreases the requirements for parenteral narcotics, prevents fatigue, and provides excellent anesthesia.^[26] If, however, general anesthesia is elected for cesarean section, nondepolarizing muscle relaxants should be used with great care, if at all. Myasthenics are sensitive to these agents, and a prolonged response is usually seen.^[186] It is also imperative to remember that certain inhalation agents may potentiate these agents. If general anesthesia is elected, the patient and her family should be warned that she may need ventilatory support for a period of time after the surgery.

If the patient develops a puerperal infection, aminoglycosides should be used with extreme caution. These agents can block the motor end-plate and cause a myasthenic crisis.^[26]

Occasionally, myasthenia will be exacerbated during pregnancy. In such cases, therapy with extremely large doses of acetylcholinesterase inhibitors yields little response. These patients can be treated with plasmapheresis. The procedure may need to be repeated as needed, but dramatic results can be seen. After plasmapheresis, symptoms improve and the dose of acetylcholinesterase inhibitors can often be temporarily reduced. The procedure should be carried out with the patient in the left lateral position and with the uterus tilted off the inferior vena cava. It should be performed relatively slowly, with careful attention to maternal blood pressure. If plasmapheresis is being performed after 24 weeks' gestation, continuous fetal monitoring should be employed. Intravenous immunoglobulin (IVIG) is being used now in patients with myasthenia gravis. Dramatic results have been seen. The proposed mechanism, although oversimplistic, is that the infused antibody saturates muscle receptors so that the autoantibody has no sites to bind.

Neonatal Myasthenia Gravis

Neonatal myasthenia occurs in 10 to 25 percent of infants born to mothers with myasthenia gravis.^[187]^[188]^[189]^[190] In his review series, Plauché^[179] reported a 20.2 percent incidence of neonatal myasthenia, with a 2.1 percent stillbirth rate and a 3.8 percent neonatal mortality rate. Again, that study reviewed cases over a 40-year period. With modern neonatal care, the neonatal mortality rate is probably considerably lower. Neonatal myasthenia does not begin at birth but is usually evident within the first 2 days of life. For this reason, mothers with myasthenia gravis are not candidates for early discharge even if their disease is well controlled. It lasts an average of 3 weeks but can persist up to 15 weeks.^[190] Symptoms usually include a weak cry, poor sucking effort, and, rarely, respiratory distress. Neonatal myasthenia is thought to be secondary to transplacental passage of IgG antibodies directed against acetylcholine receptors.

Key Points

Systemic lupus erythematosus is associated with an increase in poor pregnancy outcome (i.e., from IUGR, stillbirth, and spontaneous abortion).

The rate of pregnancy complications is decreased if patients with SLE have quiescent disease for 6 months prior to conception.

Glucocorticoids are safe to use in pregnancy for the treatment of patients with SLE.

The lupus inhibitor and anticardiolipin antibodies are found in 50 percent of patients with SLE. They are associated with an increased risk of pregnancy loss, including second- and third-trimester losses.

Anti-SSA (Ro) and anti-SSB (La) antibodies are associated with complete congenital heart block and other manifestations of neonatal lupus.

Low-dose heparin and low-dose aspirin are the therapies of choice for patients with lupus inhibitor/antiphospholipid antibodies who do not have active SLE.

Rheumatoid arthritis tends to improve during pregnancy but may relapse in the postpartum period.

Rheumatoid arthritis does not appear to have a major deleterious effect on pregnancy.

Pyridostigmine can be safely used to treat patients with myasthenia gravis in pregnancy.

Infants born to mothers with myasthenia gravis can have muscle weakness and even problems feeding. This usually manifests itself after the second day of life.

Chapter 36a - Hepatic Disease

Philip Samuels

Liver dysfunction and disease occasionally complicate pregnancy. The most commonly seen problems include liver dysfunction associated with preeclampsia and hepatitis. These topics are covered in detail elsewhere in this text ([see Chapter 28](#)) and ([see Chapter 40](#)). This chapter focuses on acute fatty liver, intrahepatic cholestasis of pregnancy, and gallbladder disease associated with gestation ([Table 36-1](#)).

ACUTE FATTY LIVER

Acute fatty liver is a rare condition that has an incidence of between 1 in 6,692 and 1 in 15,900 pregnancies.^[1] Since 1975, maternal survival has been reported as 72 percent, with neonatal survival slightly lower. The results are undoubtedly better now. These improved outcomes have been attributed to early recognition of the disorder followed by prompt delivery.^[1] In a recent series, 28 cases of acute fatty liver of pregnancy were reviewed.^[7] They occurred between 1982 and 1997, with an incidence of 1 in 6,659 births. There were no maternal mortalities and only two (7.6 percent) perinatal deaths.^[7] Usually beginning late in the third trimester, acute fatty liver often presents with nausea and vomiting,^[1] followed by severe abdominal pain and headache. The right upper quadrant is generally tender, but the liver is not enlarged to palpation. Within a few days, jaundice appears, and the patient becomes somnolent and eventually comatose. Hematemesis and spontaneous bleeding result when the patient develops hypoprothrombinemia and disseminated intravascular coagulation (DIC). Oliguria, metabolic acidosis, and eventually anuria occur in approximately 50 percent of patients with acute fatty liver of pregnancy.^[8] Diabetes insipidus may also accompany the disease, but may not manifest itself until postpartum.^[6] These patients may respond to desamino-cys-1-D-arginine-8-vasopressin (dDAVP) after delivery.^[10] If the disease is allowed to progress, labor begins and the patient delivers a stillborn infant. The etiology of these fetal losses has not been convincingly demonstrated. Moise and Shah^[2] suggest that uteroplacental insufficiency may be the cause of fetal distress and fetal death in these patients. During the immediate postpartum period, the mother becomes febrile, comatose and, without therapy, dies within a few days. DIC, renal failure, profound hypoglycemia, and occasionally pancreatitis are the most often cited immediate causes of death.^[2] Two cases of liver rupture associated with acute fatty liver have also been reported.^[11] In one case, a patient receiving intravenous heparin for thrombophlebitis suddenly expired as a result of rupture of a subcapsular hematoma of the liver.^[12] The diagnosis of acute fatty liver in pregnancy was confirmed microscopically. It is important to note that although acute fatty liver is usually a disease of late pregnancy, it has been reported at 22 weeks' gestation.^[13]

The primary differential diagnoses in cases of acute fatty liver include fulminant hepatitis and the liver dysfunction associated with the HELLP syndrome (hemolysis, elevated liver enzymes, and low platelet count) or preeclampsia (Table 36-1).^[14] Several researchers have suggested a spectrum of diseases between acute fatty liver of pregnancy and preeclampsia.^[14] Although it is often difficult, physicians are usually able to differentiate between these disorders based on physical and laboratory findings. An overdose of acetaminophen may mimic, to a certain extent, acute fatty liver of pregnancy; therefore, a careful drug history is imperative.

Etiology

The cause of acute fatty liver remains elusive. Brown et al.^[17] have proposed a spectrum of diseases that includes the entire range from mild preeclampsia to acute fatty liver of pregnancy.

Treem and co-workers^[18] note the similarities in clinical presentation and histologic appearance of the liver in pregnant women with acute fatty liver and in children with metabolic defects in the intramitochondrial α -oxidation pathway.^[18] Sims et al.^[19] found the same defect in affected children from three families, all of whose mothers had experienced acute fatty liver of

TABLE 36a-1 -- DIFFERENTIAL DIAGNOSIS OF LIVER DISEASE IN PREGNANCY

	Serum Transaminase Levels (IU/L)	Bilirubin Level (mg/dl)	Coagulopathy	Histology	Other Features
Acute hepatitis B	>1,000	>5	-	Hepatocellular necrosis	Potential for perinatal transmission
Acute fatty liver	<500	<5	+	Fatty infiltration	Coma, renal failure, hypoglycemia
Intrahepatic cholestasis	<300	<5, mostly direct	-	Dilated bile canaliculi	Pruritus, increased bile acids
HELLP	>500	<5	+	Variable periportal necrosis	Hypertension, edema, thrombocytopenia

HELLP, hemolysis, elevated liver enzymes, low platelets; -, absent; +, present.

pregnancy. Schoeman et al.^[20] discuss a similar case in which a mother had acute fatty liver in two successive pregnancies and delivered two healthy infants. Both infants died at approximately 6 months of age with fatty infiltration of the liver, with similar disorders of fatty acid oxidation. Ibdah et al. found that HELLP and acute fatty liver occur more frequently in women whose fetuses have a deficiency of long-chain 3-hydroxyacyl-CoA. This enzyme resides in the mitochondrial trifunctional protein, which also contains the active site of long-chain 2,3-enoyl CoA hydratase and long-chain 3-ketoacyl-CoA thiolase. While carrying fetuses with the homozygous mutation, 79 percent of mothers had acute fatty liver or HELLP.^[21] Baldwin describes how this enzyme deficiency is similar to that found in pediatric Reye's syndrome and how the hepatic pathology of acute fatty liver and Reye's syndrome are similar.^[22] Baldwin hypothesizes that the use of nonsteroidal anti-inflammatory agents in pregnancy may predispose the susceptible gravida to acute fatty liver. In Finland, Tyni et al.^[23] examined 63 pregnancies in 18 mothers of 28 infants diagnosed with long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency. Preeclampsia, HELLP, or acute fatty liver were found in 31 percent of pregnancies carrying an affected fetus, but in none of the pregnancies carrying a healthy fetus.^[23]

Clinical Diagnosis

Malaise, nausea with vomiting, and epigastric and/or right upper quadrant pain are usually present. The duration of these prodromal symptoms and signs is variable. In a study of 14 cases over 8 years, Usta et al.^[6] reported a mean gestational age of 34.5 weeks, with a range of 28 to 39 weeks. Four patients had hepatic encephalopathy, three had pulmonary edema, and three had ascites.^[6] Reyes et al.^[3] report lethargy and jaundice as the main presenting symptoms and signs in 11 patients with acute fatty liver of pregnancy in Chile. Unusual findings included seven patients with pruritus, two of whom experienced itching weeks before the clinical onset of disease, and nine with polydipsia.^[3] In his review, Bacq found that diabetes insipidus is a frequent finding.^[24] Patients may also be febrile or present with hepatorenal syndrome.^[25] By the time the diagnosis is made, patients often have a clinically manifested coagulopathy. Rarely, acute fatty liver may occur concomitantly with other diseases such as severe preeclampsia,^[25] chronic active hepatitis,^[26] and pregnancy-induced cholestasis.^[3] Pereira et al. found that 17 of 32 (53 percent) patients with acute fatty liver developed an infectious complication.^[26]

Laboratory Diagnosis

In acute fatty liver of pregnancy, serum transaminase levels are elevated but usually remain below 500 IU/L.^[5] In acute hepatitis, however, these levels are frequently above 1,000 IU/L. In liver dysfunction associated with preeclampsia or the HELLP syndrome, the transaminases are often in the same range as in acute fatty liver of pregnancy, but are occasionally higher. As a result of DIC, the prothrombin time and activated partial thromboplastin time (aPTT) are often prolonged. The prothrombin time is usually increased before the aPTT because it reflects the vitamin K-dependent clotting factors synthesized in the liver. A decreased fibrinogen level is accompanied by an elevation in fibrin degradation products, the D-dimer, and prothrombin.^[1],^[2] Although the serum bilirubin level is elevated, it usually remains below 5 mg/dl and only rarely rises as high as 10 mg/dl, a level lower than one would expect in acute hepatitis. A liver biopsy specimen will reveal pericentral microvesicular fatty change. There is little inflammatory cell infiltration or hepatic necrosis. Periportal areas are usually preserved.^[5],^[29] This picture is very different from fulminant hepatitis in which hepatocellular necrosis is significant. Special staining and electron microscopy yield no evidence of viral particles in acute fatty liver of pregnancy. The diagnosis can be made on frozen section

of the liver biopsy material using oil red O stain. This staining is very sensitive but not specific for acute fatty liver of pregnancy. Similar staining is also seen in patients with severe preeclampsia and the HELLP syndrome. Barton and colleagues^[30] believe that electron microscopy is more beneficial in establishing a definitive diagnosis. Reyes et al.^[3] showed mega-mitochondria with paracrystalline inclusions in all patients who underwent liver biopsy. Because of the coagulopathy associated with acute fatty liver of pregnancy, liver biopsy is not advisable in most cases. If biopsy is essential to make the diagnosis and establish a plan of treatment, fresh frozen plasma can be administered to correct the coagulopathy before performing the procedure. Good-acre and colleagues^[31] and Mabie and colleagues^[32] believe that the diagnosis of acute fatty liver of pregnancy can occasionally be made using computed tomography (CT). The finding of decreased attenuation over the liver is consistent with fatty infiltration. Usta et al.^[6] found that CT resulted in a large number of false-negative diagnoses. Thus, a negative scan does not rule out acute fatty liver of pregnancy. This finding was corroborated by Van Le and Podrasky.^[33] In their study of five patients with acute fatty liver, none had an abnormal CT scan, and only one had an abnormal right upper quadrant ultrasound examination. Siegelman has demonstrated that fatty infiltration can be diagnosed with magnetic resonance imaging utilizing T2-weighted gradient-echo sequences.^[34]

Management

Once the diagnosis has been established, delivery should be accomplished as quickly as is safely possible.^[35] Important supportive measures must first be undertaken to ensure maternal well-being. The patient's coagulopathy must be corrected with fresh frozen plasma. If more concentrated fibrinogen is needed, cryoprecipitate can be administered. In a study by Castro et al.,^[1] 28 patients with acute fatty liver were identified at the University of Southern California Medical Center. All 28 had evidence of persistent DIC, and 23 had a markedly depressed level of antithrombin III. Intravenous fluids containing adequate glucose should be given. This will prevent hypoglycemia, which can be fatal. If there is not a severe coagulopathy or the coagulopathy has been corrected, invasive hemodynamic monitoring may be instituted if necessary before delivery. This technique will allow the anesthesiologist and obstetrician to monitor the patient's fluid status.

Delivery soon after diagnosis is paramount. Vaginal delivery is preferable. If the patient's cervix is not ripe, cervical ripening agents may be employed to maximize the likelihood of a vaginal delivery. Cesarean delivery, however, is warranted if it appears that delivery cannot be effected in a timely fashion, and the patient is deteriorating. If the patient's coagulopathy has been corrected, epidural anesthesia is the best choice. Spinal anesthesia can also be used. Regional anesthesia is preferable, because it allows adequate assessment of the patient's level of consciousness. General anesthesia should be avoided if possible because of the hepatotoxicity of some anesthetic agents. Narcotic doses must be adjusted, as these drugs are metabolized by the liver.

Early diagnosis and delivery afford both mother and neonate an excellent chance for survival.^[4],^[5] If delivery is effected before hepatic encephalopathy and renal failure develop, patients usually improve rather rapidly.^[4],^[5],^[6],^[9],^[14] Davidson et al. report three cases of acute fatty liver occurring in triplet pregnancies.^[36] All underwent cesarean delivery as soon as the diagnosis was suspected. All three had biopsy-proven disease and improved rapidly after delivery.^[36] In Pereira's case review of extremely ill patients admitted to the Liver Failure Unit at Guy's Hospital in London, 4 of 32 women (12.5 percent) died, and the perinatal mortality was 9 percent.^[29] Thus, even in the best tertiary care units, maternal mortality still occurs. Therefore, we must be vigilant and deliver these patients as soon as the diagnosis is seriously suspected. Ockner and colleagues^[37] have reported a case in which the patient did not improve postpartum. After orthotopic liver transplantation, the multisystem failure rapidly reversed.^[37] In that case, the diagnosis of acute fatty liver was documented histopathologically. Southern blot analysis for viral DNA was also negative, ruling out hepatitis. Amon et al.^[29] also reported as successful postpartum liver transplant in a patient with acute fatty liver and severe preeclampsia.

The classic teaching is that there is little risk of recurrence of acute fatty liver in subsequent pregnancies. Barton and colleagues^[38] described the first case of recurrent acute fatty liver in pregnancy confirmed by biopsy. Schoeman et al.^[20] also reported a case of a mother who had acute fatty liver in two successive pregnancies. However, with the previously cited enzymatic defect found to be associated with acute fatty liver and with more pregnant women surviving the disease, we may encounter more recurrent cases in the future.

INTRAHEPATIC CHOLESTASIS OF PREGNANCY

Intrahepatic cholestasis is characterized by pruritus and mild jaundice usually occurring in the last trimester of pregnancy. It can, however, occur earlier in gestations. It has an uneven worldwide incidence of 1 in 1,000 to 1 in 10,000 deliveries.^[39] The disease is reported to affect up to 14 percent of pregnancies in Chile.^[39] Gonzalez

1219

et al.^[40] determined the prevalence of intrahepatic cholestasis of pregnancy in Chile to be 4.7 percent in singleton pregnancies. In twin pregnancies, the incidence was 20.9 percent. The disease is also common in the Swedish population.^[41] Berg et al.^[41] reported the incidence in Sweden to be between 1 and 1.5 percent. In their study, the incidence of intrahepatic cholestasis of pregnancy had a distinct seasonal variation, peaking in November. This disorder is much less common in the United States, but appears to have a familial predisposition in Sweden.^[42] In 1987, Wilson^[43] reported the first case of intrahepatic cholestasis of pregnancy in an African-American patient. Abedin et al. found that cholestasis of pregnancy occurred in up to 1.5 percent of Asian women of Pakistani and Indian origin.^[44] Intrahepatic cholestasis tends to recur in subsequent pregnancies, but the severity may vary from one pregnancy to the next. In their Chilean study, Gonzalez et al.^[40] reported a recurrence rate of 70.5 percent in singleton pregnancies. Locatelli et al. found cholestasis of pregnancy in 15.9 percent of patients with hepatitis C compared with 0.8 percent of controls, suggesting that individuals with hepatitis C are more prone to cholestasis of pregnancy.^[45]

Clinical Manifestations

Patients with intrahepatic cholestasis usually begin having pruritus at night. It progresses, and the patient is soon experiencing bothersome pruritus continuously. Approximately 2 weeks later, clinical jaundice will develop in 50 percent of cases. The jaundice is usually mild, soon plateaus, and remains constant until delivery. The pruritus worsens with the onset of jaundice, and the patient's skin can become excoriated. The symptoms usually abate within 2 days after delivery. The differential diagnosis must include viral hepatitis and gallbladder disease. There is usually no fever or abdominal discomfort, as in hepatitis, or nausea or vomiting, as seen in hepatitis and gallbladder disease.

Laboratory Findings

Serum alkaline phosphatase levels are increased 5- to 10-fold in intrahepatic cholestasis of pregnancy. Alkaline phosphatase, however, is normally increased in pregnancy. This is due to placental production of this enzyme. Upon fractionation, most of the alkaline phosphatase is hepatic in origin rather than placental. Serum 5'-nucleotidase levels are also increased. Serum and urinary excretion of total sulfated progesterone metabolites are increased in cholestasis of pregnancy, whereas glucuronide metabolites are unchanged or low.^[46] This shows that there is a primary change in the reductase metabolism of progesterone in cholestasis of pregnancy.^[46] Bilirubin is elevated, but usually not above 5 mg/dl. Most is the direct, conjugated form. If intrahepatic cholestasis lasts for several weeks, liver dysfunction may result in decreased vitamin K reabsorption or decreased prothrombin production, leading to a prolongation of the prothrombin time. Serum transaminase levels are usually normal or moderately elevated, remaining well below the levels associated with viral hepatitis. Serum cholesterol and triglyceride levels may also be markedly elevated.

The serum bile acids (chenodeoxycholic acid, deoxycholic acid, and cholic acid) are increased. The levels are often more than 10 times the normal concentration. These acids are deposited in the skin and probably cause the extreme pruritus. The degree of pruritus, however, is not always related to the serum level of bile acids.^[47] To make the diagnosis of intrahepatic cholestasis of pregnancy, the fasting levels of serum bile acids should be at least three times the upper limit of normal. Elevation of serum bile acids alone cannot be used to make the diagnosis. The patient must also have clinical symptoms. Serum transaminase levels may also be elevated 5 to 10 times normal. Reyes et al. found that serum copper is significantly higher and selenium levels are significantly lower in individuals with cholestasis of pregnancy.^[48] Wojcicka-Jagodzinska and colleagues^[49] reported that carbohydrate metabolism is disturbed in patients with intrahepatic cholestasis of pregnancy. These patients should therefore be screened for gestational diabetes when the diagnosis of cholestasis is made.

Histologically, the periportal areas show no change, and the hepatocellular architecture remains undisturbed. The centrilobular areas, however, reveal dilated bile canaliculi, many containing bile plugs. Ultrastructurally, there appears to be some destruction and atrophy of microvilli in the bile canaliculi.^[50] These changes tend to regress after pregnancy.

Perinatal Outcome

The risk of preterm birth and fetal death may be increased in patients suffering from intrahepatic cholestasis of pregnancy.^[51] Fisk and Storey^[52] studied 83 pregnancies complicated by intrahepatic cholestasis over a 10-year period. Meconium staining occurred in 45 percent of the pregnancies, spontaneous preterm labor occurred in 44 percent, and intrapartum fetal distress complicated 22 percent. Of the 86 infants, 2 were stillborn and 1 died soon after birth. The overall perinatal mortality in this group of patients was 35 per 1,000.^[53] Nonstress tests, serial ultrasonography to assess amniotic fluid volume, and estriol determinations failed to predict fetal compromise. Early intervention was indicated in 49 pregnancies, 12 because of suspected fetal distress. In light of this study, antepartum fetal heart rate testing and intense surveillance should be undertaken in gravidas with intrahepatic cholestasis of pregnancy. It

1220

may also be prudent to induce labor at term or when amniotic fluid studies indicate fetal lung maturity.^[54] Heinonen and Kirkinen^[52] reviewed 91 cases of cholestasis in pregnancy in Finland from 1990 to 1996. The cesarean section rate was 10 percent higher in the group of women with cholestasis. The risk of preterm delivery was higher (odds ratio, 2.73) and the need for neonatal intensive care was also higher (odds ratio, 2.15).^[52] Matos et al.^[54] report a full-term infant with unexplained intracerebral hemorrhage in a patient with cholestasis of pregnancy.

Management

Treatment is aimed at reducing the intense pruritus. Diphenhydramine, hydroxyzine, and other antihistamines help only slightly. Cholestyramine is an anionbinding resin that interrupts the enterohepatic circulation, reducing the reabsorption of bile acids. A total of 8 to 16 g/day in three to four divided doses is often helpful in relieving pruritus. It is most effective if started as soon as the pruritus is noted, before it becomes severe. It often takes up to 2 weeks to work. Because cholestyramine also interferes with vitamin K absorption, the prothrombin time should be checked at least weekly. If prolonged, parenteral vitamin K should be administered. When the prothrombin time returns to normal, the frequency of injections can be decreased. Cholestyramine causes a sensation of bloating and often results in constipation. Cholestyramine also can interfere with the absorption of other ingested medications, including prenatal vitamins. If the patient cannot tolerate

cholestyramine, antacids containing aluminum may be used to bind bile acids. These medications are usually not as effective as cholestyramine. Phenobarbital, in a dose of up to 90 mg daily given at bedtime, can be helpful. Phenobarbital induces hepatic microsomal enzymes, increasing bile salt secretion and bile flow. ^[56] ^[57] ^[58] This medication usually takes more than 1 week to be effective. It has not been shown to change the serum concentration of bile acids. ^[59] It is important to remember that phenobarbital must not be given within 2 hours of cholestyramine, or the phenobarbital will be bound and excreted without being absorbed. The key to treating pregnancy-induced cholestasis is to begin therapy as soon as the diagnosis is made.

Dexamethasone has also been used with some success in treating pregnancy-induced cholestasis. Dexamethasone suppresses fetalplacental estrogen production, which is out of balance in the patient with cholestasis of pregnancy. Leslie et al., however, have shown that downstream placental production of estrogen is compromised in patients with cholestasis of pregnancy. ^[60] Two studies have investigated using guar gum, a gelforming fiber that increases fecal elimination of bile acids, to treat the pruritus associated with pregnancy-induced cholestasis. ^[62] ^[63] This dietary fiber was randomly assigned to 24 of 48 women with cholestasis of pregnancy in Finland. ^[62] In patients taking the guar gum, bile acids remained stable, whereas they increased in those taking the placebo. Pruritus improved in those taking guar gum and worsened in the placebo group. ^[62] Similar results were obtained in 48 patients in a more recent study in Finland. ^[63]

The two most recently studied medications for the treatment of intrahepatic cholestasis of pregnancy are S-adenyl-methionine (SAM-e) and ursodeoxycholic acid (UDCA). SAM-e may work by reversing estrogen-induced impairment of bile secretion. UDCA is a naturally occurring hydrophilic bile acid that replaces other more cytotoxic bile acids. Nicastri et al. studied 32 women with intrahepatic cholestasis. ^[64] There were four study groups: the first group received DCA; the second SAM-e; the third both drugs; and the fourth received placebo. A combination of both drugs was more effective than either drug alone. ^[64] Palma et al. compared 1 g daily of UDCA with a placebo over 3 weeks and found a significant decrease in pruritus and a significant decrease in liver function studies. ^[65] Other studies have shown similar results. ^[66] ^[67] It appears that the proper dosage of UDCA is 14 to 16 mg/kg/day. ^[65] ^[66] Because of intolerable pruritus and the possible impact on perinatal outcome, delivery may be undertaken at term or as soon as fetal lung maturity has been documented. Jaundice usually disappears within 2 days after delivery. The patient should be counseled that the condition may recur during subsequent pregnancies. ^[40] It is also important to note that some patients may manifest symptoms of intrahepatic cholestasis when taking oral contraceptives. ^[41] ^[68]

PREGNANCY AND LIVER TRANSPLANTATION

At present, pregnancy in the liver transplant patient is a rare occurrence. As the procedure becomes more widespread, more liver transplant recipients will become pregnant. Laifer and colleagues^[69] reported the results of eight pregnancies in women with liver transplants. Seven of the eight patients conceived between 3 weeks and 24 months after transplantation. Six had live births, and one electively terminated her pregnancy. Five patients developed pregnancy-induced hypertension, including three with severe preeclampsia. The six infants born to these women were delivered between 26 and 37 weeks.^[69] Five of the six infants survived, and

1221

none had structural anomalies. One patient underwent orthotopic liver transplantation at 26 weeks' gestation after presenting in hepatic coma from fulminant hepatitis B. She was delivered on postoperative day 7 because of fetal distress. Laifer et al.^[69] concluded that pregnancy does not appear to have a deleterious effect on hepatic graft function or survival. All eight of the patients in their series survived without permanent sequelae. As in the case of patients with a renal allograft, liver transplant recipients should continue their immunosuppressive medications throughout pregnancy. Furthermore, they should wait several years before conception to make certain that liver function is acceptable and there are no signs of rejection. As previously cited, liver transplantation has been used in acute fatty liver of pregnancy.^[37] ,^[38]

GALLBLADDER DISEASE

Cholelithiasis is responsible for approximately 7 percent of cases of jaundice occurring during gestation. ^[70] Gallstones are present in 12 percent of all pregnancies. ^[71] Pregnancy appears to increase the likelihood of gallstone formation but not the risk of developing acute cholecystitis. ^[72] ^[73] ^[74]

Pregnancy markedly alters gallbladder function. Ultrasound studies performed after 14 weeks' gestation have shown that fasting gallbladder volume is twice normal, the rate of gallbladder emptying is decreased, and the percentage of emptying is lower, thus leaving a higher residual than in the nonpregnant patient. ^[73] Cholecystokinin is the major stimulus for gallbladder contraction. It appears that estrogen and/or progesterone may make these contractions less effective, leading to an increased residual volume.

Once the diagnosis is confirmed, attacks of biliary colic should be treated symptomatically during gestation. Ultrasound examination of the gallbladder will aid in the evaluation and diagnosis of these patients. Hiatt and colleagues ^[75] report that ultrasound successfully confirmed the presence of gallstones in 18 of 26 patients. Before resorting to surgery, attempts should be made to treat these patients medically. Attacks usually respond to intravenous hydration, analgesics, nasogastric suction, and antibiotics. Lockwood and associates ^[76] have also utilized total parenteral nutrition. Their patient did well with no fetal or maternal morbidity.

If possible, cholecystectomy should be postponed until after delivery. In their study of 26 patients, Hiatt and co-workers ^[75] found it necessary to perform cholecystectomy and cholangiography on 19 women, with 4 requiring common bile duct explorations. They noted that only two of seven patients who presented in the first trimester with cholecystitis carried their pregnancies to term. Daradkeh and colleagues studied 42 women suffering from gallstones during pregnancy. ^[77] In this study, 26 of 42 patients responded to conservative therapy and were able to postpone surgery until after delivery.

If ascending cholangitis develops, cholecystectomy should not be postponed. Cholecystectomy should also be performed if common bile duct obstruction occurs or severe pancreatitis develops. Certainly, surgery should not be delayed if an acute abdomen develops. In these instances, temporizing will only increase perinatal and maternal risk. ^[72] If cholecystectomy is performed in the second or third trimester, fetal mortality is less than 5 percent. ^[74] If pancreatitis secondary to biliary tract stones remains untreated, however, the fetal mortality approaches 60 percent. ^[74]

Dixon and colleagues, ^[78] reviewing their experience with 44 patients, found that conservative management of cholecystitis was followed by recurrent episodes of biliary tract symptoms requiring multiple hospitalizations. Cholecystectomy performed in the second trimester was associated with little maternal morbidity, no fetal loss, and a substantial reduction of total hospital days.

Laparoscopic cholecystectomy has been safely carried out in a number of pregnancies. In Austria, seven patients underwent laparoscopic cholecystectomy between 13 and 32 weeks with no complications and all deliveries occurring at term. ^[71] Insufflation pressures were 8 to 10 mm Hg. Mean operating time was 62 minutes. Cosenza et al. compared 12 laparoscopic cholecystectomies to 20 open cholecystectomies between 1993 and 1997. ^[78] There were no perinatal mortalities or major maternal morbidities in those undergoing laparoscopy. ^[79] Affleck and co-workers report 45 laparoscopic cholecystectomies and 22 laparoscopic appendectomies performed during pregnancy from 1990 to 1998. ^[79] Lemaire and van Erp report performing a laparoscopic cholecystectomy in a patient at 33 weeks gestation without incident. ^[80] Barone et al. compared 20 laparoscopic with 26 open cholecystectomies performed between 1992 and 1996. ^[81] Each group experienced one fetal death. Only one patient undergoing laparoscopic cholecystectomy developed preterm contractions compared with the open group. Indeed, there is a growing body of literature indicating that laparoscopic cholecystectomy is safe during pregnancy.

Finally, as obstetricians, it is our duty to help establish the proper diagnosis and, if therapy is out of our field, to encourage our colleagues to undertake appropriate therapy in a manner that is most beneficial to mother and fetus.

Key Points

Acute fatty liver of pregnancy is a medical emergency requiring stabilization of the patient and timely delivery. Almost all cases will be complicated by disseminated intravascular coagulation.

Liver transaminase levels in acute fatty liver of pregnancy are lower than what one would see in acute hepatitis.

Profound hypoglycemia is a frequent concomitant of acute fatty liver and can cause death if untreated.

Pregnancy-induced cholestasis usually occurs in the third trimester, causing intense pruritus and jaundice. Elevated serum bile acids are the best laboratory test for making the diagnosis in symptomatic patients.

Chapter 36b - Gastrointestinal Disease

Mark B. Landon

PEPTIC ULCER DISEASE

The symptoms and complications of peptic ulcer seem to decrease during pregnancy. This observation is supported by Clark, who interviewed pregnant women with a previous history of peptic ulcer disease and found that in 313 pregnancies, 44 percent became asymptomatic and 44 percent demonstrated a marked improvement in symptoms.^[1] Only 12 percent remained the same or experienced worsening symptoms during gestation. There were no serious complications reported in this series. Of note, nearly half of the patients relapsed by 3 months postpartum and 75 percent of the patients questioned had experienced recurrent symptoms by 6 months after delivery. Vessey and colleagues have also reported a low rate of hospitalization for peptic ulcer disease in pregnant women and users of the contraceptive pill.^[2] Of 175 women hospitalized for advanced symptoms of ulcer disease, none were pregnant.

Several factors that might improve the clinical course of patients with peptic ulcer disease during pregnancy have been investigated. It is well known that patients with duodenal ulcer have higher levels of basal and stimulated acid secretion. It has been suggested that the amelioration of symptoms during pregnancy may in part be secondary to progesterone-induced lower gastric acid output as well as increased mucus production. The latter may exert a protective effect on the intestinal mucosa. The placenta is also rich in histaminase, which may inactivate histamine or block its action at the level of the parietal cell. Plasma levels of histaminase increase dramatically during pregnancy and may be responsible for a decline in gastric acid output in patients who exhibit hyperacidity in the nonpregnant state.^[3] Finally, pregnancy may favorably affect the gastric and duodenal mucosa's ability to regenerate as a result of increased levels of epidermal growth factor.^[4]

The interplay of acid secretion and mucosal resistance is believed to be important in the pathogenesis of peptic ulceration. Infection of the stomach and duodenum with *Helicobacter pylori* has been implicated as a significant factor, as well. This organism is found in nearly all patients with duodenal ulceration. Its presence, however, is associated with ulcer formation in a minority of individuals.^[5] Various physiologic alterations affecting acid secretion can result from *H. pylori* infection, which when combined with destruction of the hydrophobic phospholipid surface within the mucosa, predispose to ulcer formation. Host response, bacterial virulence, genetic predisposition, stress, and nonsteroidal anti-inflammatory drug use are other factors involved in the pathogenesis of ulcer disease.

Most physicians, when evaluating pregnant women with dyspepsia, attribute this complaint to gastric reflux in the lower esophagus. Heartburn is most often observed in the second and third trimesters. It usually responds to antacid therapy, and minimizing reflux by having the mother assume a semirecumbent position when she is supine. This regimen will often bring relief to patients with underlying peptic ulcer disease as well, and further diagnostic procedures are rarely needed. Duodenal ulcers produce either sharp or burning epigastric pain that is episodic following meals or it may awaken patients from sleep. Pain radiating to the back suggests posterior penetration. In patients with profound pain that is unresponsive to antacid regimens, panendoscopic examination of the stomach and upper duodenum may be performed. These procedures performed with appropriate analgesia are generally well tolerated during pregnancy.

The primary medical treatment for the symptomatic patient with peptic ulcer disease during pregnancy remains antacid therapy and diet. Administration of antacid 1 hour after meals and at bedtime usually provides relief of symptoms and promotes ulcer healing. In refractory cases, a dose may be added at 3 hours after meals. It is important to be aware that potential side effects of antacid therapy exist. Patients with peptic ulcer disease should be maintained on a normal diet, avoiding caffeine, salicylates, ethanol, or any gastric stimulant that aggravates their condition. Because basal acid output may normally rise during evening hours, it follows that patients should avoid bedtime snacks.

H₂ antagonists (cimetidine, ranitidine, famotidine)

continue to remain a second-line choice for therapy in pregnancy. If possible, these agents should be reserved for use during the second and third trimesters.^[6] Cimetidine, ranitidine, and famotidine are category B medications.^[7] The use of omeprazole, a powerful inhibitor of acid secretion, has been limited during pregnancy. This compound blocks hydrogen potassium ATPase in gastric parietal cells. Studies have suggested a potential for teratogenesis in animal studies, and this drug is category C.^[8] Elective treatment of *H. pylori* with antibiotics and bismuth subsalicylate is generally recommended following delivery and breast-feeding.

Fewer than 100 cases of pregnant women who developed serious complications from peptic ulcer disease have been reported in the literature.^[9] Bleeding, perforation, and obstruction should be treated as they would be in nonpregnant patients. Becker-Andersen and Husfelt, in reviewing 30 cases of hemorrhage from peptic ulcer during pregnancy, clearly demonstrated a decrease in maternal and fetal mortality rates with prompt surgical exploration.^[9] The only two maternal deaths in their series occurred in patients who were in shock at the time of operation. However, a 44 percent fetal mortality rate was recorded in cases that were first managed conservatively. These authors stress that perforation and hemorrhage must be treated surgically using the same indications as in nonpregnant patients. If a partial gastrectomy is to be performed in the third trimester, it may be advisable to begin the procedure with a cesarean section. The fetus appears to be quite sensitive to maternal circulatory failure due to hypovolemia, and, in addition, gastric surgery may be facilitated after the gravid uterus has been evacuated.

ACUTE PANCREATITIS

The true incidence of pancreatitis complicating pregnancy is difficult to ascertain. In a review of 500 cases of acute pancreatitis, only 7 patients developed the disease while pregnant.^[10] Reported incidences have ranged from 1 in 1,066 pregnancies to 1 in 2,888 deliveries.^[11] , ^[12] Maternal death is uncommon compared with decades ago, especially if the diagnosis is established promptly.^[11] There appears to be a greater association of gallstones with the development of pancreatitis during gestation. McKay et al. noted that 18 of 20 patients who developed pancreatitis while pregnant or within 5 months postpartum had cholelithiasis.^[10] In a 22-year study, Block and Kelly reported that all 21 cases of pancreatitis during pregnancy in their institution were associated with gallstones.^[13] In nonpregnant individuals, alcoholism is by far the most common etiologic factor. Other causes for pancreatitis include hyperlipidemia, idiopathic factors, infection, previous surgery, preeclampsia, hyperparathyroidism, thiazide ingestion, and penetrating duodenal ulcer. The normal hypertriglyceridemia of pregnancy may be exaggerated in patients with hyperlipidemia, thereby inducing acute pancreatitis.^[14] These rare cases have been treated with either hyperalimentation or lipoprotein apheresis when dietary fat restriction failed to improve symptoms during pregnancy.^[14] , ^[15]

The clinical presentation of pancreatitis is not significantly altered in pregnancy. The disease may occur at any stage of gestation, but is more common in the third trimester and the puerperium. Epigastric pain, which may radiate to the flanks or shoulders along with abdominal tenderness, should prompt appropriate laboratory investigation. Occasionally, a patient will present with nausea and vomiting as her only complaints. Mild fever and leukocytosis may be present. Radiographic examination of the abdomen may simply reveal an adynamic ileus. Ultrasound imaging of the pancreas can be difficult. Therefore, if significant pancreatic necrosis is suspected, CT imaging becomes preferable. Such images should be limited to reduce fetal exposure. In most cases, this radiologic study is unnecessary.

In evaluating the pregnant patient with suspected pancreatitis, the differential diagnosis includes most causes of abdominal pain in young women. These are principally peptic ulcer disease including perforation, acute cholecystitis, biliary colic, and intestinal obstruction. Specific tests employed to corroborate the diagnosis of pancreatitis rely on the measurement of pancreatic enzymes, principally amylase. Elevated values should suggest pancreatitis, although they may be present with other conditions such as cholecystitis, intestinal obstruction, peptic ulcer disease, hepatic trauma, and ruptured ectopic pregnancy. There is controversy as to whether serum amylase values are affected during gestation.^[16] For this reason, serum lipase levels should be measured in suspected cases.

In most cases, acute pancreatitis resolves spontaneously within several days. However, in some 10 percent of cases, the illness is complicated and such patients are best managed in an intensive care environment. Pancreatic secretory activity should be reduced by keeping the patient NPO. Nasogastric suction is reserved for those with nausea and vomiting. Meperidine is the drug of choice for analgesia as, unlike morphine, it does not constrict the sphincter of Oddi. Fluid and electrolyte replacement, and serial laboratory assays of hemoglobin, white blood cell count, amylase, liver function enzymes, glucose, and calcium are essential. In advanced cases, hypocalcemia may be present, and calcium replacement is necessary. Patients who have been unable to eat for periods of greater than 1 week may benefit from intravenous alimentation.

Percutaneous aspiration of pancreatic exudate is important in refractory cases. This CT-guided procedure

may be necessary to distinguish between sterile and infected pancreatic necrosis. For infected cases, surgical drainage of the pancreatic exudate is necessary. Jacobs et al. found that profoundly ill patients survived twice as often if they underwent surgical drainage.^[17] Of course, laparotomy, carries with it the added risks of preterm labor and delivery. Patients who relapse may also develop a pseudocyst. This complication requires surgical intervention after a period of time in which an adequate drainage procedure can be accomplished. In spite of the high rate of preterm labor even in conservatively managed cases, the fetal salvage rate, in cases of maternal pancreatitis, has been reported to be as high as 89 percent.^[12]

INFLAMMATORY BOWEL DISEASE

The inflammatory bowel diseases, ulcerative colitis (UC) and Crohn's disease (CD), or regional enteritis, are idiopathic disorders that have their peak incidence in the reproductive age group. UC is a disease of the colon or rectum, marked by acute attacks of bloody stools, diarrhea, cramping, abdominal pain, weight loss, and dehydration. The histologic findings include a decreased number of goblet cells, crypt abscesses, ulcerations, and an inflammatory infiltrate consisting of lymphocytes, plasma cells, and polymorphonuclear cells. The prevalence of UC in the female population under 40 years of age is 40 to 100 per 100,000. ^[18] CD is considerably less common than UC with an incidence of 2 to 4 per 100,000. The average age of onset is between 20 and 30 years. CD, in contrast to UC, tends to run a more subacute and chronic course, with symptoms including fever, diarrhea, and cramping abdominal pain. ^[19] CD may be found anywhere from mouth to anus including the perineum. However, the distal ileum, colon, and anorectal region are most frequently involved. Histologically, the inflammation is focal with fissuring, ulcerations and prominent lymphoid aggregates present. The hallmark of the histologic diagnosis is transmural involvement of the bowel coupled with the presence of multiple noncaseating granulomas. Because CD may involve only the colon, histologic differentiation from UC becomes important.

Ulcerative Colitis

The primary symptom in UC is bloody diarrhea. Frequent bowel movements with pus, intestinal cramping, fever, dehydration, and anemia are also observed with flaring of disease. Physical examination and laboratory data are nonspecific, with the diagnosis resting on endoscopic examination and biopsy.

Most studies have failed to provide adequate information on the specific effects of this disease on fertility. Early reports suggested a fertility rate of 15 to 31 percent, however, few data were provided about fertility assessment in these women as well as their partners. ^[20], ^[21] Subsequently, Willoughby and Truelove provided data that suggested that UC had little if any effect on fertility. ^[22] Of 137 women desiring pregnancy, 119 (87 percent) conceived, a rate similar to most normal populations. This study, however, spanned 10 years and may not reflect periods of impaired fertility related to increased activity of the disease.

Data describing the influence of UC on pregnancy outcome is more conclusive. Abramson first described the pregnancy outcome of patients with UC according to their disease during gestation. ^[24] In this report, group I consisted of women with inactive disease at the start of pregnancy; group II, patients with active disease in early pregnancy; group III, patients with onset of disease during gestation; and group IV, patients in whom disease developed during the puerperium. ^[24] The data revealed that patients in group I had the best prognosis, as 18 of 20 had full-term pregnancies, with 7 experiencing exacerbation of disease during gestation or in the postpartum period. Of 12 patients in group II, all had term pregnancies marked by exacerbation of disease during pregnancy or the puerperium. Of five women in group III whose disease commenced during pregnancy, three fetal deaths occurred. It should be remembered, however, that this report antedated the use of steroids and other medications presently available to control active disease.

In 1956, Crohn et al. published their experience with UC in pregnancy. ^[25] They analyzed the perinatal outcomes in 110 women during 150 pregnancies using Abramson's classification. Group I contained 74 pregnancies in which 62 were successful. The disease was reactivated in 54 percent of cases including all six spontaneous abortions. Group II patients suffered reactivation of disease during pregnancy or postpartum in nearly 75 percent of cases. Pregnancy was successful in 84 percent (32 of 38) of women in this group. The Crohn et al. data suggested that patients with reactivation of quiescent disease during pregnancy had higher rates of abortion. ^[25] However, their 19 group III patients with new-onset disease experienced only one stillbirth and no spontaneous losses. In contrast, a Danish study demonstrated a higher probability of miscarriage in women with active disease at conception. Seven of 19 women in this category versus 9 of 133 with quiescent disease suffered a miscarriage. ^[26]

Willoughby and Truelove have confirmed that a good outcome can generally be expected in pregnancies complicated by UC. ^[22] Furthermore, their study described a group of 102 patients treated with modern therapies, including either steroids, sulfasalazine, or

both. They recorded a spontaneous abortion rate of only 11 percent in 216 women followed over a 20-year period. ^[25] Women with quiescent disease at conception had a slightly greater chance of successfully reaching term when compared with patients whose disease was active during pregnancy. The proportion of low-birth-weight babies and the incidence of anomalies was similar to that of the general population. This study also examined the effect of pregnancy on UC. Of the 129 pregnancies in which colitis was quiescent at the time of conception, 90 (70 percent) of the patients remained free of symptoms throughout pregnancy and the puerperium.

Crohn's Disease

As Crohn's disease may affect any part of the gastrointestinal tract, its clinical presentation depends on the area of involvement. In most cases, abdominal pain with fever and nonbloody diarrhea are observed.

It has been difficult to determine the effect of CD on fertility. In studies that lacked full evaluation and follow-up, Crohn et al. ^[27] and Fielding and Cooke ^[28] reported infertility rates of 38 percent and 26 percent, respectively. Interestingly, Fielding and Cooke's study revealed a much higher infertility rate (67 percent) if CD involved the colon. DeDombal et al. ^[29] have confirmed that a high proportion of patients with large bowel disease are "subfertile." They suggest that temporary infertility may be related to the activity of the disease. ^[22] Khosla et al. ^[30] described infertility in 112 patients with CD and reported a 12 percent rate, similar to that seen in the general population. In a case-control study, the number of offspring of women with CD was 57 percent of that of paired controls. This study concluded that disease location had no influence on fertility. ^[31]

Studies describing the effect of CD on pregnancy suggest minimal if any increased risk to both mother and fetus. In Crohn's original report, 53 patients with regional ileitis had 84 pregnancies, and 75 (89 percent) infants survived. Seventy-one of these deliveries occurred at term. ^[27] However, the three patients who developed CD during pregnancy suffered two stillbirths and one preterm delivery. The only maternal death occurred in this group. Fielding and Cooke also reported favorable outcomes in a series of patients with both regional ileitis and Crohn's colitis. Their study described an 85 percent live-birth rate among 52 women in 98 pregnancies. Other studies confirm these excellent results, with full-term delivery rates of 73 to 83 percent. ^[32], ^[33]

Three investigations suggest that active CD carries with it a greater risk of spontaneous miscarriage. ^[30], ^[32], ^[33] Khosla et al. ^[30] reported a spontaneous loss rate of 35 percent in patients with active disease at the time of conception and 50 percent in patients with severe disease. These data are supported by Danish and Canadian studies in which the risk of both preterm delivery and spontaneous abortion were found to be significantly higher in women with active disease at conception. ^[32], ^[33]

A subgroup of patients deserves further mention, those who first develop disease during pregnancy. The caution about unfavorable outcomes in such patients has

been supported by Martimbeau et al.^[34] They reported 10 patients including one with twins in whom infant deaths occurred. Four of these neonatal deaths followed an operative procedure. However, tocolytics and neonatal intensive care were unavailable in most of these cases.

The effect of pregnancy on CD is similar to that reported for patients with UC. DeDombal et al.^[29] reported that 73 percent of patients had no change in disease activity, 15 percent improved and 10 percent worsened during pregnancy. If a woman conceives while CD is in remission, she is just as likely to remain in remission as a nonpregnant patient. In Woolfson et al.'s study, 18 of 73 (25 percent) women with quiescent CD at conception relapsed during pregnancy.^[33] Maintenance on medication did not affect the relapse rate. In a study by Khosla et al.,^[30] postpartum flare-ups were virtually absent in contrast to DeDombal et al.'s^[29] report of a 40 percent postpartum recurrence rate. Khosla et al.^[30] also noted that patients with clinically active disease at the time of conception usually continue to have symptoms during pregnancy. Only 7 of 20 patients (35 percent) in this category went into remission or had slight improvement with pregnancy. Overall, the risk of exacerbation during pregnancy is not higher than that in the nonpregnant population.^[31]

Treatment of Inflammatory Bowel Disease During Pregnancy

The medical treatment of inflammatory bowel disease is not altered greatly by pregnancy. All patients should be followed closely so that the activity of their disease may be assessed and psychological support can be provided. Since emotional tension may adversely affect both UC and CD, it is important that patients with inflammatory bowel disease have the opportunity to discuss the stress of pregnancy openly. Dietary counseling for patients with UC should emphasize proper nutritional intake. Patients with mild disease may respond to a low-roughage diet or the exclusion of milk products if they are lactose intolerant. In contrast, patients with CD often benefit from low-residue diets, presumably because the caliber of their small bowel may be limited by inflammation.

The initial therapy for inflammatory bowel disease during pregnancy is 5-aminosalicylic acid (5-ASA)

1228

products and corticosteroid therapy. The safety of both of these classes of medication has been well established in pregnancy. Sulfasalazine (Azulfidine) is most effective in maintaining remission and preventing further attacks. Patients who present early in pregnancy on sulfasalazine for a recent flare of their disease should probably be maintained on this therapy, as active colitis may develop if the drug is discontinued. The active metabolite of sulfasalazine, 5-ASA and its *N*-acetyl derivative, are also available for treatment.^[35] These medications (Rowasa, Penta, Asocol) are all category B drugs. Concerns about the use of sulfasalazine in late pregnancy centered on its ability to cross the placenta, displace bilirubin, and cause kernicterus. However, the active fetal metabolite, sulfapyridine, has weak bilirubin displacing activity, and the actual risk is small. Jaundice was not increased in 209 neonates of women treated with Azulfidine. The safety of sulfasalazine in breast-feeding has raised some concern. The concentration of sulfapyridine in breast milk is approximately 45 percent that of maternal serum. Similarly, concentrations of 5-ASA are lower in fetal plasma and breast milk than in maternal serum.^[36] Thus, sulfasalazine and 5-ASA can be given safely to nursing mothers.^[36]

Steroids are indicated in patients who fail to respond to simple supportive measures. Steroid retention enemas may be effective for mild to moderate distal colitis or proctitis. Patients with severe disease are initially treated with high doses of intravenous hydrocortisone or its equivalent. Oral prednisone can then be substituted and tapered as the attack subsides. The safety of corticosteroids and sulfasalazine in pregnancy associated with inflammatory bowel disease was addressed in a national survey by Mogadam et al.^[39] In examining 287 pregnancies in which either or both drugs were employed versus 244 untreated patients, no adverse effects could be found that were attributable to these drugs. The higher complication rates associated with severe CD in this study seemed to be more related to disease activity rather than the use of medication.

Occasionally, patients with inflammatory bowel disease may receive azathioprine for treatment. The safety of this medication during pregnancy remains controversial. Similarly, mercaptopurine (class D) or cyclosporine (class C) should be avoided in most cases during pregnancy. Alstead and colleagues^[37] recently reported 16 pregnancies in 14 women receiving azathioprine for inflammatory bowel disease. There was one infectious complication of pregnancy (hepatitis B infection), but no congenital abnormalities or health problems in the offspring.^[37] The decision to utilize this medication must be made after consultation with the patient including weighing the risk of exacerbation of disease upon discontinuation.

Patients with severe disease who become profoundly dehydrated require hospitalization and intravenous fluids. The development of significant hypoalbuminemia coupled with inadequate caloric intake may require the institution of parenteral hyperalimentation. The benefits of such nutritional therapy include diminished gastrointestinal secretion and motility, potential relief of partial obstruction, closure of fistulas, and renewal of immunocompetence. Anemia should also be treated aggressively by transfusion, although mild anemias will generally respond to oral iron therapy.

Surgical Treatment

Although most acute episodes of inflammatory bowel disease respond to medical treatment, operative intervention will occasionally be necessary to treat perforation, obstruction, or patients unresponsive to standard therapies. While elective surgery for medically intractable disease or recurrent dysplastic lesions of the colon is best accomplished following pregnancy, patients who have undergone definitive surgical procedures for UC seem to fare well during pregnancy. Surgery during pregnancy does carry a significant risk of preterm delivery, probably due to the amount of uterine manipulation required during efforts to reach the distal colon. Surgery should not be delayed, however, in cases of perforation or complete obstruction. Anderson and colleagues^[38] have reported three cases of emergency colectomy during pregnancy for toxic megacolon in women with fulminant UC. There were no maternal deaths; however, two stillbirths occurred as well as one preterm delivery.^[38]

Ileostomy function during pregnancy is normal in most cases. Of 84 term pregnancies reported by Hudson, intestinal obstruction occurred in just 7 cases.^[39] Of 17 cesarean sections performed in his series, all were done for obstetric indications. Similarly, Gopal and colleagues^[40] described 82 pregnancies in 66 women following colostomy or ileostomy. Stomal dysfunction responded to conservative measures in all but three women who required surgery for intestinal obstruction. Complications from an episiotomy have been uncommon in patients previously operated on for UC. Data is not available for CD. However, the higher rate of perineal involvement in these patients should warrant a thorough evaluation before contemplating vaginal delivery.

Surgery for CD, unlike UC, is generally not curative. It is estimated that 40 percent of patients with ileitis will require surgery at some time for obstruction, perforation, extensive fistulas, or perirectal suppuration.^[38] Most surgical procedures must limit the amount of bowel resection because of the diffuse nature of this disease. Prior bowel resection has been associated with increased risk of preterm delivery and spontaneous miscarriage.

Patients with Crohn's colitis who have undergone

1229

proctocolectomy are at substantial risk for recurrent disease including persistent perineal wounds in up to 60 percent of cases.^[41] Cesarean delivery should be considered for patients with perianal disease who have been diverted to promote healing. Those patients with CD who require surgery during pregnancy are usually operated on for obstruction.^[42] As with UC, there may be a high incidence of fetal loss. The decision to perform a simultaneous cesarean delivery must be individualized according to the type of procedure involved, its indications and the gestational age of the pregnancy.

Key Points

Women with peptic ulcer disease usually have improvement in symptoms during pregnancy. Primary medical treatment for symptomatic cases is antacid therapy and diet. Secondary therapy is H₂ blockers.

Most cases of pancreatitis during pregnancy are associated with gallstones. Conservative supportive care aimed at decreasing pancreatic secretion is generally successful.

Women with active ulcerative colitis in early pregnancy usually have recurrent flare-ups during gestation and postpartum.

The onset of ulcerative colitis or Crohn's disease during pregnancy is associated with increased miscarriage and fetal loss rates.

Sulfasalazine (Azulfidine) and 5-ASA metabolite drugs may be safely used to treat inflammatory bowel disease during pregnancy and in lactating women.

Chapter 37 - Neurologic Disorders

Philip Samuels

SEIZURE DISORDERS

Affecting approximately 1 percent of the general population, seizure disorders are the most frequent major neurologic complication encountered in pregnancy. Seizure disorders may be divided into those that are acquired and those that are idiopathic. Acquired seizure disorders, which account for less than 15 percent of all seizures, may result from trauma, infection, space-occupying lesions, or metabolic disorders. Over 85 percent of seizure disorders are classified as idiopathic, meaning that no etiologic agent or inciting incident can be identified. Idiopathic seizures can be divided into types such as tonic-clonic, partial complex with or without generalization, myoclonic, focal, or absence.

In general, initial therapy is based on the type of seizure disorder experienced by the patient. There are, however, many crossovers, and patients may respond differently to each medication despite their seizure type. It is, therefore, not unusual to encounter a patient with any seizure type who may be taking any of the major antiepileptic medications. Furthermore, patients may be placed on a certain medication because they did not tolerate the side-effect profile of another anticonvulsant (Table 37-1). Because of the prevalence of this group of disorders in women of childbearing age, the stigmata surrounding epilepsy, and the misguided fears many patients and physicians have surrounding epilepsy in pregnancy, the treatment of the pregnant patient with a seizure disorder can create quite a challenge for the obstetrician. In addition, many patients with epilepsy have done very well on their medications so they have not been evaluated by a neurologist in many years. Some patients have been seizure free for many years and have stopped their medications, while others have been seizure free for many years but have continued to take their medication without being reevaluated. Still others have poorly controlled seizures, and it is unclear whether this is due to noncompliance with or ineffectiveness of their medication regimen. Other patients may be taking two medications when they may need only one. The obstetrician and neurologist must work closely together to guide the patient through her pregnancy and find the safest and most effective medical therapy for the patient. Through this cooperation, the vast majority of pregnant women with seizure disorders can have a successful pregnancy with minimal risk to mother and fetus.

Effects of Epilepsy on Reproductive Function

Women with seizure disorders should seek care from an obstetrician/gynecologist as soon as they become sexually active. Contraception may present a challenge to women with epilepsy, and the use of oral contraceptives may require special adjustments. Certain antiepileptic medications have been associated with contraceptive failure. Carbamazepine, phenobarbital, and phenytoin enhance the activities of hepatic microsomal oxidative enzymes. The cytochrome P450 system is shared by these medications as well as by the steroid hormones. This increased enzymatic activity may lead to rapid clearance of these hormones, which may allow ovulation to occur. Therefore, medicated patients taking low-dose oral contraceptives, which are being prescribed with increasing frequency, may have more breakthrough bleeding and may be at increased risk for unplanned pregnancy. This rapid clearance does not appear to be induced by valproate or benzodiazepines.

Fertility rates may be lower in patients with epilepsy. A

TABLE 37-1 -- COMMON SIDE EFFECTS OF ANTICONVULSANTS

Drug	Maternal Effects	Fetal Effects
Phenytoin	Nystagmus, ataxia, hirsutism, gingival hyperplasia, megaloblastic anemia	Possible teratogenesis and carcinogenesis, coagulopathy, hypocalcemia
Phenobarbital	Drowsiness, ataxia	Possible teratogenesis, coagulopathy, neonatal depression, withdrawal
Primidone	Drowsiness, ataxia, nausea	Possible teratogenesis, coagulopathy, neonatal depression
Carbamazepine	Drowsiness, leukopenia, ataxia, mild hepatotoxicity	Possible craniofacial and neural tube defects
Valproic acid	Ataxia, drowsiness, alopecia, hepatotoxicity, thrombocytopenia	Neural tube defects and possible craniofacial and skeletal defects
Ethosuximide	Nausea, hepatotoxicity, leukopenia, thrombocytopenia	Possible teratogenesis

retrospective study by Webber and colleagues reviewed fertility rates in individuals with epilepsy over a 50-year period. They found that fertility rates were significantly lower in both men and women with epilepsy and that this could not be explained solely by the rate of marriage in these patients. Men appeared to be more adversely affected than women. Women with epilepsy had fertility rates 85 percent of the expected. Furthermore, in this retrospective review, women with partial seizures seemed to have lower fertility rates than those with generalized seizures. In a study by Dansky et al., fertility rates appeared to be lower in those women with early-onset epilepsy than those with late onset. Cramer and Jones also reviewed a study published in Poland in 1979 that investigated the fertility rate in 263 unselected patients with epilepsy. They found that the fertility rate was half that of the general population, and 25 percent of married patients had no children. All of these cited studies concerning lower fertility rates have many methodologic problems. Yet, even in these studies, the majority of patients with epilepsy were able to conceive without difficulty. Nonetheless, the practicing obstetrician/gynecologist should be prepared to undertake an infertility evaluation of these patients or to refer them to an infertility specialist should the need arise.

Effect of Pregnancy on Epilepsy

It has been taught that between 30 percent and 50 percent of patients will show an increase in seizure frequency during pregnancy. This was confirmed in the classic study of Knight and Rhind of 153 pregnancies in 59 patients between 1953 and 1973. In that study, 45 percent of patients showed an increase in seizure frequency during pregnancy, while 50 percent had no change and 4.8 percent experienced a decrease. It is very important to note that anticonvulsant levels could not be readily measured until the mid 1970s. When the study of Knight and Rhind was performed, anticonvulsant doses were usually only increased by physicians when patients

had breakthrough seizures. An important finding from that study, however, was that patients with more frequent seizures tended to have exacerbations during pregnancy.^[9] In fact, virtually all patients who had more than one seizure each month experienced worsening of their epilepsy during pregnancy, whereas only about 25 percent of patients who had not had a seizure in over 9 months experienced exacerbation of epilepsy during pregnancy. With the introduction of new medications and the ability to monitor anticonvulsant levels, these absolute numbers are no longer true. The relationship, however, does remain. Patients with more frequent seizures tend to have exacerbations of seizures during pregnancy. In a large study by Schmidt et al.,^[8] 63 percent of patients had no change or a decrease in seizure frequency during pregnancy, while only 37 percent of patients had an increase of seizures during pregnancy. Importantly, in 34 of the 50 patients who showed an increase in seizure frequency during pregnancy, the increase was associated with noncompliance with their drug regimen or sleep deprivation. Conversely, in 7 of the 18 pregnancies in which improvement of seizure frequency was shown, this was related to improved compliance with the drug regimen or a correction of sleep deprivation for the 9 months preceding pregnancy. In a study by Tanganelli and Regesta,^[9] seizure frequency did not change or improved in 82.6 percent of pregnancies. As has been shown in other studies, increases in seizure frequency were often due to noncompliance with medication regimens as well as frequent seizures in the preconception period. In contrast, Sabers et al. summarized 151 pregnancies in 124 women with epilepsy between 1978 and 1992.^[10] They found 21 percent of patients has exacerbations of their seizures during pregnancy and 71 percent were only taking one medication.^[10]

In summary, we now have the means to monitor anticonvulsant levels in patients frequently, and we have the medications to control seizures. We also understand

1233

that sleep deprivation can be a catalyst for seizures. With patient cooperation and close surveillance, seizure frequency should remain the same or even improve in most epileptic patients during pregnancy.

Effects of Pregnancy on the Disposition of Anticonvulsant Medications

It is well known that the levels of anticonvulsant medications can change dramatically during pregnancy. They usually decrease in total concentration as pregnancy progresses. Many factors including altered protein binding, delayed gastric emptying, nausea and vomiting, changes in plasma volume, and changes in the volume of distribution can affect the levels of anticonvulsant medications. It is beyond the scope of this chapter to elucidate these mechanisms. Without some understanding of this subject, however, it is difficult to manage the patient with epilepsy correctly. Therefore, some of the salient points of this topic are covered.

As phenytoin is one of the most widely prescribed anticonvulsant medications, its metabolism and elimination are discussed. Landon and Kirkley^[11] and Kochenour et al.^[12] showed that the serum concentration of phenytoin tends to fall during pregnancy and rise again during the puerperium and postpartum periods. Several factors can account for this. In early gestation, patients often have nausea and vomiting. Phenytoin is usually administered on a once-daily basis. If the patient vomits the medication, the drug levels will be highly variable. Furthermore, an increase in calcium intake during pregnancy, as well as the use of antacids, will lead to the formation of insoluble complexes with phenytoin, resulting in lower total drug levels. Also, with delayed gastric emptying in pregnancy, the time to peak drug level will be lengthened. Phenytoin is inactivated in the liver. Its rate of conversion may increase greatly during pregnancy, as the activity of oxidative enzymes increases. This is due to increased progesterone levels, which induce enzyme activity. This may also be enhanced by increased folic acid, which serves as a cofactor in these metabolic processes. Outside of pregnancy, approximately 90 percent of phenytoin is protein bound. Plasma albumin levels decrease during pregnancy while other protein levels may rise. This will cause changes in the total phenytoin level that do not necessarily reflect the free, active phenytoin concentrations. This effect is also enhanced by free fatty acids displacing phenytoin from albumin. In a recent study by Yerby et al.,^[13] free levels of phenobarbital, carbamazepine, and phenytoin rose significantly throughout pregnancy while total levels fell. Therefore, the non-pregnant relationship between total drug and free (active) drug is not maintained. Free phenytoin levels, therefore, should be measured if possible. If free levels are unavailable, drug doses should be adjusted according to the total serum level and the clinical picture. If the patient has increased seizure activity, medication doses should be increased as long as the patient is not showing signs of toxicity. Likewise, if the medication level is low but the patient is seizure free, no adjustment in dosing is necessary.

Similar pharmacokinetic changes occur in phenobarbital and carbamazepine, but to different degrees. Both of these drugs also show changes in protein binding and increased hepatic clearance during pregnancy. With phenobarbital, the protein binding is considerably less than phenytoin, and changes in plasma protein are less likely to be clinically significant. Primidone is an anticonvulsant medication that is metabolized to phenobarbital and another active metabolite, phenylethylmalonic acid diamide. When checking primidone levels, one must also check levels of phenobarbital. Infants born to mothers who have been taking barbiturates during pregnancy may exhibit some withdrawal symptoms that begin about 1 week after birth and usually last 1 to 2 weeks.^[14] These symptoms usually involve minor irritability but may occasionally be more serious.

Carbamazepine also has an active metabolite, carbamazepine 10,11-epoxide. This metabolite can be measured and this measurement can be clinically useful in many instances. Carbamazepine is not as highly protein bound as phenytoin and is therefore not subject to as wide a fluctuation due to changes in protein levels. Carbamazepine also induces its own metabolic enzymes in the liver, so the half-life changes as the dose increases.^[12]

All anticonvulsants interfere with folic acid metabolism. Patients on anticonvulsants may actually become folic acid deficient and develop macrocytic anemia. Folic acid deficiency has been associated with neural tube defects and other congenital malformations.^[15],^[16] Because organogenesis occurs during the first weeks after conception, folic acid supplementation should be begun before pregnancy if possible. A dose of 4 mg daily is more than sufficient. As previously stated, increasing folic acid ingestion may increase the activity of hepatic microsomal enzymes and thus the clearance of anticonvulsant medications. Levels should be checked frequently, therefore, after folic acid therapy is implemented. Furthermore, therapy with phenytoin may result in increased metabolism of vitamin D, leading to decreased vitamin D levels. This has been shown to cause neonatal hypocalcemia in one case report.^[17] The patient should be reminded to take her prenatal vitamins, which include an adequate amount of vitamin D to prevent problems.

Neonatal hemorrhage, due to decreased vitamin K-dependent clotting factors (II, VII, IX, X), has been seen in infants born to mothers taking phenobarbital, phenytoin, and primidone.^[18] In one series,^[18] 8 of 16 infants exposed to these medications had a cord blood

1234

coagulation pattern similar to that of a vitamin K deficiency. This occurred earlier than the customary hemorrhagic disease of the newborn. These infants responded to vitamin K infusion. Bleyer and Skinner^[19] reviewed a case of their own and another 21 cases of hemorrhagic disease following anticonvulsant therapy that have appeared in the literature. They reached similar conclusions that these cases are vitamin K-dependent clotting factors deficiencies and that, at birth, infants should be given 1 mg of vitamin K intramuscularly.

Effect of Epilepsy on Pregnancy

The majority of women with seizure disorders who become pregnant will have an uneventful pregnancy with an excellent outcome. There appear, however, to be several pregnancy complications that are more prevalent in the mother with epilepsy than in the general population. In a review of all birth certificates for infants born in the state of Washington in 198081, Yerby and co-workers^[20] identified 200 births to mothers with seizure disorders. Although birth certificate studies are often limited, these researchers controlled for many variables including previous adverse pregnancy outcome and socioeconomic status.^[20] They found that mothers with seizure disorders were 2.66 times more likely to have had a previous fetal death after 20 weeks' gestation than the control population. Because of the retrospective nature of this study, the authors were unable to correlate this with growth restriction or other fetal problems. This increased incidence of stillbirth is confirmed in other studies.^[7],^[21],^[22] It is unclear in any of these studies what type of fetal surveillance was utilized and if there were any predictors that these fetuses were at risk. Because of the long duration of many of these studies, many patients were pregnant during the 1970s and early 1980s. With the increased use of ultrasound to identify fetal growth restriction, malformations, and oligohydramnios, many of the stillborn fetuses may have been identified as being at risk and might have undergone antepartum fetal testing and intervention before the fetal demise occurred. These studies also were not stratified by medications taken, dosages, drug levels, or seizure activity during pregnancy.

Hiilesmaa et al.,^[23] in a study of 150 pregnant women with seizure disorders, found no difference in perinatal mortality between patients and controls. There were, however, three third-trimester stillbirths in the epileptic group and two in the control group. Yerby and colleagues^[19] also found an increased incidence of preeclampsia in women with seizure disorders. This has also been identified in other large retrospective studies.^[7],^[21] Hiilesmaa et al.,^[23] however, found no difference in the rate of preeclampsia between pregnant women with epilepsy and controls. Yerby et al.^[20] also showed a 2.79-fold increase in low-birth-weight infants. In a carefully

performed study in Italy, Mastroiacovo and co-workers^[24] found that the mean birth weight in neonates born to women with epilepsy was 107 g lower than controls. The mean birth weight in the epilepsy group, however, still fell within the normal range for gestational age. The clinical significance of this finding, therefore, is questionable. When considering all commonly used anticonvulsants, this decrease in neonatal weight appeared to be more common in infants exposed in utero to phenobarbital.

Mastroiacovo et al.^[24] also found a decrease in head circumference in infants of mothers with epilepsy. This effect was seen both in untreated women with epilepsy and in those receiving medications.^[24] Although this change was statistically significant, the mean head circumferences of both study and control infants still fell within the normal range. These authors found no difference in neonatal length comparing groups of mothers with epilepsy and control populations. Hiilesmaa et al.^[25] also found a decrease in head circumference in neonates born to women with epilepsy. This decrease was most marked in women taking carbamazepine both alone or in combination with phenobarbital. Again, the mean head circumferences, however, were still within the expected normal range.^[25] In the follow-up of this study, head circumferences were still smaller at 18 months of age.

Along similar lines, Hvas et al. compared pregnancy outcomes in 193 women with epilepsy to 24,094 women without epilepsy delivering between 1989 and 1997.^[26] They found that birth weight of infants born to women with epilepsy was 208 g less than those born to women without a seizure disorder. The odds ratio that a woman treated with epilepsy would give birth to an infant with IUGR was 1.9.^[26] Head circumference and body length were also diminished in the infants born to women taking antiepileptic drugs. When smokers with and without epilepsy were compared, there was an increased risk of preterm birth in those who smoked.^[26] Battine et al. examined anthropometrics in children born to women with epilepsy in Canada, Japan, and Italy.^[27] They found some distinct geographic differences in risk for decreased head circumference that may or may not be drug regimen related. The relative risk for small head circumference in infants exposed to more than one medication (polytherapy) was 2.7.^[27] A dose-dependent response for both head circumference and body weight was seen with the use of phenobarbital and primidone.^[27] The authors state that in addition to drug regimen, genetic, ethnic, and environmental effects should be taken into account when considering explanations for decreased head circumference and birth-weight in infants born to women treated for epilepsy.^[27]

Yerby and colleagues^[20] found a sixfold increased rate of maternal herpes in women with epilepsy. There is no readily available explanation for this, and it has not

1235

been seen in other studies, although it is doubtful that anyone has looked for this as an endpoint. They further found a significant decrease in 1- and 5-minute Apgar scores. This may be attributed to fetal effect of maternal depressant medications such as phenobarbital. Conversely, Hiilesmaa et al.^[23],^[25] found no increase in pregnancy complications in women with epilepsy. They found no increase in preterm labor, bleeding, pregnancy-induced hypertension, operative vaginal delivery, or cesarean delivery rates. These authors imply that the lack of increased operative deliveries in their study is due to the comfort of the obstetrician in caring for patients with seizure disorders. However, Yerby et al.^[20] found an increased rate of cesarean deliveries in their review. For uncertain reasons, they also found an unexplained increase in third trimester amniocentesis and labor inductions. This may be construed as insecurity on the part of the obstetrician in caring for the patient with a seizure disorder and the desire to effect a delivery as soon as fetal pulmonary maturity could be documented.

In summary, there appears to be an increased risk of stillbirths in women with seizure disorders. The cause of this is not readily apparent but may be due to factors that are easily detectable today (such as intrauterine growth restriction) that were not detected when these studies were carried out. It also appears that infants born to mothers with seizure disorders, on average, are smaller than their control counterparts. It is uncertain whether the incidence of actual intrauterine growth restriction is higher. Furthermore, the incidence of preeclampsia may be higher in mothers with seizure disorders. The vast majority of pregnancies, however, will be uncomplicated with no increase in complications over the expected rate. Nonetheless, because of these few potential problems, the obstetrician should be more surveillant for pregnancy-related complications in pregnant women with seizure disorders.

Effects of Anticonvulsant Medications on the Fetus

There is little doubt that anticonvulsant medications are associated with an increase in congenital malformations, but the magnitude of this risk and the association of certain anomalies with specific drugs remain debatable. Although there was some evidence for teratogenicity related to phenytoin in the 1960s, Hanson and Smith^[28] identified a specific fetal hydantoin syndrome in 1975. They noted growth and performance delays, craniofacial abnormalities (including clefting), and limb anomalies (including hypoplasia of nails and distal phalanges). They first reported this syndrome in five infants exposed to phenytoin in utero. Hanson et al.^[29] later reported that 7 to 11 percent of infants exposed to phenytoin had this recognizable pattern of malformations. They furthermore found that 31 percent of exposed fetuses had some aspects of the syndrome. Yet in 1988 Gaily et al.^[30] reported no evidence of the hydantoin syndrome in 82 women exposed in utero to phenytoin. Some of the patients had hypertelorism and hypoplasia of the distal phalanges, but none had the full hydantoin syndrome.

Since the original reports by Hanson and colleagues, many studies have reported congenital malformations in infants born to mothers taking anticonvulsant medications. These reports typify the discrepancies that fill the medical literature concerning this subject. There are studies that report each of the commonly used anticonvulsant medications (phenytoin, phenobarbital, carbamazepine, and valproate) is the worst teratogen, yet there are other studies that report each of these medications has a weak teratogenic potential. It remains of prime importance, therefore, to treat the patient with the medication that best controls her seizures. Another example of discrepancies and the need for more research involves the incidence of facial clefting among infants born to mothers with epilepsy. This is one of the most common anomalies found in these neonates. In a study by Friis et al.^[31] untreated epileptics had an incidence of facial clefting 2.7 times the expected rate, whereas infants of mothers treated with anticonvulsants had 4.7 times the expected rate of clefting. All of the observed clefts in these groups were cleft lip with or without cleft palate. There was no increased incidence of isolated cleft palate. These authors concluded that epilepsy itself may increase the risk for cleft lip, with anticonvulsant medications increasing the risk even more.^[31] A study by Kelly et al.^[32] demonstrated that the association between epilepsy and facial clefting is in large part due to shared causal determinants that are probably both genetic and environmental in origin. They believe that the role of anticonvulsant medications in this association seems to be overestimated and probably represents only a modest additive influence. In contrast, however, Hecht et al.^[33] in an epidemiologic study, found no evidence for familial association between epilepsy and clefting disorders.

It has now been two decades since Nakane and colleagues^[34] published the first major, multi-institutional study investigating the teratogenicity of antiepileptic medications. This study, carried out between 1974 and 1977, examined 902 pregnancies in mothers with idiopathic epilepsy. The overall rate of congenital malformations was 7.2 percent. This included 8.7 percent in the mothers who received anticonvulsant medications during pregnancy and 1.9 percent in nonmedicated mothers. Looking only at liveborn infants, 9.9 percent had malformations (11.5 percent in the medicated group and 2.3 percent in the nonmedicated group). The incidence of malformations in mothers receiving anticonvulsant therapy was therefore about five times that

1236

of the nonmedicated group. Interestingly, Canger et al.^[35] began collecting data in Italy at the time Nakane's group completed their data collection. Canger and co-workers studied 517 women with epilepsy throughout pregnancy. They found a 9.7 percent rate of malformations, a proportion strikingly similar to that of Nakane.^[34]

In Nakane's study,^[34] the predominant malformations were cleft lip/palate (3.14 percent) and cardiovascular malformations (2.95 percent). Nakane et al. also noted that as the number of anticonvulsant medications used in combination during pregnancy increased, the incidence of fetal malformations rose dramatically.^[34] The malformation rate was less than 5 percent when one medication (monotherapy) was used and was greater than 20 percent when four medications were used. Of note, 537 patients were taking two or more medications while 93 patients were only taking one medication. This is fairly reflective of the prescribing patterns for anticonvulsant medications in the 1970s and shows why many of the studies and case reports from the 1970s are not relevant today, as many more patients are receiving monotherapy. In this study, only 15 percent of patients were treated with a single antiepileptic medication.^[34] Congenital heart disease was significantly higher in infants born to mothers taking phenobarbital, and cleft lip/palate was more common in infants born to women taking primidone.

Kaneko and colleagues performed a prospective study to determine primary factors responsible for the increased incidence of malformations in infants born to mothers being treated with anticonvulsants.^[36] They specifically looked at various drug combinations. The overall malformation rate was 14 percent. In the 16.1 percent of patients who were receiving a single medication, the malformation rate was 6.5 percent.^[36] The malformation rate for those treated with multiple medications was 15.6 percent. There was no dose-dependent increase in the incidence of malformations associated with any individual medication. In this study there was also no relationship between the type of defect and the individual anticonvulsant. This contrasts with the study by Nakane et al.^[34] In that study, polypharmacy had a

significantly higher risk of causing congenital malformations than other medications. ^[29]

Kaneko et al.^[37] published a follow-up study looking at malformations in infants exposed in utero to anticonvulsant medications. They compared these results with their previous study.^[36] The first study looked at infants born between 1978 and 1984, while the later study looked at infants born between 1985 and 1989. Whereas 14 percent of infants had some malformation in the previous study, the malformation rate was only 6.3 percent in the second group.^[37] Again, there was no relationship between the medication taken and the type of malformation found.^[37] The lower rate of malformations may be attributable to the increase in patients receiving monotherapy. In the earlier study 16.1 percent of patients received a single medication, whereas 63.4 percent received a single medication in the later study.^[37] Jick and Terris^[38] matched 2 nonexposed pregnant women to each of 297 pregnant women exposed to antiepileptic medication. The rate of anomalies in infants born to women with epilepsy was 3.4 percent,^[38] a rate even lower than that found by Kaneko et al. in their 1992 study.^[37] In fact, 3.4 percent does not appear to be much higher than the background rate for congenital anomalies. Nonetheless, Jick and Terris found the relative risk for a woman on antiepileptic medications to give birth to an infant with an anomaly was 3.3.^[38]

Most neurologists are treating patients with a single agent. Now that blood levels of anticonvulsant medications can be easily measured, single medications can be given at higher doses to make certain that therapeutic levels are achieved. This has lessened the need for multiple medications in the same patient. Prior to the ability to measure these levels, empiric doses of medication were given. If the patient continued to have seizures, another medication was often added rather than increasing the dose of the initial medication.

The same concept was verified in a study by Lindhout et al.^[39] They compared the pattern of malformations in the offspring of two cohorts of women with seizure disorders, one from 1972 to 1979 and one from 1980 to 1985. In the earlier cohort, 15 of 151 (10 percent) of liveborn infants had at least one congenital anomaly. The most common anomalies were those most frequently reported for anticonvulsant medications: congenital heart defects, facial clefts, facial dysmorphism, and developmental retardation. In the later cohort, 13 of 172 infants (7.6 percent) exposed in utero to anticonvulsant medications had congenital malformations.^[42] The most frequent anomalies in this group were spinal defects and hypospadias. All of these were associated with maternal therapy with valproate, carbamazepine, or both.^[39] In the earlier cohort of patients, the mean number of drugs used during gestation was 2.2 compared with 1.7 in the later cohort. Whereas only 28 percent of women in the earlier cohort received only one medication, 47 percent of the women received monotherapy in the second group of patients. The lower overall rate of malformations in the latter cohort appeared to be due to the reduction in the number of pregnancies during which a combination of medications was used.^[39] It is also apparent in this study that neither the duration of maternal epilepsy nor the maternal age was associated with malformations in the infants born to these mothers.

Dravet et al.^[40] studied 227 women participating in a prospective study between 1984 and 1988. In that study there was a 7 percent malformation rate among

1237

infants born to mothers taking antiepileptic medications compared with 1.36 percent in the control group. Therefore, fetuses exposed in utero to anticonvulsants had a relative risk of 6.9 of being born with a congenital malformation. This is double the risk demonstrated by Jick and Terris.^[38] In this study, the frequency of spina bifida was 17 times more than would be expected in the general population, and heart defects were 9.6 times greater than expected. Cleft lip with or without cleft palate was 8.4 times more frequent than expected in the general population. Using logistic regression, these authors concluded that valproate and phenytoin were the two most teratogenic medications.^[40] Also in this study, there was a high correlation with congenital heart defects and maternal ingestion of phenobarbital.^[40] This finding confirms that of Nakane et al.^[34] The cases of neural tube defect and congenital heart defect were studied carefully and could not be related to a familial disposition to these defects. As other studies have shown, there was a higher incidence of malformations in infants born to mothers receiving polytherapy (16 percent) than in those receiving monotherapy (6 percent).

A study by Koch et al.^[41] however, shows no difference between the rate of malformations in mothers receiving polytherapy and mothers receiving a single medication. Furthermore, they found that the infants born to mothers with epilepsy, regardless of therapy, had only twice as many major malformations as infants born to the control population. The number of minor anomalies, however, was approximately three times greater in infants born to mothers receiving anticonvulsant medication than in the control group. In the mothers receiving monotherapy, those taking valproate had the highest rate of minor malformations.^[41] In this study, there appeared to be a link between the dose of valproate and the rate of malformations.

Gaily and Granstrom^[42] also investigated minor anomalies in children of mothers with epilepsy. These authors point out that many of the supposedly specific syndromes resulting from intrauterine exposure to certain medications have many common features. They argue that specific syndromes and their association with specific drugs, as well as the frequencies of these syndromes, have not been confirmed in epidemiologic studies. They found that many of the minor anomalies that are thought to be specific features of a medication appear to be genetically linked with epilepsy.^[42] Indeed, this is in contrast to many of the other published studies. In this study only distal digital hypoplasia appeared to be a specific marker for phenytoin teratogenicity. Again, this points out that there is no uniform consensus concerning the teratogenicity of anticonvulsant medications.

Yerby and colleagues^[43] also looked prospectively at malformations in infants born to mothers with epilepsy. They further investigated whether pure folate deficiency might be responsible for the malformations. None of the women in their study had deficient folate levels. There was no difference in major malformations between patients and controls in this study.^[43] The infants born to mothers taking anticonvulsant medications, however, had a higher mean number of minor anomalies. They found no difference in the number of minor anomalies whether the child was exposed in utero to one anticonvulsant medication or to several.^[43] The only specific minor anomaly that was found statistically more frequently in infants born to mothers with epilepsy than in the control population was a prominent occiput. The authors also confirm the great overlap in minor anomalies and various medications, further casting doubt upon whether individual medications cause specific syndromes.^[43]

Nulman and colleagues^[44] examined 36 mother-child pairs exposed to carbamazepine, 34 pairs exposed to phenytoin, 9 pairs of nonmedicated epileptic women and matched each to 9 mother-child pairs exposed to nonteratogens. Minor anomalies were more common in offspring of mothers exposed to either carbamazepine or phenytoin (relative risk 2.1).^[44] In a blended study of 43 children exposed to in utero antiepileptic medications and 47 controls, Fahnehjelm et al. found no difference in eye anomalies, nystagmus, or visual acuity between the two groups.^[45]

Teenagers are often treated with valproate as the anticonvulsant of choice because of its low side-effect profile in this age group. It has, however, been reported to be associated with specific anomalies. DiLiberti et al.^[46] in 1984, reported a specific fetal valproate syndrome. This was based on seven infants. They found a consistent facial phenotype in all seven children and other birth defects in four. This syndrome phenotype was confirmed by Ardinger and colleagues^[47] in 1988. Jager-Roman et al.^[48] in 1986, reported fetal distress in 50 percent of 14 infants receiving valproate. Furthermore, 28 percent had low Apgar scores. They also found the same craniofacial defects as reported by DiLiberti et al.^[46] Lindhout and Schmidt^[49] confirmed the association between neural tube defects and valproate exposure in utero. They contend that there is a 1.5 percent risk of an infant being born with a neural tube defect if the mothers took valproate in the first trimester. Lindhout et al.^[50] also studied 34 cases of neural tube defects in mothers taking anticonvulsant medications. In 33 of the 34 cases, mothers were exposed to either valproate or carbamazepine. Most of the cases of neural tube defects were lumbosacral. There was only one case of anencephaly. This implies that these medications have a predisposition to cause lumbosacral defects, since in the general population spina bifida and anencephaly are equally distributed. In only two cases were other major malformations found. The development of neural tube

1238

defects in these infants of mothers taking valproate also appeared to be a dose-dependent phenomenon. Wegner and Nau^[51] have shown, in a mouse model, that valproate alters folic acid metabolism in embryos. This could account for the increased risk of neural tube defects in infants born to mothers who have taken valproate.

Carbamazepine, at one time, was thought to be safer than the other anticonvulsant medications for use in pregnancy. In 1989, Jones et al.^[52] reported a pattern of minor craniofacial defects, fingernail hypoplasia, and developmental delay in infants exposed in utero to carbamazepine. Rosa^[53] has also shown that there is a 1 percent risk of spina bifida in infants of mothers taking carbamazepine. Because this spectrum of defects (except spina bifida) is similar to that in the fetal hydantoin syndrome, Jones et al.^[52] hypothesized that, as both drugs are metabolized through an arene oxide pathway, perhaps an epoxide intermediary is the teratogenic agent. Those fetuses with low levels of epoxide hydrolase are exposed to higher levels of epoxide intermediaries, and this may lead to an increase in malformations. Conversely, fetuses with high enzyme levels clear epoxides rapidly, minimizing exposure to the potential teratogens. Phenytoin, phenobarbital, and, to a lesser extent, carbamazepine are metabolized through this pathway.^[54] Much work in this area is being performed by Finnell et al.,^[54] who believe that low levels of epoxide

hydrolase activity may be the common link explaining why only certain fetuses exposed to anticonvulsant medications in utero develop congenital malformations.

New antiepileptic drugs have been approved and rapidly clinically adopted since the last edition of this text. There is a need for these medications because 25 to 30 percent of epileptic patients are not adequately controlled by conventional therapies.^[55] These newer medications work at the level of neurotransmitters such as aminobutyric acid (GABA) and also by blockade of sodium channels. Table 37-2 lists these drugs, with their dosages, and describes other considerations in their use. Gabapentin is probably the most frequently used of these medications. Many other applications have been found for this medication. It is used in chronic pain, mood stabilization, and neuropathies. The obstetrician, therefore, may encounter patients other than those with epilepsy on gabapentin. In epilepsy, it is only approved for use as an adjunct to other medications, but may soon have an indication for monotherapy. The usual maintenance dose is 900 to 2,400 mg daily in three divided doses, but doses up to 3,600 mg have been administered with only a minor increase in side effects. At present there are no studies of its use in pregnancy, although we have encountered 12 patients treated throughout pregnancy without incident. Nevertheless, patients should be warned that we do not know enough about the drug to appropriately counsel about its effects on the developing fetus. Nonetheless, if this medication is necessary to keep seizures under control, it should be used.

Lamotrigine is an adjunctive therapy for the treatment of simple and complex seizures with and without secondary generalization. It is important to note that approximately 10 percent of patients discontinue the medication because of a rash.^[56] Severe rashes such as Stevens-Johnson syndrome and toxic epidermal necrolysis have been reported. It is important to note that the severe rashes have occurred with more frequency in pediatric patients. In a more recent study, rash necessitating discontinuation of therapy was found in only 2 percent of 11,316 treated patients.^[57] The incidence was much higher in children aged 2 to 12. Ohman et al. report a successful pregnancy and note that the cord blood levels of lamotrigine were equal to those of maternal serum.^[58] Also, the median milk/maternal plasma concentration ratio of 0.61 indicates that there are significant milk levels. We still do not have enough data to counsel patients concerning the use of this medication during pregnancy.

Topiramate and tiagabine are also used as adjunctive therapies for epilepsy. Both are effective, but there is little information on the use of these medications in pregnancy. The information will eventually be reported, as all four drugs are being administered more frequently.

I still believe that the neurologist and obstetrician should work together and use whichever medication(s)

TABLE 37-2 -- NEWER ANTIEPILEPTIC AGENTS

Medication	Usual Dose (mg/day)	Doses/Day	Special Notes
Gabapentin	1,200-3,600	3	Not enzyme inducer Antacids interfere
Lamotrigine	300-500	1 or 2	Rash in 11.2% Half-life affected by meds
Topiramate	100-400	2	May interfere with O.C.s
Tiagabine	856	2 to 4	Does not interfere with O.C.s

1239

works best for the patient. It is bothersome, however, that after so many years of leading patients toward monotherapy, neurologists are swinging back toward using two drugs. As several studies that were previously reviewed in this chapter show, using multiple drugs in pregnancy increases the risk of a poorer pregnancy outcome.

There has been much debate over whether epilepsy itself and/or the use of antiepileptic medications is associated with psychomotor delays or mental retardation. In the landmark study by Nelson and Ellenberg,^[21] an IQ below 70 was seen in 65.2 per 1,000 7-year-old children in the seizure group compared with 34 per 1,000 in the age-matched control group, a statistically significant difference. Before generalizations can be made, many confounding factors must be evaluated including other anomalies and social environment. In a review by Granstrom and Gaily,^[59] none of the major antiepileptic medications appeared to carry special risk for mental retardation. They suggest, however, that polytherapy and inherited deviations in antiepileptic medication metabolism in the fetus increase the risk for mental retardation. This study is important because these researchers stress that other factors associated with maternal epilepsy such as seizures during pregnancy, inherited brain disorders, and a nonoptimal psychosocial environment can also affect a child's psychomotor development.^[59] These factors are hard to control in any study. In a study by Gaily et al.,^[60] 2 of 48 (4.1 percent) infants of mothers with epilepsy had mental retardation, and two additional infants had borderline intelligence. The mean IQ of the infants exposed in utero to anticonvulsant medications was statistically lower than the control group. When these four children were excluded from the analysis, the difference in mean IQ disappeared.^[60] There was no increased risk of low intelligence attributable to fetal exposure either to antiepileptic medications below toxic levels or to brief maternal convulsions. No particular medication appeared to be associated with a lower IQ. Social class also appeared to play a role in the differences in IQs in these patients.^[60] Moore et al.^[61] reviewed 57 infants with fetal anticonvulsant syndromes. Eighty-one percent reported behavioral problems, with hyperactivity being the most common (34 percent). Two or more autistic features were found in 34 (60 percent) of the 57 children. Four were diagnosed with autism and two with Asberger's syndrome. Learning difficulties were found in 77 percent; and speech delay in 81 percent. Gross and fine motor delays were identified in 60 percent and 42 percent, respectively.^[61] These percentages seem high, but it is important to remember that all of these children had already been identified as having an anticonvulsant syndrome.

In short, there appears to be a small, undefined risk of a slightly lower IQ and an increase in behavior problems in infants born to mothers with epilepsy. It does not appear that any particular medication results in a higher risk of this outcome.

Preconceptual Counseling for the Reproductive Age Woman with a Seizure Disorder

Although not always possible, it is preferable to counsel the patient with epilepsy before she becomes pregnant. A detailed history should be taken to see if there are any seizure disorders or congenital malformations in the family. This could provide a clue for fetal risks. The obstetrician must stress that the patient has greater than a 90 percent chance of having a successful pregnancy resulting in a normal newborn. A detailed history of medication use and seizure frequency should be obtained. The patient must be informed that if she has frequent seizures before conception, this pattern will probably continue. If she has frequent seizures, she should delay conception until control is better, even if this entails a change or addition of medication. The obstetrician must stress that controlling seizures is of primary importance and that the patient will need to take whatever medication(s) are necessary to achieve this goal throughout her pregnancy. If the patient has had no seizures during the past 2 to 5 years, an attempt may be made to withdraw her from anticonvulsant medications. This is usually done over a 1- to 3-month period, slowly reducing the medication. Up to 50 percent of patients will relapse and need to start their medications again. This withdrawal should be attempted only if the patient is completely seizure-free and only with the help of a neurologist. During the period of withdrawal from medications, patients should refrain from driving.

Furthermore, as previously shown, it is best to have the patient taking a single medication during pregnancy. If the patient is on multiple medications, the patient can be changed to monotherapy (over a several month period). The drug of choice for the specific type of epilepsy should be the one chosen for monotherapy. As the other medications are gradually withdrawn, levels of the remaining medication should be monitored frequently to make certain that the level remains therapeutic. When other medications are withdrawn, the level of the primary medication often increases without a dose increment. If it does not, however, the dose of the primary medication may need to be increased. The patient should refrain from conceiving until seizures have been well controlled for several months on the single medication. The patient must also be counseled that she should get adequate rest and sleep during pregnancy, as sleep deprivation is associated with increased seizure frequency.

1240

The choice of antiepileptic medication depends on the seizure type. As the foregoing literature review has shown, there are studies claiming teratogenesis for each of the major anticonvulsant medications, yet there are also studies showing that each medication individually may not be particularly teratogenic. The most important point is to control maternal seizures. There may be some additional concern for using valproate in pregnancy due to the reported increased incidence of fetal

distress.^[48] It is important to note that this finding has not been corroborated in other studies. Therefore, if valproate is the anticonvulsant that works best for the patient, it should be used without hesitation. If valproate is used, the dose should be divided over three to four administrations daily to avoid high peak plasma levels.

In the past, it was thought that carbamazepine was the anticonvulsant of choice and had the least teratogenic effect. As has been shown in the foregoing literature review, there are studies that report malformations with the use of carbamazepine.^{[46], [47]} It is important to stress again that the anticonvulsant that does the best job of controlling seizures is the one that should be used for the patient. There is little information concerning the newer antiepileptic drugs and teratogenesis. If, however, they need to be used for good seizure control, they should be implemented as part of the patient's therapy.

Folic acid supplementation should be begun before or early in pregnancy. Folic acid supplementation may help to prevent neural tube defects, which are more common in treatment with carbamazepine and valproate but have been reported in women taking other anticonvulsants. Studies have shown that folic acid may decrease the incidence of neural tube defects in at-risk women.^[49] It is important that this be implemented early in pregnancy, as open neural tube defects occur by the end of the fifth week of gestation. Furthermore, low folate levels have been associated with an increase in adverse pregnancy outcomes in women taking anticonvulsants.^[62] Anticonvulsant levels should be checked frequently after implementing or increasing folic acid administration, as it leads to lower anticonvulsant levels.^[62] A daily dose of 4 mg/day should be more than ample. Patients should also be encouraged to take their prenatal vitamins, which contain vitamin D. This is because anticonvulsants may interfere with the conversion of 25-hydroxycholecalciferol to 1-25-dihydroxycholecalciferol, the active form of vitamin D.

Whether or not they ask, all mothers with idiopathic epilepsy wonder if their child will develop epilepsy. There is a surprising paucity of studies in this area. Children of parents without seizures have a 0.5 to 1 percent risk of developing epilepsy. It appears that the infant born to a mother with a seizure disorder of unknown etiology has a four times greater chance of developing idiopathic epilepsy than the general population.^[63] Furthermore, it appears that epilepsy in the father does not increase a child's risk of developing a seizure disorder. Many of the rare seizure disorders have a stronger genetic component.^[64]

Care of the Patient During Pregnancy

Once the patient becomes pregnant, it is of the utmost importance to establish accurate gestational dating. This will prevent any confusion over fetal growth in later gestation. The patient's anticonvulsant level should be followed as needed and dosages adjusted accordingly to keep the patient seizure free. It is a common pitfall to monitor levels too frequently and adjust dosages in a likewise frequent manner. It is important to remember that it takes several half-lives for a medication to reach a steady state (Table 37-3). Drugs like phenobarbital have extremely long half-lives, and the levels should not be checked too frequently. If levels are measured before the drug reaches a steady state and the dosage is increased, the patient will eventually become toxic from the medication. Drug levels should be drawn immediately before the next dose (trough levels) in order to assess if dosing is adequate. If the patient is showing signs of toxicity, a peak level may be obtained.

At approximately 16 weeks' gestation, the patient should undergo blood testing for maternal serum

TABLE 37-3 -- ANTICONVULSANTS COMMONLY USED DURING PREGNANCY

Drug	Therapeutic Level (mg/L)	Usual Nonpregnant Dosage	Half-Life
Carbamazepine	410	6001,200 mg/day in three or divided doses (Two doses if extended-release forms are used)	Initially 36 h, chronic therapy 16 h
Phenobarbital	1540	90180 mg/day in two or three divided doses	100 h
Phenytoin	1020, total; 12, free	300500 mg/day in single or divided doses [*]	Avg 24 h
Primidone	515	7501,500 mg/day in three divided doses	8 h
Valproic acid	50100	5502,000 mg/day in three or divided doses	Avg 13 h

* If a total dose of more than 300 mg is needed, dividing the dose will result in a more stable serum concentration.

marker screening in an attempt to detect neural tube defect. This, coupled with ultrasonography, gives a more than 90 percent detection rate for open neural tube defects. If the patient is difficult to scan or if she wants to be even more certain that there is no neural tube defect, amniocentesis can be undertaken. This should be considered if the patient is taking valproate or carbamazepine, as these medications appear to carry almost the same risk as if the patient had a family history of a neural tube defect.^{[49], [50], [53]} At 18 to 22 weeks, the patient should undergo a comprehensive, targeted, ultrasound examination by an experienced obstetric sonographer to look for congenital malformations. A fetal echocardiogram can be obtained at 20 to 22 weeks to look for cardiac malformations, which are among the more common malformations of women taking any antiepileptic medications. If fetal echocardiography is not readily available, it is reassuring to remember that an adequate "four-chamber view" of the heart on ultrasound will identify 68 to 95 percent of major cardiac anomalies.^{[65], [66]}

As previously noted, there appears to be an increased risk for intrauterine growth restriction for fetuses exposed in utero to anticonvulsant medications. If the patient's weight gain and fundal growth appear appropriate, regular ultrasound examinations for fetal weight assessment are probably unnecessary. If, however, there is a question of fundal growth or if the patient's habitus precludes adequate assessment of this clinical parameter, serial ultrasonography for fetal weight assessment can be performed.

In older and retrospective studies, there appears to be an increased risk of stillbirth in mothers taking anticonvulsant medications.^{[7], [20], [21], [22]} In a prospective study, however, this complication was not seen.^[23] As previously noted, in the studies that showed an increase in stillbirths, factors such as intrauterine growth restriction or oligohydramnios were not prenatally identified. With modern surveillance and the more common use of ultrasonography, many of these risk factors can be detected before the fetus faces imminent risk. Non-stress testing, therefore, is not necessary in all mothers with seizure disorders. It should be limited to those who have other medical or obstetric complications that place the patient at increased risk of stillbirth.

If at all possible, the patient should be maintained on a single medication, and drug levels should be drawn at appropriate intervals to make certain that the patient is receiving enough medication. If the patient is taking phenytoin, free levels should be obtained if possible. A drug dosage should not be increased only because the total level of drug is falling. The free level of drug may still be therapeutic. If, however, the patient develops any seizure activity, dosages should then be adjusted upward. A brief seizure during pregnancy does not appear to be deleterious to the fetus.^[24] It is best to use the lowest dose of a single medication possible that will keep the patient seizure free. This, however, must be individualized. For instance, if the patient usually experiences seizures during the day and drives, it is important to make certain that the patient remains seizure free. For this type of patient, drug dosages should be increased if levels fall. If, on the other hand, the patient only has brief partial complex seizures that do not generalize and occur only during her sleep, it is optimal to keep the medications at the lowest serum concentration that will keep her seizure free. An occasional seizure of this type would not harm either patient or fetus. The key to managing anticonvulsants in pregnancy is individualization of therapy.

Early hemorrhagic disease of the newborn can occur in infants exposed to anticonvulsants in utero, and this appears to be a deficiency of the vitamin K-dependent clotting factors II, VII, IX, and X. The use of vitamin K in the third trimester to prevent hemorrhagic disease is somewhat controversial. Although some advocate administering 10 to 20 mg of vitamin K orally, daily, to mothers during the final few weeks of pregnancy, this is certainly not the standard of care. There appears to be no adverse effect of administering this vitamin, but, on the other hand, its utility has not been clearly demonstrated. Very little hemorrhagic disease of the newborn is seen today, and this is probably because most infants receive 1 mg of vitamin K intramuscularly at birth. This certainly should be given to all infants of mothers receiving anticonvulsants. Because of early discharges and the shortened time of neonatal observation, it might be prudent to check a prothrombin time on the cord blood at birth. This can be done by taking fresh cord blood and placing it in a citrated blood tube and having it sent immediately for prothrombin time. This might be especially prudent if the child is to undergo a very early circumcision.

Labor and Delivery

Vaginal delivery is the route of choice for the mother with a seizure disorder. If the mother has frequent seizures brought on by the stress of labor, she may undergo cesarean delivery after stabilization. Furthermore, seizures during labor may cause transient fetal bradycardia.^[29] The fetal heart rate should be given time to recover. If it does not, then one must assume fetal distress and/or placental abruption and deliver by cesarean section. Because stress often exacerbates seizure disorders, an epidural anesthetic can benefit many laboring patients with epilepsy.

Management of anticonvulsant medications during a prolonged labor presents a challenge. During labor, oral absorption of medications is erratic and, if the patient vomits, almost negligible. If the patient is taking phenytoin or phenobarbital, these medications may be

1242

administered parenterally. An anticonvulsant level should be obtained first to help ascertain the appropriate dosage. Phenobarbital may be given intramuscularly, and phenytoin may be given intravenously. Fosphenytoin, although expensive, is available and makes the administration of intravenous phenytoin much easier. If the patient's phenytoin level is normal, the usual daily dose may be administered intravenously. The medication may only be mixed in normal saline and must be administered at a rate no faster than 50 mg/min. Fosphenytoin is easier to use. Because of the long half-life of phenobarbital, if the patient's serum level is therapeutic, a 60- to 90-mg intramuscular dose will probably be sufficient to maintain the patient throughout labor and delivery. The main problem arises if the patient is taking carbamazepine. This medication is not manufactured in a parenteral form, although extended-release forms now exist. Oral administration may be attempted, but, if the patient has seizures or a pre-seizure aura, she may be loaded with a therapeutic dose of phenytoin to carry her through labor. The usual loading dose is 10 to 15 mg/kg administered intravenously at a rate no faster than 50 mg/min. This should be effective in controlling seizures. Benzodiazepines may also be used for acute seizures, but one must remember that they can cause early neonatal depression as well as maternal apnea.^[67] Prenatal diagnostic techniques are not perfect. Even if the infant appears to have no anomalies, an experienced pediatrician should be present at the delivery of the infant born to a mother taking anticonvulsant medications.

New Onset of Seizures in Pregnancy and the Puerperium

Occasionally, seizures will be diagnosed for the first time during pregnancy. This may present a diagnostic dilemma (Table 37-4). If the seizures occur in the third trimester, they are eclampsia until proven otherwise and should be treated as such until the attending physician can perform a proper evaluation. The treatment of eclampsia is delivery, but the patient must first be stabilized. It is often difficult, however, to distinguish eclampsia from an epileptic seizure. The patient may be hypertensive initially after an epileptic seizure and may

TABLE 37-4 -- DIFFERENTIAL DIAGNOSIS OF PERIPARTUM SEIZURES

	Blood Pressure	Proteinuria	Seizures	Timing	CSF	Other Features
Eclampsia	+++	+++	+++	Third trimester	Early: RBC, 01,000; protein, 50150 mg/dl Late: grossly bloody	Platelets normal or RBC normal

1243

exhibit some myoglobinuria secondary to muscle breakdown. The diagnosis becomes clearer over time, but in either case, rapid, thoughtful action must be undertaken. The first physician to attend a patient after a seizure may not be an obstetrician/gynecologist, and magnesium sulfate may not be started acutely. This should be remedied as soon as possible.

If the patient at an earlier gestational age develops seizures for the first time, she should be evaluated and started on the proper medication. The physician must be alert to look for acquired causes of seizures including trauma, infection, metabolic disorders, space-occupying lesions, central nervous system bleeding, and ingestion of drugs such as cocaine and amphetamines. The patient must be stabilized, and the physician must make certain that an adequate airway is established for the protection of both mother and fetus. The physician should also look for focal signs that may be more suggestive of a space-occupying lesion, central nervous system bleeding, or abscess.

Blood should be obtained for electrolytes, glucose, calcium, magnesium, renal function studies, and toxicologic studies, while intravenous access is being established. If the patient had a tonic-clonic seizure, and the attending physician feels that this is probably new-onset epilepsy, she should be started on the appropriate anticonvulsant medication while awaiting results of laboratory studies. If she is not in status epilepticus, this medication may be given orally.

If the patient presents with recurrent generalized seizures, status epilepticus, immediate therapeutic action must be taken. The drug of choice is intravenous phenytoin, as it is highly effective, has a long duration of action, and a low incidence of serious side effects. This medication should be administered in a loading dose of 18 to 20 mg/kg at a rate not exceeding 50 mg/min. Rapid infusion may cause transient hypotension and heart block. If possible, the patient should be placed on a cardiac monitor while receiving a loading dose of phenytoin. Also, this medication must be given in a glucose-free solution to avoid precipitation.^[68] Fosphenytoin, if available, can be given more rapidly with fewer side effects. If phenytoin is unavailable, a benzodiazepine may be used as a first-line drug for status epilepticus. These drugs, however, cause respiratory depression, and the physician must have the ability to intubate the patient if necessary when these medications are used. If these measures are ineffective, an anesthesiologist and neurologist should be immediately consulted if they are not already involved in the patient's care.

Any patient experiencing seizures for the first time during pregnancy without a known cause should undergo an EEG and some type of intracranial imaging. In looking only at eclamptic patients, Sibai et al.^[69] found that EEGs were initially abnormal in 75 percent of patients but normalized within 6 months in all patients studied. While this group found no uniform computed tomography (CT) abnormalities in this set of eclamptics, they did find that 46 and 33 percent of eclamptics had some abnormalities in the magnetic resonance imaging (MRI) and CT, respectively. Most of the findings were nonspecific and were not helpful in diagnosis or treatment. If the physician is not certain that the patient has eclampsia, an imaging study should be part of the evaluation described above.

Postpartum Period

The levels of anticonvulsant medications must be monitored frequently during the first few weeks postpartum, as they can rapidly rise. If the patient's medication dosages were increased during pregnancy, they will need to be decreased rather rapidly after delivery to prepregnancy levels. All of the major anticonvulsant medications cross into breast milk. The levels vary in breast milk from 18 to 79 percent of the plasma levels.^[67],^[70] The use of these medications, however, is not a contraindication to breast-feeding. Primidone, phenobarbital, and benzodiazepines may have a sedative effect on the fetus with later withdrawal symptoms. Should the infant exhibit these types of symptoms, breast-feeding should be discontinued.

All methods of contraception are available to women with idiopathic seizure disorders. The majority of women are able to take oral contraceptives without any adverse side effects.^[71] Oral contraceptive failures are more common in women taking anticonvulsants. This is due to the fact that all of the major anticonvulsant medications induce hepatic enzymes, which metabolize estrogen faster.^[71],^[72] These patients may, therefore, require oral contraceptives with higher dosages of estrogens. The amount of enzyme induction, however, varies and oral contraceptive doses must be individualized.

In conclusion, the majority of women with idiopathic epilepsy will have an uneventful pregnancy with an excellent outcome. To optimize neonatal outcome, the patient should take only one medication and, when possible, use the lowest dose effective in keeping her free of seizures. It is important, though, for the patient to realize that prevention of seizures is the most important goal during pregnancy. Simple interventions such as taking folic acid prior to conception, taking prenatal vitamins containing vitamin D, and giving the infant vitamin K at birth will help to optimize the outcome. There is an increase in congenital malformations in infants exposed to anticonvulsant medications in utero. The majority of infants exposed to these medications, however, will have no malformations. With modern techniques for prenatal diagnosis, including ultrasound and -fetoprotein determination, many of these malformations can be detected early. The majority of women

with epilepsy will labor normally and have spontaneous vaginal deliveries. In short, with close cooperation and excellent communication among the obstetrician, neurologist, and pediatrician, the vast majority of these patients will have a safe pregnancy with an excellent outcome.

MIGRAINE

Headaches are extremely common in women, and the majority of migraine headaches occur in women of childbearing age. Migraines can be classified as those with aura (other neurologic signs and symptoms) and those without aura. Maggioni and colleagues^[73] surveyed 430 women 3 days postpartum about their headache histories and 126 (29.3 percent) were found to be primary headache sufferers. Of these patients, 81 suffered from migraine without aura, 12 suffered from migraine with aura, and 33 had tension type headaches.^[73] The headaches, which are associated with vasodilation of the cerebral vasculature, last a variable amount of time. They are often accompanied by photosensitivity and nausea. Migraines with aura may be accompanied by sensations in the extremities and other lateralizing signs, sometimes making them difficult to distinguish from transient ischemic attacks.

Migraine symptoms tend to improve during pregnancy.^[73] Maggioni et al. found that 80 percent of patients experienced either complete remission or a 50 percent reduction in headaches during pregnancy. Improvement was more common after the first trimester. Granella and co-workers^[74] found that migraines disappeared during pregnancy in 67 percent of cases. Granella et al.^[75] also confirmed this. Aube found that 60 to 70 percent of women either go into remission or improve significantly, usually in the second and third trimesters.^[76] The migraine type did not seem to be a prognostic factor. Those with menstrual migraines showed the most improvement.^[76] In this study, however, 4 to 8 percent showed significant worsening during pregnancy.^[76] Chen and co-workers^[77] identified 508 women with a history of migraine from the Collaborative Perinatal Project of the National Institute of Neurological and Communicative Disease Disorders and Stroke. They found that patients with migraines smoke more heavily and had a longer smoking history than did their headache-free peers. They also found that in nonsmokers migraine was often associated with allergies.^[77]

Chancellor and colleagues^[78] followed nine patients whose migraines first occurred during pregnancy at various gestational ages. They were followed for more than 4 years after pregnancy, and the prognosis for headache was excellent. Four of the nine patients developed complications of pregnancy, including preeclampsia in two.^[78] Maggioni found no increase in pregnancy complications in patients with migraine.^[73] It is unknown if the headaches were caused by developing preeclampsia. It is important to rule out other severe complications of pregnancy before assigning a new diagnosis of migraine to a pregnant patient. Jacobson and Redman^[79] reported a patient who actually lost consciousness during pregnancy because of a basilar migraine.

Supportive therapy is recommended for patients who experience migraine attacks during gestation. Both narcotic and nonnarcotic analgesics can be used as necessary. The use of nonsteroidal anti-inflammatory agents should be avoided if possible in late pregnancy, because when used over a long period they can cause premature closure of the ductus arteriosus and/or oligohydramnios. Nonetheless, they can be used for brief periods under physician supervision. When pain is severe, parenteral narcotics and appropriate anti-emetic therapy may be used. -Blockers may be safely administered during pregnancy for prophylaxis. The calcium channel blockers used in the treatment of migraine can also be safely administered during gestation. Fluoxetine is occasionally successfully used for migraine prophylaxis. The same is true for the tricyclic antidepressants and is generally safe for use during pregnancy.

Ergotamine is best avoided during pregnancy. Previous reports have suggested it may cause birth defects that have a vascular disruptive etiology. Hughes and Goldstein^[80] report a case in which an infant showed evidence of early arrested cerebral maturation and paraplegia. They hypothesize that ergotamine, acting either alone or in synergy with propranolol and caffeine, produced fetal vasoconstriction resulting in tissue ischemia and subsequent malformation.^[80] It is important to note that this etiology is strictly theoretical. In addition, ergots are uterotonic and have an abortifacient potential. These drugs, however, should be avoided during pregnancy. Sumatriptan, a serotonin receptor agonist, is very successful in treating migraines. It has a potential for vasoconstriction in the fetal placental unit. In a review by O'Quinn and colleagues, there were no untoward effects in 76 first-trimester exposures to sumatriptan.^[81] Using logistic regression, Olesen and colleagues^[82] compared 34 sumatriptan exposures to 89 migraine controls and 15,995 healthy women. They found the risk of preterm birth was elevated (odds ratio 6.3). They also found the risk of IUGR was greater.^[82] They do state that they did not control for disease severity. Sumatriptan, therefore, should only be used if the physician feels that the potential benefit clearly outweighs the potential risk. [Table 37-5](#) lists some medications that can be used for treating migraines.

Dietary factors may precipitate migraine attacks. Careful history may uncover foods that should be

TABLE 37-5 -- DRUG THERAPY FOR MIGRAINE HEADACHES IN PREGNANCY

Medication	Class	Use	Dosage	Route of Administration	Safe for Pregnancy
Acetaminophen	Pain reliever	Acute pain	4 g/day maximum	PO or PR	Yes
Codeine	Narcotic	Acute pain	3090 mg q34 h	PO	Yes
Meperidine	Narcotic	Acute pain	25100 mg q36 h	PO, IM, or IV	Yes
Ibuprofen	Nonsteroidal	Acute pain	2,400 mg/day in divided doses	PO	Do not use in late pregnancy
Prochloroperazine	Phenothiazine	Nausea	525 mg q28 h depending on route	PO, PR, IM, IV	Yes
Promethazine	Phenothiazine	Nausea	12.550 mg q28 h depending on route	PO, PR, IM, IV	Yes
Butalbital (50 mg), acetaminophen 325 mg, caffeine 40 mg	Sedative, pain reliever, vasoconstrictor	Acute migraine	2 tablets q4 h, not to exceed 6 tablets daily	PO	Yes
Isometheptene mucate (65 mg), Dichloralphenazone (100 mg), Acetaminophen (325 mg)	Vasoconstrictor, sedative, pain reliever	Acute migraine	2 capsules immediately followed by 1 hourly for no more than 5 capsules in 12 hours	PO	Yes
Caffeine	Vasoconstrictor	Acute pain	500 mg in 50 ml IV solution may repeat	PO or IV	Yes
Sumatriptan	Vasoconstrictor	Acute pain relief	300 mg/day PO max 6 mg SQ X 2/day max	PO or SQ	No
Ergotamine with caffeine	Vasoconstrictor	Acute pain relief	2 mg/200 mg (PO), then 1 mg/100 mg q½ h for 6 tab/day max or 2 mg/100 mg PR and repeat once in 1 h	PO or PR	No

Nortriptyline	TCA	Prophylaxis	25100 mg qhs	PO	Yes
Amitriptyline	TCA	Prophylaxis	50150 mg qhs	PO	Yes
Sertraline	SSRI	Prophylaxis	50100 mg qhs	PO	Probably
Fluoxetine	SSRI	Prophylaxis	2040 mg qhs	PO	Probably
Propranolol	-blocker	Prophylaxis	80120 mg bid	PO	Small risk for IUGR
Nadolol	-blocker	Prophylaxis	2080 mg qd	PO	Caution for IUGR
Atenolol	-blocker	Prophylaxis	25100 mg qd	PO	Caution for IUGR
Carbamazepine	Membrane stabilizer	Prophylaxis	Up to 1,200 mg/day in three divided doses	PO	Risk of NTD, other problems

IUGR, intrauterine growth restriction; NTD, neural tube defect; SSRI, serotonin-selective reuptake inhibitor; TCA, tricyclic antidepressant.

avoided, including foods containing monosodium glutamate, red wine, cured meats, and strong cheeses containing tyramine. Relative hypoglycemia and alcohol can also trigger migraine attacks.

CEREBROVASCULAR DISEASES

Arterial Occlusion

Twelve percent of arterial occlusions occur in women between the ages of 15 and 45 years, and approximately one third of these patients may be pregnant.^[83] In a study from India, 37 percent of patients affected with cerebrovascular disease were under the age of 40 years, with a significant number of thromboses occurring during pregnancy and the puerperium.^[84] Overall, the incidence of cerebral arterial occlusion in pregnancy is approximately 1 per 20,000 live births.^[83],^[85] The mortality rate for pregnant women with cerebral arterial occlusion is twice that of men and three times that of non-pregnant women. According to Jennett and Cross,^[83] middle cerebral artery occlusion is most common during pregnancy, whereas internal carotid artery occlusion is observed most often in the puerperium. Hemiplegia

1246

and dysphasia are frequent findings.^[85] Predisposing factors such as preeclampsia, chronic hypertension, or hypotensive episodes can be demonstrated in about one third of these patients. Brick and Riggs^[86] have shown that oral contraceptives also raise the risk of ischemic cerebral vascular disease. Perhaps because of its relative frequency in the general population, the factor V Leiden mutation may be a predisposing factor in many of these patients. One half of the pregnancy-related cases occur during the immediate postpartum period and the remainder during the second and third trimesters. In a recent study, Lidegaard^[87] concluded that pregnancy was associated with an elevated odds ratio of only 1.3 for cerebral thromboembolism. Brick^[88] reported the case of a woman who had a documented partial obstruction of the left middle cerebral artery during the third trimester of pregnancy. Following delivery, her symptoms abated, and angiography 11 weeks later revealed complete resolution of the obstruction. Brick^[88] therefore thought that this lesion was the result of reversible intimal hyperplasia from the increased estrogen and progesterone levels of pregnancy.

In cases of cerebral arterial occlusion, care must be taken to avoid increased intracranial pressure. If signs of increased intracranial pressure develop, parenteral dexamethasone should be administered. Osmotic diuresis can be used if needed. Supportive measures are also necessary, including close monitoring of electrolytes to detect inappropriate secretion of antidiuretic hormone. Physical and rehabilitative therapy should be started as soon as possible. These patients can progress normally through pregnancy and deliver vaginally.

A case of maternal death from carotid artery thrombosis associated with the HELLP syndrome (hemolysis, elevated liver enzymes, and low platelet count) has been reported by Katz and Cefalo.^[89] They proposed that the infarction occurred because the patient experienced a rebound thrombocytosis leading to a hypercoagulable state. They stress the importance of closely following patients with HELLP syndrome so that those who develop a reactive thrombocytosis can be monitored for signs and symptoms of cerebral thrombosis.

Cortical Vein Thrombosis

The chief symptoms in patients with cortical vein thrombosis are headache, lethargy, and vomiting. Hemiplegia has a gradual onset, and seizure activity is common (Table 37-4).^[90],^[91] This disorder occurs most frequently during the immediate postpartum period and may be attributed to a hypercoagulable state.^[92] An incidence of 1 in 10,000 pregnancies was suggested in one study.^[93] With the availability of CT and MRI, accurate diagnosis is possible. The actual incidence may be higher if patients are asymptomatic. Many patients with cortical vein thrombosis show signs of seizure activity, and prophylactic anticonvulsants were once routinely given.^[94] The drug of choice is phenytoin. The patient should be given a loading dose of 10 mg/kg followed by 300 to 500 mg orally each day. Phenytoin levels should be checked frequently to make certain that they are therapeutic and that the patient does not develop phenytoin toxicity. Some neurosurgeons are advocating expectant management and do not routinely give anticonvulsants.

Subarachnoid Hemorrhage

The rate of subarachnoid hemorrhage complicating pregnancy is approximately 1 per 10,400.^[94] With cocaine abuse occurring across the country, the incidence may rise, as the associated increase in vasospasm associated with this drug is bleeding from preexisting berry aneurysms and arterial-venous (A-V) malformations.^[95] Most subarachnoid hemorrhages occurring in pregnant patients are caused either by rupture of a berry aneurysm or bleeding from a congenital A-V malformation. Most berry aneurysms are thought to be due to a congenital defect in the elastic and smooth muscle layers of cerebral blood vessels. They are usually located in the vessels of the circle of Willis or those arising from it. Robinson and co-workers^[96] evaluated 26 patients with spontaneous subarachnoid hemorrhage during pregnancy and found that approximately one half were caused by berry aneurysms and one half by A-V malformations. They observed that A-V malformations are more common in patients below the age of 25 years and usually bleed before 20 weeks' gestation. Conversely, berry aneurysms occur in patients over the age of 30 years and usually bleed in the third trimester.^[96] Pregnancy appears to increase the risk of bleeding from an A-V malformation. The maternal mortality rate associated with an untreated A-V malformation is reported to be 33 percent. This figure, however, is based on old data, and the rate is significantly lower today. Most are treated rapidly and aggressively.

Diagnosis and Treatment

Any patient with localized signs of cerebral or meningeal irritation must be thoroughly evaluated. If the clinical examination dictates that further evaluation is necessary, MRI/MRA or a CT scan should be performed. If necessary, contrast dyes may be used. Cerebral angiography can be safely used to pinpoint the origin of cerebral bleeding. Subarachnoid hemorrhages, whether caused by A-V malformations or berry aneurysms, should be treated surgically when possible. Surgery under hypothermia or hypotension appears to cause no adverse fetal effects. The fetal heart rate should be monitored. If fetal bradycardia occurs, blood pressure should be raised sufficiently to normalize the fetal heart

1247

rate.^[97] Kawasaki and colleagues^[98] report a case of cerebellar hemorrhage in a 32-week primigravida. She was treated conservatively until term and was delivered by elective cesarean section. Her surgery, which was delayed until after delivery, was successful. D'Haese et al. have reported a case of combined cesarean delivery and aneurysm clipping.^[99]

If the patient has undergone corrective surgery for an aneurysm or A-V malformation, she should be allowed to deliver vaginally. Because the Valsalva maneuver can increase intracranial pressure,^[96] epidural anesthesia is recommended. Interestingly, Szabo and colleagues^[100] have reported that moderate increases in blood pressure do not cause spontaneous hemorrhage in nonpregnant patients with intracranial A-V malformations. If the aneurysm or A-V malformation has not been

surgically corrected, Robinson et al. ^[96] recommend elective cesarean delivery. However, there are no hard data on which to make this decision. Therefore, the mode of delivery should be determined by the obstetrician after discussion about the individual case with neurologists, neurosurgeons, and anesthesiologists. Laidler and colleagues^[101] discussed the advantages of regional anesthesia in these patients. Buckley and co-workers ^[102] have described a case of simultaneous cesarean delivery and ablation of a cerebral A-V malformation. Levy and Jaspán discuss the anesthetic and obstetric management of an untreated vascular anomaly that had bled earlier in pregnancy in a patient who developed severe preeclampsia. ^[103]

As pregnancy has a deleterious effect on A-V malformations, those patients with inoperable lesions should be counseled about the dangers of future childbearing. With improved imaging techniques, the patient should be thoroughly evaluated before any recommendations are made for permanent sterilization.

Venous-venous (V-V) malformations are low-pressure phenomena. Patients should progress to term and deliver vaginally without any hemorrhagic event or complications.

Gabbe: Obstetrics - Normal and Problem Pregnancies, 4th ed. , Copyright © 2002 Churchill Livingstone, Inc.

MULTIPLE SCLEROSIS

Multiple sclerosis (MS) is a demyelinating disease that attacks men and women equally. The onset of symptoms usually occurs between the ages of 20 and 40 years. In the United States, the disease is more common in those residing above 40 degrees north latitude. The prevalence for those living in the southern United States is 10 per 100,000, while it is approximately 50 per 100,000 in those living in the northern states. ^[104] MS has no clear genetic predisposition.

The diagnosis of MS is often made years after the initial onset of sensory symptoms. The onset is usually subtle. Common presenting symptoms include weakness of one or both lower extremities, visual complaints, and loss of coordination. Because the disease primarily affects the white matter of the central nervous system, symptoms attributable to disruption of gray matter are uncommon. The disease is characterized by exacerbations and remissions. Less than one third of patients show steady progression of their disease after its onset.

It is impossible to predict the long-range prognosis of a patient with MS. About one half of patients are still able to work at their usual profession 10 years after the onset of the illness. After 20 years, however, only about one third remain employed. In a study of 185 women with MS, Weinshenker and colleagues ^[105] showed that there was no association between long-term disability and (1) total number of term pregnancies, (2) the timing of pregnancy relative to the onset of MS, or (3) the worsening of MS in relation to a pregnancy. The average life expectancy in patients with MS is also impossible to predict. Patients may live with the disease for more than 25 years. When death does occur, it is usually attributable to infection.

MS and pregnancy can coexist without unusual complications. Leibowitz and colleagues ^[106] found no decrease in fertility and no increase in perinatal mortality in patients with MS. Their study suggested that pregnancy does not predispose a patient to MS but that patients with "premorbid" disease are more likely to have the onset of early symptoms during pregnancy.

In fact, Runmanker and Andersen ^[107] demonstrated that the risk of onset of MS is reduced during gestation while the risk of onset during the postpartum period was no different than for the nonpregnant state. Furthermore, these investigators demonstrated a lower risk of onset of MS in parous than in nulliparous patients. Of 170 pregnant patients with MS studied by Millar and co-workers, ^[108] relapses occurred in only 45, the majority during the puerperium and postpartum periods. Birk and co-investigators ^[109] carefully followed pregnancies in eight women with MS. None of the women worsened during pregnancy. Six of the eight women, however, experienced relapses within the first 7 weeks after delivery. They also reported that there were differences in suppressor T cell levels during pregnancy, but these were not predictive of changes in clinical disease. ^[109] Frith and McLeod ^[110] studied 85 pregnancies and found no increased risk of relapse during pregnancy. They noted that most of the relapses that did occur during pregnancy took place in the third trimester. In another series, Frith and McLeod ^[111] reported that relapses occur most frequently in the last trimester and also in the first 3 months postpartum. In a large study, Nelson and colleagues ^[112] analyzed 191 pregnancies in women with nonprogressive MS. The exacerbation rate during the 9-month postpartum period was 34

1248

percent, three times that of the 9 months during pregnancy. The rate was highest in the 3 months immediately following delivery and stabilized after postpartum month 6. ^[112] The exacerbation rates were the same in breast-feeding and non-breast-feeding women. The average time to flare was also similar in both groups. This study verifies that it is safe for women with MS to breast-feed their newborns. ^[112]

Bernardi and colleagues showed a decreased risk of relapse during the 9 months of pregnancy and the first 6 months postpartum. ^[113] In this study of 52 women, these researchers concluded that pregnancy, as a whole, is a protective event. Worthington et al., ^[114] however, found more frequent relapses in the first 6 months postpartum, but not after that. Long-term prognosis was unaffected by pregnancy. ^[114] Vendru et al. ^[115] demonstrated that pregnancy delays the onset of long-term disability. As an index of progression, they used the length of time from onset of disease until wheel chair dependence. In patients with at least one pregnancy after onset, the mean time to wheel chair dependence was 18.6 years compared with 12.5 years for other women. ^[115] In a study encompassing 12 European countries, Confavreux and colleagues studied 269 pregnancies in 254 women with multiple sclerosis. ^[116] They determined the relapse rate in each trimester using the Kuntzke Expanded Disability Status Scale with 0 as good function and 10 as very disabled. They found the rate of relapse declined during pregnancy, especially in the third trimester. Relapses increased in the first 3 months postpartum before returning to prepregnancy rates. ^[116] The Kuntzke Disability Score worsened at the same rate for the year prior to pregnancy, during the pregnancy, and the years postpartum. Neither breast-feeding nor epidural analgesia had an adverse effect on the rate of relapse or on the progression of disability. ^[116]

Paraplegic patients are more susceptible to urinary tract infections during pregnancy but may feel no symptoms. Therefore, they should be screened routinely. If the patient has become paraplegic as a result of MS, there may be little pain associated with labor. It might be difficult therefore for the patient to discern when labor begins. Uterine contractions occur normally, but voluntary expulsive efforts may be hindered in the second stage of labor. Delivery by forceps or vacuum extraction therefore may be indicated. Bader and colleagues ^[117] report that women with MS who receive epidural anesthesia for vaginal delivery do not have a significantly higher incidence of exacerbation of their MS than those receiving only local anesthesia.

Corticosteroids and immunosuppressive agents are occasionally used to treat multiple sclerosis. In one case report, plasmapheresis was used with dramatic improvement in a woman with rapidly progressive MS. ^[118] Orvieto et al. report using intravenous immunoglobulins to successfully prevent multiple sclerosis relapses for 6 months postpartum in 14 patients. ^[119] There are several new drugs and biopharmaceuticals available for treatment of multiple sclerosis. There is virtually no pregnancy experience with many of these agents. Therefore, they should be used if the neurologist and obstetrician feel that the benefits outweigh the potential risks.

CARPAL TUNNEL SYNDROME

The medial border of the carpal tunnel consists of the pisiform and hamate bones, and its lateral border consists of the scaphoid and trapezium bones. They are covered on the palmar surface by the flexor retinaculum. The median nerve and flexor tendons pass through this carpal tunnel, which has little room for expansion. If the wrist is extremely flexed or extended, the volume of the carpal tunnel is reduced. In pregnancy, weight gain and edema can produce the carpal tunnel syndrome that results from compression of the median nerve. Wallace and Cook^[120] first reported the association between carpal tunnel syndrome and pregnancy in 1957. Although 20 percent of pregnant women complain of pain on the palmar surface of the hand, few actually have the true carpal tunnel syndrome.^[121] In a 1998 study, Stolp-Smith et al. found 50 of 14,579 (0.34 percent) pregnant patients presenting between 1987 and 1992 actually met criteria for carpal tunnel syndrome.^[122] Commonly, the syndrome consists of pain, numbness, and/or tingling in the distribution of the median nerve in the hand and wrist. This includes the thumb, index finger, long finger, and radial side of the ring finger on the palmar aspect. Compressing the median nerve and percussing the wrist and forearm with a reflex hammer, the Tinel maneuver, often exacerbates the pain. In severe cases, weakness and decreased motor function can occur. The definitive diagnosis is made by electromyography, but this test is often unnecessary.

McLennan and co-workers^[123] studied 1,216 consecutive pregnancies. Of these patients, 427 (35 percent) reported hand symptoms. Fewer than 20 percent of these 427 affected women described the classic carpal tunnel syndrome. No patient required operative intervention. Most symptoms were bilateral and commenced in the third trimester of pregnancy. Ekman-Ordeberg et al.^[124] found a 2.3 percent incidence of carpal tunnel syndrome in a prospective study of 2,358 pregnancies. The syndrome appeared to be more common in primigravidas with generalized edema. Conservative therapy with splinting of the wrist at night completely relieved

1249

symptoms in 46 of 56 patients. Of the remaining 10, three required surgery before delivery. In Stolp-Smith's study, symptoms began with equal frequency in all trimesters, but diagnosis was delayed until the third trimester in 50 percent of patients.^[122] Only four patients required surgical intervention during gestation, and three additional patients required surgery postpartum. Wand^[125] retrospectively studied 40 women with carpal tunnel syndrome developing in pregnancy and 18 women with carpal tunnel syndrome that developed in the puerperium. He confirmed that the syndrome occurs most frequently in primigravidas over the age of 30 years. All cases that developed before delivery occurred during the third trimester and resolved within 2 weeks after delivery. In those cases developing during the puerperium in women who breast-fed their infants, the symptoms lasted longer, a mean of 5.8 months.^[125] In another series, Wand^[126] studied 27 women who developed carpal tunnel syndrome during the puerperium. The condition was associated with breast-feeding in 24 of these women. Symptoms lasted an average of 6.5 months in the breast-feeding women. Only two of these patients required surgical decompression.^[126]

Supportive and conservative therapies are usually adequate for the treatment of carpal tunnel syndrome. Symptoms usually subside in the postpartum period as total body water returns to normal.^[127] Splints placed on the dorsum of the hand, which keep the wrist in a neutral position and maximize the capacity of the carpal tunnel, often provide dramatic relief. Local injections of glucocorticoids may also be used in severe cases. Although diuretics may help to control carpal tunnel syndrome symptoms over a short period of time, their use is not recommended because the symptoms return rather rapidly after the cessation of treatment. In an uncontrolled series, Ellis^[128] reported that pyridoxine in a dose of 100 to 200 mg daily for 12 weeks can provide relief in a large percentage of patients with carpal tunnel syndrome. Before this can be recommended, controlled trials need to be undertaken.

Surgical correction of this syndrome should not be delayed in patients with deteriorating muscle tone and motor function. Decompression surgery for carpal tunnel syndrome is a simple procedure that can be safely carried out during pregnancy using local anesthesia, an axillary block, or a Bier block. With new endoscopic procedures, the procedure is even less invasive. Assmus and Hashemi report 314 hands surgically treated during pregnancy or the puerperium for carpal tunnel syndrome.^[129] One hundred thirty-three cases were performed during pregnancy, most in the last trimester including four who had both hands treated simultaneously. Of the patients, 98 percent reported good or excellent results.^[129] There were no complications and local anesthesia was used in all cases. These authors recommend surgery if sensory loss is present or if motor latency is more than 5 msec.^[129] It is important to warn patients that carpal tunnel syndrome can recur in future pregnancies.^[130]

PSEUDOTUMOR CEREBRI

Pseudotumor cerebri may complicate as many as 1 in 870 births.^[131] It is seen more frequently in pregnant women, particularly those who are obese.^{[132] [133] [134]} However, in a study by Ireland and colleagues^[135] the incidences in pregnant women and in oral contraceptive users were no higher than in control groups. More than 95 percent of these patients present with headaches, and 15 percent have diplopia. Papilledema is found in virtually all patients.^{[132] , [134]} To establish the diagnosis, one must demonstrate elevated cerebrospinal fluid (CSF) pressure, normal CSF composition, and the absence of an intracranial mass on MRI or CT scan.^[137]

The pathogenesis of this disorder is unknown. Bates and colleagues^[138] found CSF prolactin to be markedly elevated in cases of pseudotumor cerebri. Prolactin appears to have an affinity for receptors in the choroid plexus, where CSF is produced. Prolactin has osmoregulatory functions and therefore may have a role in the increased CSF production found in pseudotumor cerebri.^[132] Some believe that reduced CSF reabsorption is the etiology of pseudotumor cerebri. Ahlskog and O'Neill^[139] noted an association between the occurrence of pseudotumor cerebri and the following conditions: corticosteroid therapy and its withdrawal, nalidixic acid therapy, nitrofurantoin therapy, tetracycline therapy, hypoparathyroidism, deficiencies or excesses of vitamin A, and iron deficiency anemia.

Pregnancy outcome appears to be unaffected by the illness.^{[132] , [136]} There is no increase in fetal wastage or congenital anomalies.^[132] Koppel and colleagues^[140] reported a case of pseudotumor cerebri that presented in a 15-year-old primigravida following eclampsia. It lasted for 3 weeks. Wheatley and colleagues^[141] noted a case of pseudotumor cerebri occurring in a diabetic pregnancy. They caution that it is important to make the distinction between symptoms of pseudotumor cerebri and visual impairment caused by diabetic retinopathy, as the treatments are different.^[141] Thomas^[142] described a case of pseudotumor cerebri occurring in two consecutive pregnancies in a woman with hemoglobin SC. In both instances, symptoms resolved following delivery and both infants were born at term.

Most patients respond well to conservative management.^[131] The main objectives of treatment are relief of pain and preservation of vision. The patient should be

followed closely with visual acuity and visual field determinations at intervals indicated by the clinical condition. In patients with mild disease, analgesics may be adequate. If pain persists, diuretics may be used. Acetazolamide, a carbonic anhydrase inhibitor, will reduce CSF production in many patients.^[143] The usual dose is 500 mg twice daily. In more difficult cases, prednisone in doses of 40 to 60 mg daily usually provides good results.^[131] Patients may be treated for 2 weeks, with the dose being tapered over the next month.^[132] Serial lumbar punctures to reduce CSF pressure are rarely necessary today. Surgical approaches are reserved for refractory patients in whom rapid visual deterioration occurs.

Pseudotumor cerebri is not an indication for cesarean delivery. A review of the literature reveals that 73 percent of the reported patients delivered vaginally.^[132] Cesarean delivery should be undertaken only for obstetric indications. Both epidural and spinal anesthesia, when expertly administered, can be safely used in patients with pseudotumor cerebri.^[144] Bearing down, which can increase CSF pressure, should be avoided when possible. The second stage of labor should therefore be shortened by outlet forceps or by vacuum extraction.

The recurrence rate for pseudotumor cerebri appears to be between 10 and 12.3 percent in nonpregnant patients.^{[133] , [134]} Pregnancy does not appear to predispose to a recurrence.^[132]

Key Points

Idiopathic seizures affect approximately 1 percent of the general population and are the most frequent neurologic complication of pregnancy. Prepregnancy counseling is imperative in the patient with a seizure disorder, and preconceptual folic acid therapy should be implemented under the direction of an obstetrician and a neurologist. Those with seizures occurring less than once each month will have the best control during pregnancy. The anticonvulsant medication that best controls the patient's seizures should be used during pregnancy. Because of the changes in plasma volume, drug distribution, and metabolism that occur during pregnancy, anticonvulsant levels should be checked frequently and dosages adjusted accordingly. Patients taking anticonvulsants have an increased risk of giving birth to an infant with both major and minor anomalies, but this risk is probably less than 10 percent. Therefore, the majority of patients with epilepsy will give birth to healthy infants. Carbamazepine and valproate are associated with neural tube defects, and these patients should receive 4 mg folic acid daily before and during early pregnancy. The vasoconstrictor drugs used to treat migraines should be avoided during pregnancy and lactation. Pregnancy does not hasten the onset of multiple sclerosis, nor does it hasten the onset of disability from multiple sclerosis. Carpal tunnel syndrome is common in pregnancy and usually responds to conservative splinting and/or glucocorticoid injection. Surgery can be safely undertaken if indicated during pregnancy.

Chapter 38 - Malignant Diseases and Pregnancy

Larry J. Copeland
Mark B. Landon

The juxtaposition of life and death presents numerous emotional and ethical conflicts to the patient, her family, and her physicians. The diagnosis of cancer for anyone is understandably frightening. To deal with cancer in the context of a pregnancy is particularly burdensome, since the patient may need to, or may perceive that she needs to, choose between her life or the life of her unborn. Cancer in pregnancy complicates the management of both the cancer and the pregnancy. Both diagnostic and therapeutic interventions must carefully address the associated risks to both the patient and the fetus. Informed decisions will require evaluation of a number of factors, and after careful counseling these considerations will be the foundation on which treatment decisions will be made. Over recent years there has been an evolution in the philosophy of care from one of total disregard of the pregnancy with frequent immediate termination to a more thoughtful approach in which management decisions attempt to balance the maternal and fetal interests ideally to limit risk of death or injury to both.

While cancer is the second most common cause of death for women in their reproductive years, only about 1 in 1,000 pregnancies ^[1] is complicated by cancer. Since there are no large prospective studies that address cancer treatment in pregnancy, physicians tend to base treatment strategies on small retrospective studies or anecdotal reports that occasionally present conflicting information. ^[2]

A successful outcome is dependent on a cooperative multidisciplinary approach. The management plan must be formulated within a medical, moral, ethical, legal, and religious framework acceptable to the patient and guided by and dependent on the communication and education resources of the health care team.

The malignancies most commonly encountered in the pregnant patient are, in descending order, breast cancer, cervical cancer, melanoma, ovarian cancer, thyroid cancer, leukemia, lymphoma, and colorectal cancer. ^[3] The frequencies of these diseases may increase secondary to the trend to delay childbearing. Before specific malignancies are discussed, some of the general issues are reviewed.

CHEMOTHERAPY DURING PREGNANCY

Pharmacology of Chemotherapy during Pregnancy

Since pregnancy alters physiology, there is the potential for altered pharmacokinetics of the chemotherapy. Orally administered medications will be subjected to altered gastrointestinal motility. Peak drug concentrations will be decreased due to the 50 percent expansion in plasma volume, producing a longer drug half-life unless there is a concurrent increase in metabolism or excretion. The increase in plasma proteins and fall in albumin may alter drug availability, and amniotic fluid may act as a pharmacologic third space, potentially increasing toxicity due to delayed metabolism and excretion. Hepatic oxidation and renal blood flow are both elevated during pregnancy and may influence the metabolism and excretion of most drugs.^[4] However, since pharmacologic studies in the pregnant woman are lacking, we currently assume that initial drug dosages are similar to the nonpregnant woman and adjustments to dose are based on toxicity on a course-by-course basis.

Since antineoplastic agents can be found in breast milk, breast-feeding is contraindicated.^[5]

1256

Drug Effects on the Fetus

Acute Effects

Because antineoplastic agents are targeted for the rapidly dividing malignant cell, one would expect the fetus with its accelerated growth pattern to be particularly subject to a high rate of serious toxicities. Clear documentation of such is not the case. Spontaneous abortions, fetal organ toxicity, premature birth, and low birth weight are potential risks in the pregnant patient receiving chemotherapy. Excluding the intentional use of abortifacients, it is difficult to demonstrate clearly that the use of chemotherapy results in an increase in the spontaneous abortion rate over the expected 15 to 20 percent. Fetal organ toxicity has not been reported as a major problem, although neonatal myelosuppression^[6] and hearing loss in a 1-year-old^[7] have been reported. Since early induction of labor or surgical delivery is often a component of the overall treatment plan, it is difficult to identify premature birth as a specific result of the chemotherapy. On the other hand, it appears that low birth weight is associated with the administration of chemotherapy in the second and third trimesters.^[8]

Teratogenicity

All drugs undergo animal teratogenicity testing, and based on these results the drugs are assigned risk categories (Table 38-1) by the U.S. Food and Drug Administration (FDA).^[9] Based on this system, most chemotherapeutic agents are rated as C, D, or X.^[9] However, animal teratogenicity testing cannot always be reliably extrapolated to the human. For example, a drug (e.g., aspirin) may show teratogenic effects in animals and not affect humans. The opposite is also true and as such has serious potential to do harm; for example, a drug may show no animal teratogenicity (e.g., thalidomide) but cause serious human anomalies (see Chapter 7) and Chapter 9).

While the literature addressing chemotherapy administration during pregnancy is somewhat limited and dated, reviews by Nicholson^[10] and Doll and colleagues^[4] provide us with some information regarding the frequency of affected offspring. Nicholson reported that first-trimester exposure resulted in about a 10 percent frequency of major fetal malformations. For a similar situation, Doll and colleagues reported 17 and 25 percent frequencies for single-agent chemotherapy and combination chemotherapy, respectively. However, some of the patients from the later study also received irradiation, and exclusion of these cases drops the malformation rate to 6 percent. The risk of fetal malformation varies with the drug classification and specific drug. In general, antimetabolites and the alkylating agents appear to carry the highest risk.^[11]

TABLE 38-1 -- FDA RISK CATEGORIES FOR DRUG USE DURING PREGNANCY

Category	Definition
A	Controlled studies have demonstrated no risk, and the possibility of fetal harm appears remote.
B	<i>Either</i> animal studies have failed to identify a risk but there are no controlled studies in women, <i>or</i> animal studies have shown an adverse effect that was not confirmed in controlled studies in women.
C	<i>Either</i> animal studies have revealed adverse effects and there are no controlled studies in women, <i>or</i> studies in women and animals are not available. Use drugs only if the potential benefit justifies the potential risk to the fetus.
D	There is evidence of fetal risk, but the benefits may be acceptable despite the risk in either a life-threatening situation or a serious disease for which safer drugs are ineffective.
X	Studies in animals or humans have demonstrated fetal abnormalities, and the risk of the drug in pregnant women clearly outweighs any possible benefit.

Adapted from Briggs GG, Freeman RK, Yaffe SJ: Instructions for use of the reference guide. In Briggs GG, Freeman RK, Yaffe SJ (eds): A Reference Guide to Fetal and Neonatal Risk: Drugs in Pregnancy and Lactation. 5th ed. Baltimore, Williams & Wilkins, 1998, p xxii.

ANTIMETABOLITES.

Historically, aminopterin was used as an abortifacient, and in cases of failed abortion the risk of fetal malformation was about 50 percent. Methotrexate has replaced aminopterin for chemotherapeutic purposes, and, while similar types of anomalies occur, the 7 percent frequency is much reduced.^[11] The use of low-dose methotrexate for systemic diseases (e.g., rheumatic disease and psoriasis) does not appear to produce teratogenicity.^[12]

ALKYLATING AGENTS.

The alkylating agents are a commonly used group of drugs for the management of malignancies. Unfortunately, most of the alkylating agents have demonstrated some teratogenic potential. Since these drugs are frequently given in combination with other nonalkylating agents, it is often difficult to identify the risk specific to the

alkylating agent.

Because detailed ultrasonography may fail to identify subtle anatomic but serious functional abnormalities prior to 20 weeks' gestation, patients may want to consider the option of pregnancy termination if first-trimester chemotherapy is planned or administered.

The risk of teratogenicity during the second and third trimesters is significantly reduced, possibly no different from that for pregnant woman who are not exposed to chemotherapy.^[4]

ANTITUMOR ANTIBIOTICS.

Even when administered in early pregnancy, antitumor antibodies appear to be associated

1257

with a low risk of teratogenicity. There is conflicting information in the literature as to whether the anthracyclines cross the placenta.^{[13] [14] [15]} There is no evidence of bleomycin or dactinomycin teratogenicity.^{[16] [17] [18]} Elit and colleagues report a fetus diagnosed with ventriculomegaly 1 week after one cycle of bleomycin, cisplatin, and etoposide for an ovarian germ cell malignancy. No baseline study was performed. The infant developed significant ventriculomegaly and cerebral atrophy. Causation between the chemotherapy and fetal complication seems unlikely but is unknown.^[19]

VINCA ALKALOIDS.

Vincristine and vinblastine, while potent teratogens in animals, do not appear to be as teratogenic in humans.^[20]

MISCELLANEOUS.

Cisplatin has been used in at least 10 pregnancies^{[7] , [16] [17] [18] [19] [20] [21] [22] [23] [24] [25] [26]} without fetal malformation or toxicity, other than the possible abnormality reported by Elit and colleagues.^[19] Henderson and colleagues^[7] report bilateral sensorineural hearing loss at age 1 following in utero second-trimester exposure to carboplatinum. However, there were other potential causes of the hearing loss in this patient, including prematurity, prior cisplatin exposure, and neonatal gentamicin. Procarbazine and asparaginase have both been associated with subsequent fetal malformations.^{[4] , [10] , [27]}

COMBINATION CHEMOTHERAPY.

There is no convincing evidence that there is a synergistic increase in malformations with the use of multiple-agent regimens when compared with single-agent therapy.^{[4] , [10]}

NATIONAL REGISTRY.

In 1984 the National Cancer Institute established a national registry for in utero exposure to chemotherapy.^[28] The registry is currently located at the University of Oklahoma and is under the direction of Dr. John J. Mulvihill. Through August 2000, the registry had summaries of approximately 302 patients. Of the first 210 case studies there were 29 abnormal outcomes with a total of 52 defects. Only two abnormal outcomes were associated with exposure after the first trimester.

Delayed Effects

While second malignancies, impaired growth and development, intellectual impairment, and infertility have been reported after chemotherapy administration to children, the delayed effects of in utero exposure are less well documented.^{[6] , [29]}

In summary, the risks of exposing a fetus to chemotherapy correlate highly with the gestational age at the time of the exposure. Most organogenesis occurs between 3 and 8 weeks of embryonic life, and it is during this time that major morphologic abnormalities are most likely to occur from exposure to any chemotherapeutic agent. Second- and third-trimester chemotherapy exposure does not appear to carry a significantly increased risk of major fetal anomalies.

RADIATION, DIAGNOSTIC AND THERAPEUTIC

The potential for fetal injury arises from exposure to ionizing radiation, both the low-dose diagnostic procedures and the more intense doses associated with radiation therapy. This subject is discussed [in Chapter 7](#) .

SURGERY AND ANESTHESIA, GENERAL FACTORS

While aspects of surgery are addressed below under the specific cancer sites, there are some general considerations worthy of review. Although complications of surgery can threaten the fetus, extraperitoneal surgery is not related to spontaneous abortion or preterm labor. Abdominal or pelvic surgery, if timing flexibility exists, is best performed in the second trimester to limit the risk of first-trimester spontaneous abortion or preterm labor. In the first trimester, progesterone therapy is indicated (weeks 7 to 12) following a bilateral oophorectomy. Perioperative cautions include attention to the relative safety of all drugs administered. Fever secondary to either infection or atelectasis should be treated promptly, since it may be associated with fetal abnormalities.

There is no evidence that there are significant risks of anesthesia independent of coexisting disease. ^[30] In the second and third trimesters, careful attention to positioning is required so as to avoid vena cava compression from the enlarged uterus.

Gabbe: Obstetrics - Normal and Problem Pregnancies, 4th ed. , Copyright © 2002 Churchill Livingstone, Inc.

PREGNANCY FOLLOWING CANCER TREATMENT

With improved survival rates for many childhood and adolescent malignancies, one must be prepared to offer prenatal counseling to the young woman who presents with a personal cancer history. Issues worthy of review and in need of clarification for the obstetrician and the patient are listed [in the box "Counseling Issues for Pregnancy Following Cancer Treatment."](#)

While previous abdominal irradiation for a Wilms' tumor appears to adversely affect the risk of pregnancy complications, including increased perinatal mortality, low birth weight, and abnormal pregnancy, a review of

1258

pregnancies following treatment for Hodgkin's lymphoma revealed no increased poor pregnancy outcome.^[31] However, the rate of ovarian failure following the multiple drug combinations is over 50 percent in some reports.^[32] Also, a combination of pelvic irradiation and chemotherapy for Hodgkin's disease results in an even higher rate of ovarian failure.

Counseling Issues for Pregnancy Following Cancer Treatment

1. What is the risk of recurrence of the malignancy?
2. If a recurrence was diagnosed, depending on the most likely sites, what would be the nature of the probable treatment? How would such treatment compromise both the patient and the fetus?
3. Will prior treatments pelvic surgery, radiation to pelvis or abdomen, or chemotherapy affect fertility or reproductive outcome?
4. Will the hormonal milieu of pregnancy adversely affect an estrogen-receptor positive tumor?

Will a pregnancy increase the risk of recurrence or accelerate recurrence? Even in women with estrogen receptor positive breast cancer, there is no evidence that pregnancy adversely affects survival. In addition to the altered hormonal milieu, concern is also directed toward the potential for accelerated tumor activity associated with alterations in the pregnant patient's immune system. There are no data to support this concern. Long-term follow-up studies of children with in utero exposure to antineoplastic agents have not demonstrated any impairment in growth, despite an increased frequency of intrauterine growth restriction.^[6],^[25] In those children who have been tested for intellectual development, no impairment has been identified.^[33]

Gabbe: Obstetrics - Normal and Problem Pregnancies, 4th ed. , Copyright © 2002 Churchill Livingstone, Inc.

CANCER DURING PREGNANCY

General Considerations

The risk of having a coincident malignant tumor during pregnancy is approximately 0.1 percent. Approximately one third of recorded maternal deaths are secondary to a coexisting malignancy. Delays in diagnosis of the cancer during pregnancy are common for a number of reasons: (1) many of the presenting symptoms of cancer are often attributed to the pregnancy; (2) many of the physiologic and anatomic alterations of pregnancy can compromise the physical examination; (3) many serum tumor markers (-human chorionic gonadotropin [hCGs], -fetoprotein, CA 125, and others) are increased during pregnancy; and (4) our ability to perform either imaging studies or invasive diagnostic procedures is often altered during pregnancy.

Since the gestational age is significant when evaluating the risks of treatments, it is important to determine gestational age accurately. An early ultrasound evaluation may be useful in this regard.

Gabbe: *Obstetrics - Normal and Problem Pregnancies, 4th ed.* , Copyright © 2002 Churchill Livingstone, Inc.

BREAST CANCER

The predicted number of breast cancer cases in women in the United States for the year 2000 is 184,200, and the predicted number of related deaths is 41,200.^[34] Approximately 2 to 3 percent of all breast cancers in women under age 40 occur concurrent with pregnancy or lactation, and approximately 1 in 1,360 to 3,330 pregnancies is complicated by breast cancer.^[35] However, there may be an increase in the frequency of breast cancer complicating other forms of cancer due to delayed childbearing.^[36]

In general, the risk of breast cancer is directly related to the duration of ovarian function. Therefore, both early menarche and late menopause appear to increase the likelihood of developing breast cancer. However, interruption of the normal cyclic ovarian function by pregnancy appears protective. This apparent protective effect may be secondary to the normal hormonal milieu of pregnancy that produces epithelial proliferation, followed by marked differentiation and mitotic rest. Multiparity and in particular multiparous patients who breast-feed have a lower risk of developing breast cancer than does the nulliparous woman. Based on one study of almost 90,000 women, breast-feeding may not be an independent protective factor.^[37]

Paradoxically, carriers of BRCA1 and BRCA2 mutations may have an increased risk of developing breast cancer by having children.^[38]

Diagnosis and Staging

Breast abnormalities should be evaluated in the same manner as if the patient were not pregnant. The most common presentation of breast cancer in pregnancy is a painless lump discovered by the patient. Despite the striking physiologic breast changes of pregnancy, including nipple enlargement and increases in glandular tissue resulting in engorgement and tenderness, breast cancer should be screened for during pregnancy. Since the breast changes become more pronounced in later

pregnancy, it is important to perform a thorough breast examination at the initial visit. Diagnostic delays are often attributed to physician reluctance to evaluate breast complaints or abnormal findings in pregnancy. While bilateral serosanguinous discharge may be normal in late pregnancy, masses require prompt and definitive evaluation. The lengths of delays in diagnosis of breast cancer in pregnancy are commonly 3 to 7 months or longer.^[39]

A case-control study from Princess Margaret Hospital suggested that pregnant patients are at higher risk of presenting with advanced disease because pregnancy impedes early detection.^[40] Mammography in pregnancy is controversial. While the radiation exposure to the fetus is negligible,^[41] the hyperplastic breast of pregnancy is characterized by increased tissue density, making interpretation more difficult.^[42]

Fine-needle aspiration (FNA) of a mass for cytologic study is recommended. FNA is reliable for a diagnosis of carcinoma (false-positive results are rare), but if a solid mass is negative for tumor it should be evaluated by excisional biopsy. Similar to the nonpregnant patient, approximately 20 percent of breast biopsies performed in pregnancy reveal cancer. Tissue biopsies should be submitted for estrogen receptor (ER) and progesterone receptor (PR) analyses. Consistent with the fact that these patients are young, the majority are receptor negative.^[43] There is concern that false-negative ER results performed by the ligand-binding method may occur in pregnancy because of either competitive inhibition by high levels of estrogens or by down-regulation. Immunologic assays that use monoclonal antibody recognize both occupied and unoccupied receptors and therefore may more accurately reflect the receptor status.

Prior to proceeding with treatment, the patient requires staging. All draining lymph nodes should be evaluated. The contralateral breast must be carefully assessed. Laboratory tests should include baseline liver function tests and serum tumor markers, carcinoembryonic antigen (CEA), and CA 15-3. CA 15-3 appears to be a useful tumor marker for monitoring breast cancer in pregnancy.^[44] A chest x-ray is indicated and, if the liver function tests are abnormal, the liver can be evaluated by ultrasound. With precautions of good hydration and insertion of a urinary bladder catheter, a bone scan can be performed in pregnancy. However, in an asymptomatic patient with normal blood tests, the yield is low, and therefore it is not usually performed in those circumstances. In a symptomatic patient, radiographs of the specific symptomatic bones are advised.

While one report suggests an increased incidence of inflammatory breast cancer in pregnancy,^[45] other reviews have not confirmed this observation, and it is generally thought that breast cancers in pregnancy are histologically identical to the nonpregnant patient of the same age. Because inflammatory breast cancer can be mistaken for mastitis, a biopsy of breast tissue should be performed when a breast suspected of being infected is incised and drained.

Treatment

The treatment of breast carcinoma at any time is often overshadowed by psychologic and emotional factors. Because of potential risks to the developing fetus, treatment decisions carry an additional burden. Patients with advanced disease and a poor prognosis may consider termination on this basis alone. Therapy, however, must be individualized in accordance with present knowledge and with the specific desires of the patient.

Local Therapy

The usual criteria for breast-preserving therapy versus modified radical mastectomy pertain to the patient with breast cancer, stages I to III.^[46] However, the option of lumpectomy, axillary node dissection, and irradiation is complicated by the presence of the pregnancy. One publication presents a mathematical model suggesting the risk of axillary metastases due to treatment delay is minimal and may be acceptable to some third-trimester patients with early breast cancer who prefer lumpectomy with radiation postpartum.^[47] Consideration should be given to the delay of irradiation until after delivery. Experimental calculations suggest that a tumor dose of 5,000 cGy will expose the fetus to 10 to 15 cGy while the fetus is within the true pelvis. Later in pregnancy, parts of the fetus may receive as much as 200 cGy.^[48] Brent^[49] has suggested that 5 cGy is a relatively safe upper limit of fetal exposure. While the potential for teratogenesis is reduced later in pregnancy, radiation can affect fetal growth and may carry a risk for future carcinogenesis or secondary birth defects.

Pregnancy Termination

Since early studies suggested a poorer outcome in the pregnant patient, it was assumed that the hormonal changes of pregnancy contributed to rapid growth. Therefore, therapeutic abortion was frequently advised. At present, a harmful effect of continuing pregnancy has not been demonstrated in most published series (Table 38-2). However, it is difficult to evaluate the potential bias toward performing abortion in patients with advanced disease. Since young women tend to have hormone-receptor-negative tumors,^[50] it is difficult to make an argument, based on hormonal concerns, for either termination of pregnancy or oophorectomy as an

adjunct to therapy.^{[52] [53] [54]}

Patients who present with either metastatic breast carcinoma or rapidly progressive inflammatory carcinoma

TABLE 38-2 -- SURVIVAL FROM BREAST CANCER IN PATIENTS UNDERGOING THERAPEUTIC ABORTION COMPARED TO THOSE NOT UNDERGOING ABORTION

Authors	Delivered		Therapeutic Abortion		Comments

Modified from Holmes FA: Breast cancer during pregnancy. *Cancer Bull* 46:405, 1994.

frequently elect pregnancy termination. In general, delays of therapy should be avoided, especially for the patient with inflammatory breast cancer. Immediate initiation of chemotherapy is critical to providing the patient with inflammatory carcinoma with any chance for long-term survival. In the patient with a clinical indication for adjuvant chemotherapy, other than inflammatory carcinoma, the delay of instituting chemotherapy and awaiting fetal pulmonary maturity should be considered in select third-trimester situations. A recent French study reported 17 of 20 pregnancies, in patients treated with chemotherapy for breast carcinoma, resulted in live births.^[55] Others concur with the use of chemotherapy in the second and third trimesters in the management of breast cancer.^{[56] , [57]}

Prognosis

As with any malignant disease, the prognosis best correlates with the anatomic extent of disease at the time of diagnosis. The presence and extent of nodal involvement is especially predictive of prognosis in both nonpregnant and pregnant patients. [Table 38-3](#) provides 5- and 10-year survival data by nodal status.^{[45] , [52] , [58] [59] [60] [61] [62] [63]} While nodal status is of prognostic significance, the number of positive nodes is also important. In the pregnant

patient, the 5-year survival rate is 82 percent for patients with three or fewer positive nodes and 27 percent if greater than three nodes contain tumor.^[45] Pregnancy, probably due to the associated delays in diagnosis, appears to increase the frequency of nodal disease, with 60 to 85 percent of patients exhibiting axillary nodal disease at diagnosis.^{[45] , [64]}

When controlled for age and stage, pregnancy does not seem to affect prognosis adversely.^{[40] , [63] , [65] , [66]} Some have suggested a worse prognosis if the cancer is diagnosed in the second trimester.^[65]

Subsequent Pregnancy

While the consensus is that subsequent pregnancies do not adversely affect survival, there are recommendations regarding the timing of a subsequent pregnancy.^[67] , ^[68] It is generally advised that women with node-negative disease wait for 2 to 3 years, and this interval should be extended to 5 years for patients with positive nodes. Others have advised that no delay is indicated for the patient with good prognostic disease who does not receive postoperative adjuvant chemotherapy.^[69] It has been advised that patients should undergo a complete metastatic work-up prior to a subsequent pregnancy.

While no studies indicate that subsequent pregnancy adversely affects survival, the retrospective reports that suggest a potential favorable affect of subsequent pregnancy are too small to draw firm conclusions.^{[65] , [70]} The trend to better survival is also noted in patients who received adjuvant chemotherapy and subsequently became pregnant.^[71]

LACTATION AND BREAST RECONSTRUCTION

Lactation is possible in a small percentage of patients after breast-conserving therapy for early stage breast cancer. ^[72] , ^[73] Lumpectomy using a radial incision rather than the cosmetically preferred circumareolar incision is less likely to disrupt ductal anatomy. Disruption of the ductal system may increase the rate of mastitis. Breast-feeding is contraindicated in women receiving chemotherapy, since significant levels can be found in breast milk.

Breast reconstruction with the use of autologous tissue has increased secondary to questions about the use of silicone-filled implants. The transverse rectus myocutaneous flap (TRAM) is one popular method of breast reconstruction. Since the donor site is a portion of the anterior abdominal wall, there is potential concern when the patient develops abdominal distention from pregnancy. In one case report and review of the literature, nine cases of pregnancy following breast reconstruction experienced no problem with anterior abdominal wall integrity. ^[74]

HODGKIN'S DISEASE AND NON-HODGKIN'S LYMPHOMA

Hodgkin's Disease

Approximately 35,900 cases of lymphoma will be diagnosed in women in the United States in the year 2000, and only about 12 percent of these will be Hodgkin's disease.^[34] Hodgkin's disease, commonly encountered in patients in their late teens and twenties, occurs at a mean age of 32 years. Non-Hodgkin's lymphomas occur at a mean age of 42 and therefore are reported less frequently in association with pregnancy. Lymphomas complicate approximately 1 in 6,000 pregnancies. Spontaneous abortion, stillbirth rates, and preterm births do not appear to be increased.^[75], ^[76] Pregnancy does not appear to affect adversely the course of the disease.^[77], ^[78] Routine termination of pregnancy should not be advised. While some advocate therapeutic abortion for the patient with a first-trimester pregnancy and Hodgkin's disease to allow complete staging, others, probably more appropriately, have limited the role of therapeutic abortion to those women requiring infradiaphragmatic irradiation or those with systemic symptoms or visceral disease, which are best managed with multiagent chemotherapy.

Hodgkin's disease frequently presents with enlarged cervical or axillary lymph nodes. The diagnosis is established by biopsy of the suspicious nodes. The presence of systemic symptoms such as night sweats, pruritis, or weight loss suggests more extensive disease. Two histologic variants, nodular sclerosis and lymphocyte-predominant, have a better prognosis than mixed cellularity and lymphocyte-depleted tumors.

Clinical staging for lymphoma necessitates the systemic evaluation by history, laboratory findings, bone marrow, and radiographic imaging. Clinical treatment and staging should be individualized. Pathologic staging for Hodgkin's disease may involve laparotomy and splenectomy; however, this is not usually necessary for non-Hodgkin's lymphoma, as disseminated disease can usually be documented without surgery. The minimal staging for Hodgkin's disease during pregnancy includes radiographic examination of the chest, liver function tests, bone marrow biopsy, complete blood count, and urinalysis. Chest tomography or computed tomographic (CT) scan of the mediastinum may be necessary

TABLE 38-4 -- STAGING CLASSIFICATION OF HODGKIN'S DISEASE*

Stage	Description
I	Involvement of a single lymph node region (I) or of a single extralymphatic organ site (I _E)
II	Involvement of two or more lymph node regions on the same side of the diaphragm (II) or localized involvement of an extralymphatic organ site and of one or more lymph node regions on the same side of the diaphragm (II _E)
III	Involvement of lymph node regions on both sides of the diaphragm (III), which also may be accompanied by localized involvement of an extralymphatic organ or site (III _E), of the spleen (III _S), or of both (III _{SE})
IV	Diffuse or disseminated involvement of an extralymphatic organ with or without localized lymph node involvement (liver, bone marrow, lung, skin)

*Symptoms of unexplained fever, night sweats, and unexplained weight loss of 10 percent of normal body weight results in classification of patients as B; absence of these symptoms is denoted as A.

to evaluate nodal enlargement in the chest. Evaluation of the abdomen is compromised by the gravid uterus, and some consideration should be given to delaying abdominal imaging until after the first trimester. Magnetic resonance imaging (MRI) may be the safest technique for demonstrating intra-abdominal adenopathy. Isotope scans of the liver and bone are best avoided during pregnancy. A single-shot lymphangiogram results in an exposure of less than 1 rad to the fetus and is probably safe after the first trimester.^[79] Ultrasonography is safe and may provide useful information.

Disease stage (Table 38-4) is the most important factor in treatment planning and prognosis. Survival for early-stage Hodgkin's disease exceeds 90 percent, whereas patients with disseminated nodal disease have a 5-year survival rate of about 50 percent. As expected, patients with stage IV disease have poor survival rates. While radiation therapy is the mainstay of treatment for early-stage Hodgkin's disease, combination chemotherapy is employed for the treatment of advanced-stage disease with organ involvement. The MOPP regimen (nitrogen mustard, vincristine, procarbazine, and prednisone) in combination with radiation is often used to treat patients with bulky, large mediastinal masses or disseminated nodal disease. Most investigators agree that treatment should not be withheld during pregnancy except in early-stage disease, particularly if the diagnosis is made in late gestation. Radiotherapy to the supradiaphragmatic regions may be performed with abdominal shielding after the first trimester. Thomas and Peckham^[79] reported three cases of mantle field irradiation with abdominal shielding for supradiaphragmatic disease. The estimated radiation exposures to the fetus for these patients at 10, 15, and 16 weeks were 2.5, 4.4, and 10.4 rad, respectively. While these pregnancies went to term with apparent normal outcomes, long-term follow-up on these infants was not presented. Spontaneous abortion has been reported with an estimated first-trimester fetal dose of 9 rad secondary to scatter from delivering 4,400 rad to the chest of a patient receiving treatment for a recurrence.^[80] Another patient in the same report received 3,300 rad to a mantle field at 16 weeks' gestation, and no adverse effects were noted. In general, if the estimated exposure to a first-trimester fetus is expected to exceed 10 rad or if combination chemotherapy is planned for the first trimester, therapeutic abortion should be considered because of the risk of fetal malformation.^[81] Asymptomatic early-stage disease presenting in the second half of pregnancy may be followed closely while preparations are made for early delivery.^[80] The use of steroids and single-agent chemotherapy has been proposed for the patient with systemic symptoms.

Subdiaphragmatic or advanced disease requires chemotherapy. Since many of the most commonly used chemotherapeutic agents are known teratogens, such treatment is best avoided in the first trimester. Similar treatments should also be approached with caution later in pregnancy, although most case reports have documented only intrauterine growth restriction and neonatal neutropenia as complications. Long-term follow-up toxicity studies are lacking.

Following therapy for Hodgkin's disease, it has been suggested that pregnancy planning should take into consideration that about 80 percent of recurrences will manifest within 2 years. Treatments for Hodgkin's disease may compromise the reproductive potential of young patients.^[82], ^[82] As reflected in Figure 38-1, ovarian

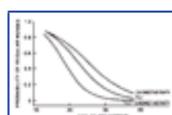

Figure 38-1 Probability of regular menses after chemotherapy, total lymphoid irradiation (TLI), and TLI and chemotherapy in patients with Hodgkin's disease. The synergistic effect

failure is more likely to occur in older patients, even if treated with fewer courses of chemotherapy.^[83] Some studies have reported a rate of only 12 percent of normal ovarian function following therapy for Hodgkin's disease.^[84] Combined treatment with irradiation and chemotherapy provides the highest risk of ovarian failure.

Bilateral midline oophorectomy at staging laparotomy has been advocated for the patient requiring pelvic node irradiation.^[85] Even with this technique the ovaries may be exposed to a significant dose of irradiation, ranging from 600 to 3,500 rad.^[75] Additionally, there are concerns of adhesions and ovum pick-up and transport. While combined oral contraceptives have been advocated to preserve ovarian function, there is no evidence that the gonads are protected.^[85] Depending on their availability, new reproductive technologies, including oocyte donation and embryo cryopreservation, can be considered for select situations.^[86]

Patients who become pregnant after treatment for Hodgkin's lymphoma do not demonstrate increased adverse perinatal outcomes such as fetal wastage, term birth, and birth defects when compared with sibling controls.^[87], ^[88] While fetal anomalies have occurred after treatment for Hodgkin's disease,^[89] chromosomal abnormalities or a new gene mutation have not been diagnosed.^[82] The absence of a repetitive pattern of malformations makes it difficult to imply a casual relationship between any birth defects observed and previous therapy for Hodgkin's disease.

Non-Hodgkin's Lymphoma

Non-Hodgkin's lymphoma occurs at a mean age of 42 years and therefore is reported less frequently than Hodgkin's disease in association with pregnancy. In general, non-Hodgkin's disease is more likely to affect a pregnancy adversely because patients usually have an aggressive histology and advanced-stage disease. Burkitt's lymphoma is usually rapidly progressive and may involve the breast and ovary. Lymphoma of the breast has a particularly poor prognosis, and it has been speculated that there may be a hormonal influence on this malignancy in pregnant patients.^[90]

In a report by Ward and Weiss,^[91] about 60 percent (12 of 21) of second- and third-trimester cases resulted in surviving infants. The perinatal mortality rate associated with patients who were either not treated or treated by surgery was almost 40 percent (5 of 13), while almost 90 percent (seven of eight) of infants of mothers treated by chemotherapy survived. Of the mothers treated with chemotherapy, 50 percent (four of eight) survived. Of the 13 patients who were not treated or who were treated with surgical resection, 5 (38 percent) survived. The nature of the presenting disease probably played a preselection role regarding the treatments. Including additional, more recent, reports, it is evident that about 60 to 70 percent of patients and about 75 percent of infants survive.

Adult T-cell leukemia/lymphoma, caused by the human T-cell lymphotropic virus type I, is found in Japan, the Caribbean, and the southern United States. The virus is present in familial clusters and is transmitted by sexual intercourse, blood transfusions, and breast milk. Infants seroconvert between 12 and 19 months of age at a rate of 20 to 25 percent.^[92], ^[93]

ACUTE LEUKEMIA

While the incidence of leukemia in pregnancy is not specifically known, it is estimated to occur in less than 1 in 75,000 pregnancies. Acute leukemia represents about 90 percent of leukemias coexisting with pregnancy. Acute myeloid leukemia accounts for about 60 percent and acute lymphoblastic leukemia (ALL) for about 30 percent of cases. Over three fourths of the cases are diagnosed after the first trimester. ^[6], ^[94]

The prognosis for acute leukemia in pregnancy is guarded. ^[6], ^[94] ^[95] ^[96] ^[97] In adults, acute leukemia in the nonpregnant patient, if untreated, has a median survival of about 2 months. ^[98] In the treated patient, the median survival is between 1 and 2 years. Immediate and aggressive therapeutic intervention will yield complete remission rates of about 75 percent, and 40 percent of these are sustained. While there is no evidence that pregnancy adversely affects the prognosis of acute leukemia, a 1987 report identified a median survival of 16 months in the pregnant patient, ^[6] and another study in 1988 reported a median survival of 27.5 months in a nonpregnant population. ^[99] However, the differences in patient populations (the latter study was a report on the more favorable ALL) and the varied treatments precludes any reliable comparison. ^[98] Optimal care of the pregnant patient with acute leukemia necessitates a team effort and is best achieved in a cancer referral center.

The diagnosis of acute leukemia is rarely difficult. The signs and symptoms of anemia, granulocytopenia, and thrombocytopenia, including fatigue, fever, infection, and easy bleeding or petechiae, usually prompt a complete blood count. A normal or elevated white blood cell count is present in up to 90 percent of patients with ALL. Counts in excess of 50,000 are found in only one fourth of patients. In contrast, patients with acute nonlymphocytic leukemia (ANLL) may present with markedly elevated white blood cell counts, although one third will present with leukopenia. ^[100] The diagnosis of leukemia should be confirmed by bone marrow biopsy and aspirate. The biopsy material is

1264

usually hypercellular with leukemic cells. The smear of the aspirate reveals decreased erythrocyte and granulocytic precursors as well as megakaryocytes. Leukemic cells comprise greater than one half of the marrow's cellular elements in most patients. The morphology of the marrow and the peripheral leukemic cells help to distinguish between lymphocytic and nonlymphocytic leukemias. This latter group includes acute myelocytic (granulocytic), promyelocytic, monocytic, and myelomonocytic leukemias, and erythroleukemia. Acute myelocytic leukemia is the most common form of ANLL. Patients who develop ANLL as a result of previous chemotherapy have a particularly poor response to treatment.

There are numerous reports of successful pregnancies in patients aggressively treated with combination chemotherapy for acute leukemia. Acute leukemia and its therapy are associated with an increase in stillbirths (approximately 15 percent), prematurity (approximately 50 percent), and growth restriction. ^[95], ^[98] In 1988 and 1991, reports by Aviles and colleagues, ^[33], ^[101] no serious long-term effects of in utero exposure to chemotherapy were reported. The first report included 17 children, aged 4 to 22, whose mothers received treatment for acute leukemia. ^[102] In the second report, 43 children who were born to mothers with a variety of hematologic malignancies were examined at 3 to 19 years of age. ^[33] In both studies, greater than 40 percent of the cases involved exposure during the first trimester.

If the mother is exposed to cytotoxic drugs within 1 month of delivery, the newborn should be monitored closely for evidence of granulocytopenia or thrombocytopenia.

Gabbe: Obstetrics - Normal and Problem Pregnancies, 4th ed. , Copyright © 2002 Churchill Livingstone, Inc.

CHRONIC LEUKEMIA

Chronic leukemia accounts for approximately 10 percent of cases of leukemia during pregnancy, with the majority of these being patients with chronic myelocytic leukemia (CML).^[98] Chronic lymphocytic leukemia has a median age of onset of about 60 years, making cases during pregnancy rare. The median age of patients with CML is 35 years. CML is characterized by excessive production of mature myeloid cell elements, with granulocyte counts averaging 200,000/dl. Most patients have thrombocytosis and a mild normochromic normocytic anemia. Platelet function is often abnormal, although hemorrhage is usually limited to patients with marked thrombocytopenia. CML tends to be indolent, and normal hematopoiesis is only mildly affected in the early stages of disease. Therefore, delay of aggressive treatment is a more feasible option than with acute leukemia. Unless complications such as severe systemic symptoms, autoimmune hemolytic anemia, recurrent infection, or symptomatic lymphatic enlargement occur, treatment for chronic leukemia should be withheld until after delivery. Therapy, when necessary, usually includes prednisone and an alkylating agent such as chlorambucil or cyclophosphamide. High dose steroids alone may be used to treat autoimmune hemolytic anemia. Currently, the median survival for CML is over 60 months, with survivals up to 10 years common.

Often, the diagnosis of CML antedates the pregnancy. While pregnancy does not appear to affect CML adversely, therapy does increase the frequency of preterm birth and low birth weight. Information about contemporary management and prognosis is scarce secondary to the fact that few recent cases of CML during pregnancy have been reported. There are reports of CML treatment with leukapheresis during pregnancy. This treatment appears to be both safe and effective. Leukapheresis results in improvement of blood counts, systemic symptoms, and splenomegaly. Also, this treatment, although costly and involved, offers less risk of teratogenesis than cytotoxic treatments.^[94] , ^[102] Other treatment regimens reported include biologic modifiers, such as interferon-^[103] , ^[104] and hydroxyurea.^[104] ^[105] ^[106] ^[107]

Hairy cell leukemia during pregnancy is rare, with only six reported cases. A predilection for men and the older age groups is the reason for the infrequency. Interferon- treatment has been used in two cases with no adverse fetal effects.^[103]

MELANOMA

The incidence of malignant melanoma is increasing in the childbearing years, and it is estimated that 1 percent of the population will develop this disease.^[108] Since the median age at onset is approximately 50 years, the disease is relatively uncommon. However, one study reported malignant melanoma in 2.8 per 1,000 deliveries.^[109] The understanding of the natural history of melanoma has been advanced by the identification of prognostic variables.^[110] Prognostic features of the primary tumor include tumor thickness, Clark's level of invasion, Breslow's modifications, and Chung's modifications (Fig. 38-2), ulceration, and body location.

A topic of continued debate is whether pregnancy exerts a negative effect on the course of malignant melanoma. Reports from the 1950s suggested that melanoma arising during pregnancy is associated with an aggressive clinical course.^{[112], [113]} Subsequent reports, some being controlled studies, suggest melanoma diagnosed during pregnancy is more likely to be diagnosed at an advanced stage.^{[114], [115], [116]} Most of the more recent studies are limited to patients with stage I disease and

1265

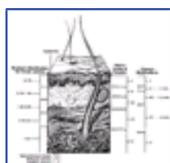

Figure 38-2 Schematic comparison of the different levels of invasion for melanoma. (From Gordon AN: *Vulvar tumors*. In Copeland LJ [ed]: *Textbook of Gynecology*. 2nd ed. Philadelphia, WB Saunders Company, 2000, p 1202, with permission.)

thus do not address this issue.^{[117], [118]} While many studies suggest that melanoma developing during pregnancy is more likely to appear in locations associated with a poor prognosis,^{[114], [115], [116], [117], [118]} others show no increase in poor prognostic location of lesions in the pregnant patient.^{[119], [120]}

The World Health Organization (WHO) 1991 study examined the relevant prognostic features of melanoma in the childbearing years and in pregnancy.^[119] This report suggested that patients who were diagnosed during pregnancy had tumors demonstrating significantly greater tumor thickness (Table 38-5). However, after correcting for tumor thickness, survival rates were similar. Additional studies from Massachusetts General Hospital and Duke University have supported the observation of greater tumor thickness in patients diagnosed during pregnancy (Table 38-6). Other investigators have found no difference in lesion thickness in pregnancy.^[121] The issue remains unsettled, and explanations for the increased tumor thickness include hormonal stimulation, growth factor stimulation, immunologic alterations of pregnancy, and delays in diagnosis. Delays in diagnosis are understandable, since it is not uncommon for pigmentation changes to take place during pregnancy. Therefore, tissue sampling is often delayed secondary to abnormalities being dismissed as a normal change of pregnancy.

Surgery remains the most effective modality for the treatment of melanoma. For patients with stage I or II tumors, the standard surgical excision with margins appropriate for tumor thickness should be performed. Regional lymph node dissection can be done in the patient with regional (stage III) disease. Since adjuvant chemotherapy is experimental and has not demonstrated improved survival, it is not recommended for the pregnant patient because of the potential risk to the fetus. Adjuvant interferon and vaccines for the nonpregnant patient are also under evaluation. These treatments hold

1266

more promise for the pregnant patient, based on fetal considerations. Advanced metastatic disease carries a poor prognosis. Since chemotherapy with dacarbazine results in a clinical response, usually of short duration, in no more than 30 percent of patients, it is usually most appropriate to plan for early delivery in cases of disseminated disease presenting late in pregnancy.

Is there a role for therapeutic abortion? Despite rare reports of regression after delivery, no studies support any therapeutic benefit associated with therapeutic abortion.^{[123], [124]} However, given the aggressive nature of the current therapies available for metastatic disease, it is not inappropriate to consider abortion when managing advanced disease presenting in the first trimester.^[124]

The patient who has undergone apparent successful treatment for a malignant melanoma may express concern about the safety of a future pregnancy. No adverse impact on recurrence or survival has been identified in the majority of the literature on this issue.^{[115], [118], [119]} However, the timing of the subsequent pregnancy deserves some consideration. The probability of survival of a specific cancer should be evaluated based on the known prognostic variables. The 5-year survival rate for the patient with a melanoma less than 1.5 mm thick is 90 percent. For a tumor of intermediate thickness (1.5 to 4 mm) the 5-year survival rate is 50 to 75 percent, and for a more deeply invasive tumor survival is less than 50 percent. While some report that approximately 60 to 70 percent of patients will develop their recurrence within 2 years and 80 to 90 percent within 5 years, the WHO study claimed that 83 percent of recurrences develop within the first 2 years.^[124] Based on this information, it is generally recommended that patients wait 2 to 3 years before attempting another pregnancy, especially with nodal disease.^[119] There are insufficient data on the select group of patients who develop their initial melanoma during pregnancy to make recommendations regarding the safety of a subsequent pregnancy.

Another issue of concern is which form of birth control

TABLE 38-5 -- WHO STAGES I AND II STUDY OF MALIGNANT MELANOMA

CERVICAL CANCER

Approximately 3 percent of all invasive cervical cancers occur during pregnancy. Cervical cancer is the most common gynecologic malignancy associated with pregnancy, occurring in approximately 1 per 2,200 pregnancies.^{[127] [128] [129]}

However, the true incidence is difficult to ascertain due to the reporting biases associated with the reports originating from large referral centers. Also, various reports may include patients who have preinvasive lesions as well as patients who are diagnosed postpartum.

All pregnant patients should be evaluated on their initial obstetric visit with visualization of the cervix and cervical cytology, including an endocervical brush. The general principles of screening for cervical neoplasia apply to the pregnant patient. The Papanicolaou smear is used to screen the normal-appearing cervix. If the cervix appears friable, cervical cytology alone may not be sufficient to alert the physician to the presence of a malignant tumor. False-negative cervical cytology is at increased risk in pregnancy due to excess mucus and bleeding from cervical eversion. Therefore, it is necessary to obtain a biopsy to ensure that tissue friability is not secondary to tumor. Also, an ulcerative or exophytic lesion must have histologic sampling performed. While approximately one third of pregnant patients with cervical cancer are asymptomatic at the time of diagnosis, the most common symptoms are vaginal bleeding or discharge. Evaluation for the possibility of neoplastic disease of the lower genital tract is required in the evaluation of vaginal bleeding in the pregnant as well as the nonpregnant patient.

Considering the routine practice of performing cervical cytology in early pregnancy, one would expect there to be a preponderance of early-stage disease diagnosed in the first trimester. Surprisingly, this is not the situation. The

1267

diagnosis of cervical cancer is commonly made postpartum rather than during pregnancy and, while stage IB disease is the most commonly diagnosed stage, all stages are represented in significant numbers. Both patient and physician factors, including lack of prenatal care, failure to obtain cervical cytology or to biopsy gross cervical abnormalities, false-negative cytology, and failure to evaluate abnormal cytology or vaginal bleeding properly, contribute to the delays in diagnosis. Unfortunately, the complaint of spotting or bleeding during pregnancy is common and usually secondary to pregnancy-related conditions.

Cervical cytology suggestive of a squamous intraepithelial lesion or a report of atypical glandular cells during pregnancy requires appropriate clinical evaluation (Fig. 38-3). The colposcopic evaluation of the pregnant cervix is altered by the physiologic changes of pregnancy and, since most practicing physicians will diagnose invasive cervical cancer associated with pregnancy only once or twice in their careers, it may be prudent to consult a gynecologic oncologist. While colposcopy during pregnancy is usually enhanced by the physiologic eversion of the lower endocervical canal, vascular changes and redundant vagina may alter or obscure normal visualization. During pregnancy, failure to visualize the entire transformation zone and squamocolumnar junction is uncommon. While endocervical curettage is not generally recommended during pregnancy, lesions involving the lower endocervical canal can often be directly visualized and biopsied. While the pregnant cervix is hypervascular, serious hemorrhage from an outpatient biopsy is uncommon, and the risk of bleeding is offset by the risk of missing an early invasive cancer. Following a colposcopic evaluation with appropriate tissue sampling, most patients with preinvasive lesions can be followed with repeat colposcopy at 6- to 8-week intervals to delivery.^{[130] , [131]}

Patients then require a careful and complete colposcopic evaluation 6 weeks' postpartum. Cone biopsy during pregnancy, when necessary, should ideally be performed during the second trimester to reduce the risks of first-trimester abortion and rupture of membranes or premature labor in the third trimester.^{[132] [133] [134]} Complications from conization of the pregnant cervix

Figure 38-3 Suggested protocol for evaluation of abnormal cervical cytology in pregnancy. ECC, endocervical curettage; CIN, cervical intraepithelial neoplasia. (From Hacker NF, Berek JS, Lagasse LD, et al: *Carcinoma of the cervix associated with pregnancy*. *Obstet Gynecol* 59:735, 1982, with permission.)

1268

are common. Therapeutic conization for intraepithelial squamous lesions is contraindicated during pregnancy. Diagnostic cone biopsy in pregnancy is reserved for patients whose colposcopic-directed biopsy has shown superficial invasion (suspect microinvasion) or in other situations where an invasive lesion is suspected but cannot be confirmed by biopsy. When a cone biopsy is necessary during pregnancy, one should keep in mind the anatomic alteration of the cervix secondary to pregnancy. A shallow disk-like cone is usually satisfactory to clarify the diagnosis with a minimum of morbidity. It should be kept in mind that patients who have had a conization during pregnancy are at higher risk for residual disease. Therefore, close follow-up is essential.

Following the diagnosis of invasive cervical cancer, a staging evaluation is indicated. The standard cervical staging is clinical and usually based on the results of physical examination, cystoscopy, proctoscopy, chest x-ray, and intravenous pyelogram. CT scan or, in some centers, lymphangiography is often performed to identify lymph node metastasis. In the pregnant patient, the standard staging evaluation is modified. The chest radiograph is performed with abdominal shielding. Sonography is used to detect hydronephrosis and, if additional retroperitoneal imaging is desired for the evaluation of lymphadenopathy, consideration should be given to using MRI. While the use of MRI during pregnancy is not approved, there have been no reported sequelae and the theoretical risks are less than the risks associated with ionizing radiation techniques.

Microinvasion

In patients with a microinvasive squamous carcinoma with negative margins on cone biopsy, consideration can be given to conservative management until delivery. The risk of occult metastatic disease is predominantly dependent on two pathologic features: (1) the depth of invasion and (2) the presence or absence of lymphovascular space involvement.^[135] Whether the cone biopsy can be considered sufficient long-term therapy or whether a postpartum hysterectomy with or without lymphadenectomy should be performed is also based on the detailed analysis of the pathologic features of the cone biopsy. In these cases, consultation with a

gynecologic oncologist is appropriate.

Invasive, Early-Stage Disease

Since the definitive treatment of invasive cervical cancer is not compatible with pregnancy continuation, the clinical question that must be addressed is when to conclude the pregnancy so that therapy can be completed. Considering this requirement, treatment options will be influenced by gestational age, tumor stage and metastatic evaluation, and maternal desires and expectations regarding the pregnancy. The management of early invasive cervical cancer (stages IB and IIA) in the young patient is usually by radical hysterectomy, pelvic lymphadenectomy, and aortic lymph node sampling. ^[136] The primary advantage over radiation therapy for these patients is preservation of ovarian function. For the patient with a high probability of having a poor prognostic lesion and therefore requiring postoperative irradiation, consideration can be given to performing a unilateral or bilateral oophorectomy at the time of the hysterectomy. The ovarian suspension should be intraperitoneal, as retroperitoneal placement seems to predispose to subsequent ovarian cyst formation. In the first trimester, this surgery is usually carried out with the fetus in utero. In the third trimester, the radical hysterectomy and pelvic lymphadenectomy are performed after completion of a high classic cesarean delivery. Delays in therapeutic intervention have not been reported to increase recurrence rates for patients with small-volume stage I disease. ^[136] While the pelvic vessels are large, the dissection is enhanced by more easily defined tissue planes. ^[139], ^[140]

Second-trimester situations are more problematic. Serious consideration should be given to administering one to three cycles of platinum-based chemotherapy and thereby allowing an additional 7 to 15 weeks of fetal maturation. In one study, maturation from 26 to 27 weeks' gestation compared with 34 to 35 weeks increased fetal viability from 67 percent to 97 percent. ^[141] The neoadjuvant chemotherapy approach (chemotherapy prior to either surgery or irradiation) would unlikely compromise and may enhance the overall efficacy of treatment. Also, having passed the primary interval of organogenesis, it is unlikely that serious fetal sequelae will occur secondary to the chemotherapy. Certainly in terms of general fetal salvage and outcome, the risk of extreme prematurity would far outweigh the risk of the chemotherapy exposure. While this management of second-trimester cervical cancer presentations seems logical, there is scant information about this treatment approach. However, neoadjuvant chemotherapy with vincristine and platinum-based chemotherapy for ovarian cancers has been reported with no fetal sequelae identified. ^[142]

Invasive, Locally Advanced Disease

The management of the patient with more advanced local disease is based on treatment with chemotherapy and irradiation, both external beam to treat the regional nodes and shrink the central tumor and brachytherapy to complete the delivery of a tumoricidal dose to the cervix and adjacent tissues. ^[136] Coordinating a chemoradiation treatment plan for pregnant patients with stages IIB, stage III, and stage IVA is challenging. The patient with a first-trimester pregnancy can usually

1269

be treated in the standard fashion with initiation of chemotherapy and external therapy to the pelvis or extended field, as dictated by standard treatment guidelines. Most of these patients will proceed to abort spontaneously within 2 to 5 weeks of initialing the radiation. Patients in the late first trimester are least likely to abort spontaneously, and it may be necessary to perform a uterine evacuation on the completion of external therapy in some patients. Following either spontaneous abortion or uterine evacuation, the brachytherapy component of the radiation therapy can proceed in the standard fashion. Patients in either their second or third trimester should have a high classic cesarean delivery prior to starting standard chemotherapy and irradiation. Again, it would seem appropriate to strongly consider neoadjuvant chemotherapy for this group of patients, especially the patient with a second-trimester or early third-trimester presentation, when the opportunity for fetal maturation could be provided.

Invasive, Distant Metastasis

Metastatic disease to extrapelvic sites carries a poor prognosis. While a select few patients with aortic node metastasis may receive curative therapy, it is unlikely for the patient with pulmonary metastasis, bone metastasis, or supraclavicular lymph node metastasis to be cured. Personal patient choices and ethical considerations will be the major factors guiding treatment in these situations.

Small cell neuroendocrine tumors of the cervix associated with pregnancy are rare. Neoadjuvant or adjuvant chemotherapy with cisplatin, etoposide, and doxorubicin is recommended, and long-term survivors have been reported. ^[142], ^[143]

Method of Delivery

Controversy continues to surround the issue of the method of delivery for the term patient with cervical cancer. It seems heroic and unjustifiably risky to encourage vaginal delivery of a patient with a large, firm, barrell-shaped tumor or a large friable and hemorrhagic exophytic tumor. However, many small-volume stage IB, IIA, and early IIB tumors are potential candidates for vaginal delivery. Whether vaginal delivery promotes systemic dissemination of tumor cells is unknown. While the general opinion is that survival rates are not influenced by the mode of delivery, ^[127], ^[144] a recent multivariate analysis "showed a possible trend ($p = 0.08$) toward a negative outcome after vaginal delivery." ^[129]

Although systemic tumor dissemination secondary to vaginal delivery has not been documented, there are reports of episiotomy implants for both squamous carcinoma and adenocarcinoma following vaginal delivery. ^[145] ^[146] ^[147] Episiotomy implants are sufficiently rare that the risk should not be a determining factor for a given patient. However, the episiotomy should be carefully followed in a cervical cancer patient who delivers vaginally. Episiotomy nodules in these patients must be promptly evaluated by biopsy, as an early diagnosis may permit curative therapy. ^[145] Diagnostic delays secondary to suspicion of the nodules representing stitch abscess should be avoided.

Survival

While some authors have suggested that the survival of patients with cervical cancer associated with pregnancy is compromised, ^[148] most reports indicate that the prognosis is not altered. ^[127] ^[128] ^[129], ^[148], ^[149]

OVARIAN CANCER

With the increased use of diagnostic ultrasound, ovarian cysts and masses are more frequently encountered in early pregnancy.^[150] While adnexal masses are frequently encountered in pregnancy, only 2 to 5 percent are malignant ovarian tumors.^[151],^[152] Ovarian cancer occurs in approximately 1 in 18,000 to 1 in 47,000 pregnancies.^[153],^[154]

While the three major categories of ovarian tumor—epithelial, germ cell, and stromal—occur during pregnancy, there is a disproportionate number of patients with germ cell tumors compared with the nonpregnant patient. A review of the literature since 1984 reveals 40 patients having malignant primary ovarian tumors during pregnancy. Germ cell tumors account for 45 percent (Fig. 38-4); 37.5 percent are epithelial tumors, 10 percent are stromal tumors, and 7.5 percent are categorized as miscellaneous. This distribution is undoubtedly skewed by the reporting bias associated with rare tumors. Characteristic of epithelial tumors in young patients who are not pregnant, the majority of epithelial ovarian tumors complicating pregnancy are of low grade (grade 1 or low malignant potential) or early stage, not uncommonly both low grade and stage I.

Management of the adnexal mass in pregnancy is the subject of some controversy. The risks of surgical intervention may favor a conservative approach.^[156] Serial sonograms may be of some value in determining the nature and biologic potential of the tumor. If the clinical presentation is consistent with torsion, rupture, or hemorrhage, immediate surgical intervention is indicated. Prompt surgical exploration is also performed for the mass associated with ascites or when there is evidence of metastatic disease. Since surgical exploration during pregnancy is associated with an increase in pregnancy loss and neonatal morbidity, it is ideal to

1270

Figure 38-4 Dysgerminoma, the most common malignant ovarian neoplasm found in pregnancy, characterized by a lobulated solid gross appearance. (From Copeland LJ: *Gestational trophoblastic neoplasia*. In Copeland LJ [ed]: *Textbook of Gynecology*. 2nd ed. Philadelphia, WB Saunders Company, 2000, p 1391, with permission.)

delay surgical intervention until term or after delivery. A number of opposing risks require consideration prior to following a conservative approach. The risk of greatest concern is that a delay of surgical intervention could permit a malignant ovarian tumor to spread, resulting in a decreased opportunity for cure. However, considering the rarity of advanced-stage poorly differentiated epithelial tumors in this age group, this risk is relatively small. There does appear to be an increased probability that an adnexal mass during pregnancy will undergo torsion or rupture.^[157],^[158] and surgical intervention for these events is associated with higher fetal loss than an elective procedure.^[151],^[159] While ovarian tumors may be the cause of obstructed labor,^[151] this is uncommon. Serial sonographic evaluations will identify the rare tumor that remains pelvic as the gestation progresses. Since most ovarian masses relocate to the abdomen as the pregnancy advances, other explanations should be considered for persistent pelvic masses, including pelvic kidney, uterine fibroids, and colorectal or bladder tumors.

When a malignant ovarian tumor is encountered at laparotomy, surgical intervention should be similar to that for the nonpregnant patient. If the patient is preterm and the tumor appears confined to one ovary, consideration should be given to limiting the staging to removal of the ovary, cytologic washings, and a thorough manual exploration of the abdomen and pelvis. The potential benefit of more extensive staging, including aortic node sampling, may be offset by higher pregnancy loss or neonatal morbidity. Prior to surgery, a comprehensive discussion with the patient should guide the extent of surgery if metastatic disease, especially a high-grade epithelial lesion, is encountered. Depending on the gestational age and the patient's desires, limited surgery followed by chemotherapy and additional extirpative surgery following delivery must be offered in select cases.

Preoperative serum tumor markers are of limited value during pregnancy secondary to the physiologic increases in hCG, -fetoprotein, and CA 125. Kobayashi and colleagues^[160] have reported the mean CA 125 levels during pregnancy. CA 125 increases during the first trimester (mean, 72 U/ml) and then normalizes during the second trimester. CA 125 values tend to be significantly elevated following second-trimester abortion (mean, 447 U/ml) and term delivery (mean, 204 U/ml). Following diagnostic confirmation of a malignant ovarian tumor, the appropriate serum markers are useful to monitor the course of the disease.

Virilizing ovarian tumors during pregnancy are most commonly secondary to theca-lutein cysts, and their evaluation and management should be conservative. These benign exaggerated physiologic "tumors" may redevelop with subsequent pregnancies.^[161]

Postoperative Adjuvant Therapy

Postoperative adjuvant therapy should follow the treatment guidelines for the nonpregnant patient. Following tumor debulking, patients with advanced epithelial tumors should receive combination chemotherapy. Until 1995, the standard therapy was a platinum and alkylating combination. However, with the recent demonstration of the superior effectiveness of the combination of cisplatin and Taxol,^[162] these agents may offer the patient a better survival. Unfortunately, there is no information available regarding the potential toxic effects of Taxol on a developing fetus. There are favorable case reports on the treatment of stage III serous ovarian carcinoma with postoperative platinum-based chemotherapy.^[163]^[164]^[165] There are a number of favorable treatment outcomes reported in patients with malignant germ cell tumors and pregnancy.^[166]^[167]^[168]^[169]^[170]^[171]^[172]^[173]^[174]^[175]^[176]

Young and colleagues^[177] reviewed their collective experience with stromal ovarian tumors in pregnancy. One third of the patients presented with tumor rupture. Since the role of adjuvant chemotherapy for stromal tumors is complex and controversial, consultation with a gynecologic oncologist is recommended.

VULVAR AND VAGINAL CANCER

Since vulvar and vaginal cancers usually occur after age 40, the diagnosis of either disease concurrent with pregnancy

1271

is rare. Fewer than 20 cases of vulvar carcinoma diagnosed and treated during pregnancy have been reported. [\[178\]](#) [\[179\]](#) [\[180\]](#)

Vulvar carcinoma in pregnancy is usually stage I or II disease. The diagnosis is based on biopsy, and neither pregnancy nor the young age of a patient should discourage the biopsy of a vulvar mass. Since verrucous squamous carcinoma tends to be misdiagnosed as condyloma, it is important to inform the pathologist of the clinical characteristics of unusually large or aggressive condyloma-like lesions. Surgical management is similar to that used in the nonpregnant patient, with the preference being to perform surgery in the second trimester to avoid the fetal risks of anesthesia exposure in the first trimester and the maternal risks associated with operating on the hypervascular vulva in the third trimester. The surgical management of vulvar carcinoma is trending to more conservative procedures. [\[181\]](#) Vaginal delivery has been reported following surgical resection of vulvar cancers during pregnancy. [\[178\]](#) , [\[179\]](#)

Vaginal carcinoma is less common than vulvar carcinoma. The same limitations apply to vaginal cancer as apply to locally advanced cervical cancer in pregnancy. The cornerstone of treatment is irradiation therapy. Clear cell adenocarcinoma of the vagina has been reported in 16 pregnant patients, and 13 were long-term survivors. [\[182\]](#)

ENDOMETRIAL CANCER

Approximately 30 cases of endometrial cancer associated with pregnancy have been reported. While many of these cases are diagnosed in the first trimester, abnormal bleeding later in pregnancy or postpartum may be the presenting symptom of this tumor. Only about 30 percent of these cases are associated with a viable fetus.^{[183] [184] [185] [186]}

GASTROINTESTINAL CANCERS

Upper Gastrointestinal Cancers

The diagnostic delay in detecting an upper gastrointestinal cancer is often attributable to the frequency and duration of gastrointestinal symptoms in pregnancy. In the United States, stomach cancer is rarely diagnosed in women during the reproductive years. During pregnancy, persistent severe upper gastrointestinal symptoms are best evaluated by gastroduodenoscopy rather than radiologic studies. Since curative resection of localized stomach cancer is possible in only approximately 30 percent of patients, it is imperative that treatment not be delayed.

Malignant hepatic tumors are rare during the reproductive years. Hepatocellular tumors detected during pregnancy should be resected, since the maternal and fetal mortality associated with subcapsular hemorrhage and liver rupture during pregnancy is high. Elevated steroid levels may predispose the tumor to rupture during pregnancy. There is no increase in the vascularity of the liver during pregnancy. In patients with unresectable hepatomas, therapeutic abortion may be considered to decrease the risk of subsequent rupture and bleeding.

Colon and Rectal Cancer

The incidence of colon cancer during pregnancy is about 1 in 13,000 live-born deliveries.^[187] Colorectal carcinoma is usually found in women beyond childbearing age, with only 8 percent of patients diagnosed before age 40. Over 200 cases of colorectal cancer in pregnancy have been reported.^[188]

Since pregnancy is often accompanied by constipation and exacerbations of hemorrhoids and anal fissures, the symptoms of colorectal carcinoma, namely, rectal bleeding, constipation, pain, and backache, tend to be attributed to the pregnancy, and diagnostic delays occur. The majority of colorectal carcinomas during pregnancy are rectal and palpable on rectal examination, contrary to what is found in the nonpregnant patient (Table 38-7).^[189] Patients with unexplained hypochromic microcytic anemia should be evaluated with stool guaiac testing. If a colorectal lesion is suspected, endoscopic methods of evaluation are preferred to radiologic imaging studies. Unfortunately, most cases of colorectal cancer are not diagnosed until late pregnancy or at the time of delivery. Delays in diagnosis are probably responsible for a higher likelihood of advanced stage colorectal cancer in pregnancy and an associated poor prognosis. The hormonal effect of pregnancy on tumor development is unknown.^[188] A report by Woods

TABLE 38-7 -- DISTRIBUTION OF COLON AND RECTAL CARCINOMAS IN NONPREGNANT AND PREGNANT POPULATIONS

Patient Group	Total	Colon	Rectum
General population	1,704	1,244 (73%)	460 (27%)
Age under 40 years	186	127 (68%)	59 (32%)
Pregnant	244	41 (17%)	203 (83%)

From Medich DS, Fazio VW: Hemorrhoids, anal fissure, and carcinoma of the colon, rectum, and anus during pregnancy. *Surg Clin North Am* 75:77, 1995, with permission.

and colleagues^[187] suggests that colorectal carcinoma in pregnancy adversely affects the pregnancy. Only 78 percent of their cases resulted in healthy live-born infants.^[187]

Management of colon cancer is determined by gestational age at diagnosis and tumor stage. During the first half of pregnancy colon resection with anastomosis is indicated for colon cancers.^[190] Abdominoperineal resection or low anterior resection has been accomplished up to 20 weeks' gestation without disturbing the gravid uterus. In some cases, access to the rectum may be impossible without a hysterectomy or uterine evacuation.

In late pregnancy, a diverting colostomy may be necessary to relieve a colonic obstruction and allow the development of fetal maturity before instituting definitive therapy. Some patients with a diagnosis after 20 weeks may opt to continue the pregnancy to fetal viability. Vaginal delivery is planned unless the tumor is obstructing the pelvis or is located on the anterior rectum. If cesarean delivery is performed, tumor resection can be accomplished immediately. Neoadjuvant chemotherapy or radiation therapy for colorectal carcinoma in the pregnant patient has not demonstrated sufficient response to risk fetal exposure.

In the most recent report, the stage-specific survival rates for pregnant patients with rectal cancer were 83, 27, and 0 percent for stages B, C, and D, respectively.^[188] The corresponding survival rates for the same stages of colon cancer were 75, 33, and 0 percent.^[189] No Duke's A classification rectal or colon cancer was reported, consistent with the frequency of diagnostic delays.^[188]

Gabbe: Obstetrics - Normal and Problem Pregnancies, 4th ed. , Copyright © 2002 Churchill Livingstone, Inc.

URINARY TRACT CANCERS

Fewer than 50 cases of renal cell carcinoma and less than 10 cases of bladder cancer have been reported during pregnancy. Urethral carcinoma during pregnancy is also rare. The hallmark of urinary tract cancers is hematuria. The initial evaluation of hematuria in pregnancy should be urethrocytology, urinary cytology, and renal ultrasonography. The primary therapy for renal cell carcinoma is surgery, and the survival rate for localized disease may exceed 50 percent. While preoperative arterial embolization may facilitate surgery on hypervascular tumors, improved survival rates have not been conclusively demonstrated. Adjuvant radiotherapy or chemotherapy tends to have minimal impact on long-term outcomes.

Transitional carcinoma of the bladder can be managed by local fulguration or resection if it is well differentiated and superficial. Less differentiated, deeply invasive, and recurrent tumors may require a partial or complete cystectomy. Urethral carcinoma treatment varies with the size and location. Distal urethral tumors are usually treated with excision and interstitial brachytherapy implants.

Gabbe: Obstetrics - Normal and Problem Pregnancies, 4th ed. , Copyright © 2002 Churchill Livingstone, Inc.

CENTRAL NERVOUS SYSTEM TUMORS

The spectrum of central nervous system tumors found in pregnant patients is similar to that of the nonpregnant patient.^[191] In pregnancy, 32 percent of brain tumors are gliomas, 29 percent meningiomas, 15 percent acoustic neuromas, and the other 24 percent are divided among other more rare subtypes. Spinal tumors account for only about one eighth of the central nervous system tumors. Vertebral hemangiomas comprise 61 percent of the spinal tumors and meningiomas, 18 percent. Unfortunately, the presenting symptoms of headache and nausea and vomiting are often attributed to normal complaints of pregnancy, and delays in diagnosis result. Meningiomas, pituitary adenomas, acoustic neuromas, and vertebral hemangiomas may demonstrate rapid enlargement during pregnancy. This may be secondary to fluid retention, increase in blood volume, or hormonal stimulation.^[192] MRI is the most common form of imaging used to diagnose intracranial neoplasms.

Since painful contractions and pushing increase intracranial pressure, it is recommended that labor be as pain free as possible, and the second stage of labor should be assisted with forceps to reduce the risk of herniation.^[192] The anesthetic management of labor and delivery for patients with intracranial neoplasms has been reviewed by Finfer.^[193]

While high-grade glial tumors should undergo prompt diagnosis and treatment, low-grade glial tumors such as astrocytomas and oligodendrogliomas do not usually require immediate intervention. Adjuvant cranial radiotherapy with abdominal shielding should be considered for patients with high-grade tumors. Adjuvant chemotherapy is not usually effective and therefore should probably be delayed until after delivery.

Successful surgical removal of a variety of central nervous system tumors has been reported.^[192] , ^[194] ^[195] ^[196] ^[197] ^[198] Corticosteroids are recommended to reduce the surrounding edema of intracranial masses.

The use of bromocriptine in pregnancy is controversial. A report of no adverse fetal effects in over 1,400 pregnancies in which bromocriptine was taken in the first trimester supports the use of bromocriptine during pregnancy if expansion of a prolactinoma is detected.

MISCELLANEOUS TUMORS

Similar to the management for small cell neuroendocrine tumors of the cervix,^[142] neuroendocrine tumors or neuroblastomas of other primary sites tend to demonstrate excellent response to chemotherapy.^[199] Pheochromocytoma during pregnancy is rare and may mimic hypertensive disorders of pregnancy^[200] ([see Chapter 33](#)) .

FETAL-PLACENTAL METASTASIS

Metastatic spread of a maternal primary tumor to the placenta or fetus is rare. One review identified 45 cases of placental metastases and 7 cases of fetal metastases.^[201] Malignant melanoma is the most frequently reported tumor metastatic to the placenta. Hematologic malignancies are the second most common tumor to spread to the placenta. Placental and fetal dissemination of lymphomas have been reported.^[202] ^[203] ^[204] ^[205] One case of vertical transmission of a mother's leukemia cell line was demonstrated through identification of a leukemia clone.^[207] There is one case report of a central nervous system tumor metastatic to the placenta.^[208] Choriocarcinoma metastatic to a fetus usually results in death within a few months of age.^[209] , ^[210]

GESTATIONAL TROPHOBLASTIC DISEASE AND PREGNANCY-RELATED ISSUES

It is uncommon for a normal viable pregnancy to be complicated by gestational trophoblastic disease (GTD). A comprehensive summary of the evaluation and management of the complete spectrum of GTD is beyond the scope of this textbook. However, the aspects of GTD related to the general obstetric and postpartum care are reviewed.

Hydatidiform Mole (Complete Mole)

The incidence of hydatidiform mole has great geographic variability. In the United States it occurs in approximately 1 in 1,000 to 1 in 1,500 pregnancies. The two clinical risk factors that carry the highest risk of a molar pregnancy are (1) the extremes of the reproductive years (age 50 or older carries a relative risk of over 500)^[211] and (2) the history of a prior hydatidiform mole (the risk for development of a second molar pregnancy is 1 to 2 percent,^[212] ^[213] ^[214] and the risk of a third after two is approximately 25 percent).^[215] Patients with these risk factors should have an ultrasound evaluation of uterine contents in the first trimester. While historically approximately 50 percent of patients were not diagnosed with a molar pregnancy prior to vaginal expulsion of molar tissue, currently in developed countries most patients are diagnosed either by ultrasound while asymptomatic or by ultrasound for the evaluation of vaginal spotting or cramping symptoms. Approximately 95 percent of complete hydatidiform moles have a 46,XX paternal homologous chromosomal pattern.

The safest technique of evacuating a hydatidiform mole is with the suction aspiration technique. Oxytocin should not be initiated until the patient is in the operating room and evacuation is imminent in order to minimize the risk of embolization of trophoblastic tissue. The alternative management for the elderly patient who requests concurrent sterilization is hysterectomy. Following either evacuation or hysterectomy, weekly -hCG is drawn until the hCG titer is within normal limits for 3 weeks. The titers are then observed at monthly intervals for 6 to 12 months. [Figure 38-5](#) illustrates an algorithm for molar pregnancy management.^[216]

For the patient with a complete molar pregnancy, the risk of requiring chemotherapy for persistent GTD is approximately 20 percent. Clinical features that increase this risk include delayed hemorrhage, excessive uterine enlargement, theca-lutein cysts, serum hCG greater than 100,000 mIU/ml, and maternal age over 40. It is obviously particularly important not to misinterpret a rising -hCG due to a new intervening pregnancy as persistent GTD, since intervention with chemotherapy would be a significant risk to a new gestation, inducing either abortion or possible teratogenic defects.

Invasive Mole (Chorioadenoma Destruens)

Since invasion of the myometrium by molar tissue is clinically occult, it is difficult to assess the true incidence, estimated to be between 5 and 10 percent. The clinical hallmark of invasive mole is hemorrhage, often severe, either vaginal or intraperitoneal.

Partial Hydatidiform Mole

Most partial moles have a triploid karyotype, and the next most common is a trisomy 16. A minority of partial moles exhibit normal diploidy. Karyotype analysis of the accompanying fetus is important in planning therapeutic intervention. A partial mole associated with a nonviable fetal chromosomal abnormality will require

1274

Figure 38-5 Algorithm for the management of molar pregnancy. (From Copeland LJ: *Gestational trophoblastic neoplasia*. In Copeland LJ [ed]: *Textbook of Gynecology*. 2nd ed. Philadelphia, WB Saunders Company, 2000, p 1414, with permission.)

either mechanical or medically induced uterine evacuation ([Fig. 38-6](#)). In the presence of an abundance of hydropic tissue, there is always the concern that trophoblastic tissue embolization may occur during uterine contractions induced to evacuate molar tissue. The management of a patient with sonographic findings suggestive of a diagnosis of a partial mole is particularly challenging if the karyotype analysis of the fetus is diploid, especially if the diagnosis is made in the second or third trimester. When a normal karyotype exists, it is appropriate to consider diagnostic possibilities other than partial mole, such as a twin gestationone normal developing fetus and one molar pregnancy. Also, degenerative changes (hydropic villi), retroplacental hematomas, placental abnormalities (chorioangiomas), degenerative uterine myomas, and aborted tissue, sometimes referred to as a "transitional mole," may lead to imaging abnormalities that are difficult to interpret.

1275

Figure 38-6 Partial mole with dead fetus of abnormal karyotype. (From Copeland LJ: *Gestational trophoblastic neoplasia*. In Copeland LJ [ed]: *Textbook of Gynecology*. 2nd ed. Philadelphia, WB Saunders Company, 2000, p 1416, with permission.)

Approximately 2 to 6 percent of patients develop persistent GTD after a partial molar pregnancy.^[216] ^[219] Therefore, these patients require the same postevacuation surveillance and management as the patient with a complete mole.

Placental Site Trophoblastic Tumor

Less than 1 percent of all patients with GTD have placental site trophoblastic tumor. While this tumor usually presents with abnormal vaginal bleeding following a term pregnancy, it can also be a sequela to a molar pregnancy or abortion. The postpartum presentation is characterized by a slightly enlarged uterus, persistent

* Frequencies vary, depending on whether data are based on autopsy studies or are obtained from pretreatment imaging.

bleeding or, occasionally, amenorrhea, and a slightly elevated -hCG level. The hCG may not reliably reflect disease progression. The histologic diagnosis may be obtained by uterine curettage, possibly hysteroscopically directed. Since this disease tends to metastasize late and be somewhat resistant to chemotherapy, surgical excision (hysterectomy) should be considered.^[220] If the patient is desirous of future childbearing, management considerations that have been reported with some success include systemic chemotherapy, regional infusion chemotherapy, uterine curettage, and local excision of tumor by hysterotomy and uterine reconstruction.^[221]

Choriocarcinoma

Choriocarcinoma develops in approximately 1 in every 40,000 term pregnancies and this clinical presentation represents about one fourth of all cases of choriocarcinoma. The other cases follow molar disease or an abortion (spontaneous, therapeutic, or ectopic). GTD following a term pregnancy is always either choriocarcinoma or a placental site trophoblastic tumor, assuming a singleton pregnancy.

Choriocarcinoma is notorious for masquerading as other diseases. This is secondary to hemorrhagic metastases producing symptoms such as hematuria, hemoptysis, hematemesis, hematochezia, stroke, or vaginal bleeding. The common sites for metastatic disease are listed [in Table 38-8](#). The diagnosis of choriocarcinoma is based on history, imaging studies, and a serum -hCG level. Histologic confirmation is neither necessary

for the diagnosis nor a prerequisite to initiate therapy. Again, it is necessary to exclude the presence of a new gestation as the source of a rising -hCG level prior to extensive diagnostic imaging or therapeutic intervention.

The complexities of the general treatment approach or treatment for special situations is beyond the scope of this textbook. It is recommended that the reader refer to a gynecology or gynecologic oncology resource for discussions of the therapeutic subtleties and pitfalls. Choriocarcinoma should be managed by a gynecologic oncologist, preferably one with a special interest in the disease.

Key Points

Since many of the common complaints of pregnancy are also early symptoms of metastatic cancer, pregnant women with cancer are at risk for delays in diagnosis and therapeutic intervention.

The safest interval for most cancer therapies in pregnancy is the second trimester, thereby avoiding induction of teratogenic risks or miscarriage in the first trimester and avoiding neonatal morbidity associated with preterm delivery in the third trimester.

Antimetabolites and alkylating agents present the greatest hazard to the developing fetus.

Diagnostic delays of breast cancer in pregnancy are often attributed to physician reluctance to properly evaluate breast complaints or abnormal findings in pregnancy.

Treatment for Hodgkin's disease may compromise the reproductive potential, and combined treatment with irradiation and chemotherapy provides the highest risk of ovarian failure.

If a mother is exposed to cytotoxic drugs within 1 month of delivery, the newborn should be monitored closely for evidence of granulocytopenia or thrombocytopenia.

The effect of pregnancy on the clinical course of melanoma has been the subject of debate. When corrected for tumor thickness, pregnancy does not appear to be an independent prognostic variable for survival.

After stratifying for stage and age, patients with pregnancy-associated cervical carcinoma have survival rates similar to the nonpregnant patient.

Since most malignant ovarian tumors found in pregnancy are either germ cell tumors or low-grade, early-stage epithelial tumors, the therapeutic plan will usually permit continuation of the pregnancy and preservation of fertility.

While rare, most colorectal carcinomas in pregnancy are detectable on rectal examination, underscoring the need for a rectal examination at the patient's first prenatal visit.

Chapter 39 - Dermatologic Disorders

Roxanne Stambuk
Roy Colven

Most of the skin changes that occur during pregnancy are consequences of dramatic mechanical, hormonal, and blood volume changes. However, there are some specific dermatoses that only affect pregnant patients. This chapter first reviews the physiologic skin changes that occur during pregnancy and then discusses specific dermatoses associated with pregnancy. This chapter aims to enable the practitioner to distinguish between common skin changes with pregnancy and those that are more serious for the pregnant patient or her unborn child.

PHYSIOLOGIC SKIN CHANGES DURING PREGNANCY

Hypermelanosis

Hypermelanosis, or darker than constitutive skin color, occurs in 90 percent of pregnancies.^[1],^[2] Darkly complected women are more likely to manifest hypermelanosis during pregnancy. The hypermelanosis may be generalized or localized to areas of increased melanocyte density. The areolae, umbilicus, vulva, and perianal skin may darken as early as the first trimester. The linea alba often becomes the hyperpigmented linea nigra. Pigmented nevi, freckles, and recent scars may also deepen in color.

Melasma, or chloasma, is an acquired facial hypermelanosis. It manifests with symmetric, well-defined hyperpigmented patches distributed on the cheeks, chin, eyebrows, nose and upper lip. Melasma affects at least 70 percent of pregnant women, with equal racial predilection.^[3] Besides pregnancy, melasma can affect patients on oral contraceptive pills; with liver disease, hyperthyroidism, and nutritional deficiencies; and as a phototoxic reaction to certain cosmetics and medications. Melasma also uncommonly affects males, even in the absence of the above disorders or medications.

The pathogenesis of melasma is unknown. The role of hormonal factors such as melanocyte-stimulating hormone (MSH) is unclear. Levels of estrogen which, like MSH, can stimulate melanogenesis, are not consistently elevated in women with melasma.^[4]

Ultraviolet (UV) radiation exposure, including sunlight, accentuates the hyperpigmentation. Patients with melasma should protect themselves from UV exposure by avoiding the most intense hours of sunlight, seeking shade, wearing shading clothing including a hat, and applying a broad-spectrum UV sunscreen of sun protection factor (SPF) 15 or greater. Melasma normally regresses or disappears in the majority of women. However, nearly 30 percent of patients will have persistent hyperpigmentation at 10 year follow-up.^[5]

Women with persistent melasma may be treated with 2 to 4 percent hydroquinone cream combined with sunscreen applied in the morning. Hydroquinone cream combined with retinoic acid 0.05 to 0.1 percent cream,^[6] and hydrocortisone 1 percent cream also appear to improve the condition, perhaps more rapidly.^[6] Other options include chemical peels with trichloroacetic acid or glycolic acid performed postpartum by an experienced dermatologist.^[7] Consistent sunscreen use must continue to avoid recurrence of melasma.

Melanocytic Nevi and Pregnancy

During pregnancy, some melanocytic nevi ("moles") may increase in size, and new nevi may develop.^[8],^[9] If atypical clinical features are present, one may need to biopsy a suspicious pigmented lesion to rule out dysplasia or melanoma. A recent study of pregnant women without multiple nevi or a family history of melanoma

showed no significant change in the sizes of their pigmented nevi.^[10] However, a special subgroup of women with the "atypical mole syndrome" appear to be at increased risk for dysplastic changes during pregnancy.^[11] These women have a family history of melanoma and multiple clinically atypical nevi.^[11] The atypical mole syndrome itself in these pregnant women who were objectively studied more likely accounted for the dysplastic changes noted in the moles rather than the pregnancy.

Studies to date have not provided evidence that hormonal changes during pregnancy put the pregnant patient at increased risk of melanoma.^[12]^[13]^[14]^[15] Although there are detectable estrogen-binding proteins on melanoma cells, there are no estrogen or progesterone receptors.^[16]

When a pregnant woman is diagnosed with melanoma, the pregnancy does not adversely affect her prognosis.^[17],^[17]^[18]^[19]^[20] Because melanoma incidence overall is increasing, all pregnant women with mole changes including asymmetry, increase in size or elevation, irregular border configuration, or variegation in color should be examined with the same care and scrutiny as all individuals with mole changes.

Hair Changes

Hirsutism

Hirsutism is excessive coarse, or terminal, body hair growth. Mild hirsutism commonly affects pregnant women. The face is frequently affected, though terminal hair growth may be pronounced on the extremities as well. Terminal hairs grow less commonly on the abdomen during pregnancy. Hirsutism is believed to be primarily an endocrinologic phenomenon. During normal pregnancy, the proportion of hair in the anagen (growing) phase is higher than that in the telogen (resting) phase. Hirsutism may result from placental androgen production during normal pregnancy. Mild hirsutism rarely requires therapy. It normally regresses following delivery, but does recur with subsequent pregnancies. Severe hirsutism with virilization should warrant investigation for an androgen-secreting tumor.

Telogen Effluvium

The normal hair cycle consists of three phases: anagen, the growing phase; telogen, or resting phase; and catagen, or the transitional phase in between anagen and telogen. Telogen hair normally sheds due to reactivation of the hair follicle with the beginning of anagen hair growth.^[21] Eighty to ninety percent of hairs are in anagen, compared to 13 percent, on average, in telogen. *Telogen effluvium*, or hair loss after a proportional increase of anagen hairs becoming telogen, is often seen 4 to 6 months into the postpartum period, with average hair loss at two to three times the normal rate of 100 scalp hairs per day. The postpartum drop in estrogen levels precipitates telogen effluvium. Patients should be reassured that normal hair growth will occur 6 to 15 months postpartum, with reestablishment of normal hair cycle proportions. However, in rare circumstances, the hair may not return to its prepregnancy thickness. Persistent alopecia may indicate thyroid dysfunction or low iron stores.

Striae Distensae

Striae distensae, thin atrophic pink or purple linear bands that appear on the abdomen, breasts, and thighs, begin in the late second trimester in up to 90 percent of pregnant women.^[4] Striae likely result from a combination of two factors. Stretching produces striae. Also, adrenocorticosteroids and estrogen promote tearing of the collagen matrix of the dermis and weakening of elastic fibers.^[4] Electron microscopy demonstrates rearrangement and reduction of fibrillin fibers in biopsies of

striae.^[22] Most striae fade postpartum to thin flesh-colored atrophic bands.

Although treatment of early striae with topical retinoic acid improves stretch marks,^[23] retinoids, even used topically, are contraindicated during pregnancy due to the potential risk of absorption and teratogenicity. Treatment of striae with a 585-nm pulsed dye laser increases dermal elastin and results in clinical improvement.^[24] A trial of topical treatment of striae using glycolic acid and tretinoin versus glycolic acid and topical ascorbic acid demonstrated equal improvement and increased elastin after 12 weeks of daily application.^[25] Despite these therapeutic advances, no evidence demonstrates complete resolution of striae with treatment.

Vascular Changes

Most pregnant women exhibit vascular changes within the skin. High levels of estrogen cause proliferation of cutaneous blood vessels. Vasomotor instability may also produce pallor, flushing, and mottling of the skin in response to temperature changes. Scattered petechiae may manifest on the lower extremities due to increased cutaneous capillary hydrostatic pressure and fragility common in late pregnancy. Mucous membranes may also manifest vascular changes; gingival swelling during gestation gives rise to pregnancy gingivitis.^[26]

Spider angiomata occur in up to 70 percent of white women during pregnancy.^[1] Blood quickly refills a compressed spider angioma from a central arteriole outward to tortuous radiating capillaries; the shape resembles a spider. One sees spider angiomata distributed sparsely on the face, trunk, and upper extremities, areas drained by the superior vena cava. Most lesions fade within 3 months during the postpartum period. Hepatic

1285

Figure 39-1 Pyogenic granuloma. This bright red papule appeared and grew to this size during 1 week. Due to its rapid appearance and friability, this pregnant patient in her second trimester sought medical attention promptly.

cirrhosis also causes spider angiomata, likely due to higher circulating estrogen levels.

Similar to spider angiomata, *palmar erythema* affects two thirds of pregnant women. Erythema of the thenar and hypothenar eminences may occur as early as the first trimester as a result of a sixfold increase in blood flow to the hands.^[27] Hepatic cirrhosis, systemic lupus erythematosus, and hyperthyroidism also cause palmar erythema. When a manifestation of pregnancy, palmar erythema typically resolves following delivery.

Small *capillary hemangiomas* may occur during the second and third trimesters in up to 5 percent of pregnant women.^[1] Unlike spider angiomata, these lesions do not completely compress. Most small hemangiomas will involute after delivery. Large hemangiomas may persist and rarely are associated with arteriovenous shunting and high-output cardiac failure.

Pyogenic granuloma (Fig. 39-1), also called granuloma gravidarum, occurs in 2 percent of pregnant women.^[4] Usually solitary, a pyogenic granuloma develops rapidly as a brightly erythematous sessile or pedunculated friable papule with a collar of thickened epidermis at its base. They can be distributed anywhere on the skin or mucous membranes. Most women seek attention because of the granuloma's rapid growth and recurrent bleeding. This lesion consists of capillary proliferation and mixed inflammatory infiltrate, similar to granulation tissue. Pyogenic granuloma is thought to be an abnormal tissue response to trauma. However, most patients report no trauma history. Although these masses usually remit during the postpartum period, surgical excision may be required if the lesion fails to resolve.

SPECIFIC DERMATOLOGIC CONDITIONS ASSOCIATED WITH PREGNANCY

Dermatologic disorders specific to pregnancy that present with pruritus as a common symptom include pemphigoid gestationis, polymorphic eruption of pregnancy, prurigo gestationis, and pruritic folliculitis of pregnancy (Table 39-1).^[28]^[29]^[30] The difficulty in classifying and diagnosing these disorders stems from confusing nomenclature and lack of specific diagnostic criteria,

TABLE 39-1 -- SPECIFIC INFLAMMATORY DERMATOSES OF PREGNANCY

Disease	Onset	Degree of Pruritus	Types of Lesions	Distribution	Increased Incidence of Fetal Morbidity or Mortality
Pemphigoid gestationis	First month to postpartum	Moderate to severe	Erythematous papules, vesicles, bullae	Abdomen, extremities, generalized	Unresolved
Prurigo gestationis	Fourth to ninth month	Moderate	Excoriated papules	Extensor surfaces of extremities	No
Impetigo herpetiformis	First to ninth month	Minimal	Pustules	Genitalia, medial thighs umbilicus, breasts, axillas	Yes
Polymorphic eruption of pregnancy	Third trimester	Severe	Erythematous urticarial papules and plaques	Abdomen, thighs, buttocks, occasionally arms and legs	No
Pruritic folliculitis of pregnancy	Third trimester	Moderate	Erythematous papules or pustules	Shoulder, back, arms, chest, abdomen	No
Cholestasis of pregnancy	Third trimester	Moderate to severe	None or excoriations	Generalized	Unresolved

with the exception of pemphigoid gestationis. Newer classification schemes help to differentiate between these entities.^[31]^[32]^[33] In general, it is most important to distinguish between pruritus without rash or with secondary excoriations versus pruritus with primary skin lesions.

Pruritus

Pruritus is a common symptom in pregnancy, occurring in 3 to 14 percent of all women.^[34] In a prospective study of 3,192 pregnant women, 1.6 percent suffered from persistent pruritus severe enough to warrant treatment.^[31] Pruritus is a common symptom in most pregnancy-specific inflammatory skin diseases. Atopic dermatitis, which may lead to considerable pruritus, is more prevalent than previously recognized in pregnant women.^[35] Pruritus can also be caused by systemic entities such as liver disease, thyroid dysfunction, diabetes mellitus, drug eruptions, parasites, and malignancy.

Intrahepatic cholestasis, which occurs in 0.5 percent of pregnancies, is one of the most common causes of pregnancy-related pruritus. Intrahepatic cholestasis leads to increased levels of serum bile salts, and increased deposition of bile salts in the skin leads to itching.^[32]^[34] Cholestatic pruritus occurs in the second or third trimester of pregnancy.^[36] The pregnant patient experiences itch mainly on the palms and soles, although the itch can become generalized. There are no primary skin lesions. Changes on the skin are secondary from excoriations.^[31] Liver function tests demonstrating increased serum levels of hepatic transaminases and bilirubin confirm the diagnosis of cholestasis.^[37] Although the maternal prognosis is good, cholestasis has been associated with increased risks for the fetus, with risks of fetal prematurity and fetal death. Both estrogen and progesterone propagate cholestasis.^[38]

Pemphigoid Gestationis

Pemphigoid gestationis is a rare, pruritic, autoimmune, bullous skin disease that occurs during the second and third trimesters of pregnancy and the puerperium.^[39] The term *pemphigoid gestationis* supercedes the older term, *herpes gestationis*, because it does not involve the herpes viruses and because of its antigenic and clinical similarity to bullous pemphigoid. It affects only female patients and occurs only in the presence of placental tissue. Outside of pregnancy, choriocarcinoma and hydatidiform disease have also incited pemphigoid gestationis. The disease occurs in 1 per 1,700 to 50,000 pregnancies.^[32]^[39]^[40] In a prospective study in which all pregnant women with pruritic skin lesions had skin biopsies, the incidence of pemphigoid gestationis was found to be 1 per 7,000.^[40] The occurrence during the third trimester of pregnancy and the recurrence of pemphigoid gestationis with menstruation and with oral contraceptive use strongly implicates a hormonal influence. The increased frequency of certain histocompatibility locus antigens (HLA) in women with pemphigoid gestationis suggests a genetic predisposition. Up to 85 percent of women with pemphigoid gestationis have HLA-DR3, and 45 percent have the combination of HLA-DR3 and HLA-DR4.^[39]^[41]^[42] An increased frequency of these HLA antigens also has been found with other autoimmune disorders. Graves' disease occurs in patients with pemphigoid gestationis with a higher than expected incidence.^[43]

Clinically, pemphigoid gestationis typically presents with severely pruritic erythematous, urticarial, or hivelike, papules and plaques around the umbilicus (Fig. 39-2). Within days to weeks, the eruption spreads to involve the trunk, back, buttocks, forearms, palms, and soles, usually sparing the face, scalp, and mucosa. Within 2 to 4 weeks of the onset of the disease, vesicles and tense serum-filled bullae develop either at the margins of the edematous, erythematous plaques or de novo in clinically uninfamed skin. Sometimes vesicles and bullae do not develop, adding confusion to the diagnosis.^[38] The lesions tend to heal without scarring if secondary infection does not ensue.

Pemphigoid gestationis usually presents during the second or third trimester, with a mean of 21 weeks' gestation, although patients may present with recurring crops of blisters at any time during pregnancy. It occurs for the first time during the early postpartum period in 20 percent of patients.^[39] Many patients with pemphigoid gestationis transiently improve during the last 6 to 8 weeks of pregnancy only to experience an uncomfortable flare of their disease within 24 to 48 hours of delivery. The postpartum duration varies; the bullous lesions persist 5 to 24 weeks and urticarial lesions

Figure 39-2 Pemphigoid gestationis during the third trimester. This patient developed erythematous urticarial superficial plaques on the thighs and abdomen that progressed to bullae formation. Biopsy revealed a heavy linear complement deposition at the basement membrane zone, consistent with pemphigoid gestationis.

1287

longer.^[38] Pemphigoid gestationis usually recurs and may be more severe with an earlier onset in subsequent pregnancies. A small proportion of women (8 percent) do not develop pemphigoid gestationis in subsequent pregnancies.^[43]

One can easily make a presumptive diagnosis of pemphigoid gestationis in a pregnant woman with a typical distribution of vesicles and bullae. Skin biopsy, including a sample processed for direct immunofluorescence (DIF), confirms the diagnosis. This confirmation distinguishes pemphigoid gestationis from polymorphic eruption of pregnancy, which does not recur with subsequent pregnancies. Distinguishing these two diseases enables counseling of the patient about the recurrence risk in future pregnancies.

Skin sampling technique involves taking two 3-mm punch biopsies. One biopsy is taken from a new skin lesion and is placed in formalin for histologic evaluation. The second is taken from perilesional normal skin (within 1 to 2 cm of a lesion) and placed in transfer media for direct immunofluorescence studies. If the tissue sample for direct immunofluorescence is placed in formalin, the appropriate reactive antigens may be masked or destroyed.

Histology reveals intercellular epidermal edema, with basal keratinocyte necrosis, and occasionally eosinophils and lymphocytes along the dermal-epidermal junction. Subepidermal bullae containing eosinophils with edema of the papillary dermis are also seen. An inflammatory infiltrate of eosinophils and lymphocytes invades the dermis in a perivascular distribution. Immunopathology of these specimens demonstrates the third component of complement in a linear band of fluorescence along the basement membrane zone between the epidermis and dermis.^[44] Immunoglobulin G (IgG) deposits in the basement membrane in a minority of cases.

A circulating IgG1 autoantibody with complement-fixing capability, previously referred to as the *herpes gestationis factor* (HG factor), incites the pathology of pemphigoid gestationis.^[44] Like bullous pemphigoid, the autoantigen involved in pemphigoid gestationis is a 180-kDa transmembrane collagenous protein found in basal keratinocytes in the anchoring complex of the hemidesmosome.^[49] This protein, called bullous pemphigoid antigen 180 (BP180), mediates the attachment of these keratinocytes to the underlying basement membrane.^[45] Sera from patients with pemphigoid gestationis recognize a major epitope on the C-terminal domain of BP180.^[47] Antibodies generated to this domain produce subepidermal blistering when injected into neonatal mice, implicating the importance of this domain in pathogenesis.^[48] Circulating IgG1 autoantibodies have not been isolated from the sera of all affected women and, when found, rarely exceed a titer of 1:16.^[35] Antibodies to BP180 are detectable with indirect immunofluorescence on epithelial substrates for up to 5 months after the skin lesions have resolved.^[45]

Investigators hypothesize that the expression of major histocompatibility complex (MHC) proteins in the placenta triggers an allogenic reaction between maternal lymphocytes and the paternal-derived MHC molecules. This results in the formation of an IgG1 autoantibody against a placental antigen that cross-reacts with maternal cutaneous basement membrane and causes the skin lesions.^[50]

Pemphigoid gestationis does not increase the risk of maternal mortality. Therefore, treatment is aimed at controlling pruritus, suppressing formation of new vesicles and bullae, and preventing secondary infection of skin lesions. Topical steroids and antihistamines may be used initially if the symptoms are mild. Most patients, however, will require systemic corticosteroid therapy. Prednisone dosages start at 40 to 60 mg/day. With improvement of clinical symptoms and no new bullae formation, the dose can then be tapered to 10 to 20 mg/day if clinical improvement is noted. Azathioprine, dapsone and, rarely, plasmapheresis have been employed in cases that fail to respond to corticosteroids.^[38] For postpartum patients who experience a flare of pemphigoid gestationis requiring continued steroids, prednisone doses of 20 mg/day still allow safe breast-feeding. McKenzie et al. suggest taking the steroid 4 hours prior to breast-feeding to minimize levels in breast milk.^[51]

Prior to the development of immunologic techniques that permitted an accurate diagnosis, pemphigoid gestationis was believed to have minimal adverse effects on the fetus.^[52] In 1969, Kolodny reported no increase in preterm births, stillbirths, or abortions.^[39] However, Lawley et al. subsequently reviewed 40 immunologically proven cases of pemphigoid gestationis and documented serious fetal morbidity and mortality: preterm births occurred at a rate of 22 percent and three women suffered stillbirths.^[53] These authors suggested that high levels of circulating antibasement membrane antibody and peripheral eosinophilia caused the increased fetal risk. Shornick and Black described 74 patients with pemphigoid gestationis confirmed by immunofluorescence studies.^[54] They found an increased frequency of fetal growth restriction and prematurity, but not stillbirth or miscarriage.^[54] The recent most comprehensive study of pemphigoid gestationis in 87 patients with a total of 278 pregnancies concludes that the rate of spontaneous abortion and ectopic pregnancy in women with pemphigoid gestationis is similar to the normal population.^[43] Although there is evidence in the literature for prematurity with pemphigoid gestationis, all current studies indicate no increased risk of miscarriage or stillbirth. Not enough evidence currently exists to determine whether systemic therapy for pemphigoid gestationis reduces the risk of fetal prematurity.

The HG factor, which is now known to be IgG1

1288

autoantibody, crosses the placenta, binds with the basement membrane of the amnion,^[55] and deposits in fetal skin.^[38] Transient newborn pemphigoid gestationis has been reported in up to 5 percent of newborns.^[43] Neonatal pemphigoid gestationis is usually mild and presents with erythematous papules or frank bullae.^[56] Passive transfer of antibody probably incites this process, which generally resolves within a short period of time.^[56]

Polymorphic Eruption of Pregnancy

In 1979, Lawley et al. described seven patients with a severe pruritic eruption that first occurred during the third trimester of pregnancy.^[58] The authors felt this eruption, termed *pruritic urticarial papules and plaques of pregnancy* (PUPPP), could be differentiated by clinical and histologic findings from any other previously described pregnancy-associated skin condition. In the United Kingdom, the term *polymorphic eruption of pregnancy* (PEP) was coined by Holmes and Black^[29] to better describe the variable skin features of this disease. The incidence of PEP ranges from 1 in 240 to 1 in 200 pregnancies.^[31]

The etiology and pathogenesis are unknown.^[59] No hormonal or autoimmune abnormalities had been found previously in women with PEP.^[60] A more recent study shows decreased cortisol levels in women with PEP.^[35] Increased skin tension resulting in skin damage may play a role in the etiology of PEP. The majority of women affected by PEP are primigravidae with prominent striae or have uterine distention with twins or hydramnios.^[32] Skin biopsies of lesions from affected women giving birth to male neonates demonstrate detectable fetal male DNA.^[62] Seventy percent of pregnant women with PEP give birth to male fetuses.^[35] A provocative new hypothesis proposes that fetal male DNA acting as a skin antigen precipitates PEP.^[62]

The lesions of PEP typically begin in the abdominal striae distensae of primigravidas during the third trimester (Fig. 39-3). Lesions initially present as 1- to 2-mm erythematous papules, surrounded by a narrow pale halo of vasoconstriction, that coalesce into urticarial plaques.^[63] Small vesicles also can develop on the plaques. Lesions usually spread to the thighs and may involve the buttocks and arms. In contrast to pemphigoid gestationis, the periumbilical area is often spared in PEP. The face is also spared. Most patients experience intense pruritus that improves rapidly following delivery and resolves 1 to 2 weeks postpartum. The mean onset of skin lesions is 36 weeks' gestation; PEP rarely commences postpartum.^[63] In general, PEP does not recur with subsequent pregnancies.

Histologic findings in this disorder most often demonstrate a superficial perivascular dermal infiltrate of lymphocytes and histiocytes and edema of the papillary

Figure 39-3 Polymorphic eruption of pregnancy (pruritic urticarial papules and plaques of pregnancy [PUPPP] syndrome). Erythematous urticarial plaques and small papules

erupted on the abdomen of this patient pregnant with conjoined female twins during the third trimester.

dermis; the epidermis is normal.^[58] Another histologic pattern shows spongiosis of the epidermis and marked dermal edema, with a dermal perivascular and interstitial infiltrate of lymphocytes and eosinophils.

In contrast to pemphigoid gestationis, PEP shows no specific immunofluorescence pattern from skin biopsies. Many patients' direct immunofluorescence demonstrate nonspecific immunoreactants and a small subset reveals granular deposits at the dermal-epidermal junction.^[64], ^[65] These histologic and immunofluorescence findings may be associated with many urticarial allergic responses and several viral exanthems.

As with pemphigoid gestationis, the main goal of therapy is symptomatic relief of the intense pruritus.^[63] High-potency topical steroids generally effect a response in the vast majority of women, though some will require systemic steroids.^[63] Antipruritic drugs such as hydroxyzine or diphenhydramine also may help. Fortunately, for these patients, delivery brings relief of both symptoms and lesions.^[66] In some women, the severe pruritus will warrant induction of labor once fetal lung maturity is ensured.^[66]

Prurigo Gestationis and Papular Dermatitis

Prurigo gestationis consists of pruritic excoriated papules usually limited to the extensor surfaces of the extremities. The disease occurs in 1 per 50 to 200 pregnancies.^[67], ^[68] Lesions generally appear during the second half of gestation as small, symmetrically distributed, 1- to 2-mm papules. Vesicle or bullae formation does not occur. The condition usually resolves following delivery. Maternal and fetal health is not impacted, and recurrence during subsequent gestations is uncommon.

1289

Papular dermatitis likely represents a more severe and widespread form of prurigo gestationis. In the past, papular dermatitis was considered a separate skin disorder. Spangler et al. originally reported this disorder in association with increased urinary chorionic gonadotropin, decreased plasma hydrocortisone levels, and increased fetal risk.^[69] However, because of inadequate assessment of fetal risk, absence of adequate controls of the biochemical findings, and lack of further reports substantiating this specific skin rash, most current authors do not recognize this as a separate entity with an impact on fetal health.^[30] ^[31] ^[32] ^[33]

The diagnosis of prurigo gestationis is made by the clinical appearance of a primary papular eruption in a woman without laboratory evidence of cholestasis of pregnancy. The histologic findings show a nonspecific dermal perivascular lymphohistiocytic infiltrate. The pruritus responds to mid- to high-strength topical steroids and oral antipruritics. Systemic corticosteroid therapy is rarely necessary for the treatment of prurigo gestationis.

Pruritic Folliculitis of Pregnancy

In 1981, Zoberman and Farmer first described *pruritic folliculitis of pregnancy* in six women who presented with a generalized erythematous, hair follicle-centered rash.^[70] Roger et al. found the incidence of this skin disorder to be 1 per 3,000 pregnancies.^[31] The eruption consists of numerous 2- to 4-mm follicular papules or pustules distributed on the shoulders, upper back, arms, chest, and abdomen, and clinically resembles acne. Most women present in the third trimester. Histopathologic findings show acute folliculitis with a neutrophilic infiltrate of the follicle and the surrounding dermis.^[70] Cultures are usually sterile.

The exact etiology is unknown, but could be hormonally induced, since the lesions disappear within 2 to 3 weeks following delivery and look similar to corticosteroid-, androgen-, and progesterone-related acneiform eruptions.^[32] A recent study of pregnant patients with pruritic neutrophilic folliculitis did not show any changes in androgen levels compared to controls.^[71] No microorganism appears to cause the eruption.

The disorder does not cause significant maternal morbidity. In one study, however, fetal birth weight was significantly reduced compared to controls.^[71] Treatment is similar to that of mild acne, using 10 percent benzoyl peroxide and oral antihistamines if severe pruritus exists.

Impetigo Herpetiformis

Though clinically similar to pustular psoriasis, *impetigo herpetiformis* typically occurs in women without a previous personal or family history of psoriasis. The condition is rare, with less than 100 pregnancies reported.^[72] Authors disagree whether impetigo herpetiformis stands as a distinct entity caused by pregnancy or is a form of pustular psoriasis triggered by pregnancy.^[73] A reported patient who developed impetigo herpetiformis 1 day postpartum^[74] and a pregnant patient with both psoriatic pustules and typical psoriatic plaques^[75] emphasize the relationship of this disorder to pustular psoriasis. Also, both pustular psoriasis and impetigo herpetiformis share the common feature of decreased levels of skin-derived antileukoprotease.^[77]

Impetigo herpetiformis begins in the second half of gestation, with groups of painful sterile pustules on an erythematous base distributed on the inner thighs and groin. The pustules coalesce and spread to the trunk and extremities. Lesions may become secondarily infected. Unlike many of the dermatoses of pregnancy, lesions do not itch. Mucous membranes are frequently affected. Histologically, impetigo herpetiformis demonstrates spongiform intraepidermal and subcorneal pustules. A dense lymphocytic infiltrate surrounds dermal blood vessels. The histopathologic features cannot be differentiated from pustular psoriasis.^[73] Histologically, impetigo herpetiformis is distinguishable from impetigo, herpes, and pemphigoid gestationis.

Impetigo herpetiformis may incite systemic symptoms, including fever, chills, arthralgias, vomiting, diarrhea, and lymphadenopathy.^[73] Prostration with septicemia, and cardiac and renal failure have rarely occurred in severe cases. Hypocalcemia and hyperphosphatemia are not uncommon in this setting and have led investigators to postulate that hypoparathyroidism is associated with this disorder.

Systemic corticosteroids are the first-line treatment for impetigo herpetiformis. Prednisone, or an equivalent steroid, in doses up to 60 mg/day, may be required. Once the disease responds, a slow taper is recommended, as too rapid a taper can cause disease rebound. Antibiotics are used for secondary infection when indicated. Some authors report only a moderate response to corticosteroid treatment.^[73] However, other medications used for pustular psoriasis, including methotrexate, retinoids, and hydroxyurea, are contraindicated in pregnancy. Cyclosporin A has been used successfully and safely in one pregnant patient with psoriasis.^[77]

The disease resolves following delivery, though it can recur in subsequent pregnancies. One reported patient had subsequent recurrences during each of eight pregnancies.^[78] Increased fetal morbidity has been observed in a few cases. Authors have recommended close fetal surveillance and consideration of elective delivery after fetal lung maturity has been ensured.^[79]

Key Points

Pregnancy is associated with several physiologic changes of the skin that may concern the pregnant woman. These include hyperpigmentation, mild hirsutism, hair loss, striae distensae, and vascular changes.

During pregnancy, some nevi may increase in size, and new nevi may develop. This may necessitate the need to perform a biopsy if one suspects melanoma.

Pruritus is a common symptom in pregnancy and usually resolves postpartum; infrequently, it is due to a serious dermatologic disease. In addition to evaluating the pregnant woman for dermatologic diseases that occur unassociated with pregnancy, the health care provider must evaluate for pregnancy-specific dermatologic diseases.

The most common pregnancy-specific causes of pruritic rashes are polymorphic eruption of pregnancy, prurigo gestationis, and cholestasis of pregnancy.

Rare dermatologic conditions associated with pregnancy are pemphigoid gestationis, pruritic folliculitis of pregnancy, and impetigo herpetiformis.

The only dermatologic diseases of pregnancy that have been shown to cause fetal morbidity are pemphigoid gestationis and impetigo herpetiformis. Antepartum testing for fetal well-being should be utilized in these women. Transient newborn pemphigoid gestationis has also been reported.

Pemphigoid gestationis can be difficult to clinically distinguish from polymorphic eruption of pregnancy. Skin biopsies with immunofluorescence studies differentiates the two disorders.

The treatment for pemphigoid gestationis is aimed at controlling symptoms. Most patients will require systemic corticosteroid therapy.

Topical steroid therapy generally induces a response in the vast majority of women with polymorphic eruption of pregnancy, but some will require systemic steroids. The main goal of therapy is symptomatic relief of the intense pruritus. In some women, the pruritus will be significant enough to warrant induction of labor once fetal lung maturity is ensured.

Chapter 40 - Maternal and Perinatal Infection

Patrick Duff

Infection is the single most common complication encountered by the obstetrician. Some infections such as puerperal endometritis, candidiasis, trichomoniasis, and lower urinary tract infection are of principal concern to the mother and pose little or no risk to the fetus or neonate. Others, such as rubella, cytomegalovirus infection, and parvovirus infection cause minimal maternal morbidity but devastating fetal injury. Still others, for example, chorioamnionitis, gonorrhea, syphilis, toxoplasmosis, pyelonephritis, group B streptococcal infection, rubeola, and human immunodeficiency virus (HIV) infection, may cause serious morbidity, and even mortality, for both the mother, fetus, and/or neonate.

The purpose of this chapter is to review in detail the major maternal and perinatal infections that the obstetrician confronts in clinical practice. The first portion of the chapter focuses primarily on bacterial infections of the lower and upper genital tract. The second portion considers the infections that pose special risks to the fetus. The principal features of these infections are summarized [in Table 40-1](#) and [Table 40-2](#) .

VAGINAL INFECTIONS

Bacterial Vaginosis

Epidemiology

Bacterial vaginosis (BV) is responsible for approximately 45 percent of cases of vaginitis. It is a polymicrobial infection, and the predominant pathogens are anaerobes, *Gardnerella vaginalis*, *Mobiluncus* species, and genital mycoplasmas.^[1] BV usually results from disturbances in the normal vaginal ecosystem caused by hormonal changes, pregnancy, or antibiotic administration. The principal feature of this alteration in vaginal flora is a marked decrease in the lactobacilli species that produce lactic acid and a corresponding increase in anaerobic organisms. In some instances, BV can result from sexual contact with an infected partner. In contrast to trichomoniasis and candidiasis, symptomatic BV in pregnancy has been associated with several serious maternal complications, including preterm labor, preterm premature rupture of membranes, chorioamnionitis, and puerperal endometritis.^{[2] [3] [4]}

Diagnosis

The most prominent clinical manifestation of BV is a thin, gray, homogeneous, malodorous vaginal discharge. The odor is often accentuated after intercourse. Vulvar or vaginal pruritus is uncommon, and the vaginal pH is characteristically greater than 4.5. When vaginal secretions are mixed with several drops of a 10 percent potassium hydroxide (KOH) solution, a pungent fishy odor is produced ("whiff test" or amine test). On microscopic examination of a saline preparation, the normal lactobacilli flora is largely replaced by multiple small bacilli and cocci. Motile, comma-shaped *Mobiluncus* species, and clue cells are present (Fig. 40-1). Culture of vaginal secretions is not indicated in routine clinical practice.^[5]

Treatment

Symptomatic patients with BV should be treated.^{[5] [6] [7]} In addition, asymptomatic patients who are at increased risk of preterm delivery (e.g., history of prior preterm birth) also should be screened for BV and treated if positive. Several investigations have demonstrated a decreased rate of preterm delivery and decreased frequency of maternal and neonatal infection when such

TABLE 40-1 -- ETIOLOGY, DIAGNOSIS, AND MANAGEMENT OF MAJOR OBSTETRIC INFECTIONS

Condition	Microbiology	Confirmatory Diagnostic Test	Treatment*
Vaginal infection			
Bacterial vaginosis	<i>Gardnerella vaginalis</i> , <i>Mobiluncus</i> species, anaerobes, mycoplasmas	Saline preparation	Topical or oral clindamycin or metronidazole
		Vaginal pH	
		Amine test	
Candidiasis	<i>Candida albicans</i> , <i>C. tropicalis</i> , <i>C. glabrata</i>	KOH preparation	Topical antifungal cream
Trichomoniasis	<i>Trichomonas vaginalis</i>	Saline preparation	Oral metronidazole
Endocervical infection			
Gonorrhea	<i>Neisseria gonorrhoeae</i>	Endocervical culture	Oral cefixime or intramuscular ceftriaxone
Chlamydia	<i>Chlamydia trachomatis</i>	Endocervical culture	Oral erythromycin, azithromycin, or amoxicillin
		Antigen detection	
Urinary tract infection			
Urethritis	<i>N. gonorrhoeae</i>	Culture of urethral discharge	Oral cefixime or intramuscular ceftriaxone
	<i>C. trachomatis</i>	Culture of urethral discharge or antigen detection	Oral erythromycin, azithromycin, or amoxicillin
Asymptomatic bacteriuria or cystitis	<i>E. coli</i> , <i>Klebsiella pneumoniae</i> , <i>Proteus</i> species	Urinalysis	Sulfisoxazole, nitrofurantoin monohydrate macrocrystals, trimethoprim-sulfamethoxazole DS
		Culture	
Pyelonephritis	As above	As above	Intravenous cefazolin and/or gentamicin or aztreonam
Chorioamnionitis	Group B streptococci, coliforms, anaerobes	Clinical examination	Intravenous penicillin or ampicillin plus gentamicin; add clindamycin or metronidazole if cesarean delivery is required
		Amniotic fluid leukocyte esterase, glucose, Gram's stain, and culture	
Puerperal endometritis	Group B streptococci, coliforms, anaerobes	Clinical examination	Intravenous clindamycin plus gentamicin or extended spectrum cephalosporin or penicillin or carbapenem

* See text for detailed prescribing information.

patients received therapy.⁶³ However, the value of *routine* screening of asymptomatic, low-risk patients has *not* been confirmed.

The drug of choice for treating BV in pregnancy is oral metronidazole (250 mg three times daily for 7 days). For patients who are unable to tolerate metronidazole, clindamycin (300 mg orally [PO] twice daily for 7 days) can be used. Although the topical preparations of metronidazole and clindamycin are effective in eradicating BV from the vagina, they are not of proven value in preventing adverse pregnancy complications such as preterm delivery.^{65 66 67 68}

Candidiasis

Epidemiology

Candidiasis is responsible for approximately 25 to 30 percent of all cases of vaginitis. The three principal candida species that cause symptomatic infection are, in descending order of frequency, *C. albicans*, *C. tropicalis*, and *C. glabrata*.⁶⁹ Candidiasis is not usually a sexually transmitted disease. Yeast are part of the normal vaginal flora in many women, and symptoms develop only when overgrowth of these organisms occurs. Several conditions predispose to symptomatic moniliasis, including recent antibiotic or corticosteroid therapy, diabetes, use of oral contraceptives, pregnancy, and immunodeficiency states. Although isolated cases of chorioamnionitis due to candida species have been reported, serious systemic infections are uncommon unless the patient is receiving hyperalimentation or is immunocompromised.

Diagnosis

Infected patients usually report vaginal and vulvar pruritus and a white, curd-like vaginal discharge. The vaginal pH is typically less than 4.5. The vaginal mucosa and vulva may be erythematous and edematous, and punctate, erythematous satellite lesions may be present on the lateral aspect of the vulva and medial aspect of the thighs.⁶⁹

The simplest test for confirmation of this diagnosis is microscopic examination of a KOH preparation for hyphae, pseudohyphae, and budding yeast. Cultures are

TABLE 40-2 -- SUMMARY OF ETIOLOGY, DIAGNOSIS, AND MANAGEMENT OF MAJOR PERINATAL INFECTIONS

Condition	Complications		Diagnosis		Management*	
	Maternal	Fetal/Neonatal	Maternal	Fetal/Neonatal	Maternal	Fetal/Neonatal
CMV	Chorioretinitis, pneumonia in immunocompromised patient	Congenital infection	Detection of antibody	Amniocentesis/culture amniotic fluid	Ganciclovir for severe infection	Consider pregnancy termination when mother has primary infection
				Ultrasound		
Group B streptococci	UTI	Sepsis	Culture	Culture	Intrapartum antibiotic prophylaxis	Treatment with ampicillin or penicillin
	Chorioamnionitis	Pneumonia				
	Endometritis	Meningitis				
	Wound infection					
	Preterm labor					
	PROM					
Hepatitis						
A	Rare	None	Detection of antibody	N/A	Prevention hepatitis A vaccine	Administer immune globulin to neonate if mother acutely infected at delivery
					Supportive care	
B	Chronic liver disease	Neonatal infection	Detection of surface antigen	N/A	Prevention HBIG + HBV for susceptible household contacts	HBIG + HBV immediately after delivery
C	Chronic liver disease	Neonatal infection	Detection of antibody	N/A	Supportive care	Nonimmunoprophylaxis available
					Interferon	
D	Chronic liver disease	Neonatal infection	Detection of antigen and antibody	N/A	Supportive care	HBIG + HBV immediately after delivery
E	Increased mortality	None	Detection of antibody	N/A	Supportive care	None
Herpes simplex	Disseminated infection in immunocompromised patient	Neonatal infection	Clinical examination, culture, PCR	Clinical examination, culture	Acyclovir, valacyclovir, or famciclovir for severe primary infection	Cesarean delivery when mother has overt infection

Hillier, Ph.D., University of Washington.)

indicated only for patients who have persistent clinical findings and a negative microscopic examination and for those with recurrent infections who have had a poor response to treatment. Sabouraud's agar is the optimal medium for culture and may permit identification of a species of candida with an unusual pattern of sensitivity to antimicrobial compounds.

Treatment

For uncomplicated candida infections, topical therapy for 3 to 7 days with agents such as miconazole, terconazole, clotrimazole, and butoconazole is usually highly effective. Treatment of women with persistent or recurrent infection is more problematic. These patients should be counseled about preventive measures such as avoidance of bubble baths, use of cotton undergarments, and close attention to perineal hygiene.^[9], ^[10] In particularly refractory cases, administration of systemic antimicrobials such as ketoconazole or fluconazole should be considered because of their greater activity against reservoirs of yeast in the gastrointestinal tract.^[11] ^[12] ^[13] Neither drug has been studied extensively in pregnancy. However, fluconazole appears to have a more favorable toxicity profile. The appropriate oral dose of this compound for treatment of a refractory infection is 150 mg in a single dose.

Trichomoniasis

Epidemiology

Trichomoniasis is a sexually transmitted disease caused by the protozoan *Trichomonas vaginalis*. *Trichomonas*

1297

is responsible for approximately 25 percent of cases of vaginitis. It is an extremely contagious infection; virtually 100 percent of women who have sexual contact with an infected partner contract the disease.^[1] Trichomoniasis is not commonly associated with serious maternal or neonatal complications.

Diagnosis

The usual symptoms of trichomoniasis are vaginal pruritus, superficial dyspareunia, frequency, dysuria, and a malodorous, yellow-green, frothy vaginal discharge. On physical examination, the vaginal mucosa is typically erythematous, and punctate hemorrhages may be present on the cervix ("strawberry cervix"). The pH of the vagina is usually in the range of 5 to 7.^[1]

The most useful test for rapid confirmation of infection is direct visualization of the flagellated organisms in a saline preparation (wet mount). The sensitivity of this test is 60 to 80 percent, depending on the size of the inoculum and the thoroughness with which the slide is inspected. The Papanicolaou smear has similar sensitivity, but it is not as readily available to the office-based practitioner. *T. vaginalis* can be cultured on specialized media such as Hollander's medium or Feinberg-Whittington medium. However, culture is a more expensive and time consuming diagnostic test and, accordingly, it is rarely indicated in clinical practice.^[1]

Treatment

Metronidazole is the only antibiotic with uniform activity against *T. vaginalis*. Treatment efficacy is 95 percent or higher if the patient is compliant and her sexual partner is treated concurrently. Absolute resistance of the organism to metronidazole is uncommon, and relative resistance can usually be overcome by administering the drug in higher doses for longer periods of time.^[2], ^[3]

Metronidazole can be given in three oral dosage regimens: a single dose of 2 g; 250 mg three times daily for 7 days, or 500 mg twice daily for 7 days. The former dosage schedule improves compliance and reduces expense.^[9] In laboratory models, metronidazole has been associated with both mutagenicity and carcinogenicity. Although these effects have not been documented in humans (Food and Drug Administration [FDA] pregnancy category B), use of the drug in the first trimester of pregnancy raises theoretical concerns.^[4], ^[10] Accordingly, if the patient is relatively asymptomatic, treatment should be delayed until organogenesis is complete.

ENDOCERVICAL INFECTIONS

Chlamydia

Epidemiology

Chlamydia trachomatis is the most common sexually transmitted pathogen in Western nations. The organism can cause localized infection of the urethra, endocervix, and rectum. It also is the most common cause of perihepatitis (Fitz-HughCurtis syndrome) and an occasional cause of pneumonia. In addition, in the developing nations of the world, *C. trachomatis* is responsible for inclusion conjunctivitis, a leading cause of blindness. Infants delivered to infected women may develop either conjunctivitis and/or pneumonia. The former complication occurs in up to 50 percent of infants delivered to infected mothers; the latter affects 3 to 18 percent of infants.^[17], ^[18]

Diagnosis and Clinical Management

C. trachomatis may be grown in tissue culture. However, this methodology is relatively expensive and time consuming. Fortunately, less expensive, rapid identification tests such as nucleic acid probes are sufficiently sensitive to justify their clinical use for identification of chlamydia infection. In high-risk populations, the sensitivity and specificity of the newest tests exceed 90 percent.^[17], ^[19]

Although tetracycline and doxycycline have the greatest activity against *C. trachomatis*, these drugs should not be used in pregnancy because of their harmful effects on fetal teeth. For several years, erythromycin had been considered the drug of choice for treatment of chlamydia infection in pregnancy. However, many pregnant patients fail to complete the full course of erythromycin because of gastrointestinal side effects.^[20] Therefore, the preferred agent now is azithromycin, 1,000 mg (powder formulation) PO in a single dose.^[21] Amoxicillin (500 mg PO three times a day for 7 days) also is an acceptable alternative.^[22]

In view of the fact that 5 to 10 percent of patients do not respond to the initial course of treatment, a test of cure should be performed approximately 2 weeks after therapy is completed. In addition, infected patients should be screened for other sexually transmitted diseases such as gonorrhea, syphilis, hepatitis B, and human immunodeficiency virus infection. Neonates delivered to infected mothers should receive prophylaxis with tetracycline or erythromycin ophthalmic preparations and observed for evidence of an ensuing respiratory tract infection.

Gonorrhea

Epidemiology

Gonorrhea is caused by the gram-negative, intracellular diplococcus, *Neisseria gonorrhoeae*. The infection is transmitted primarily by sexual contact. Gonorrhea also may be transmitted perinatally from mother to infant and cause serious ophthalmic injury (*ophthalmia neonatorum*).

In pregnant women, gonorrhea may be manifested as an asymptomatic to mildly symptomatic localized infection of the urethra, endocervix, and/or rectum. Local infection may increase the risk of preterm labor and preterm premature rupture of membranes and predispose to intrapartum and postpartum infection. Gonorrhea also may present as a moderately severe pharyngitis or as a disseminated infection.^[17] The most common manifestation of disseminated gonococcal infection is arthritis, typically affecting several small to medium size joints. The next most common manifestation is a diffuse violaceous, papular skin rash. Less common but potentially more serious sequelae of disseminated infection include meningitis, pericarditis, endocarditis, and perihepatitis (Fitz-HughCurtis syndrome).^[23]

Diagnosis and Management

The most reliable test for confirmation of gonococcal infection is culture of the organism on selective agar such as Thayer-Martin medium. Gram's stain and nucleic acid probes are helpful when positive, but their sensitivity varies widely.

The drugs of choice for treating *localized* gonococcal infection in pregnancy are ceftriaxone (125 intramuscularly [IM] in a single dose) and cefixime (400 mg PO once). The former drug is the preferred agent for treatment of *disseminated* infection and should be administered in a dose of 1 g intravenously (IV) or IM every 24 hours until a clinical response has been achieved.^[8], ^[17] Tetracyclines and quinolones should not be used in pregnancy because of their injurious effects on fetal teeth and cartilage. Patients who are allergic to -lactam antibiotics may be treated with a single 2-g IM dose of spectinomycin.^[8] Treatment of the neonate with either silver nitrate or tetracycline ophthalmic preparations is effective in preventing most cases of ophthalmia neonatorum.

Patients who test positive for gonorrhea should be screened for other sexually transmitted diseases. Because of the uniformly excellent activity of ceftriaxone and cefixime against *N. gonorrhoeae*, tests of cure are not *routinely* indicated when patients are treated with these agents. However, patients with persistent symptoms and/or signs of infection should be carefully reevaluated.

URINARY TRACT INFECTIONS

Acute Urethritis

Acute urethritis (acute urethral syndrome) is usually caused by one of three organisms: coliforms (principally *Escherichia coli*), *Neisseria gonorrhoeae*, or *Chlamydia trachomatis*. Coliform organisms are part of the normal vaginal and perineal flora and may be introduced into the urethra during intercourse or when wiping after defecation. *N. gonorrhoeae* and *C. trachomatis* are sexually transmitted pathogens.^[24]

Affected patients typically experience frequency, urgency, and dysuria. Hesitancy, dribbling, and a mucopurulent urethral discharge also may be present. On microscopic examination, the urine usually has white blood cells (WBCs), but bacteria are not consistently present. Urine cultures may have low colony counts of coliform organisms, and cultures of the urethral discharge may be positive for gonorrhea and chlamydia. A rapid diagnostic test, such as a nucleic acid probe, may be used in lieu of culture for *C. trachomatis*.^[24]

Most patients with acute urethritis warrant empiric treatment before the results of urine or urethral cultures are available. Infections caused by coliforms will usually respond to the antibiotics described below for treatment of asymptomatic bacteriuria and cystitis. If gonococcal infection is suspected, the patient should be treated with either oral cefixime (400 mg in a single dose) or intramuscular ceftriaxone (125 mg in a single dose).^{[8], [17]} The former is approximately one third the cost of the latter. If the patient is allergic to -lactam antibiotics, an effective alternative is spectinomycin, administered intramuscularly in a single dose of 2 g. If chlamydial infection is suspected or confirmed, appropriate treatment regimens include: erythromycin base (500 mg PO four times daily for 7 days), amoxicillin (500 mg PO three times daily for 7 days), or azithromycin (1000 mg PO in a single dose).^[9] The latter drug is a long-acting derivative of erythromycin and is presently the only antibiotic that is effective in a single dose against *C. trachomatis*. When administered in a powder formulation, it is relatively inexpensive and is a cost-effective alternative to multiday treatment regimens. Doxycycline or tetracycline should not be used in pregnancy because of their adverse effects on fetal bone and teeth.

Asymptomatic Bacteriuria and Acute Cystitis

The prevalence of asymptomatic bacteriuria in pregnancy is 5 to 10 percent, and the vast majority of cases antedate the onset of pregnancy. The frequency of

acute cystitis in pregnancy is 1 to 3 percent. Some cases of cystitis arise de novo; others develop as a result of failure to identify and/or treat asymptomatic bacteriuria.^[25]

E. coli is responsible for 80 to 90 percent of cases of *initia* infections and 70 to 80 percent of recurrent cases. *Klebsiella pneumoniae* and *Proteus* species also are important pathogens, particularly in patients who have a history of recurrent infection. Approximately 3 to 7 percent of infections will be caused by gram-positive organisms such as group B streptococci, enterococci, and staphylococci.^{[24], [25]}

All pregnant women should have a urine culture at their first prenatal appointment to detect preexisting asymptomatic bacteriuria. If the culture is negative, the likelihood of the patient subsequently developing an *asymptomatic* infection is 5 percent or less. If the culture is positive (defined as 10^5 colonies/ml urine from a midstream clean-catch specimen), prompt treatment is necessary to prevent ascending infection.^[25]

Patients with acute cystitis usually have symptoms of frequency, dysuria, urgency, suprapubic pain, hesitancy, and dribbling. Gross hematuria may be present, but high fever and systemic symptoms are uncommon. In symptomatic patients, the leukocyte esterase and nitrate tests will usually be positive. When a urine culture is obtained, a catheterized sample is preferred because it minimizes the probability that urine will be contaminated by vaginal flora. With a catheterized specimen, a colony count greater than or equal to 10^2 /ml is considered indicative of infection.^[26]

Asymptomatic bacteriuria and acute cystitis characteristically respond well to short courses of oral antibiotics. Single dose therapy is not as effective in pregnant women as in nonpregnant patients. However, a 3-day course of treatment appears to be comparable to a 7- to 10-day regimen for an initial infection.^[24] The longer courses of therapy are most appropriate for patients with recurrent infections. [Table 40-3](#) lists several antibiotics of value for treatment of asymptomatic bacteriuria and cystitis.

When sensitivity tests are available (e.g., in patients with asymptomatic bacteriuria), they may be used to guide antibiotic selection. When empiric treatment is indicated, the choice of antibiotics must be based on established patterns of susceptibility. In recent years, 20 to 30 percent of strains of *E. coli* have developed resistance to ampicillin. Thus, this drug should not be used when the results of sensitivity tests are unknown unless the suspected pathogen is enterococcus.^[27]

When choosing among the drugs listed in [Table 40-3](#), the clinician should consider the following factors. First, the sensitivity patterns of ampicillin, amoxicillin, and cephalexin will be the most variable.^[27] Second, these drugs, along with amoxicillin-clavulanic acid, will also have the most pronounced effect on normal bowel and vaginal flora and thus be the most likely to cause diarrhea or monilial vulvovaginitis. Third, amoxicillin-clavulanic acid and trimethoprim-sulfamethoxazole will usually be the best empiric agents for treatment of patients with suspected drug-resistant pathogens.^[28] In this situation, the latter drug offers a major cost advantage

TABLE 40-3 -- ANTIBIOTICS FOR TREATMENT OF ASYMPTOMATIC BACTERIURIA AND ACUTE CYSTITIS

Drug	Strength of Activity	Oral Dose X 3 Days	Relative Cost
Amoxicillin	Some <i>E. coli</i> , most <i>Proteus</i> species, group B streptococci, enterococci, some staphylococci	875 mg bid	Low
Amoxicillin-clavulanic acid (Augmentin)	Most gram-negative aerobic bacilli and gram-positive cocci	875 mg bid	High
Ampicillin	Some <i>E. coli</i> , most <i>Proteus</i> species, group B streptococci, enterococci, some staphylococci	250/500 mg qid	Low
Cephalexin (Keflex)	Most <i>E. coli</i> , most <i>Klebsiella</i> and <i>Proteus</i> species, group B streptococci, staphylococci	250 mg qid	Low

Nitrofurantoin monohydrate macrocrystalssustainedrelease preparation (Macrobid)	Most gram-negative aerobic bacilli	100 mg bid	Moderate
Sulfisoxazole (Gantrisin)	Most gram-negative aerobic bacilli	2 g X 1 dose, then 1 g qid	Low
Trimethoprim-sulfamethoxazole double strength (Bactrim-DS, or Septra-DS)	Most gram-negative aerobic bacilli	800 mg/160 mg bid	Low

bid, twice daily; qid, four times daily.

1300

over the former. Finally, because of theoretical concerns about their effect on protein binding of bilirubin, sulfonamide drugs should probably be avoided near the time of delivery.

For patients who have an initial infection and experience a prompt response to treatment, a urine culture for test of cure is probably unnecessary. ^[29] Cultures during, or immediately after, treatment are indicated for patients who have a poor response to therapy or who have a history of recurrent infection. During subsequent clinic appointments, the patient's urine should be screened for nitrites and leukocyte esterase. If either of these tests is positive, repeat urine culture and retreatment are indicated. ^[30]

Acute Pyelonephritis

The incidence of pyelonephritis in pregnancy is 1 to 2 percent. ^[29] The vast majority of cases develop as a consequence of undiagnosed or inadequately treated lower urinary tract infection. Two major physiologic changes occur during pregnancy that predispose to ascending infection of the urinary tract. First, the high concentration of progesterone secreted by the placenta has an inhibitory effect on ureteral peristalsis. Second, the enlarging gravid uterus often compresses the ureters, particularly the right, at the pelvic brim, thus creating additional stasis. Stasis, in turn, facilitates migration of bacteria from the bladder into the ureters and renal parenchyma (Fig. 40-2).

Approximately 75 to 80 percent of cases of pyelonephritis occur on the right side. Ten to 15 percent are left sided, and a slightly smaller percentage are bilateral. ^[25] *E. coli* is again the principal pathogen. ^[25], ^[27] *Klebsiella pneumoniae* and *Proteus* species also are important causes of infection, particularly in women with recurrent episodes of pyelonephritis. ^[27] Highly virulent gram-negative bacilli, such as *Pseudomonas*, *Enterobacter*, and *Serratia* are unusual isolates except in immunocompromised patients. Gram-positive cocci do not usually cause upper tract infection. Anaerobes also are unlikely pathogens unless the patient is chronically obstructed or instrumented.

The usual clinical manifestations of acute pyelonephritis in pregnancy are fever, chills, flank pain and tenderness, frequency, urgency, hematuria, and dysuria. Patients also may have signs of preterm labor, septic shock, and adult respiratory distress syndrome (ARDS). Urinalysis is usually positive for white cell casts, red blood cells, and bacteria. Urine colony counts greater than 10^2 colonies/ml, in samples collected by catheterization, confirm the diagnosis of infection.

Pregnant patients with pyelonephritis may be considered for outpatient therapy if their disease manifestations are mild, they are hemodynamically stable, and they have no evidence of preterm labor. If an outpatient

Figure 40-2 Intravenous pyelogram in a pregnant woman shows marked dilation of the right ureter and mild dilation of renal collecting system.

approach is adopted, the patient should be treated with agents that have a high level of activity against the common uropathogens. Acceptable oral agents include amoxicillin (875 mg)-clavulanic acid (125 mg), one tablet twice daily or trimethoprim-sulfamethoxazole-DS (one tablet twice daily for 7 to 10 days). Alternatively, a visiting home nurse may be contracted to administer a parenteral agent, such as ceftriaxone (2 g IM or IV once daily).

Pregnant patients who appear to be moderately to severely ill or who show any signs of preterm labor should be hospitalized for intravenous antibiotic therapy. They should receive appropriate supportive treatment and be monitored closely for complications such as sepsis, ARDS, and preterm labor. One of the best choices for empiric intravenous antibiotic therapy is cefazolin (1 to 2 g every 8 hours). ^[27] For hospitalized patients, this drug is less expensive to administer than the newer broader spectrum cephalosporins or penicillins and has an equivalent spectrum of activity against the

1301

coliform organisms most likely to be responsible for infection. If the patient is critically ill or is at high risk for a resistant organism, a second antibiotic, such as gentamicin (1.5 mg/kg every 8 hours) or aztreonam (500 mg to 1 g every 8 to 12 hours) should be administered, along with cefazolin, until the results of susceptibility tests are available.

Once antibiotic therapy is initiated, approximately 75 percent of patients defervesce within 48 hours. By the end of 72 hours, almost 95 percent of patients will be afebrile and asymptomatic. ^[31] The two most likely causes of treatment failure are a resistant microorganism or obstruction. The latter condition is best diagnosed with renal ultrasonography or intravenous pyelography and typically results from a stone or physical compression of the ureter by the gravid uterus.

Once the patient has begun to defervesce and her clinical examination has improved, she may be discharged from the hospital. Oral antibiotics should be prescribed to complete a total of 7 to 10 days of therapy. Selection of a specific oral agent should be based on considerations of efficacy, toxicity, and expense.

Approximately 20 to 30 percent of pregnant patients with acute pyelonephritis will develop a recurrent urinary tract infection later in pregnancy. ^[25] The most cost-effective way to reduce the frequency of recurrence is to administer a daily prophylactic dose of an antibiotic, such as sulfisoxazole (1 g) or nitrofurantoin monohydrate macrocrystals (100 mg). Patients receiving prophylaxis should have their urine screened for bacteria at each subsequent clinic appointment. They also should be questioned about recurrence of symptoms. If symptoms recur, or the dipstick test for nitrite or leukocyte esterase is positive, a urine culture should be obtained to determine if retreatment is necessary.

CHORIOAMNIONITIS

Epidemiology

Chorioamnionitis (amnionitis, intra-amniotic infection) occurs in approximately 1 to 5 percent of term pregnancies.^[32] In patients with preterm delivery, the frequency of clinical or subclinical infection may approach 25 percent.^[33] Although chorioamnionitis may result from hematogenous dissemination of microorganisms, it more commonly is an ascending infection caused by organisms that are part of the normal vaginal flora. The principal pathogens are *Bacteroides* and *Prevotella* species, *E. coli*, anaerobic streptococci, and group B streptococci.^[34] Several clinical risk factors for chorioamnionitis have been identified. The most important are young age, low socioeconomic status, nulliparity, extended duration of labor and ruptured membranes, multiple vaginal examinations, and preexisting infections of the lower genital tract.^[32]

Diagnosis

In most situations, the diagnosis of chorioamnionitis can be established on the basis of the clinical findings of maternal fever and maternal and fetal tachycardia, in the absence of other localizing signs of infection. In more severely ill patients, uterine tenderness and purulent amniotic fluid may be present.^[32] The disorders that should be considered in the differential diagnosis of chorioamnionitis include upper respiratory infection, bronchitis, pneumonia, pyelonephritis, viral syndrome, and appendicitis.

Laboratory confirmation of the diagnosis of chorioamnionitis is not routinely necessary in term patients who are progressing to delivery. However, in preterm patients who are being evaluated for tocolysis or corticosteroids, laboratory assessment may be of value in excluding or establishing the diagnosis of intrauterine infection. In this clinical context, amniotic fluid should be obtained by transabdominal amniocentesis. Table 40-4 summarizes the abnormal laboratory findings that may be present in infected patients.^[32],^[35]^[36]^[37]^[38]^[39]^[40]

Management

Both the mother and infant may experience serious complications when chorioamnionitis is present. Bacteremia occurs in 3 to 12 percent of infected women. When cesarean delivery is required, up to 8 percent of women develop a wound infection, and approximately 1 percent develop a pelvic abscess. Fortunately, maternal death due to infection is exceedingly rare.^[32]

Five to 10 percent of neonates delivered to mothers with chorioamnionitis have pneumonia or bacteremia. The predominant organisms responsible for these infections are group B streptococci and *E. coli*. Meningitis occurs in 1 percent or less of term infants and in a slightly higher percentage of preterm infants. Mortality due to infection ranges from 1 to 4 percent in term neonates but may approach 15 percent in preterm infants because of the confounding effects of other complications such as hyaline membrane disease and intraventricular hemorrhage.^[32]

In order to prevent maternal and neonatal complications, parenteral antibiotic therapy should be initiated as soon as the diagnosis of chorioamnionitis is made, unless delivery is imminent. Three separate investigations have demonstrated that mother-infant pairs who receive prompt intrapartum treatment have better outcomes than patients treated after delivery.^[41]^[42]^[43] The principal benefits of early treatment include decreased frequency of neonatal bacteremia and pneumonia and

TABLE 40-4 -- DIAGNOSTIC TESTS FOR CHORIOAMNIONITIS

Test	Abnormal Finding	Comment
Maternal white blood cell (WBC) count ^[32]	15,000 cells/mm ³ with preponderance of leukocytes	Labor and/or corticosteroids may result in elevation of WBC count.
Amniotic fluid glucose ^[35] ^[36] ^[37]	10 to 15 mg/dl	Excellent correlation with positive amniotic fluid culture and clinical infection.
Amniotic fluid interleukin-6 ^[38]	7.9 ng/ml	Excellent correlation with positive amniotic fluid culture and clinical infection.
Amniotic fluid leukocyte esterase ^[39]	1 + reaction	Good correlation with positive amniotic fluid culture and clinical infection.
Amniotic fluid Gram's stain ^[32]	Any organism in an oil immersion field	Allows identification of particularly virulent organism such as group B streptococci; however, the test is very sensitive to inoculum effect. In addition, it cannot identify pathogens such as mycoplasmas.
Amniotic fluid culture ^[32]	Growth of aerobic or anaerobic microorganism	Results are not immediately available for clinical management.
Blood cultures ^[32] , ^[40]	Growth of aerobic or anaerobic microorganism	Will be positive in 510% of patients. However, will usually not be of value in making clinical decisions unless patient is at increased risk for bacterial endocarditis, is immunocompromised, or has a poor response to initial treatment.

decreased duration of maternal fever and hospitalization.

The most extensively tested intravenous antibiotic regimen for treatment of chorioamnionitis is the combination of ampicillin (2 g every 6 hours) or penicillin (5 million units every 6 hours) plus gentamicin (1.5 mg/kg every 8 hours).^[19],^[32] These antibiotics specifically target the two organisms most likely to cause neonatal infection: group B streptococci and *E. coli*. With rare exceptions, gentamicin is preferred to tobramycin or amikacin because it is available in an inexpensive generic formulation. Amikacin should be reserved for immunocompromised patients who are particularly likely to be infected by highly virulent, drug-resistant, aerobic gram-negative bacilli. In patients who are allergic to -lactam antibiotics, either vancomycin (500 mg every 6 hours or 1 g every 12 hours), erythromycin (1 g every 6 hours), or clindamycin (900 mg every 8 hours) can be substituted for ampicillin.

If a patient with chorioamnionitis requires cesarean delivery, a drug with activity against anaerobic organisms should be added to the antibiotic regimen. Either clindamycin (900 mg every 8 hours) or metronidazole (500 mg every 12 hours) is an excellent choice for this purpose. Failure to provide effective coverage of anaerobes may result in treatment failures in 20 to 30 percent of patients.

Extended spectrum cephalosporins, penicillins, and carbapenems also provide excellent coverage against the bacteria that cause chorioamnionitis. Dosages and dose intervals for several of these agents are listed in Table 40-5. ^[44] Less information is available concerning the effectiveness of these drugs compared to the ampicillin or penicillin plus gentamicin regimen. In addition, the toxicity profile for the fetus and neonate has not been as well delineated.

As a general rule, parenteral antibiotics should be continued until the patient has been afebrile and

TABLE 40-5 -- SINGLE AGENTS OF VALUE IN TREATMENT OF CHORIOAMNIONITIS

Drug	Dosage and Dose Interval	Relative Cost to the Pharmacy*
Extended spectrum cephalosporins		
Cefotaxime	2 g q8h	Intermediate
Cefotetan	2 g q12h	Low
Cefoxitin	2 g q6h	High
Ceftizoxime	2 g q12h	Intermediate
Extended spectrum penicillins		
Ampicillin-sulbactam	3 g q6h	Low
Mezlocillin	34 g q6h	Intermediate
Piperacillin	34 g q6h	Intermediate
Piperacillin-tazobactam	3.375 g q6h	Intermediate
Ticarcillin-clavulanic acid	3.1 g q6h	Low
Carbapenem

Meropenem	1 g q12h	High

* Cost estimates do not include dose preparation fees and administration charges.

asymptomatic for approximately 24 hours. Once an adequate clinical response has been achieved, antibiotics may be discontinued and the patient discharged. A course of oral antibiotics administered as an outpatient is rarely indicated. ^{[15], [32], [44]}

There are two principal exceptions to the above rule. First, a patient with a documented staphylococcal bacteremia may require a longer period of intravenous therapy and, subsequently, an extended course of oral antibiotics. Second, the patient who has a vaginal delivery and then experiences a rapid defervescence may be a suitable candidate for a short course of oral antibiotics administered as an outpatient. In this situation, amoxicillin (875 mg)-clavulanic acid (125 mg), one tablet twice daily for 23 days, provides effective coverage against most of the organisms responsible for chorioamnionitis and is usually very well tolerated.

Patients with chorioamnionitis are at increased risk for dysfunctional labor. Approximately 75 percent require oxytocin for augmentation of labor, and up to 30 to 40 percent require cesarean delivery, usually for failure to progress in labor. While chorioamnionitis by itself should not be regarded as an indication for cesarean, affected patients need careful monitoring during labor to ensure that uterine contractility is optimized. In addition, the fetus also needs close surveillance. Fetal heart rate abnormalities such as tachycardia and decreased variability (Fig. 40-3) occur in over three fourths of cases, and additional tests such as vibroacoustic stimulation, scalp stimulation, or scalp pH assessment may be necessary to evaluate fetal well-being. ^{[32], [45]}

PUERPERAL ENDOMETRITIS

Epidemiology

The frequency of puerperal endometritis in women having vaginal delivery is approximately 1 to 3 percent. In women having a scheduled cesarean prior to the onset of labor and rupture of membranes, the frequency of endometritis ranges from 5 to 15 percent. When cesarean delivery is performed after an extended period of labor and ruptured membranes, the incidence of infection is 30 to 35 percent without antibiotic prophylaxis and 15 to 20 percent with prophylaxis. In highly indigent patient populations, the frequency of infection may be almost double the figures cited above. ^[46]

Endometritis is a polymicrobial infection caused by microorganisms that are part of the normal vaginal flora. These bacteria gain access to the upper genital tract, peritoneal cavity and, occasionally, the bloodstream as a result of vaginal examinations during labor

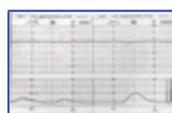

Figure 40-3 Fetal heart tracing from a patient with chorioamnionitis. Note the tachycardia of 170 beats/min and the decrease in both short- and long-term variability.

1304

and manipulations during surgery. The most common pathogenic bacteria are group B streptococci, anaerobic streptococci, aerobic gram-negative bacilli (predominantly *E. coli*, *Klebsiella pneumoniae*, and *Proteus* species), and anaerobic gram-negative bacilli (principally *Bacteroides* and *Prevotella* species). *Chlamydia trachomatis* is not a common cause of early-onset puerperal endometritis but has been implicated in late-onset infection. The genital mycoplasmas may be pathogens in some patients, but they tend to be present in association with more highly virulent bacteria. ^[46]

The principal risk factors for endometritis are cesarean delivery, young age, low socioeconomic status, extended duration of labor and ruptured membranes, and multiple vaginal examinations. In addition, preexisting infection or colonization of the lower genital tract (gonorrhea, group B streptococci, bacterial vaginosis) also predisposes to ascending infection. ^[46]

Clinical Presentation and Diagnosis

Affected patients typically have a fever of 38°C or higher within 36 hours of delivery. Associated findings include malaise, tachycardia, lower abdominal pain and tenderness, uterine tenderness, and discolored, malodorous lochia. A small number of patients also may have a tender, indurated inflammatory mass in the broad ligament, posterior cul de sac, or retrovesical space.

The initial differential diagnosis of puerperal fever should include endometritis, atelectasis, pneumonia, viral syndrome, pyelonephritis, and appendicitis. Distinction among these disorders usually can be made on the basis of physical examination and a limited number of laboratory tests such as WBC count, urinalysis and culture and, in select patients, chest x-ray. Endometrial cultures are of primary value in evaluating patients who have a poor initial response to antibiotic treatment. When these cultures are obtained, they should be collected with a double-lumen instrument to prevent contamination by lower genital tract flora. ^[47] Blood cultures also are indicated in such patients and in those who are immunocompromised or at increased risk for bacterial endocarditis. ^[46]

Management

Patients who have mild to moderately severe infections, particularly after vaginal delivery, can be treated with short intravenous courses of single agents such as the extended spectrum cephalosporins and penicillins or carbapenem antibiotics such as imipenem-cilastatin and meropenem. [Table 40-5](#) lists several antibiotics that have acceptable breadth of coverage against the polymicrobial genital tract flora. Combination antibiotic regimens should be considered for more severely ill patients, particularly those who are indigent and in poor general health and those who have had cesarean deliveries. [Table 40-6](#)

TABLE 40-6 -- COMBINATION ANTIBIOTIC REGIMENS FOR TREATMENT OF PUERPERAL ENDOMETRITIS

Antibiotics	Intravenous Dose	Relative Cost to the Pharmacy [†]
Regimen 1		
Clindamycin	900 mg q8h	Intermediate
Gentamicin	1.5 mg/kg q8h	Low
	or	
	7 mg/kg ideal body weight q24 [‡]	
Regimen 2		
Clindamycin	900 mg q8h	Intermediate
Aztreonam	12 g q8h	High
Regimen 3		
Metronidazole	500 mg q12h	Low
Penicillin	5 million units q6h	Low
	or	
Ampicillin	2 g q6h	Low
Gentamicin	1.5 mg/kg q8h	Low

or
7 mg/kg ideal body weight q24h

* Cost estimates do not include dose preparation fees and administration charges.

Single daily dosing of aminoglycoside antibiotics is more effective and less expensive than multidose treatment. In addition, it is less likely to cause toxicity. At present, there is little information concerning the effects of single large doses of aminoglycosides on the developing fetus. Therefore, this regimen should be reserved for postpartum patients.

lists several antibiotic combinations of proven value in treatment of puerperal endometritis. ^[15], ^[44]

Once antibiotics are begun, approximately 90 percent of patients will defervesce within 48 to 72 hours. When the patient has been afebrile and asymptomatic for approximately 24 hours, parenteral antibiotics should be discontinued, and the patient should be discharged. As a general rule, an extended course of oral antibiotics is not necessary following discharge.^[48] There are at least two notable exceptions to this rule. First, patients who have had a vaginal delivery and who defervesce within 24 hours are candidates for early discharge. In these individuals, a short 23 day course of an oral antibiotic such as amoxicillin (875 mg)-calvulanic acid (125 mg), one tablet twice daily, may be substituted for continued parenteral therapy. Second, patients who have had a staphylococcal bacteremia require a more extended period of administration of parenteral and oral antibiotics with specific antistaphylococcal activity. ^[49]

Patients who fail to respond to the antibiotic therapy outlined above usually have one of two problems. The first is a drug-resistant organism. [Table 40-7](#) lists possible weaknesses in coverage of selected antibiotics and indicates the appropriate change in treatment. The second major cause of treatment failure is a wound infection. Infected wounds should be opened completely to

provide drainage. If extensive cellulitis at the margin of the incision is present, an antibiotic with specific coverage against staphylococci, such as nafcillin (2 g IV every 6 hours), should be added to the treatment regimen.

When changes in antibiotic therapy do not result in clinical improvement and no evidence of wound infection is present, several unusual disorders should be considered. The differential diagnosis of persistent puerperal fever is summarized [in Table 40-8](#).^[46]

Prevention of Puerperal Endometritis

Prophylactic antibiotics are clearly of value in reducing the frequency of postcesarean endometritis, particularly in women having surgery after an extended period of labor and ruptured membranes.^[50] The most appropriate agent for prophylaxis is a limited spectrum (first-generation) cephalosporin, such as cefazolin. Cefazolin should be administered in an intravenous dose of 1 g immediately after the neonate's umbilical cord is clamped. A second dose is indicated approximately 8 hours after the first dose in high-risk patients, especially when operating time is prolonged beyond 1 hour. Although extended spectrum penicillins and cephalosporins are effective for prophylaxis, they offer no advantage over cefazolin and are severalfold more expensive. Moreover, widespread use of these drugs for prophylaxis may ultimately limit their usefulness for treatment of established infections.^[50]

Patients who have an immediate hypersensitivity to -lactam antibiotics pose a special problem. One alternative

TABLE 40-7 -- TREATMENT OF RESISTANT MICROORGANISMS IN PATIENTS WITH PUERPERAL ENDOMETRITIS

Initial Antibiotic(s)	Principal Weakness in Coverage	Modification of Therapy
Extended spectrum cephalosporins	Some aerobic and anaerobic gram-negative bacilli	Change treatment to clindamycin or metronidazole plus penicillin or ampicillin plus gentamicin
	Enterococci	
Extended spectrum penicillins	Some aerobic and anaerobic gram-negative bacilli	As above
	Enterococci	Add ampicillin or penicillin*
Clindamycin plus gentamicin or aztreonam	Enterococci	
	Some anaerobic gram-negative bacilli	Consider substitution of metronidazole for clindamycin

From Duff P: Antibiotic selection for infections in obstetric patients. *Semin Perinatol* 17:367, 1993, with permission.

* Ampicillin alone is highly active against enterococci. Penicillin plus gentamicin work synergistically to provide excellent coverage against this organism.

TABLE 40-8 -- DIFFERENTIAL DIAGNOSIS OF PERSISTENT PUERPERAL FEVER

Condition	Diagnostic Test(s)	Treatment
Resistant microorganism	Endometrial culture	Modify antibiotic therapy
	Blood culture	
Wound infection	Physical examination	Incision and drainage
		Antibiotics
	Needle aspiration	
Pelvic abscess	Ultrasound	
	Physical examination	Drainage
		Antibiotics
	CT	
Septic pelvic vein thrombophlebitis	MRI	
	Ultrasound	Heparin anticoagulation
	CT	
Recrudescence of connective tissue disease	MRI	Antibiotics
	Serology	Corticosteroids
Drug fever	Inspection of temperature graph	Discontinue antibiotics
	WBC identify eosinophilia	
Mastitis	Physical examination	Modify antibiotic treatment to provide coverage of staphylococcal organisms

From Duff P: Antibiotic selection for infections in obstetric patients. Semin Perinatol 17:367, 1993, with permission.

is to administer metronidazole, 500 mg IV. Another alternative is to administer a single dose of clindamycin (900 mg) plus gentamicin (1.5 mg/kg). Although these antibiotics are commonly used for treatment of overt infections, their administration is still warranted in penicillin-allergic patients who are at high risk for postoperative infection.

SERIOUS SEQUELAE OF PUERPERAL INFECTION

Wound Infection

Wound infection after cesarean delivery typically occurs in association with endometritis. Approximately 3 to 5 percent of patients with the latter disorder subsequently are found to have an incisional infection.^[46] The major risk factors for wound infection are listed [in the box "Principal Risk Factors for Postcesarean Wound Infection."](#) The principal causative organisms are *Staphylococcus*

1306

aureus, aerobic streptococci, and aerobic and anaerobic bacilli.^[51]

Principal Risk Factors for Postcesarean Wound Infection

- Poor surgical technique
- Low socioeconomic status
- Extended duration of labor and ruptured membranes
- Preexisting infection such as chorioamnionitis
- Obesity
- Type 1 (insulin-dependent) diabetes
- Immunodeficiency disorder
- Corticosteroid therapy
- Immunosuppressive therapy

The diagnosis of wound infection always should be considered in patients who have a poor clinical response to antibiotic therapy for endometritis.^[46] Clinical examination characteristically shows erythema, induration, and tenderness at the margins of the abdominal incision. When the wound is probed with either a cotton-tipped applicator or fine needle, pus usually exudes. Some patients, however, may have an extensive cellulitis without harboring frank pus in the incision. Clinical examination should be sufficient to establish the correct diagnosis. Gram's stain and culture of the wound exudate are not routinely needed, since the results of these tests rarely influence selection of antibiotics or duration of antibiotic treatment.

When pus is present in the incision, the wound must be opened and drained completely. Antibiotic therapy should be modified to provide coverage against staphylococci, since some regimens for endometritis may not specifically target this organism. Nafcillin (2 g IV every 6 hours) would be a suitable drug for this purpose. In a patient who is allergic to -lactam antibiotics, vancomycin (1 g IV every 12 hours) is an acceptable alternative.^[44]

Once the wound is opened, a careful inspection should be made to be certain that the fascial layer is intact. If it is disrupted, surgical intervention will be necessary to reapproximate the fascia. Otherwise, the wound should be irrigated two to three times daily with a solution such as warm saline, a clean dressing should be maintained, and the incision should be allowed to heal by secondary intention. Antibiotics should be continued until the base of the wound is clean and all signs of cellulitis have resolved. Patients usually can be treated at home once the acute signs of infection have subsided.

Necrotizing fasciitis is an uncommon but extremely serious complication of abdominal wound infection.^[52] It also has been reported in association with infection of the episiotomy site.^[53] This condition is most likely to occur in patients with type 1 (insulin-dependent) diabetes, cancer, or an immunosuppressive disorder. Multiple bacterial pathogens, particularly anaerobes, have been isolated from patients with necrotizing fasciitis.

Necrotizing fasciitis should be suspected when the margins of the wound become discolored, cyanotic, and devoid of sensation. When the wound is opened, the subcutaneous tissue is easily dissected free of the underlying fascia, but muscle tissue is not affected. If the diagnosis is uncertain, a tissue biopsy should be performed and examined by frozen section.

Necrotizing fasciitis is a life-threatening condition and requires aggressive medical and surgical management. Broad-spectrum antibiotics with activity against all potential aerobic and anaerobic pathogens should be administered. Intravascular volume should be maintained with infusions of crystalloid, and electrolyte abnormalities should be corrected. Finally, and most importantly, the wound must be debrided and all necrotic tissue removed. In many instances, the dissection must be quite extensive and may be best managed in conjunction with an experienced general or plastic surgeon.^[52]

Pelvic Abscess

With the advent of modern antibiotics, pelvic abscesses after cesarean or vaginal delivery have become extremely rare. Less than 1 percent of patients with puerperal endometritis develop a pelvic abscess.^[46] When present, abscess collections are typically located in the anterior or posterior cul de sac, most commonly the latter, or the broad ligament. The usual bacteria isolated from abscess cavities are coliforms and anaerobic gram-negative bacilli, particularly *Bacteroides* and *Prevotella* species.^[54]

Patients with an abscess typically experience a persistent fever despite initial therapy for endometritis. In addition, they usually have malaise, tachycardia, lower abdominal pain and tenderness, and a palpable pelvic mass anterior, posterior, or lateral to the uterus. The peripheral WBC count is usually elevated, and there is a shift toward immature cell forms. Ultrasound, computed tomographic (CT) scan, and magnetic resonance imaging (MRI) may be used to confirm the diagnosis of pelvic abscess.^[55] Although the latter two tests may be slightly more sensitive, the former offers the advantages of decreased expense and ready availability.

Patients with a pelvic abscess require surgical intervention to drain the purulent collection. When the abscess is in the posterior cul de sac, colpotomy drainage may be possible. For abscesses located anterior or lateral to the uterus, drainage may be accomplished by CT scan or ultrasound-guided placement of a catheter drain.^[56] When access is limited or the abscess is extensive, open laparotomy is indicated.

with excellent activity against coliform organisms and anaerobes.^[54] One regimen that has been tested extensively in obstetric patients with serious infections is the combination of penicillin (5 million units IV every 6 hours) or ampicillin (2 g IV every 6 hours) plus gentamicin (1.5 mg/kg IV every 8 hours or 7 mg/kg of ideal body weight every 24 hours) plus clindamycin (900 mg IV every 8 hours) or metronidazole (500 mg IV every 12 hours). If a patient is allergic to -lactam antibiotics, vancomycin (500 mg IV every 6 hours or 1 g IV every 12 hours) can be substituted for penicillin or ampicillin. Aztreonam (1 to 2 g IV every 8 hours) also can be used in lieu of gentamicin when the patient is at risk for nephrotoxicity. Alternatively, the single agents imipenem-cilastatin (500 mg IV every 6 hours) or meropenem (1 g every 8 hours) provide excellent coverage against the usual pathogens responsible for an abscess. Antibiotics should be continued until the patient has been afebrile and asymptomatic for a minimum of 24 to 48 hours.^[46]

Septic Pelvic Vein Thrombophlebitis

Like pelvic abscess, septic pelvic vein thrombophlebitis is extremely rare, occurring in 1 in 2,000 pregnancies overall and in less than or equal to 1 percent of patients who have puerperal endometritis.^[57] Intrauterine infection may cause seeding of pathogenic microorganisms into the venous circulation; in turn, these organisms may damage the vascular endothelium and initiate thrombosis.

Septic pelvic vein thrombophlebitis occurs in two distinct forms.^[57] The most commonly described disorder is acute thrombosis of one (usually the right) or both ovarian veins (*ovarian vein syndrome*).^[58] Affected patients typically develop a moderate temperature elevation in association with lower abdominal pain in the first 48 to 96 hours postpartum. Pain usually localizes to the side of the affected vein but may radiate into the groin, upper abdomen, or flank. Nausea, vomiting, and abdominal bloating may be present.

On physical examination, the patient's pulse is usually elevated. Tachypnea, stridor, and dyspnea may be evident if pulmonary embolization has occurred. The abdomen is tender, and bowel sounds are often decreased or absent. Most patients demonstrate voluntary and involuntary guarding, and 50 to 70 percent have a tender, rope-like mass originating near one cornua and extending laterally and cephalad toward the upper abdomen. The principal conditions that should be considered in the differential diagnosis of ovarian vein syndrome are pyelonephritis, nephrolithiasis, appendicitis, broad ligament hematoma, adnexal torsion, and pelvic abscess.

The second presentation of septic pelvic vein thrombophlebitis is termed *enigmatic fever*.^[59] Initially, affected patients have clinical findings suggestive of endometritis and receive systemic antibiotics. Subsequently, they experience subjective improvement, with the exception of temperature instability. They do not appear to be seriously ill, and positive findings are limited to persistent fever and tachycardia. Disorders that should be considered in the differential diagnosis of enigmatic fever are drug fever, viral syndrome, collagen vascular disease, and pelvic abscess.

The diagnostic tests of greatest value in evaluating patients with suspected septic pelvic vein thrombophlebitis are CT scan and MRI ([Fig. 40-4](#)). These tests are most sensitive in detecting large thrombi in the major pelvic vessels. They are not as useful in identifying thrombi in smaller vessels. In such cases, the ultimate diagnosis may depend on the patient's response to an empiric trial of heparin.^{[60], [61]}

Patients with septic pelvic vein thrombophlebitis should be treated with therapeutic doses of intravenous heparin.^{[57], [60]} The dose of heparin should be adjusted to maintain the activated partial thromboplastin time (aPTT) at approximately 2 times normal or to achieve a serum heparin concentration of 0.2 to 0.7 IU/ml. Therapy should be continued for 7 to 10 days. Longterm anticoagulation with oral agents is probably unnecessary unless the patient has massive clotting throughout the pelvic venous plexus or has sustained a pulmonary embolism. Patients should be maintained on broad-spectrum antibiotics throughout the period of heparin administration.

Once medical therapy is initiated, the patient should have objective evidence of a response within 48 to 72 hours. If no improvement is noted, surgical intervention may be necessary.^{[57], [60]} The decision to perform surgery should be based on clinical assessment and the relative certainty of the diagnosis. The surgical approach, in turn, should be tailored to the specific intraoperative

Figure 40-4 CT scan shows a thrombus (arrow) in right ovarian vein.

findings. In most instances, treatment requires only ligation of the affected vessel(s). Extension of the thrombosis along the vena cava to the point of origin of the renal veins may necessitate embolectomy. Excision of the infected vessel and removal of the ipsilateral adnexa and uterus are indicated only in the presence of a well-defined abscess. Whenever any of the above procedures are being considered, consultation with an experienced vascular surgeon is imperative.

SEPTIC SHOCK

Septic shock in obstetric patients is usually associated with four specific infections: septic abortion, acute pyelonephritis, and severe chorioamnionitis or endometritis.^[13] Fortunately, fewer than 5 percent of patients with any of these infections develop septic shock. The most common organisms responsible for septic shock are the aerobic gram-negative bacilli, principally *E. coli*, *Klebsiella pneumoniae*, and *Proteus* species. Highly virulent, drug-resistant coliforms such as *Pseudomonas*, *Enterobacter*, and *Serratia* species are uncommon except in immunosuppressed patients.^[62]

Aerobic gram-negative bacilli have a complex lipopolysaccharide in their cell wall that is termed *endotoxin*. When released into the systemic circulation, endotoxin is capable of causing a variety of immunologic, hematologic, neurohormonal, and hemodynamic derangements that ultimately result in multiorgan dysfunction. [Figure 40-5](#) presents a simplified summary of the pathophysiology of endotoxic shock.^[62]

In the early stages of septic shock, patients usually are restless, disoriented, tachycardic, and hypotensive. Although hypothermia is occasionally present, most patients have a relatively high fever (39° to 40°C). Their skin may be warm and flushed due to an initial phase of vasodilation (*warm shock*). Subsequently, as extensive vasoconstriction occurs, the skin becomes cool and clammy. Cardiac arrhythmias may be present, and signs of myocardial ischemia may occur. Jaundice, often due to hemolysis, may be evident. Urinary output typically

Figure 40-5 Pathophysiology of septic (endotoxic) shock.

decreases, and frank anuria may develop. Spontaneous bleeding from the genitourinary tract or venipuncture sites may occur as a result of disseminated intravascular coagulation (DIC). ARDS is a common complication of severe sepsis and is associated with manifestations such as dyspnea, stridor, cough, tachypnea, and bilateral rales and wheezing ([Fig. 40-5](#)).^[63] In addition to these systemic signs and symptoms, affected patients also may have findings related to their primary site of infection such as purulent lochia, uterine tenderness, peritonitis, or flank tenderness.

The differential diagnosis of septic shock in obstetric patients includes hypovolemic and cardiogenic shock, diabetic ketoacidosis, anaphylactic reaction, anesthetic reaction, and amniotic fluid or venous embolism.^[62] Distinction among these disorders usually can be made on the basis of a thorough history and physical examination and a limited number of laboratory studies. The WBC count initially may be decreased but, subsequently, is elevated in the majority of patients. A large percentage of bands is usually evident. The hematocrit may be decreased if blood loss has occurred. Tests of coagulation such as platelet count, serum fibrinogen concentration, serum concentration of fibrin degradation products, prothrombin time, and partial thromboplastin time are frequently abnormal. Serum concentrations of the transaminase enzymes and bilirubin are often increased. Similarly, increased concentrations of blood urea nitrogen (BUN) and creatinine reflect deterioration of renal function. Chest x-ray in patients with septic shock is indicated to determine if pneumonia or ARDS is present. In addition, CT scan, MRI, and ultrasound may be of value in localizing an abscess.^[55] Affected patients also require electrocardiographic monitoring to detect arrhythmias or signs of ischemic injury.

The first goal of treatment of septic shock is to correct the hemodynamic derangements precipitated by endotoxin. Two large-bore intravenous catheters and a urinary catheter should be inserted. Isotonic crystalloid such as Ringer's lactate solution or normal saline should be administered and the infusion titrated in accordance with the patient's pulse, blood pressure, and urine output. Application of the military antishock garment also may be helpful in stabilizing the patient's blood pressure, especially when bleeding is occurring.

If the initial fluid infusion is not successful in restoring hemodynamic stability, a right heart catheter should be inserted to monitor pulmonary artery wedge pressure. In addition, dopamine should be administered.^[64] In low doses, this vasopressor stimulates myocardial contractility and improves perfusion of central organs. In higher doses, the drug has primarily vasoconstrictive effects and may actually compromise tissue perfusion.

Corticosteroids no longer are recommended for treatment of septic shock. Although these drugs may initially improve hemodynamic instability, they ultimately promote superinfection with drug-resistant microorganisms and do not improve overall mortality.^{[65], [66]} In selected patients with refractory hypotension, intravenous administration of the narcotic antagonist naloxone has led to reversal of the shock state.^[67] The dose and duration of administration of naloxone have not been standardized.

The second objective of treatment is to administer broad-spectrum antibiotics targeted against the most likely pathogens.^[62] For genital tract infections, the combination of penicillin (5 million units IV every 6 hours) or ampicillin (2 g IV every 6 hours) plus clindamycin (900 mg IV every 8 hours) or metronidazole (500 mg IV every 12 hours) plus gentamicin (1.5 mg/kg IV every 8 hours or 7 mg/kg ideal body weight IV every 24 hours) or aztreonam (1 to 2 g IV every 8 hours) is an appropriate regimen. Alternatively, imipenem-cilastatin (500 mg IV every 6 hours) or meropenem (1 g every 8 hours) can be administered as single agents. Patients also may require surgery, for example, to evacuate infected products of conception, drain a pelvic abscess, or remove badly infected pelvic organs. Indicated surgery never should be delayed because a patient is unstable, because operative intervention may be precisely the step necessary to reverse the hemodynamic derangements of septic shock.

Other adjuncts in the treatment of infection include infusion of granulocytes and administration of antisera to the major antigens of coliform bacteria.^{[62], [68]} The former modality has its greatest application in treatment of neutropenic patients. The second intervention has appeared promising in some investigations but remains experimental.

Patients with septic shock require meticulous supportive care. Core temperature should be maintained as close to normal as possible by use of antipyretics and a cooling blanket. Coagulation abnormalities should be identified promptly and treated by infusion of platelets and coagulation factors, as indicated. Finally, patients should be given oxygen supplementation and observed closely for evidence of ARDS, one of the major causes of mortality in cases of severe sepsis.^[14] Oxygenation should be monitored by means of a pulse oximeter or radial artery catheter. At the first sign of respiratory failure, the patient should be intubated and supported with mechanical ventilation.

The prognosis in patients with septic shock clearly depends on the severity of the patient's underlying illness. In patients with "rapidly fatal illnesses," such as hematopoietic malignancies, mortality approaches 80 percent. In patients with "ultimately fatal illnesses" (e.g., solid tumors), mortality decreases to 40 to 50 percent.

However, in otherwise healthy patients, mortality rarely exceeds 15 percent. ^[69] Fortunately, most obstetric patients are in the latter category. Therefore, the prognosis for complete recovery is excellent provided

that the patient receives competent, timely intervention.

CYTOMEGALOVIRUS INFECTION

Epidemiology

Cytomegalovirus (CMV) is a double-stranded DNA virus that replicates within the nucleus of an infected cell. Humans are its only known host. Like herpes simplex virus, CMV may remain latent in host cells after the initial infection. Recurrent infection is usually due to reactivation of endogenous latent virus rather than reinfection with a new strain of virus. Cell-mediated immunity is more important than humoral mechanisms in controlling infection. ^[70]

CMV is not highly contagious and, therefore, close personal contact is required for infection to occur. *Horizontal transmission* may result from receipt of an infected organ or blood, from sexual contact, or from contact with contaminated saliva or urine. *Vertical transmission* may occur as a result of transplacental infection, exposure to contaminated genital tract secretions during delivery, or breast-feeding. The incubation period of the virus ranges from 28 to 60 days, with a mean of 40 days. ^[70] ^[71] ^[72]

Among young children, the most important risk factor for infection is close contact with playmates, particularly in the setting of day-care. In an early report, Pass and co-workers^[73] surveyed 70 children attending a day-care center in Birmingham, Alabama. Investigators obtained mouth swabs from 29 children and urine specimens from 68. Forty-five percent of mouth swabs and 53 percent of urine cultures were positive for CMV. Nine percent of infants less than 1 year of age shed virus in either saliva or urine; 83 percent of children 1 to 2 years of age shed virus.

Jones et al.^[74] conducted a similar survey in a regular day-care center and a facility for developmentally delayed children. Twenty-two percent of children in both centers were viruric, and 11 percent shed virus in their saliva. Hutto and co-workers^[75] surveyed 47 toddlers attending day-care. Fourteen (30 percent) shed virus in saliva. The highest rate of salivary excretion (80 percent) occurred in children 12 to 24 months of age. Forty percent of the children were viruric.

Infected children clearly pose a risk of transmitting virus to adult day-care workers. Adler^[76] recently examined the rate of seroconversion to CMV among day-care employees. At the time of initial assessment, 202 workers were seronegative. Within 10 months, 19 (11 percent) had seroconverted. The rate of seroconversion was greatest among employees who cared for children under 2 years of age.

Small children also pose a risk to members of their own family. Taber et al.^[77] performed a serologic study and identified 68 families where both parents were seronegative for CMV. Over a 3-year period, seroconversion occurred in one or more members of 37 families (53 percent). Mean annual seroconversion rates were approximately 10 percent for fathers, mothers, and children. The index case was usually a child.

In addition to acquiring infection from young children, adolescents and adults may develop infection as a result of sexual contact. CMV infection is endemic among gay men and heterosexuals with multiple partners.^[78] ^[79] Additional risk factors for infection include lower socioeconomic status, history of abnormal cervical cytology, birth outside of North America, first pregnancy at less than 15 years, and co-infection with other sexually transmitted diseases (STDs) such as trichomoniasis. ^[79]

Clinical Manifestations in Children and Adults

Most children who acquire CMV infection are asymptomatic. When clinical manifestations are present, they usually are mild and include malaise, fever, lymphadenopathy, and hepatosplenomegaly. Similarly, most adults with either primary or recurrent CMV are asymptomatic. Symptomatic patients typically have findings suggestive of mononucleosis. Respiratory infection is uncommon in adults with normal immune function, but an increasing number of cases of serious CMV infection are likely to occur as a consequence of the rising prevalence of HIV infection in women.

Diagnosis of Infection in Adults and Children

The diagnosis of CMV infection can be confirmed by isolation of virus in tissue culture. The highest concentration of CMV is usually present in urine, seminal fluid, saliva, and breast milk. Several different cell lines have been used to support viral growth, and techniques such as the viral shell assay, immunofluorescent staining, monoclonal antibody, and polymerase chain reaction (PCR) permit identification of viral antigen within 24 hours. ^[80] ^[81] ^[82] ^[83]

Serologic methods also are helpful in establishing the diagnosis of CMV infection, provided that the reference laboratory is skilled in performing such tests. In the acute phase of infection, virus-specific immunoglobulin M (IgM) antibody is present in serum. IgM titers usually decline rapidly over a period of 30 to 60 days, but they can remain elevated for several months. There is

no absolute immunoglobulin G (IgG) titer that clearly will differentiate acute from recurrent infection. However, a fourfold or greater change in the IgG titer is consistent with recent acute infection.^[79] Other laboratory tests suggestive of CMV infection include a differential WBC count showing atypical lymphocytes, low platelet count, and elevated serum transaminase concentrations.

Congenital and Perinatal Infection

As a result of exposure to either young children or an infected sexual partner, approximately 50 to 80 percent of adult women in the United States have serologic evidence of past CMV infection. Unfortunately, the presence of antibody is not perfectly protective against vertical transmission; thus, pregnant women with both recurrent and primary infection pose a special risk to their fetus. Fetal and neonatal CMV infection may occur at three distinct times: antepartum, intrapartum, and postpartum. Antepartum or congenital infection is the greatest risk to the fetus and is perhaps the most difficult to understand because of the often bewildering array of statistics reported in epidemiologic surveys.

Congenital (Antepartum) Infection

Congenital CMV infection results from hematogenous dissemination of virus across the placenta. Dissemination may occur with both primary and recurrent (reactivated) infection but is much more likely in the former setting. From 1 to 4 percent of uninfected women seroconvert during pregnancy. ^[84] In women who acquire primary infection, 40 to 50 percent of the fetuses will be infected. Based on work with a guinea pig model, Kumar and Prokay^[85] have concluded that the overall risk of congenital infection is greatest when maternal infection occurs in the third trimester, but the probability of severe fetal injury is highest when maternal infection occurs

in the first trimester.

Of fetuses with congenital infection, 5 to 18 percent will be overtly symptomatic at birth. The most common clinical manifestations are hepatosplenomegaly, intracranial calcifications, jaundice, growth restriction, microcephaly, chorioretinitis, and hearing loss. The most frequent laboratory abnormalities are thrombocytopenia, hyperbilirubinemia, and elevated serum transaminase concentrations. Approximately 30 percent of severely infected infants die. Eighty percent of the survivors have severe neurologic morbidity, ocular abnormalities, or sensorineural hearing loss. ^[86], ^[87] Approximately 85 to 90 percent of infants delivered to mothers with primary infection will be asymptomatic at birth. Ten to 15 percent subsequently develop hearing loss, chorioretinitis, or dental defects within the first 2 years of life.

Pregnant women who experience recurrent CMV infection are much less likely to transmit infection to their fetus. Recurrent infection occurs predominantly as a result of reactivation of latent infection rather than reinfection with a new viral strain. The most recent, and probably clearest, delineation of fetal risk in this situation is the report by Fowler et al. ^[87] In an excellent epidemiologic investigation, these authors studied 125 women with serologic evidence of primary infection and 64 with recurrent infection. In the former group, 18 percent of infants were symptomatic at birth. An additional 7 percent developed at least one major sequela within 5 years of follow-up. Two percent died, 15 percent had sensorineural hearing loss, and 13 percent had IQs less than 70. In contrast, none of the infants delivered to mothers with recurrent infection were symptomatic at birth. During the period of surveillance, 8 percent had at least one sequela, but none had multiple defects. The most common sequela was hearing loss. The authors concluded that maternal antibody provided substantial, but not complete, protection against serious fetal infection.

Overall, approximately 1 percent of infants (40,000) born in the United States each year have congenital CMV infection. Approximately 3,000 to 4,000 infants are symptomatic at birth, and an additional 4,000 to 6,000 subsequently have neurologic or developmental problems in the first years of life. CMV infection is now the principal cause of hearing deficits in children. Public health officials estimate that the annual cost of caring for children with congenital CMV is \$1.86 billion. ^[88]

Perinatal (Intrapartum and Postpartum) Infection

Perinatal infection may occur *during delivery* as a result of exposure to infected genital tract secretions. At the time of delivery, up to 10 percent of pregnant women may be shedding CMV in cervical secretions and/or urine. Twenty to 60 percent of exposed fetuses may subsequently shed virus in their pharynx and/or urine. The incubation period for this form of infection ranges from 7 to 12 weeks, with an average of 8 weeks. Fortunately, infected infants rarely have serious sequelae of infection acquired during delivery. ^[86], ^[89]

Perinatal infection also may develop as a *result of breast-feeding*. Stagno et al. ^[90] surveyed 278 women who had recently delivered and who agreed to provide samples of breast milk. Thirty-eight (13 percent) had CMV isolated at least once from colostrum or milk. Twenty-eight of these women were shedding CMV only in breast milk. Nineteen of their neonates were breastfed, and 11 (58 percent) acquired CMV infection, despite

1312

the presence of neutralizing antibody in breast milk. Fortunately, serious sequelae did not occur in infected infants.

Diagnosis of Fetal Infection

In recent years, much attention has focused on analysis of amniotic fluid and fetal serum as a means to diagnose congenital infection. Several authors have compared the relative value of the following diagnostic tests: viral culture of amniotic fluid and fetal serum, determination of total IgM concentration in fetal serum, identification of anti-CMV IgM in fetal serum, and assessment of fetal liver function tests. These reports uniformly have supported the superiority of amniotic fluid analysis (viral culture or nucleic acid probe for viral antigen) in confirming the diagnosis of congenital CMV infection.

Lange and co-workers ^[91] were the first to report successful diagnosis of congenital infection by sampling of fetal blood. They performed cordocentesis on a hydropic fetus at 25 weeks' gestation, and the fetal blood smear showed severe erythroblastosis. Total IgM concentration was normal, but virus-specific IgM antibody to CMV was detected by radioimmunoassay. Hohlfeld et al. ^[92] subsequently described their assessment of 15 women with documented primary CMV infection in pregnancy. Eight fetuses were infected, and all were correctly identified by detection of antigen in amniotic fluid by the shell vial assay. In each instance, the subsequent viral culture was positive. Only four fetuses (50 percent) had increased total IgM concentrations and abnormal liver function tests. Two fetuses had thrombocytopenia, and none had positive viral blood cultures. The finding of a negative amniotic fluid culture was 100 percent specific in predicting the absence of congenital infection.

Lynch and co-authors ^[82] recently described their experience with assessment of 12 patients, 7 of whom had serologically confirmed primary infection and 5 of whom were evaluated because of abnormal sonographic findings. Eleven of the patients had an amniocentesis and cordocentesis. Of the seven women with serologically confirmed primary CMV infection, only one fetus was infected. This fetus had a normal hematocrit and platelet count, negative IgM-specific antibody, elevated -glutamyltranspeptidase (GGTP) concentration, and positive amniotic fluid culture. In the group of five women with abnormal sonograms, all of the fetuses were infected. Four (80 percent) had positive amniotic fluid cultures, and none had a positive blood culture. One had thrombocytopenia, three had elevated GGTP, and four had elevated total IgM.

In the most recent and largest series of invasive diagnostic testing for congenital CMV infection, Donner et al. ^[83] assessed 52 fetuses at risk for congenital CMV. Sixteen fetuses were infected, 13 of whom were diagnosed antenatally. Thirteen of 16 (81 percent) had at least one abnormal test. Detection of virus in amniotic fluid by culture or PCR methodology correctly identified 12 (75 percent) infected fetuses. Four patients required two amniocenteses to establish the diagnosis. Nine of 16 fetuses (56 percent) had virus-specific IgM antibody in cord blood. Six of 11 (55 percent) fetuses who had hematologic assays were thrombocytopenic. A negative amniotic fluid culture was 100 percent specific in identifying an uninfected fetus.

Although identification of virus in amniotic fluid appears to be the most sensitive and specific test for diagnosing congenital infection, it does not necessarily identify the *severity* of fetal injury. This issue is obviously of great importance in counseling parents about the prognosis for their infant. Fortunately, detailed sonography can be invaluable in providing information about severity of fetal impairment. The principal sonographic findings suggestive of serious fetal injury include microcephaly, ventriculomegaly, intracerebral calcifications, hydrops, growth restriction, and oligohydramnios. ^[92] Unusual findings that also may indicate a severely infected infant include fetal heart block, ^[93] intra-abdominal echodensities, ^[94] meconium peritonitis, ^[95] and isolated serous effusions. ^[92] Clinicians should be aware that the ultrasound examination may be normal early in the course of fetal infection. Therefore, fetuses at risk should have repeat examinations to determine if anomalies are apparent.

Treatment and Prevention

At the present time, a vaccine for CMV is not available. Antiviral agents such as ganciclovir and foscarnet have moderate activity against CMV, but their use is limited primarily to treatment of severe infections in immunocompromised patients. Accordingly, obstetriciangynecologists should focus most of their attention on educating patients about preventive measures.

One of the most important interventions is helping patients understand that CMV infection can be a sexually transmitted disease and that sexual promiscuity significantly increases an individual's risk of acquiring the infection. Individuals who have multiple sexual partners should be counseled that latex condoms provide an effective barrier to transmission of CMV. ^[96] Another important intervention is educating health care workers, day-care workers, elementary school teachers, and mothers of young children about the importance of simple infection control measures such as handwashing and proper cleansing of environmental surfaces. Obstetricians and pediatricians must be consistently aware of the importance of transfusing only CMV-free blood products to fetuses, neonates, pregnant women, and immunocompromised patients, and screening potential donors

1313

of organs and semen for CMV infection. ^[71] Finally, health care workers must adhere to the principles of universal precautions when treating patients and handling potentially infected body fluids. ^[84]

For several reasons, routine prenatal screening for CMV infection is not recommended. First, laboratory resources could be overwhelmed if all pregnant women were screened. Second, if laboratories do not ensure a high level of quality control, the interpretation of serologic tests may be confusing and may lead to incorrect and irreversible interventions such as pregnancy termination. Third, neither antiviral chemotherapy nor immunoprophylaxis is available to protect the fetus or neonate. Accordingly, screening should be limited to women who have symptoms suggestive of acute CMV infection, who have had definite occupational exposure to CMV, or who are immunocompromised.

GROUP B STREPTOCOCCAL INFECTION

Epidemiology

Streptococcus agalactiae is a gram-positive encapsulated coccus that produces α -hemolysis when grown on blood agar. On average, approximately 20 to 25 percent of pregnant women harbor group B streptococci in their lower genital tract and/or rectum. The group B streptococcus is one of the most important causes of early-onset neonatal infection. The prevalence of neonatal group B streptococcal infection is 1 to 2 per 1,000 live births, and approximately 10,000 to 12,000 cases of neonatal streptococcal septicemia occur each year in the United States.^{[97], [98]}

Neonatal group B streptococcal infection can be divided into *early-onset* and *late-onset* infection. Approximately 80 to 85 percent of cases of neonatal group B streptococcal infection are early in onset and result almost exclusively from vertical transmission from a colonized mother. Early-onset infection presents primarily as a severe pneumonia and/or overwhelming septicemia. In preterm infants, the mortality from early-onset group B streptococcal infection approaches 25 percent. In term infants, the mortality is lower, averaging approximately 5 percent in recent investigations. Late-onset neonatal group B streptococcal infection occurs as a result of both vertical and horizontal transmission. It is typically manifested by bacteremia, meningitis, and pneumonia. The mortality from late onset infection is approximately 5 to 10 percent for both preterm and term infants.^{[97], [98]}

Unfortunately, obstetric interventions have proven ineffective in preventing late-onset neonatal infection. Therefore, the remainder of this discussion will focus on early-onset infection. Major risk factors for early-onset infection include preterm labor, especially when complicated by preterm premature rupture of membranes (PROM); intrapartum maternal fever (chorioamnionitis); prolonged rupture of membranes, defined as greater than 1218 hours; and previous delivery of an infected infant.^{[97], [98], [100]} Approximately 25 percent of pregnant women have at least one risk factor for group B streptococcal infection. The neonatal attack rate in colonized patients is 40 to 50 percent in the presence of a risk factor, and less than or equal to 5 percent in the absence of a risk factor. In infected infants, neonatal mortality approaches 30 to 35 percent when a maternal risk factor is present but is less than or equal to 5 percent when a risk factor is absent.^{[97], [98], [99]}

Maternal Complications

Several obstetric complications occur with increased frequency in pregnant women who are colonized with group B streptococci.^[97] The organism is a major cause of chorioamnionitis and postpartum endometritis. It also may cause postcesarean wound infection, usually in conjunction with other aerobic and anaerobic bacilli and staphylococci. Group B streptococci also are responsible for approximately 2 to 3 percent of lower urinary tract infections in pregnant women but usually do not cause pyelonephritis. Group B streptococcal urinary tract infection, in turn, is a risk factor for preterm labor. Thomsen et al.^[101] recently reported a study of 69 women at 27 to 31 weeks' gestation who had streptococcal urinary tract infections. Patients were assigned to treatment with either penicillin or placebo. Treated patients had a significant reduction in the frequency of both preterm PROM and preterm labor. Other investigations have confirmed the association between group B streptococcal colonization and preterm labor and preterm PROM. Women with the latter complication who are colonized with group B streptococci tend to have a shorter latent period and higher frequency of chorioamnionitis and puerperal endometritis compared to noncolonized women.^[102]

Diagnosis

The "gold standard" for the diagnosis of group B streptococcal infection is bacteriologic culture. Todd-Hewitt broth or selective blood agar is the preferred medium. Specimens for culture should be obtained from the lower vagina, perineum, and perianal area, using a simple cotton swab. In recent years, considerable research has been devoted to assessment of rapid diagnostic tests for the identification of colonized women. [Table 40-9](#) summarizes the results of several investigations of rapid diagnostic tests. The information in this table is based on the review by Yancey et al.^[103] These

TABLE 40-9 -- RELIABILITY OF RAPID DIAGNOSTIC TESTS FOR GROUP B STREPTOCOCCI

Test	Test Performance			
	Sensitivity (%)	Specificity (%)	PV ⁺ (%)	PV ⁻ (%)
Gram's stain	34100	6070	1333	86100
Growth in starch medium	9398	9899	6598	8999
Antigen detection (coagglutination, latex particle agglutination, enzyme immunoassay)	488 [*]	92100	15100	7699
DNA probe	71	90	61	94

PV⁺, positive predictive value; PV⁻, negative predictive value.

Information in this table is from Yancey et al.^[103]

* Sensitivities for identification of heavily colonized women ranged from 29100%. Specimens were grown in culture for 3.5 hours before DNA probe was used.

authors noted that, although the rapid diagnostic tests had reasonable sensitivity in identifying heavily colonized patients, they had poor sensitivity in identifying lightly and moderately colonized patients. This latter finding severely limits the usefulness of the rapid diagnostic tests in clinical practice.

Prevention of Group B Streptococcal Infection

In the past 20 years, several different strategies have been proposed for the prevention of neonatal group B streptococcal infection.^{[98], [99], [100], [101], [102], [103], [104], [105], [106]} Each strategy has had major imperfections. In 1996, however, the Centers for Disease Control and Prevention (CDC) published a series of recommendations that incorporated the major advantages of previous protocols and minimized some of the more problematic aspects of selected strategies.^[107] The CDC guidelines recommend universal culturing of all patients at 35 to 37 weeks. Samples should be obtained from the lower vagina, perineum, and perianal area and cultured in selective media such as Todd-Hewitt broth. Patients who are colonized should receive intrapartum prophylaxis with one of the antibiotic regimens listed [in Table](#)

[40-10](#) . If culture results are unavailable (e.g., a patient with preterm labor or a patient who failed to register for prenatal care), the patient should receive intrapartum prophylaxis if she has a recognized

TABLE 40-10 -- ANTIBIOTICS WITH ACTIVITY AGAINST GROUP B STREPTOCOCCI

Drug	Dose for Intrapartum Prophylaxis
Ampicillin	2 g initially, then 1 g q4h
Penicillin	5 million units initially, then 2.5 million units q4h
Erythromycin	500 mg q6h
Clindamycin	900 mg q8h
Vancomycin	500 mg q6h

risk factor for early-onset neonatal group B streptococcal infection.

Ideally, antibiotics should be administered at least four hours prior to delivery. DeCueto et al. [\[109\]](#) recently demonstrated that the rate of neonatal group B streptococcal infection was significantly reduced when patients had been treated for at least this period of time. In a large population-based survey, Rosenstein and Schuchat [\[109\]](#) assessed the theoretical impact of the CDC recommendations and showed that a strategy of universal culturing and treatment of *all* colonized patients would prevent 78 percent of cases of neonatal infection. In contrast, only 41 percent of cases were prevented when patients were targeted for prophylaxis only on the basis of risk factors. In addition, Locksmith et al. [\[110\]](#) recently confirmed that the CDC strategy also was of value in decreasing the rate of maternal infection compared to a strategy of only treating on the basis of risk factors.

HEPATITIS

Hepatitis is one of the most common and most highly contagious viral infections. At present, six distinct types of hepatitis virus have been identified: A, B, C, D, E, and G. Each type of hepatitis has a slightly different clinical implication for the pregnant woman and her fetus.

Hepatitis A

Hepatitis A is responsible for approximately 30 to 35 percent of cases of hepatitis in the United States. It is caused by a 27-nm ribonucleic acid (RNA) virus that is a member of the picornavirus family. The virus is transmitted by person-to-person contact through fecal-oral contamination. Poor hygiene, poor sanitation, and intimate personal or sexual contact facilitate transmission. Epidemics frequently result from common exposure to

1315

contaminated food and water. In the United States, individuals at particular risk for hepatitis A are those who have recently immigrated from, or traveled to, developing nations of the world where the disease is endemic.^[111] Drug abusers, gay men, and children in day-care centers also are at increased risk of acquiring hepatitis A.^[112],^[113]

The incubation period of hepatitis A ranges from 15 to 50 days, with a mean of 28 to 30 days. The highest concentration of viral particles is in fecal material. The virus is not normally excreted in urine or other body fluids.

Some patients with hepatitis A are relatively asymptomatic. When symptoms do occur, they usually include malaise, fatigue, anorexia, nausea and vomiting, and right upper quadrant pain. The characteristic physical findings of acute hepatitis A are jaundice, hepatic tenderness, darkened urine, and acholic stools.

The most useful diagnostic test for hepatitis A is detection of IgM-specific antibody. IgM antibody usually is detectable 25 to 30 days following the initial exposure and persists in the serum for up to 6 months. IgG antibody is detectable within 35 to 40 days of exposure and persists indefinitely, thus conferring life-long immunity. In addition, the serum concentration of alanine aminotransferase (ALT), aspartate aminotransferase (AST), and bilirubin are usually moderately to markedly elevated. Liver biopsy is rarely indicated to confirm the diagnosis of viral hepatitis.^[114] When performed, it characteristically shows extensive hepatocellular injury and a prominent inflammatory infiltrate (Fig. 40-6).

Figure 40-6 Photomicrograph of liver biopsy shows characteristic histologic changes of acute viral hepatitis. Note the intense inflammatory infiltrate.

Fortunately, acute hepatitis A is usually a self-limited illness, and only supportive care is required for the vast majority of patients. Recovery is typically complete within 4 to 6 weeks. Fewer than 0.5 percent of affected patients develop fulminant hepatitis, coagulopathy, or encephalopathy. Such individuals clearly require hospitalization; others may be treated as outpatients. Infected patients should be advised of the need for sound nutrition. Physical activity should be limited to prevent upper abdominal trauma. Drugs with potential hepatotoxicity should be avoided. Sexual and household contacts should receive immunoprophylaxis with a single intramuscular dose of immune globulin, 0.02 ml/kg within 2 weeks of exposure. In addition, they also should receive the formalin-inactivated hepatitis A vaccine, in a single intramuscular dose of 0.06 ml. The vaccine is highly immunogenic and is safe for use in pregnancy.^[115],^[116]

As a general rule, unless the pregnant mother becomes severely ill, hepatitis A does not pose a serious risk to the fetus. Perinatal transmission of infection rarely occurs, and a chronic carrier state does not exist. An infant delivered to an acutely infected mother should receive immune globulin to prevent horizontal transmission of infection after delivery.^[114]

Hepatitis B

Approximately 40 to 45 percent of all cases of hepatitis in the United States are caused by hepatitis B virus. Over 300,000 new cases of hepatitis B occur annually,

1316

and about 1 million Americans are chronic viral carriers. The frequencies of acute and chronic hepatitis B in pregnancy are 1 to 2 per 1,000 and 5 to 15 per 1,000, respectively.^[117]

Hepatitis B is caused by a DNA virus, and the intact virus is termed the Dane particle. The virus has three major structural antigens: surface antigen (HBsAg), core antigen (HBcAg), and e antigen (HBeAg). Transmission of hepatitis B occurs primarily as a result of parenteral injection, sexual contact, and perinatal exposure.^[114] Certain population groups have an increased prevalence of hepatitis B: Asians, Eskimos, drug addicts, transfusion recipients, dialysis patients, residents and employees of chronic care residencies, prisoners, and recipients of tattoos.

Following an acute infection caused by hepatitis B virus, less than 1 percent of patients develop fulminant hepatitis and die. Eighty-five to 90 percent experience complete resolution of their physical findings and develop protective levels of antibody. Ten to 15 percent of patients become chronically infected. Of these, 15 to 30 percent subsequently develop chronic active or persistent hepatitis or cirrhosis, and a small percentage develop hepatocellular carcinoma. Chronic liver disease is particularly likely to occur in patients who remain seropositive for HBeAg or who become superinfected with the hepatitis D virus.^[114]

The diagnosis of *acute* hepatitis B is confirmed by detection of the surface antigen and IgM antibody to the core antigen. Identification of HBeAg is indicative of an exceptionally high viral inoculum and active viral replication. Patients who have *chronic* hepatitis B infection have persistence of the surface antigen in the serum and liver tissue. Some individuals, particularly Asians, also remain seropositive for HBeAg.^[114],^[115],^[118]

Patients with acute and chronic hepatitis B infection pose a major threat of transmission to other household members, especially their sexual partner. In addition,

infected women also may transmit infection to their fetus. Perinatal transmission occurs primarily as a result of the infant's exposure to infected blood and genital secretions during delivery. In the absence of immunoprophylaxis for the neonate, perinatal transmission occurs in 10 to 20 percent of women who are seropositive for HBsAg. The frequency of perinatal transmission increases to almost 90 percent in women who are seropositive for both HBsAg and HBeAg. ^[114], ^[115], ^[119]

Fortunately, a combination of passive and active immunization is highly effective in preventing both horizontal and vertical transmission of hepatitis B infection. All individuals who have had household or sexual exposure to another person with hepatitis B infection should be tested to determine if they have antibody to the virus. If they are seronegative, they should immediately receive immunoprophylaxis with hepatitis B immune globulin (HBIG), 0.06 ml/kg IM. They then should receive the hepatitis B vaccination series. Similarly, infants who are delivered to seropositive mothers should receive HBIG, 0.5 ml IM, immediately after birth. They then should begin the hepatitis B vaccination series within 12 hours of birth. At the present time, two recombinant hepatitis B vaccines are available, Recombivax-HB and Engerix-B. ^[114], ^[119] Both products are composed of inactivated portions of the surface antigen and are prepared by recombinant DNA technology. Neither poses a risk of transmission of a bloodborne pathogen, and both are safe for administration during pregnancy to patients at risk.

Neonatal immunoprophylaxis is approximately 85 to 95 percent effective in preventing neonatal hepatitis B infection. In view of the extremely favorable results of immunoprophylaxis, the CDC recently recommended universal hepatitis B vaccination for all infants. ^[120] Dosage recommendations vary depending on the mother's serostatus. Infants born to seronegative mothers require only the vaccine. Infants born to seropositive mothers should receive both the vaccine and hepatitis B immune globulin. Therefore, obstetricians must continue to screen *all* of their patients for hepatitis B at some point during pregnancy. Selective screening on the basis of acknowledged risk factors will fail to identify 30 to 50 percent of seropositive women. ^[114]

Patients infected with hepatitis B virus also may transmit infection to medical and nursing personnel who care for them. Each year, approximately 12,000 American health care workers contract hepatitis B as a result of an occupational injury such as a needle stick or splash to a mucous membrane. Of these, approximately 200 develop fulminant hepatitis and subsequently die. ^[119], ^[121] Health care workers can protect themselves from hepatitis in three principal ways. First, they should be vaccinated for hepatitis B. Second, they should encourage *all* young adults and other individuals who have a specific risk factor to receive the hepatitis B vaccine. Third, they should consistently follow universal precautions to prevent sharp injuries and splashes to exposed mucous membrane or skin surfaces.

Conversely, health care workers who are infected with hepatitis B also pose a risk to others. They, too, must observe safeguards to prevent horizontal transmission of infection to their patients. Infection is most likely to occur as a consequence of direct blood-to-blood exposure during invasive surgical procedures. Unless the patient has documented immunity to hepatitis B, the infected health care worker has an ethical obligation to inform her that some risk of transmission exists. The attendant should then perform the procedure only if the patient explicitly consents. During the actual procedure, the operator must take every precaution to ensure that a sharp injury and resultant blood-to-blood contact do not occur.

Non-A, Non-B Hepatitis

Non-A, non-B hepatitis accounts for 10 to 20 percent of cases of hepatitis in the United States. Non-A, non-B hepatitis occurs in two forms: parenterally transmitted hepatitis C and enterically transmitted hepatitis E.

Hepatitis C

Hepatitis C is a 30- to 38-nm, single-stranded RNA virus that is similar in structure to flaviviruses and pestiviruses. Its incubation period is 5 to 10 weeks. The principal risk factors for hepatitis C are intravenous drug abuse, transfusion, and sexual intercourse. ^[122] In a recent survey by Osmond and co-workers, ^[123] two thirds of a selected population of drug abusers were seropositive for hepatitis C. In a similar survey of patients attending an STD clinic in San Francisco, Weinstock et al. ^[124] found the prevalence of hepatitis C to be 7.7 percent. Approximately 90 percent of all cases of post-transfusion hepatitis are due to hepatitis C, and 2.5 to 15 percent of patients who receive multiple transfusions become infected with this virus. Hepatitis C is particularly likely to result in chronic liver disease. Approximately 50 percent of infected patients develop biochemical evidence of hepatic dysfunction. Of these, about 20 percent subsequently develop chronic active hepatitis or cirrhosis. ^[114]

Approximately 75 percent of patients with hepatitis C are asymptomatic. The diagnosis of hepatitis C infection is confirmed by identification of anti-C antibody. Initial screening for this antibody should be performed with an enzyme immunoassay (EIA). A positive EIA should be followed with a recombinant immunoblot assay (RIBA). The present RIBA is able to detect four specific viral antigens. If at least two antigens are identified, the test is considered positive. If only one antigen is identified, the test is considered indeterminate. The present generation of laboratory assays does not precisely discriminate between IgM and IgG antibody. Moreover, antibody may not be detectable until up to 22 weeks after the onset of clinical illness. Direct detection of antigen also is possible with PCR methodology, although this test is not yet widely available. ^[114]

In a general obstetric population, the prevalence of hepatitis C is 1 to 3 percent. The principal risk factors that identify an obstetric patient at high risk for hepatitis C include concurrent STDs such as hepatitis B and HIV infection, multiple sexual partners, history of recent multiple transfusions, and history of intravenous drug abuse. ^[125] The frequency of perinatal transmission is highly variable. In women who are co-infected with human immunodeficiency virus and/or who have high serum concentrations of hepatitis C RNA, the transmission rate may be as high as 40 percent. In other patients, the rate of transmission is less than or equal to 10 percent. ^[122], ^[126]

At the present time, a vaccine for hepatitis C is not available. Passive immunization with immunoglobulin (0.06 ml/kg IM) should be administered following percutaneous exposure to a person with hepatitis C. The benefit of immunoprophylaxis for the neonate has not been proven in controlled clinical trials. Although interferon- has shown some activity against the virus, relapses occur in 44 to 80 percent of patients within 6 to 12 months of discontinuation of therapy. ^[114]

Hepatitis E

The hepatitis E virus is an RNA virus that is closely related to the calicivirus family. It may present in both an icteric and anicteric form. The virus is transmitted by the fecal-oral route and, therefore, the epidemiology of hepatitis E is similar to that of hepatitis A. The incubation period ranges from 2 to 9 weeks, with a mean of 45 days. ^[127], ^[128] Hepatitis E is rare in the United States but is endemic in developing countries. ^[129] ^[130] ^[131] In these countries, maternal mortality has been alarmingly high, ranging from 10 to 20 percent. Extreme poverty, coexisting medical illnesses, malnutrition, and poor prenatal care are at least partially responsible for the poor maternal prognosis. The only cases of hepatitis E in the United States have occurred in patients who traveled to countries where the disease was endemic. ^[132]

Three new diagnostic tests are available for confirmation of hepatitis E infection. Viral-like particles can be identified in the stool of infected patients by electron microscopy. These particles will agglutinate when combined with serum from the patient. In addition, a fluorescent antibody blocking assay and Western blot assay are now available for use. ^[114], ^[132]

Women with hepatitis E require intensive supportive care. As a general rule, if the mother survives, fetal outcome is not adversely affected. A chronic carrier state does not occur, and perinatal transmission is distinctly uncommon. However, Khuroo et al. ^[133] recently described eight mothers who developed hepatitis E in the third trimester. Six of their infants had clinical and/or serologic evidence of hepatitis E. Two infants had hypothermia and hypoglycemia and died within 24 hours of birth.

Hepatitis D

Hepatitis D, or delta hepatitis, is caused by an RNA virus that is dependent on co-infection with the hepatitis B virus for replication. Hepatitis D has an external coat of hepatitis B surface antigen and an internal delta antigen that is encoded by its own genome. The epidemiology of hepatitis D is essentially identical to that of hepatitis B. ^[134]

Acute hepatitis D occurs in two forms: *co-infection* and *superinfection*. Co-infection represents the simultaneous occurrence of acute hepatitis B and D. It is usually a self-limited disorder and rarely leads to chronic liver disease. Superinfection occurs when *acute* hepatitis D develops in a patient who is a *chronic* hepatitis B carrier. Approximately 20 to 25 percent of patients with chronic hepatitis B ultimately become superinfected with the delta virus, and about 80 percent of these individuals subsequently develop chronic hepatitis. Of those who have chronic hepatitis, 70 to 80 percent develop cirrhosis and portal hypertension and, unfortunately, almost 25 percent ultimately die of hepatic failure. [\[134\]](#) , [\[135\]](#)

The clinical manifestations of acute hepatitis D are similar to those of any acute viral hepatitis. The diagnosis of *acute co-infection* can be confirmed by detection of delta antigen in hepatic tissue or serum and IgM-specific antibody in serum. In addition, the tests for HBsAg and HBcAb-IgM are positive. In patients with acute *superinfection*, serologic tests reflect acute hepatitis D (positive antigen, positive IgM antibody) and chronic hepatitis B infection (positive surface antigen, positive HBcAb-IgG). Patients with *chronic* hepatitis D usually have detectable serum levels of IgG-specific antibody for the delta virus and are seropositive for HBsAg. Unfortunately, IgG antibody does not eradicate the delta viremia, and the antigen still can be identified in serum and hepatic tissue. [\[114\]](#) , [\[134\]](#) , [\[135\]](#)

Patients with acute hepatitis D should receive the general supportive care outlined for hepatitis A. Patients with chronic infection should be monitored periodically for worsening hepatic function or coagulopathy. At present, there is no specific antiviral agent or immunotherapy that is curative for either acute or chronic delta infection. Perinatal transmission of hepatitis D virus has been reported. Fortunately, transmission is uncommon because the neonatal immunoprophylaxis for hepatitis B is almost uniformly effective against hepatitis D. [\[114\]](#)

Hepatitis G

Hepatitis G (HGV or GBV-C) is a recently discovered single-stranded RNA virus that is related to hepatitis C. It can cause acute and persistent infections in humans, but the disease is usually mild, and the clinical significance of infection is uncertain. Persistent infection is usually not associated with biochemical evidence of ongoing hepatic injury. Hepatitis G is more prevalent, but less virulent, than hepatitis C. Co-infection with hepatitis A, B, and C and HIV is common. A chronic carrier state has been described, and perinatal transmission has been documented. Hepatitis G nucleic acid can be detected by PCR, and an envelope protein can be identified by enzyme-linked immunosorbent assay (ELISA). At present, no immunoprophylactic agent or antiviral chemotherapy for hepatitis G is available. [\[136\]](#)

HERPES SIMPLEX VIRUS INFECTION

Epidemiology

Herpes simplex virus (HSV), a double-stranded DNA virus, is transmitted by direct, intimate contact. Following the initial infection, the virus remains dormant in neuronal ganglia and may reactivate at later times. Two strains of the virus have been identified: HSV-1 and HSV-2. The former causes primarily oropharyngeal infection and the latter, genital tract infection. Approximately 0.5 to 1.0 percent of women have an overt herpetic infection during pregnancy. About 400 cases of neonatal herpes occur annually in the United States, and the estimated incidence of neonatal infection ranges from 1 in 7,500 to 1 in 30,000 live births. ^[137], ^[138]

HSV infections are classified as *primary*, *nonprimary first episode*, and *recurrent* on the basis of historical and clinical findings and serologic testing. ^[137] ^[138] ^[139] ^[140] [Table 40-11](#) summarizes the criteria for each diagnosis. Approximately 20 to 40 percent of Americans are seropositive for HSV. Up to 80 percent of these individuals do not have a history of an overt primary infection.

Clinical Manifestations

The onset of HSV infection is usually heralded by a prodrome of neuralgias, paresthesias, and hypesthesias, followed by an eruption of painful vesicles in either the orolabial area or genitalia. The vesicles typically rupture, forming a shallow-based ulcer (Fig. 40-7) (Figure Not Available), and then form a dry crust. Some vesicles become secondarily infected and evolve into frank pustules. Ultimately, the vesicles heal without scarring. ^[137], ^[138]

In patients experiencing a primary HSV infection,

TABLE 40-11 -- CLASSIFICATION OF HERPES SIMPLEX VIRUS INFECTION

Classification	Criteria
Primary	First clinical infection No preexisting antibody
Nonprimary, first episode	No history of genital tract infection Positive antibody for the other strain of the virus (HSV1 or HSV2)
Recurrent	Prior history of clinical infection Positive antibody for the same strain of virus causing the present infection

Figure 40-7 (Figure Not Available) Ulcerated lesions (arrows) characteristic of herpes simplex infection. (From Duff P, Christian JS, Yancey MK: *Infections associated with pregnancy*. In Coulam CB, Faulk WP, McIntyre JA [eds]: *Immunologic Obstetrics*. New York, WW Norton & Co, 1992, p 578, with permission.)

vesicles may be present for up to 3 weeks. Systemic symptoms may be moderately severe, and local complications such as urinary retention may occur. In recurrent infections, overt vesicles are fewer in number and less painful and typically persist for less than or equal to 14 days. [Table 40-12](#) compares the incubation period and clinical features of primary and recurrent HSV infection. ^[137]

In some patients, particularly those who are immunocompromised, HSV infection may be widely disseminated, affecting extensive areas of skin, mucosal membranes, and visceral organs. HSV also may cause a severe ocular infection, meningitis, encephalitis, and ascending myelitis.

Diagnosis

Several laboratory tests may be used to confirm the diagnosis of HSV infection. Cytologic preparations show characteristic multinucleated giant cells and intranuclear inclusions. ^[137], ^[138] PCR assays are extremely sensitive

TABLE 40-12 -- COMPARISON OF PRIMARY VERSUS RECURRENT HERPES SIMPLEX VIRUS INFECTION

Stage of Illness	Type of Infection	
	Primary	Recurrent
Incubation period and/or prodrome (days)	210	12
Vesicle, pustule (days)	6	2
Wet ulcer (days)	6	3
Dry crust (days)	8	7
Total	2230	1314

in detecting low concentrations of viral DNA, but such assays are not yet widely available. ^[141] Serology is especially useful in classifying the initial herpetic episode as *primary* versus *nonprimary first episode*. ^[137], ^[138] However, serologic testing is rarely indicated in patients who experience recurrent HSV infection.

Until the advent of PCR, viral isolation in tissue culture was considered the gold standard for confirmation of diagnosis. Viral isolation is usually possible within 72 to 96 hours of inoculation of the tissue culture. The highest rate of isolation is achieved when clinical specimens are obtained from fresh vesicles or pustules ([Table 40-13](#)). Vesicular fluid should be aspirated with a fine needle into a tuberculin syringe. Ulcers should be scraped vigorously with a wooden spatula or cotton-tipped applicator. ^[137], ^[138]

Obstetric and Perinatal Complications

Severe primary HSV infection has been associated with spontaneous abortion, preterm delivery, and intrauterine growth restriction. Isolated case reports also have

TABLE 40-13 -- FREQUENCY OF ISOLATION OF HERPES SIMPLEX VIRUS FROM SKIN LESIONS

Type of Lesion	Approximate Frequency of Viral Isolation
Vesicle	90%
Pustule	85%
Ulcer	70%
Crust	25%

1320

been published documenting in utero infection even in the presence of intact membranes.^{[137], [138], [142]} However, the greatest risk to the fetus occurs when over HSV infection is present at the time of labor. In this situation, the principal mechanism of infection is direct contact with infected vesicles during the process of vaginal birth. The frequency of neonatal infection clearly is dependent on whether the mother has a primary or recurrent HSV infection. In the setting of a primary infection, the viral inoculum in the genital tract is high, and maternal antibody is not present. Approximately 40 percent of neonates delivered vaginally to such women will become infected. In the absence of antiviral chemotherapy, almost half of these infants die, and 35 to 40 percent experience severe neurologic morbidity such as chorioretinitis, microcephaly, mental retardation, seizures, and apnea. In women who have recurrent *symptomatic* HSV infection, the risk of neonatal infection following vaginal delivery is 5 percent or less. In women who have a history of recurrent HSV infection but no prodromal symptoms or overt lesions, the risk of neonatal infection with vaginal delivery is less than or equal to 1 in 1,000.^{[137], [138], [140], [143], [144], [145]}

Neonatal HSV infection may take many forms. In its simplest manifestation, it may appear as a localized abscess at the site of attachment of a scalp electrode or as isolated mucocutaneous lesions. In its more severe forms, neonatal HSV infection may present as widely disseminated mucocutaneous lesions, visceral infection, meningitis, and encephalitis. In such instances, mortality may approach 50 to 60 percent, and up to half of the survivors may have persistent morbidity.^{[137], [138], [140], [142], [143], [146]}

Management during Pregnancy

Clinical management of HSV infection has changed dramatically in recent years. For several reasons, surveillance cultures of the genital tract in patients with a history of HSV infection have been ineffective in preventing neonatal HSV infection.^{[147], [148], [149]} First, cultures are not perfectly sensitive. In a recent report, Cone et al.^[141] detected HSV DNA by PCR in 9 of 100 asymptomatic pregnant women who had negative viral cultures. Second, culture results are not always readily available at the time a patient is admitted for delivery. Third, most children with neonatal HSV infection are actually born to women who do not have a history of prior infection and who, hence, would not be targeted for surveillance cultures.^{[145], [147], [148], [149], [150]}

Accordingly, the following simplified guidelines have now been recommended by the Infectious Diseases Society for Obstetrics and Gynecology and endorsed by the American College of Obstetricians and Gynecologists.^{[139], [144]} At the time of the patient's initial prenatal appointment, she should be questioned about a prior history of HSV infection. If her history is positive, she should be screened for other STDs such as gonorrhea, chlamydia, syphilis, hepatitis B and C, and HIV infection. When the patient ultimately is admitted for delivery, she should be asked about prodromal symptoms and examined thoroughly for cervical, vaginal, and vulvar lesions. If no prodromal symptoms or overt lesions are present, vaginal delivery should be anticipated. If symptoms or lesions are present, cesarean delivery should be performed. Cesarean section is indicated even in the presence of ruptured membranes, since operative delivery significantly decreases the size of the viral inoculum to which the infant is exposed.

Mothers with symptomatic infection do not need to be isolated from their infants or other patients. They should wash their hands carefully before handling the infant and shield the baby from any contact with vesicular lesions. Breast-feeding is permissible as long as no skin lesions are present on the breast.

In addition to the guidelines outlined above, clinicians should be aware of possible indications for use of antiviral therapy during pregnancy. Immunocompromised patients with disseminated infections require hospitalization for treatment with intravenous acyclovir. Oral acyclovir (400 mg three times daily for 5 to 10 days) should be considered for immunocompetent patients who have severe herpetic infection (e.g., prominent systemic symptoms and urinary retention), especially near term.^[151] Alternative regimens include valacyclovir (1,000 mg PO twice daily) or famciclovir (125 mg PO twice daily). Prophylactic treatment with oral acyclovir (400 mg twice daily) or valacyclovir (1,000 mg daily) may be appropriate in women with frequent recurrent infections in pregnancy, particularly near term.^{[151], [152]}

Acyclovir is classified by the FDA as a pregnancy category C drug. To date, the Acyclovir Registry has reported no increase in the frequency of adverse effects in infants exposed in utero to this antiviral agent.^{[153], [154]} Valacyclovir and famciclovir are classified as pregnancy category B.

HUMAN IMMUNODEFICIENCY VIRUS INFECTION

Epidemiology

HIV infection is caused by a ribonucleic acid (RNA) retrovirus. The principal viral strain responsible for disease in the United States is HIV-1. HIV-2 is a related strain that is endemic in Africa, Portugal, and France. HIV-2 infection is uncommon in the United States except

1321

in individuals who have traveled to endemic areas or had sexual contact or shared needles with persons from endemic areas. ^[155], ^[156]

HIV has a unique propensity to attack and infect CD4 lymphocytes. Upon entering the host cell, the virus uses its reverse transcriptase enzyme to synthesize DNA from RNA. It then integrates the DNA into the host genome. Subsequently, as the host cell replicates its nucleic acid, it also unwittingly replicates new viral nucleic acid. As viral replication continues, the CD4 lymphocyte is progressively weakened, and ultimately destroyed, thus rendering the host susceptible to an extensive variety of opportunistic infections and malignancies. ^[155]

HIV infection occurs in a continuum that can be divided arbitrarily into four stages. Stage 1 of the disease is the acute retroviral infection that develops several weeks after exposure to the virus. In this stage, the patient has symptoms similar to mononucleosis. Over a period of several weeks, the acute episode resolves, and the patient enters the latent phase of illness. During the latent phase, the patient is asymptomatic, but viral replication occurs, albeit slowly, in lymphatic tissue. The duration of the latent phase is approximately 5 to 10 years. Inexorably, the viral inoculum progressively increases, and the patient enters stage 3 of the disease. This stage is characterized by mild to moderately severe symptoms and debilitating, but usually not life-threatening, opportunistic infections. Ultimately, the patient develops acquired immunodeficiency syndrome (AIDS). Once symptomatic HIV infection develops, the patient's life expectancy is usually 3 to 5 years. ^[157]

At the present time, almost 500,000 Americans have AIDS, or have died from AIDS. An additional 1 million are infected with the virus but are not yet in the terminal stage of their illness. In the United States, approximately 15 to 20 percent of all cases of HIV infection occur in women. Almost 75 percent of infected women are black or Hispanic. In women, the two most important mechanisms of HIV infection are intravenous drug abuse and heterosexual contact with a high-risk male. In the general obstetric population in the United States, the frequency of HIV infection is approximately 1 per 1,000. However, in some inner city populations, the prevalence of infection is as high as 1 to 1.5 percent. ^[158] ^[159] ^[160]

Heterosexual transmission is increasing in importance as a mechanism of spread of HIV infection. ^[161] Several sexual practices have been shown to substantially increase the risk of transmission of infection. Of these, the most important is unprotected intercourse with multiple partners. Receptive anal intercourse is a particularly dangerous practice because the columnar epithelium of the anus and rectum is more susceptible to trauma than the stratified squamous epithelium of the vagina. The presence of other STDs that cause genital ulcers, such as herpes, syphilis, and chancroid, also is an important risk factor for HIV infection. Concurrent use of illicit intravenous drugs and crack cocaine and contact with a noncircumcised male also are independent risk factors for HIV infection.

Clinical Manifestations

Symptomatic patients with HIV infection typically have fever, malaise, fatigue, anorexia, nausea, vomiting, diarrhea, weight loss, and generalized lymphadenopathy. Neurologic manifestations may be quite prominent and debilitating, specifically peripheral neuropathy and dementia. These neurologic manifestations result both from direct injury of the central nervous system (CNS) by HIV and the effects of opportunistic infections such as toxoplasmosis. ^[155], ^[157]

Opportunistic infections, of course, are the hallmark of HIV infection. ^[162] Among the most common are *Pneumocystis carini* pneumonia, mycobacterium avium complex, pulmonary tuberculosis, toxoplasmosis, candidiasis, and cytomegalovirus infection. Genital herpes; hepatitis B, C, and D; and syphilis are common concurrent sexually transmitted diseases. Unusual malignancies occur with disturbing regularity in patients with HIV infection. ^[163] The two most common are Kaposi's sarcoma (rare in women, extremely common in homosexual men) and non-Hodgkin's lymphoma. The latter disorder has an alarming tendency for early invasion of the central nervous system.

Diagnosis

The diagnosis of HIV infection may be confirmed by direct culture of virus from peripheral blood lymphocytes and monocytes. The diagnosis also can be established by detection of viral antigen by PCR. Infected patients usually have a decreased number of CD4 cells and an inverted CD4:CD8 ratio. Serum immunoglobulin levels also are elevated. ^[164]

The principal diagnostic test at present is identification of virus-specific antibody. ^[164] The initial serologic screening test should be an enzyme immunoassay (EIA). This test is highly sensitive, inexpensive, and readily suited for screening large numbers of patients. If the initial EIA test is positive, the test should be repeated. If the second test is positive, a confirmatory Western blot assay or immunofluorescent antibody assay (IFA) should be performed. The Western blot test detects specific viral antigens and is considered positive when any two of the following three antigens are identified: p24 (viral core), gp-41 (envelope), and gp-120/160 (envelope). If a patient has two positive EIAs, followed by a

1322

confirmatory Western blot or IFA, the likelihood of a false-positive test is less than 1 in 10,000. ^[165], ^[166]

As a general rule, patients in the United States should be routinely tested only for HIV-1 infection. Testing for HIV-2 infection is indicated if the patient has had sexual contact, or has shared needles, with a partner from an area of the world where HIV-2 infection is endemic. Testing also should be done if the patient has recently traveled to an endemic area or received a blood transfusion or nonsterile injection in such a locale. In addition, testing also should be performed in individuals who have clinical evidence of HIV infection, but in whom serologic tests for HIV-1 are nonconfirmatory. Screening for HIV-2 infection may be done with a specific EIA and Western blot. In addition, a commercial EIA is now available that simultaneously screens for HIV-1 and HIV-2. ^[156]

Perinatal Transmission

Approximately 90 percent of all cases of HIV infection in children are due to perinatal transmission. Perinatal transmission may occur as a result of hematogenous dissemination, but it is most likely to result from intrapartum exposure to infected maternal blood and genital tract secretions. ^[157], ^[159] The frequency of vertical transmission of HIV infection varies from a low of 5 to 10 percent to a high of 50 to 60 percent. The average in most investigations has been 20 to 30 percent. ^[167], ^[169] Factors that increase the likelihood of vertical transmission are summarized in [Table 40-14](#).

Obstetric Complications

Studies of obstetric outcome in patients with HIV infection are difficult to interpret because affected patients have so many confounding conditions that may complicate pregnancy. Such conditions include drug addiction, poor nutrition, limited access to prenatal care, poverty, and concurrent sexually transmitted diseases. When investigators have tried to control for these confounding variables, infected women appear to be at increased risk for several major complications: preterm delivery, preterm PROM, intrauterine growth restriction, increased perinatal mortality, and postpartum endometritis. Pregnancy per se probably does not significantly accelerate the progression of HIV infection. ^[157], ^[159]

Management

All obstetric patients should be offered voluntary screening for HIV infection at the time of their first prenatal appointment. Selective screening only in patients presumed to be high risk will fail to identify approximately 50 percent of seropositive women. ^[169] Infected women should be counseled about the risk of perinatal transmission of infection and about potential obstetric complications. They should then be offered the option of pregnancy termination. In addition, arrangements should be made for patients to obtain assistance from appropriate support personnel such as social workers, nutritionists, and psychologists. Patients also should be advised to discontinue smoking, since this practice appears to accelerate the course of the disease. ^[157], ^[159]

Infected patients should be screened for other sexually transmitted diseases such as gonorrhea, chlamydia, herpes, hepatitis B and C, and syphilis. They should be tested for antibody to cytomegalovirus and toxoplasmosis because both of these infections can cause severe chorioretinitis and central nervous system disease, and both are amenable to treatment with antimicrobial agents. Patients also should have a tuberculin skin test; if this test is positive, a chest x-ray should be performed

TABLE 40-14 -- FACTORS THAT INCREASE THE RISK OF VERTICAL TRANSMISSION OF HIV INFECTION

Risk Factor	Presumed Mechanism
HIV-1 vs. HIV-2	Risk is much greater with HIV-1, presumably as a result of greater virulence of HIV-1
History of previous child with HIV infection	Higher viral inoculum in mother
Mother with AIDS	Higher viral inoculum, decreased immunocompetence of the mother
Preterm delivery	Decreased neonatal immunocompetence
Decreased maternal CD4 count	Impaired maternal immunity
High maternal viral load	Higher viral inoculum
Firstborn twin	With vaginal delivery, firstborn twin has more prolonged exposure to infected blood and genital tract secretions
Chorioamnionitis	Placental vasculitis facilitates hematogenous dissemination of virus
Vaginal delivery, particularly in the setting of prolonged rupture of membranes	Greater fetal contact with infected blood and genital secretions
Intrapartum blood exposure (e.g., episiotomy, vaginal laceration, forceps delivery)	Greater fetal contact with infected blood and genital secretions

1323

to identify active pulmonary disease. In addition, patients should receive vaccinations for hepatitis A and B, pneumococcal infection, and viral influenza. They should have a Papanicolaou smear to determine if cervical intraepithelial neoplasia is present. They also should have periodic assays for CD4 count and viral load (HIV RNA-PCR) to assess the state of their immune system and the progression or remission of their disease.

Patients also should receive treatment with antiviral chemotherapy. The rationale for treatment is twofold: prevention of perinatal transmission of HIV infection and improvement in the course of the mother's disease. Until recently, treatment guidelines in pregnancy focused primarily on the first objective and were based on the landmark study of the AIDS Clinical Trials Group (ACTG) Protocol 076. ^[170] This study was conducted in the United States and France and included a select group of obstetric patients: asymptomatic woman beyond the first trimester of pregnancy who had CD4 counts greater than 200/mm³ and who had not previously been treated with zidovudine. Women were randomized to receive placebo or zidovudine (100 mg PO five times daily) during the antepartum period. Patients then received intravenous zidovudine during labor, in a loading dose of 2 mg/kg over 1 hour, followed by 1 mg/kg/h throughout labor. Following delivery, infants in the treatment group received oral zidovudine (2 mg/kg every 6 hours) for six weeks postpartum. At the first interim data analysis, information was available for 363 infants. The independent safety monitor recommended that the study be discontinued because the frequency of perinatal transmission was 25.5 percent in the placebo arm versus 8.3 percent in the active treatment arm, representing a 67 percent reduction in the risk of vertical transmission ($p = 0.00006$).

Several other recent studies in developing nations have shown that shorter courses of inexpensive oral antiretroviral medications also are effective in decreasing the rate of perinatal transmission of HIV infection. One investigation was conducted in *non-breast-feeding* women in Thailand. ^[171] Patients received 300 mg of zidovudine twice daily, beginning at 36 weeks, and were treated with the same oral dose every 3 h during labor. The rate of perinatal transmission was reduced by 50 percent. In a similar trial in *breast-feeding* women in Cote d'Ivoire, perinatal transmission was reduced by 37 percent at 6 months postpartum.

In another investigation in sub-Saharan Africa (PETRA Trial), ^[172] patients received zidovudine (300 mg twice daily) plus lamivudine (150 mg twice daily) from 38 weeks until delivery. They also received zidovudine (200 mg) every 3 hours during labor, and the mother and baby were treated with combined therapy for 1 week postpartum. The rate of perinatal transmission was reduced by 51 percent in treated patients.

Finally, in the HIVNET 012 trial conducted in Kampala, Uganda, ^[173] patients were randomly assigned to treatment with nevirapine (200 mg PO at the onset of labor followed by oral treatment of the baby with a single dose of 2 mg/kg within 72 hours of birth) versus zidovudine (600 mg PO at the onset of labor and 300 mg every 3 hours until delivery followed by oral treatment of the baby with 4 mg/kg for 7 days after birth). Ninety-nine percent of the babies were breast-fed. At 16 weeks after delivery, the rates of neonatal infection were 25 percent in the zidovudine group and 13 percent in the nevirapine group ($p = 0.0006$). Both regimens were well tolerated and very inexpensive compared to the treatment regimen used in the ACTG 076 trial.

In addition to these new findings related to intrapartum chemoprophylaxis, several treatment trials in nonpregnant patients have demonstrated a distinct advantage for multiagent regimens compared to monotherapy with respect to suppression of viral load, elevation of CD4 count, improvement in quality of life, and prolongation of disease-free interval. Accordingly, there is a growing consensus that these new treatment options should be offered to pregnant women as well. ^[174]

[Table 40-15](#) lists the drugs most commonly used for treatment of HIV infection in pregnant women. Pending new information from ongoing trials, a reasonable approach is treatment with two nucleoside reverse transcriptase inhibitors and a protease inhibitor. ^[174] In view of the favorable results of the ACTG 076 study, one of the nucleosides should be zidovudine, administered in a dose of 300 mg orally, twice daily. Lamivudine (150 mg PO twice daily) also has an exceptionally good safety and efficacy profile. These two agents can be administered in a convenient combination formulation, Combivir, twice daily. Of the current protease inhibitors, the one

with the best combination of safety, efficacy, and expense is nelfinavir (750 mg PO three times daily).

Other combinations of agents certainly have proved effective in studies in nonpregnant patients and should be considered if the regimen outlined above is ineffective or causes adverse effects.^[174] In addition, pregnant women should be advised that the complete range of effects of these new drugs on the fetus has not been delineated.

In addition to specific antiviral chemotherapy, patients also should receive prophylaxis against the most common opportunistic infections. [Table 40-16](#) summarizes selected guidelines for use of antibiotic prophylaxis in HIV-infected patients.^[175]

When the physician is delivering the HIV-positive patient, every effort must be made to avoid instrumentation that would increase the neonate's exposure to infected maternal blood and secretions. Specifically, whenever feasible, the fetal membranes should be left

TABLE 40-15 -- AGENTS MOST COMMONLY USED FOR TREATMENT OF HIV INFECTION IN PREGNANT WOMEN

Agent	Usual Adult Dose	Remarks	Cost of 30-Day Treatment
Nucleoside analogs			
Lamivudine (3TC, Epivir)	150 mg bid	Adverse effects are similar to those of zidovudine, but are less frequent. Drug is eliminated by renal excretion.	\$230.00
Zidovudine (Retrovir)	300 mg bid	Main adverse effect is marrow suppression.	\$287.00
Nonnucleoside reverse transcriptase inhibitors			
Nevirapine (Viramure)	200 mg bid	Most common adverse effect is rash. If the rash is extensive, the drug should be permanently discontinued. Hepatitis is a rare side effect.	\$248.00
Protease inhibitors			
Indinavir (Crixivan)	800 mg q8h	Well tolerated. Most serious adverse effect is nephrolithiasis. Most common side effect is GI upset. Less expensive than Ritonavir.	\$450.00
Nelfinavir (Viracept)	750 mg tid or 1250 mg in am and 1000 mg in pm	Clinical efficacy data are limited. Most common adverse effects are diarrhea, fatigue, poor concentration.	\$557.00

GI, gastrointestinal.

intact until delivery. In addition, application of the fetal scalp electrode and scalp pH sampling should be avoided.

Several recent reports have investigated the role of elective cesarean delivery as a method for reducing the rate of perinatal transmission of HIV infection. Perhaps the two of greatest interest are the reports from the French Perinatal Cohort^[176] and the International Perinatal HIV Infection Group.^[177] In the former investigation, in women receiving monotherapy with zidovudine, elective cesarean delivery before the onset of labor or rupture of membranes was associated with a lower rate of transmission than emergent cesarean section or vaginal delivery (0.8 percent vs. 11.4 percent vs. 6.6 percent, $p = 0.002$). The latter report was a meta-analysis of 15 prospective cohort studies from North America and Europe that included 8,533 mother-child pairs. The vast majority of women received monotherapy with zidovudine. Elective cesarean delivery was associated with approximately a 50 percent decrease in the rate of perinatal transmission of HIV infection (odds ratio [OR], 0.43; 95 percent confidence interval [CI], 0.33 to 0.56). When both elective cesarean delivery and antiretroviral therapy were used, the rate of transmission was reduced

TABLE 40-16 -- PROPHYLACTIC ANTIBIOTIC REGIMENS FOR COMMON OPPORTUNISTIC INFECTIONS*

Condition	Indication for Prophylaxis	Antibiotic Regimen
<i>Pneumocystis carini</i> pneumonia	Prior infection or CD4 < 200/mm ³	TMP-SMX 1 DS tablet qd indefinitely
Toxoplasmic encephalitis	CD4 < 100/mm ³ + serology	TMP-SMX 1 DS tablet qd indefinitely
Tuberculosis	+PPD > 5 mm	INH; 300 mg qd, plus pyridoxine, 50 mg qd X 12 mo
	No active disease on chest x-ray	
Disseminated infection with mycobacterium avium complex (MAC)	CD4 < 50/mm ³	Azithromycin 1200 mg weekly
Cryptococcosis	CD4 < 50/mm ³	Routine prophylaxis not recommended
		Patients who have been treated for an acute cryptococcal infection should receive fluconazole, 200 mg qd, indefinitely

TMP-SMX, trimethoprim-sulfamethoxazole; INH, isoniazid.

* Recommendations in this table are based on information presented in Centers for Disease Control and Prevention.^[178]

by 87 percent, and the actual frequency of transmission was 2 percent (95 percent CI, 0.0 to 4.0).

Although the results of these studies are impressive, they must be interpreted with caution. Neither study was prospective or randomized with respect to mode of delivery. Patients were not stratified according to viral load. Moreover, very few of the patients were treated with the highly active multiagent regimens currently recommended.

In light of the information presented above, elective cesarean appears to be indicated for the following patients: those receiving no antiviral treatment, those receiving monotherapy alone, and those receiving combination chemotherapy but who have detectable viral loads. Women receiving optimal combination chemotherapy who have undetectable viral loads should be advised that it is uncertain whether elective cesarean delivery offers an additional protective effect against perinatal transmission.^[178]

In the postpartum period, the mother should be advised to avoid any contact between her body fluids and an open area on the skin or mucous membranes of the neonate. She also should be cautioned against breast-feeding. Initially, the risk of HIV transmission through breast milk was regarded as low. Recently, however, a report by Dunn et al.^[179] called this original assumption into serious question. In this investigation of African women, the authors divided subjects into two groups,

those who acquired HIV infection postnatally and those who were infected prenatally. In the former group, 29 percent of breast-fed infants became infected. In the latter group, the added risk of infection from breast-feeding (i.e., above the inherent risk associated with perinatal transmission) was 14 percent. Finally, infected patients should be urged to use secure contraception and adopt responsible sexual practices to prevent spread of infection to their partners.

PARVOVIRUS INFECTION

Epidemiology

Human parvovirus B19 is a member of the Parvoviridae family. It is a single-stranded DNA virus that codes for only a small number of proteins. Its reproductive capability is limited and, therefore, it can only replicate in cells that are dividing rapidly. ^[180], ^[181] The virus is distributed worldwide, and infection may occur in both a sporadic and epidemic form. Humans are the only known host for the B19 virus. The organism is transmitted by respiratory droplets and infected blood components, and the incubation period is 4 to 20 days. Serum and respiratory secretions become positive for the virus several days before clinical symptoms develop. Once symptoms appear, respiratory secretions and serum are usually free of the virus. ^[180], ^[181] Prevalence of antibody to parvovirus increases with age. In children age 1 to 5 years, approximately 2 to 15 percent are seropositive for antibody. In adolescents and adults, the seroprevalence increases to more than 60 percent. ^[180], ^[181]

Clinical Manifestations

The most common clinical presentation of parvovirus infection is *erythema infectiosum* or *fifth disease*. This illness typically occurs in elementary school and day-care populations in the late winter and early spring. Patients usually have low-grade fever, malaise, adenopathy, and polyarthritides affecting the hands, wrists, and knees. In addition, they have a characteristic pruritic, erythematous "slapped cheek" rash on the face and a finely reticulated erythematous rash on the trunk and extremities (Fig. 40-8). The rash may wax and wane over a period of several months in response to stress, exercise, sunlight, or bathing. Erythema infectiosum is a

Figure 40-8 Characteristic "slapped cheek" rash of erythema infectiosum (A). Note lace-like rash on upper extremity (B).

1326

self-limited illness. Complete recovery is the norm, and serious long-term sequelae rarely occur. ^[180], ^[181]

The second major clinical presentation of parvovirus infection is *transient aplastic crisis*. This disorder occurs almost exclusively in individuals who have an underlying hemoglobinopathy and results from viral infection of the bone marrow, with resultant destruction of red blood cell precursors. Affected patients have prodromal symptoms similar to erythema infectiosum. One to 7 days after the onset of the prodrome, signs of anemia develop, such as pallor, weakness, and lethargy. Patients with transient aplastic crisis usually do not have a skin rash. Full recovery without sequelae is the usual outcome, provided the patient receives appropriate supportive care. ^[180], ^[181]

Fetal Infection

The risk that a susceptible mother will acquire infection from an infected household member is 50 to 90 percent. ^[180] ^[181] ^[182] The risk of transmission in a day-care setting or classroom is lower, ranging from 20 to 30 percent. ^[182] ^[183] ^[184] Published information regarding subsequent risk of transmission to the fetus is based on one principal end point, namely, fetal hydrops. Hydrops appears to result primarily from viral infection of fetal erythroid stem cells, leading to an aplastic anemia and high-output congestive heart failure. Hydrops may also be due, at least in part, to direct infection of the myocardium by the virus.

The reported frequency of fetal hydrops or other adverse outcome following maternal infection has varied from 0 to 38 percent, with most authors citing frequencies in the range of 5 to 15 percent. ^[180] ^[181] ^[182], ^[185] ^[186] ^[187] The risk of fetal infection is greatest when maternal illness occurs in the first trimester, as noted in Table 40-17. ^[182] Parvovirus does not typically cause a structural defect in the fetus.

Diagnosis of Maternal Infection

Parvovirus can be grown in tissue culture consisting of fresh bone marrow supplemented with erythropoietin. The

Infection within 7120 days	+	+

virus also can be detected by DNA hybridization assays using serum, leukocytes, respiratory secretions, urine, or tissue. In addition, infection can be documented by characteristic histologic changes in infected cells, such as eosinophilic inclusion bodies, margined chromatin, and direct detection of viral particles by electron microscopy. ^[180] ^[181] ^[182] However, the mainstay of laboratory diagnosis is serologic testing. Antibody to parvovirus can be measured by ELISA, RIA, and Western blot. IgM-specific antibody is usually positive by the third day after symptoms develop. It typically disappears within 30 to 60 days, but may persist for up to 120 days. IgG antibody is detectable by the seventh day of illness and persists for life. ^[180] ^[181] ^[182] Table 40-18 summarizes the interpretation of serologic tests for parvovirus.

Diagnosis of Fetal Infection

The most valuable test for diagnosis of fetal parvovirus infection is ultrasound. Severely affected fetuses typically have evidence of hydrops. Since the incubation period of the virus may be longer in the fetus than in the child or adult, the patient should be followed with serial ultrasound examinations for 8 to 10 weeks after her acute illness. If the fetus shows no signs of hydrops during this observation period, additional diagnostic studies are unnecessary. If hydropic changes appear and the fetus is at an appropriate gestational age, cordocentesis is indicated (see below). ^{[180] [181] [182] , [188]}

Maternal Management

Following a documented exposure to parvovirus, the mother should immediately have a serologic test to determine if she is immune or susceptible to the virus. If preexisting IgG antibody is present, the patient can be reassured that second infections are extremely unlikely and that her fetus is not at risk. If the patient is susceptible, she should have a repeat serologic test in approximately 3 weeks to determine if she has seroconverted. If seroconversion is detected, serial ultrasound examinations

1327

should be performed over the ensuing 8 to 10 weeks to evaluate fetal well-being.

No antiviral agent or vaccine is presently available for treatment of parvovirus infection, but patients with erythema infectiosum rarely need more than simple supportive care. Patients with transient aplastic crisis may require red cell transfusion during the acute phase of their illness. As a general rule, isolation of patients with erythema infectiosum is not of value in reducing transmission of infection, since spread by respiratory droplets has already occurred by the time the patient has clear signs of clinical disease. Conversely, if patients with transient aplastic crisis are isolated early in the course of their illness, horizontal transmission to other susceptible individuals may be reduced. ^{[180] [181] [182]}

Fetal Management

If fetal hydrops is documented by ultrasound, cordocentesis should be performed if technically feasible. Fetal blood should be collected for determination of hematocrit and detection of IgM-specific antibody. ^[188] Although case reports have described spontaneous resolution of hydrops in infected fetuses, criteria predictive of such a good outcome are not well established. ^{[189] , [190]} Therefore, if severe anemia is present, intrauterine transfusion should be performed. ^{[191] , [192]} Fairley et al. ^[192] recently reported the outcome of 66 fetuses with hydrops due to congenital parvovirus infection. In 26 cases, the fetus was dead at the time of initial assessment, and in two cases, therapeutic abortion was performed. Twelve of the 38 fetuses who were alive at the time hydrops was diagnosed had intrauterine transfusions; 3 of the 12 died. Twenty-six fetuses did not undergo transfusion, and 13 died (OR, 0.14; 95 percent CI, 0.02 to 0.96).

In a similar analysis, Rodis et al. ^[193] surveyed members of the Society for Maternal-Fetal Medicine regarding management of patients with parvovirus infection. Members reported the outcome of 467 cases of fetal hydrops. Seven patients elected to have pregnancy terminations. One hundred sixty-four fetuses had intrauterine transfusions; 27 of these fetuses (16 percent) died. Of the 296 fetuses who *did not* undergo transfusion, 138 (47 percent) died ($p < 0.0001$).

Until recently, most authors had reported normal long-term development in surviving infants. However, in 1993, Conry and co-workers ^[194] described three children with persistent neurologic morbidity following parvovirus infection that occurred at 21 to 24 weeks' gestation. Neurologic abnormalities included hypotonia, arthrogryposis, motor developmental delay, infantile spasms, intracranial calcifications, and ventriculomegaly. One child died on the sixth day of life. In 1994, Brown et al. ^[195] described three infants with persistent severe anemia following intrauterine transfusion for parvovirus infection. One of the children died, and autopsy demonstrated widespread viral infection. The other children required regular transfusions. In view of these recent unfavorable reports, clinicians should be cautious in counseling parents regarding the long-term prognosis in affected infants.

RUBELLA

Epidemiology

Rubella is an RNA virus that is a member of the togavirus family. Only a single serotype is known.^[196] Rubella occurs primarily in young children and adolescents. The disease is most common in the springtime. Major epidemics of rubella occurred in the United States in 1935 and 1964; minor sporadic epidemics occurred approximately every 7 years until the late 1960s. With licensure of an effective rubella vaccine in 1969, the frequency of this infection has declined by almost 99 percent.^[197] In 1992, a new low of 160 cases was reported to the CDC.^[198] The persistence of this infection appears to be due to failure to vaccinate susceptible individuals rather than to lack of immunogenicity of the vaccine.

The rubella virus enters the host through the upper respiratory tract. From this site, the virus travels quickly to the cervical lymph nodes and then is disseminated hematogenously throughout the body. The incubation period is approximately 2 to 3 weeks. The virus is present in blood and nasopharyngeal secretions for several days before appearance of the characteristic rash; it also is shed from the nasopharynx for several days after appearance of the exanthem. Therefore, the patient can be contagious for an extended period of time.^[196], ^[199]

Antibody against rubella does not normally appear in the serum until after the rash has developed. Acquired immunity to rubella is usually lifelong. Second infections have occurred after both natural primary infections and vaccination. However, recurrent infections generally are not associated with serious illness, viremia, or congenital infection.

Clinical Manifestations

Most children and adults with rubella have mild constitutional symptoms such as malaise, headache, myalgias, and arthralgias. The principal clinical manifestation of this illness, of course, is a widely disseminated, nonpruritic, erythematous, maculopapular rash ([Fig. 40-9](#)). Postauricular

Figure 40-9 Photograph shows typical erythematous, maculopapular rash of rubella.

adenopathy and mild conjunctivitis also are common. These clinical manifestations usually are short-lived and typically resolve within 3 to 5 days. The differential diagnosis of rubella includes rubeola, roseola, other viral exanthems, and drug reaction.^[196]

Diagnosis

The diagnosis of rubella can usually be established on the basis of the patient's physical examination. If necessary, serologic tests can be used to confirm the diagnosis. IgM antibody usually reaches a peak 7 to 10 days after the onset of illness and then declines over a period of 4 weeks. The serum concentration of IgG antibody usually rises more slowly, but antibody levels persist throughout the lifetime of the individual. Several different types of antibody detection tests are available, including enzyme immunoassay, indirect immunofluorescence, and latex agglutination. In a recent comparative study, Sautter et al.^[200] found that the enzyme immunoassay and latex agglutination tests were the most rapid and convenient methods for screening for antibody to rubella.

Congenital Rubella Syndrome

Because of the success of rubella vaccination campaigns, the incidence of congenital rubella syndrome in the United States has declined dramatically over the past 25 years.^[196], ^[197], ^[198] In 1991, 31 cases of congenital rubella syndrome were reported to the CDC; in 1992, only five cases were reported.^[199] Unfortunately, however, approximately 10 to 20 percent of women in the United States remain susceptible to rubella and, hence, their fetuses are at risk for serious injury should the mother become infected during pregnancy.

The rubella virus crosses the placenta by hematogenous dissemination, and the frequency of congenital infection is critically dependent on the time of exposure to the virus.^[196], ^[201], ^[202] Approximately 50 percent of infants exposed to the virus within 4 weeks of conception will manifest signs of congenital infection. When maternal infection occurs in the second 4-week period after conception, approximately 25 percent of fetuses will be infected. When infection develops in the third month, approximately 10 percent of fetuses will be infected. When maternal infection occurs beyond this point in time, less than 1 percent of babies will be infected.

An entire spectrum of anomalies has been associated with congenital rubella syndrome. The four most common abnormalities are deafness (affecting 60 to 75 percent of fetuses), eye defects (10 to 30 percent), CNS anomalies (10 to 25 percent), and cardiac malformations (10 to 20 percent). The most common cardiac abnormality associated with congenital rubella is patent ductus arteriosus, although supravulvar pulmonic stenosis is perhaps the most pathognomonic. Other possible abnormalities include microcephaly, mental retardation, pneumonia, intrauterine growth restriction, hepatosplenomegaly, hemolytic anemia, and thrombocytopenia.^[201], ^[202]

A variety of tests have been proposed for the diagnosis of congenital rubella syndrome. Cordocentesis can be performed to determine the total serum IgM concentration in fetal blood and to detect virus-specific antibody. However, fetal immunoglobulin production usually cannot be detected prior to 19 to 22 weeks of gestation. Some authors have proposed chorionic villus sampling (CVS) as a diagnostic test because placental tissue infected with rubella virus produces a cytopathic effect when grown in tissue culture. Viral antigen also can be identified rapidly in tissue culture by RNA-DNA hybridization techniques, and amniotic fluid can be cultured for rubella virus. Unfortunately, although the tests outlined above can demonstrate that rubella virus is present in the fetal compartment, they do not indicate the degree of fetal injury. Accordingly, detailed ultrasound examination is the best test to determine if serious fetal injury has occurred. Abnormalities that can be identified accurately by ultrasound include intrauterine

growth restriction, microcephaly, and cardiac malformations.

The prognosis for infants with congenital rubella syndrome is guarded. Approximately 50 percent of affected individuals have to attend schools for the hearing impaired. An additional 25 percent of infected children require at least some special schooling because of hearing impairment, and only 25 percent are able to attend mainstream regular schools. Some affected individuals develop insulin-dependent diabetes later in life, presumably secondary to in utero infection of the pancreas. The estimated lifetime cost of caring for a child with congenital rubella syndrome is approximately \$200,000 to \$300,000. ^[201] ^[202] ^[203]

Obstetric Management

Ideally, women of reproductive age should have a preconception appointment when they are contemplating pregnancy. At this time, they should be evaluated for immunity to rubella. If serologic testing demonstrates that they are susceptible, they should be vaccinated with rubella vaccine prior to conception. ^[196] When preconception counseling is not possible, all obstetric patients should have a test for rubella at the time of their first prenatal appointment. Women who are susceptible to rubella should be counseled to avoid exposure to other individuals who may have viral exanthems.

If a susceptible patient subsequently has exposure to rubella, serologic tests should be obtained to determine whether acute infection has occurred. If acute infection is documented, patients should be counseled about the risk of congenital rubella syndrome. Obviously, specific counseling should be based on the time in gestation when maternal infection occurred. The diagnostic tests for detection of in utero infection should be reviewed. Patients should be offered the option of pregnancy termination based on the assessed risk of serious fetal injury. ^[199]

Susceptible patients who are fortunate enough to escape infection during pregnancy should be vaccinated immediately postpartum. The present rubella vaccine is the RA 27/3 preparation. ^[197] It is much more immunogenic than the earlier HPV-77 and Cendehill vaccines and is available in a monovalent form, bivalent form (measles-rubella [MR]), and trivalent form (measles-mumps-rubella [MMR]). Approximately 95 percent of patients who receive rubella vaccine seroconvert. Antibody levels persist for at least 18 years in more than 90 percent of vaccinees.

There are few adverse effects of vaccination, even in adults. Less than 25 percent of patients experience mild constitutional symptoms such as low-grade fever and malaise. Less than 10 percent experience arthralgias, and less than 1 percent develop frank arthritis. Interestingly, when the vaccine is administered in the immediate postpartum period, these adverse effects are often delayed for up to 21 days. Women who have received the vaccine cannot transmit infection to susceptible contacts, such as younger children in the home. Breast-feeding is not a contraindication to vaccination. In addition, the vaccine can be administered in conjunction with other immune globulin preparations such as Rh-immune globulin.

Women who receive rubella vaccine should practice secure contraception for a minimum of 3 months after vaccination. For a number of years, the CDC maintained a registry of women who received the rubella vaccine within 3 months of conception. That registry included almost 400 patients, and fortunately there were no instances in which congenital rubella syndrome resulted from vaccination. ^[204] However, there were cases in which women elected to have abortions following vaccination and rubella virus was isolated from the products of the conception. The maximum theoretical risk of congenital rubella resulting from rubella vaccine in early pregnancy is 1 to 2 percent.

RUBEOLA (MEASLES)

Virology

The measles virus is a paramyxovirus that is closely related to the canine distemper virus. The organism was first successfully isolated by Enders and Peebles in 1954. The wild virus is pathogenic only for primates, and humans are the only natural host. The organism is a single-stranded RNA virus. It is quite labile and is extremely sensitive to acid, proteolytic enzymes, strong light, and drying. ^[205] ^[206]

Epidemiology

Measles virus is highly contagious and is spread primarily by respiratory droplets. Seventy-five to 90 percent of susceptible contacts become infected after exposure. The incubation period is 10 to 14 days. Before a vaccine was available, virtually all children acquired measles. In 1963, however, inactivated and live attenuated vaccines were licensed. The inactivated vaccine was subsequently discontinued in 1967. The current vaccine used in the United States is an attenuated preparation that was licensed in 1968. ^[205] ^[206] ^[207]

Since licensure of the vaccine, the reported incidence of measles has decreased by almost 99 percent. As expected, children less than 10 years of age have shown the greatest decline in incidence of measles. During the mid 1980s, almost 60 percent of reported cases of measles affected children greater than 10 years of age, compared

1330

with only 10 percent during the period 1960 to 1964. ^[205] ^[206] ^[207] In recent years, two major types of measles outbreaks have been reported in the United States. One type has occurred among unvaccinated preschoolers, including children less than 15 months of age. Another has occurred among previously vaccinated school-age children and college students. Approximately one third of the cases in the latter type of outbreak have been in individuals who previously were vaccinated. Presumably, these cases result from either *primary failure* to respond to the first vaccine or *secondary failure*, a situation where an adequate serologic response initially develops but immunity wanes over time. ^[208] ^[209]

Clinical Manifestations

The clinical manifestations of measles usually appear within 10 to 12 days of exposure. The most common are fever, malaise, coryza, sneezing, conjunctivitis, cough, and photophobia. All patients typically develop a generalized maculopapular rash, and the majority also have Koplik's spots, which are blue-gray specks on a red base that develop on the buccal mucosa opposite the second molars. The skin exanthem typically begins on the face and neck and then spreads to the trunk and extremities. It usually lasts for approximately 5 days and then recedes in the order in which it appeared. The duration of illness is approximately 7 to 10 days. Patients are contagious from 1 to 4 days before the onset of coryza. Immunity to measles should be lifelong following wild virus infection and is mediated by both humoral and cell-mediated mechanisms.

Although measles is typically a minor illness, some patients develop serious sequelae. Otitis media occurs in 7 to 9 percent of infected patients; bronchiolitis and pneumonia affect 1 to 6 percent. A severe form of hepatitis also may occur. In a recent report by Atmar and associates, ^[210] 7 of 13 (54 percent) pregnant women with measles developed hepatitis.

Encephalitis occurs in approximately 1 per 1,000 cases of measles. It results from both viral infection of the CNS and a hypersensitivity reaction to the systemic viral infection. Measles encephalitis may result in permanent neurologic impairment, including mental retardation; the mortality rate from this complication is approximately 15 to 33 percent. ^[205] ^[206] ^[207] Another unusual but extremely serious complication of measles is subacute sclerosing panencephalitis (SSPE). This complication occurs in 0.5 to 2 per 1,000 cases. The manifestations of SSPE typically develop approximately 7 years after the acute measles infection. SSPE is more common in children who had measles before the age of 2. The disorder is characterized by progressive neurologic debilitation and a virtually uniformly fatal outcome.

A final complication is an unusual condition, termed *atypical measles*. This disorder is a severe form of measles reinfection that affects young adults previously vaccinated with the formalin-inactivated killed measles vaccine that was distributed in the United States from 1963 to 1967. Affected patients have extremely high antibody titers to measles. They typically experience high fever; pneumonitis; pleural effusion; and a coarse, maculopapular, hemorrhagic, or urticarial rash. Although the disease is usually self-limited, atypical measles can lead to hepatic, cardiac, and renal failure. Interestingly, affected patients are not contagious to others. The risk of perinatal transmission with atypical measles has not been defined precisely. ^[206]

Diagnosis

Five clinical criteria should be present to establish the diagnosis of measles: fever greater than or equal to 38.3°C, a characteristic rash lasting longer than 3 days, cough, coryza, and conjunctivitis. ^[2] Although the virus can be cultured, the mainstay of diagnostic tests is detection of antibody to measles. ^[205] ^[206] ^[207] ^[208] The simplest and most sensitive tests are the hemagglutination inhibition (HI) assay and the ELISA. The confirmation of acute measles virus infection is based on detection of IgM-specific antibody or a fourfold change in the IgG titer in convalescent, compared to acute, sera. The acute titer for IgG antibody should be obtained within 3 days of the onset of the rash and the convalescent titer should be obtained 1020 days later.

The differential diagnosis of measles can be difficult. A variety of other infections must be considered, including rubella, scarlet fever, Rocky Mountain spotted fever, toxoplasmosis, enterovirus infection, mononucleosis, meningococemia, and serum sickness.

Complications of Measles during Pregnancy

Several reports have described an increase in maternal mortality associated with measles infection during pregnancy. Most fatalities have been due to pulmonary complications. In one of the earliest reports, Christensen et al. described a serious epidemic of measles in Greenland in 1951. ^[211] Four of 83 pregnant women (4.8 percent) who developed measles died. An unspecified number of these women also had active tuberculosis. In the report by Atmar et al., ^[210] 1 of 13 pregnant women (8 percent) with measles died because of severe respiratory infection. In another report, Eberhart-Phillips and co-workers ^[212] evaluated 58 pregnant women with measles. Thirty-five (60 percent) required hospitalization. Fifteen (26 percent) developed pneumonia, and two (3 percent) died.

the recent report by Eberhart-Phillips et al.,^[212] 13 of 50 (26 percent) women with continuing pregnancies delivered preterm. The frequency of congenital anomalies is not significantly increased in women who have measles during pregnancy, although Ekbohm and associates^[213] recently reported a possible association between perinatal measles infection and subsequent Crohn's disease.

Infants of mothers who are acutely infected at the time of delivery are at risk for neonatal measles. This infection typically develops within the first 10 days of life and results from transplacental viral dissemination. In some reports, the mortality in preterm and term infants with neonatal measles has been as high as 60 percent and 20 percent, respectively.^[205],^[208],^[210],^[212],^[214] Of importance is the fact that these alarmingly high mortality figures were published prior to the era of skilled neonatal care and the availability of broad-spectrum antibiotics for treatment of secondary bacterial infections.

Management of Measles during Pregnancy

Pregnant women with measles should be observed carefully for evidence of serious complications such as otitis media, hepatitis, encephalitis, and pneumonia. Secondary bacterial infections should be treated promptly with antibiotics. Administration of aerosolized ribavirin may be of benefit in patients with severe viral pneumonitis.^[210] The affected patient should be counseled that the risk of injury to her fetus is low. Probably the most effective method for evaluating the fetus for in utero infection is detailed ultrasound examination. Findings suggestive of in utero infection include microcephaly, growth restriction, and oligohydramnios. Neonates delivered to a mother who has developed measles within 7 to 10 days of delivery should receive intramuscular immune globulin in a dose of 0.25 mg/kg. These infants should subsequently receive the live measles vaccine when they are 15 months of age.^[206],^[208]

Prevention of Infection

All children should receive measles vaccine when they are 15 months of age. The immunization should be administered as part of the trivalent MMR vaccine. The appropriate initial dose for young children is 0.5 ml subcutaneously. The original public health recommendations provided for only a single dose of measles vaccine. However, as noted previously, recent outbreaks of measles have occurred in individuals who received only one dose of the vaccine. Accordingly, the CDC now recommends that all individuals who have not been infected with the wild measles virus receive a second dose of vaccine. Children who receive their first dose at age 15 months should receive a second dose at 4 to 6 years of age. Children who are vaccinated with the live vaccine before their first birthday should be considered unvaccinated and should receive the full two-dose series. Individuals who received "further attenuated vaccine," accompanied by immune globulin or measles immune globulin, should be considered unvaccinated and receive two doses of the vaccine. Individuals who were given the inactivated vaccine during the period 1963 to 1967 are at risk for developing severe atypical measles syndrome if they are exposed to the natural virus. Accordingly, these individuals also should receive two doses of the live vaccine. Women of reproductive age who have only one documented measles vaccination also are candidates for a second immunization. The seroconversion rate with the new live virus vaccine is greater than or equal to 95 percent.^[206],^[208]

There are three specific contraindications to vaccination: pregnancy, severe febrile illness, and history of anaphylactic reaction to egg protein or neomycin. The vaccine should not be given for 3 months after a person has received immune globulin, whole blood, or other antibody-containing blood products. However, the vaccine can be administered concurrently with Rh-immune globulin in the immediate postpartum period. Although no cases of congenital infection have been described as a result of the measles vaccine, patients receiving the vaccine should practice effective contraception for 3 months following inoculation.^[206],^[208]

Few adverse effects are associated with measles vaccination. Approximately 5 to 15 percent of vaccinees develop a low-grade fever. Five percent or less develop a rash. Less than 1 percent have febrile seizures, and less than 1 per 1 million cases develop encephalitis.

When an outbreak of measles does occur, susceptible individuals should be targeted for post exposure prophylaxis. If they are not pregnant, they should receive the live measles vaccine within 72 hours of exposure. They also should receive immune globulin within 6 days of exposure. The appropriate dose of immune globulin is 0.25 ml/kg for immunocompetent patients and 0.5 ml/kg for immunocompromised individuals. The maximum dose of the immune globulin preparation is 15 ml. Pregnant patients should receive only immune globulin.^[206],^[208]

SYPHILIS

Epidemiology

Syphilis is caused by the spirochete *Treponema pallidum*. Infection occurs primarily as a result of sexual contact. The organism penetrates mucosal barriers and is highly contagious. Infection develops in 10 percent of

1332

contacts after a single exposure and in 70 percent after multiple exposures. [\[215\]](#) , [\[216\]](#) Syphilis also may be transmitted perinatally, with devastating consequences for the fetus.

The prevalence of syphilis in the United States has increased dramatically in recent years, coincident with the upsurge in cases of HIV infection and the growing epidemic of drug abuse. The greatest increase has been in females, aged 15 to 24 years, and a disproportionate number of cases have occurred in blacks and Hispanics living in urban areas. [\[215\]](#) , [\[216\]](#)

Clinical Manifestations and Staging

Syphilis may be divided into four *clinica* categories: primary, secondary, tertiary, and neurosyphilis. In addition, syphilis may present as a latent infection. Latent syphilis is subdivided into early latent (<1 year duration) and late latent infection (>1 year). [\[215\]](#) [\[216\]](#) [\[217\]](#) The incubation period of syphilis ranges from 10 to 90 days. At the end of this period, the characteristic raised, painless chancre appears. In women, the chancre is usually on the cervix or vaginal wall and may not be apparent except on close inspection (Fig. 40-10) (Figure Not Available) . In some patients, the chancre may be present in extragenital sites such as the fingers, oropharynx, nipples, or anus. The chancre usually heals in 3 to 6 weeks even without specific antimicrobial treatment. The principal disorders that must be considered in the differential diagnosis of primary syphilis are herpes simplex virus infection, chancroid, trauma, scabies, Behcet's syndrome, Stevens-Johnson syndrome, and carcinoma.

Patients who receive either no treatment, or inadequate treatment, may develop secondary syphilis 2 to 6 months after their primary infection. The principal clinical manifestation of this stage of the infection is a generalized maculopapular rash that is most obvious on the palms of the hands and soles of the feet (Fig. 40-11) (Figure Not Available) . This rash may be confused with disseminated gonococcal infection, measles, rubella, scabies, psoriasis, and drug eruption. Other findings associated with secondary syphilis include mucous patches (Fig. 40-12) (Figure Not Available) , shallow, painless ulcerations in the oropharynx; and condylomata lata, grayish, raised papules that appear near the anus and vulva. In addition, bone tenderness, iritis, alopecia, and generalized lymphadenopathy also may be present. The lesions of secondary syphilis usually resolve spontaneously in 3 to 6 weeks, even without treatment. Untreated patients then enter a latent phase of their illness. In this phase, infected women pose only a small risk of horizontal transmission of infection to their sexual partner. However, vertical transmission to the fetus still may occur. [\[215\]](#) [\[216\]](#) [\[217\]](#)

Approximately one third of patients with untreated secondary disease ultimately develop tertiary syphilis after an interval of several years. Tertiary syphilis is distinguished by three principal findings: gumma formation, cardiac lesions, and central nervous system abnormalities (neurosyphilis). The characteristic cardiac lesions are aortic insufficiency and dissecting aortic aneurysm. Neurologic manifestations include meningovascular syphilis, cranial nerve palsies, generalized paresis, tabes dorsalis, optic atrophy, uveitis, and Argyll-Robertson pupils. Four to 9 percent of patients with untreated syphilis ultimately develop neurosyphilis. In some individuals, particularly those with concurrent HIV infection, neurologic manifestations may occur early in the course of syphilis and can be responsible for severe morbidity. [\[215\]](#) [\[216\]](#) [\[217\]](#)

Diagnosis

T. pallidum cannot be cultured. It can be identified from overt lesions such as the chancre by darkfield microscopy and fluorescent antibody staining. However, most cases of infection, particularly those in the latent stage, are diagnosed by serology. The initial screening test for syphilis should be a nontreponemal assay such as the Venereal Disease Research Laboratories (VDRL) test or rapid plasma reagin (RPR) test. Several factors can cause biologically false-positive (BFP) test results such as collagen vascular disease, bacterial and viral infections, multiple myeloma, advanced cancer, chronic liver disease, IV drug use, multiple blood transfusions, and pregnancy. Accordingly, a positive screening test must be confirmed by a specific treponemal assay such as the fluorescent treponemal antibody absorption test (FTA-ABS) or microhemagglutination assay (MHATP). Biologic false-positive treponemal tests have been reported in patients with Lyme disease, leprosy, malaria, mononucleosis, and collagen vascular disease.

Lumbar puncture is indicated when neurosyphilis is suspected and in all patients who are co-infected with syphilis and HIV. Cerebrospinal fluid (CSF) abnormalities include a mononuclear pleocytosis (10 to 400 cells/mm³), elevated protein (>45 mg/dl), and a positive VDRL test. [\[215\]](#) [\[216\]](#) [\[217\]](#)

Virtually 100 percent of patients will have a positive serologic test within 4 weeks of their primary infection. With appropriate antibiotic treatment, quantitative nontreponemal tests usually decrease fourfold within 3 months in patients with primary or secondary syphilis. When this decline does not occur, patients should be reevaluated and considered for a second course of treatment. Antibody

TABLE 40-19 -- FREQUENCY OF VERTICAL TRANSMISSION OF SYPHILIS

Stage of Maternal Infection	Approximate Frequency of Congenital Syphilis
Primary	50%
Secondary	50%
Early latent	40%
Late latent	10%
Tertiary	10%

titers may decline more slowly in patients with more advanced stages of disease. Specific treponemal tests typically remain positive for life even after adequate treatment, although 13 to 24 percent of patients may ultimately become seronegative. ^[215] ^[216] ^[217] Ideally, patients should be followed with quantitative titers for up to 12 to 18 months after their initial infection to determine if they become seronegative.

Perinatal Complications

Syphilis in pregnancy may be associated with an increased risk of fetal demise, intrauterine growth restriction, and preterm delivery. ^[218] It also may accelerate the course of HIV infection in pregnant women. However, the most frequent (and potentially ominous) complication of syphilis in pregnancy is congenital infection. *T. pallidum* can cross the placenta and infect the fetus *at any stage of gestation*. Up to one third of fetuses with congenital syphilis are stillborn. ^[4] The frequency of vertical transmission varies primarily with the stage of maternal disease, as noted in [Table 40-19](#). The many possible clinical manifestations of congenital syphilis are summarized in [Table 40-20](#) and illustrated in Figure 40-13 (Figure Not Available) and Figure 40-14 (Figure Not Available).

TABLE 40-20 -- CLINICAL MANIFESTATIONS OF CONGENITAL SYPHILIS

Early	Late
Maculopapular rash	Hutchinson teeth
Snuffles (syphilitic rhinitis)	Mulberry molars
Mucous patches	Interstitial keratitis
Hepatosplenomegaly	Deafness
Jaundice	Saddle nose
Pneumonia	Rhagades
Lymphadenopathy	Saber shins
Osteochondritis	Mental retardation
Chorioretinitis	Hydrocephalus
Iritis	Generalized paresis
	Optic nerve atrophy
	Clutton joints (hydrarthrosis)

Figure 40-13 (Figure Not Available) Hutchinson teeth, a manifestation of late congenital syphilis. (From Duff P, Christian JS, Yancey MK: *Infections associated with pregnancy*. In Coulam CB, Faulk WP, McIntyre JA [eds]: *Immunologic Obstetrics*. New York, WW Norton & Co, 1992, p 578, with permission.)

T. pallidum has been recovered from fetal blood and amniotic fluid in cases of congenital infection. ^[219] However, the prenatal diagnostic test with the greatest potential for identifying the severely infected fetus is ultrasound. Ultrasound findings suggestive of in utero infection include placentomegaly, intrauterine growth restriction, microcephaly, hepatosplenomegaly, and hydrops.

Treatment

The treatment of syphilis in pregnancy is summarized in [Table 40-21](#). ^[215] ^[216] ^[217] Clearly, penicillin is the drug of

Figure 40-14 (Figure Not Available) Mulberry molar, a manifestation of late congenital syphilis. (From Duff P, Christian JS, Yancey MK: *Infections associated with pregnancy*. In Coulam CB, Faulk WP, McIntyre JA [eds]: *Immunologic Obstetrics*. New York, WW Norton & Co, 1992, p 578, with permission.)

TABLE 40-21 -- RECOMMENDATIONS FOR TREATMENT OF SYPHILIS IN PREGNANCY

Stage of Disease	Principal Treatment	Alternate Treatment if Allergic To Penicillin*
Primary, secondary, or latent syphilis <1 year's duration	Benzathine penicillin G, 2.4 million units IM x 1	Erythromycin
		500 mg PO qid x 15 days
		Ceftriaxone
Latent syphilis > 1 year's duration or cardiovascular syphilis	Benzathine penicillin G, 2.4 million units IM weekly x 3	Erythromycin
		500 mg qid x 30 days
Neurosyphilis	Aqueous crystalline penicillin G, 34 million units q4h x 1014 days, followed by benzathine penicillin G, 2.4 million units IM x 1	No regimen of proven value other than penicillin
		or
	Aqueous procaine penicillin G, 2.4 million units IM daily with probenecid, 500 mg PO qid, both for 1014 days, followed by benzathine penicillin G, 2.4 million units IM x 1	

* These regimens should be administered only if desensitization to penicillin is unsuccessful.

In patients who are concurrently infected with HIV, treat as outlined below for late latent or tertiary syphilis. Patients also should have a lumbar puncture to determine if neurosyphilis is present.

choice for this infection because of its proven ability to prevent congenital infection in most cases. Patients who have a previous history of an allergic reaction to penicillin should be skin tested to determine if their allergy persists. ^[215] ^[216] ^[217] In point of fact, approximately 10 percent of patients who report a history of severe allergy to penicillin remain allergic throughout life. They can be reliably identified by testing with major and minor penicillin determinants. If allergy is confirmed, patients should be desensitized with either oral or intravenous regimens. ^[215] ^[217] ^[220] Desensitization can usually be completed within 4 hours. It is best accomplished in consultation with an allergist and performed in an area of the hospital with immediate access to emergency resuscitative equipment. A simple regimen for desensitization is outlined by Ziaya et al. ^[220] Alternative antibiotic regimens are not of proven value for prevention of congenital syphilis or treatment of advanced stages of disease. Accordingly, they should be used only if desensitization is unsuccessful.

Pregnant women receiving penicillin for treatment of syphilis may develop uterine contractions and decreased fetal movement as a result of a Jarisch-Herxheimer reaction. In a recent report, Klein and co-workers ^[221] observed this reaction in 15 of 33 women (45 percent). The reaction was particularly likely in those patients who had primary and secondary syphilis, and the abnormalities typically appeared 2 to 8 hours after treatment and resolved within 24 hours. There are no reliable clinical or laboratory assessments that predict which patients will develop the Jarisch-Herxheimer reaction, and no specific treatment is available.

TOXOPLASMOSIS

Epidemiology

Toxoplasma gondii is a protozoan that has three distinct forms: trophozoite, cyst, and oocyst (Fig. 40-15) (Figure Not Available) . The life cycle of *T. gondii* is dependent on wild and domestic cats, which are the only host for the oocyst. The

Figure 40-15 (Figure Not Available) Life cycle of *Toxoplasma gondii*. (From Duff P, Christian JS, Yancey MK: *Infections associated with pregnancy*. In Coulam CB, Faulk WP, McIntyre JA [eds]: *Immunologic Obstetrics*. New York, WW Norton & Co, 1992, p 578, with permission.)

1336

oocyst is formed in the cat intestine and subsequently excreted in the feces. Mammals, such as cows, then ingest the oocyst, which is disrupted in the animal's intestine, releasing the invasive trophozoite. The trophozoite then is disseminated throughout the body, ultimately forming cysts in brain and muscle.

Human infection occurs when infected meat is ingested or when food is contaminated by cat feces (e.g., via flies, cockroaches, or fingers). Infection rates are highest in areas of poor sanitation and crowded living conditions. Stray cats and domestic cats that eat raw meat are most likely to carry the parasite. The cyst is destroyed by heat, and the practice of eating rare or raw meat in France may explain the high prevalence of infection in that country. ^[222]

Approximately 40 to 50 percent of adults in the United States have antibody to this organism, and the prevalence of antibody is highest in lower socioeconomic populations. The frequency of seroconversion during pregnancy is less than or equal to 5 percent, and approximately 3 in 1,000 infants show evidence of congenital infection. Clinically significant congenital toxoplasmosis occurs in approximately 1 in 8,000 pregnancies. Toxoplasmosis is more common in western Europe, particularly France. More than 80 percent of women of childbearing age in Paris have antibody to *T. gondii*, and congenital toxoplasmosis is about twice as frequent as in the United States. ^[222], ^[223]

Clinical Manifestations

The ingested organism invades across the intestinal epithelium and spreads hematogenously throughout the body. Intracellular replication leads to cell destruction. Clinical manifestations of infection are the result of direct organ damage and the subsequent immunologic response to parasitemia and cell death. Host immunity is mediated primarily through T lymphocytes.

Most infections in humans are asymptomatic. Even in the absence of symptoms, however, patients may have evidence of multiorgan involvement, and clinical disease can follow a long period of asymptomatic infection. Symptomatic toxoplasmosis usually presents as an illness similar to mononucleosis. ^[222], ^[223]

In contrast to infection in the immunocompetent host, toxoplasmosis can be a devastating infection in the immunosuppressed patient. Because immunity to *T. gondii* is cell-mediated, patients with HIV infection and those treated with chronic immunosuppressive therapy after organ transplantation are particularly susceptible to new or reactivated infection. In these patients, CNS dysfunction is the most common manifestation of infection. Findings typically include encephalitis, meningoencephalitis, and intracerebral mass lesions. Pneumonitis, myocarditis, and generalized lymphadenopathy also occur commonly. ^[222], ^[223]

Diagnosis

The diagnosis of toxoplasmosis can be confirmed by serologic and histologic methods. Serologic tests that suggest an acute infection include detection of IgM-specific antibody, demonstration of an extremely high IgG antibody titer, and documentation of IgG seroconversion from negative to positive. ^[222], ^[223] Clinicians should be aware that serologic assays for toxoplasmosis are not well standardized. When initial laboratory tests appear to indicate that an acute infection has occurred, repeat serology should be performed in a well-recognized reference laboratory.

The best tissue for identification of *T. gondii* is a lymph node or brain biopsy. Histologic preparations can be examined by light and electron microscopy. For light microscopy, specimens should be stained with either Giemsa or Wright stains. ^[222] ^[223] ^[224]

Congenital Toxoplasmosis

Congenital infection can occur if a woman develops *acute* toxoplasmosis during pregnancy. Chronic or latent infection is unlikely to cause fetal injury except perhaps in an immunosuppressed patient. Approximately 40 percent of neonates born to mothers with acute toxoplasmosis show evidence of infection. Congenital infection is most likely to occur when maternal infection develops in the third trimester. Less than half of affected infants are symptomatic at birth. The clinical manifestations of congenital toxoplasmosis are quite varied and are summarized [in the box "Clinical Manifestations of Congenital Toxoplasmosis."](#) ^[222] ^[223] ^[224]

The most valuable tests for antenatal diagnosis of congenital toxoplasmosis are ultrasound, cordocentesis, and amniocentesis. Ultrasound findings suggestive of infection include ventriculomegaly, intracranial calcifications, microcephaly, ascites, hepatosplenomegaly, and growth restriction. Fetal blood samples can be tested for IgM-specific antibody after 20 weeks of gestation. Fetal blood and amniotic fluid can be inoculated into mice, and the organism can subsequently be recovered from the blood of infected animals. In addition, Hohlfeld et al. ^[225] have now identified a specific gene of *T. gondii* in amniotic fluid using a PCR test. In their investigation, 34 of 339 infants had congenital toxoplasmosis confirmed by serologic testing or autopsy. All amniotic fluid samples from affected pregnancies were positive by PCR. Test results were available within 1 day of specimen collection.

Clinical Manifestations of Congenital Toxoplasmosis

Rash
Hepatosplenomegaly
Ascites
Fever
Chorioretinitis
Periventricular calcifications
Ventriculomegaly
Seizures
Mental retardation
Uveitis

1337

Management

Toxoplasmosis in the immunocompetent adult is usually an asymptomatic or self-limited illness and does not require treatment. Immunocompromised patients, however, should be treated, and the regimen of choice is a combination of oral sulfadiazine (4-g loading dose, then 1 g four times daily) plus pyrimethamine (50 to 100 mg initially, then 25 mg daily). In such patients, extended courses of treatment may be necessary to cure the infection.

Treatment also is indicated when acute toxoplasmosis occurs during pregnancy. Treatment of the mother clearly has been shown to reduce the risk of congenital infection and decrease the late sequelae of infection.^[224], ^[225] Pyrimethamine is not recommended for use during the first trimester of pregnancy because of possible teratogenicity. Sulfonamides can be used alone, but single-agent therapy appears to be less effective than combination therapy. In Europe, spiramycin has been used extensively in pregnancy with excellent success.^[224], ^[225] It is available for treatment in the United States through the CDC.

Aggressive early treatment of infants with congenital toxoplasmosis is indicated and consists of combination therapy with pyrimethamine, sulfadiazine, and leucovorin for 1 year.^[227] Early treatment reduces, but does not eliminate, the late sequelae of toxoplasmosis such as chorioretinitis.

In the management of the pregnant patient, *prevention* of acute toxoplasmosis is of paramount importance. Pregnant women should be advised to avoid contact with stray cats or cat litter. They should always wash their hands after preparing meat for cooking and should never eat raw or rare meat. Fruits and vegetables also should be washed carefully to remove possible contamination by oocysts.

VARICELLA

Epidemiology

The varicella-zoster (VZ) virus is a DNA organism that is a member of the herpes virus family. Humans are the only known source of infection. Natural varicella infection occurs primarily during early childhood. Less than 10 percent of cases occur in individuals greater than 10 years of age; however, older patients account for more than 50 percent of all fatalities due to varicella. Varicella is transmitted by direct contact and respiratory droplets. The virus is highly infectious, and approximately 95 percent of susceptible household contacts become infected following exposure. The incubation period is 10 to 14 days. Patients are infectious from 1 day before the outbreak of the rash until all of the cutaneous lesions have dried and crusted over. Immunity to varicella is usually lifelong. ^[228]

Herpes zoster infection occurs as a result of reactivation of latent virus infection in a patient who already has had varicella. Because of the presence in the host of virus-specific antibody, herpes zoster is usually a much less serious disorder than varicella and rarely poses a major risk to either the mother or her baby unless the former is immunocompromised. However, susceptible patients may develop acute varicella when exposed to individuals with herpes zoster and, therefore, they must be counseled appropriately about this risk. ^[228]

Clinical Manifestations

The usual clinical manifestations of varicella are fever, malaise, and a skin rash. The characteristic skin lesions usually begin as pruritic macules that appear in crops. The macules progress to papules, then to vesicles, and finally to crusts. The lesions initially appear on the trunk and then spread centripetally to the extremities.

In immunocompetent children, serious complications of varicella are exceedingly rare. However, in adults, two life-threatening sequelae may develop: encephalitis and pneumonia. The former occurs in less than or equal to 1 percent of pregnant women; the latter may develop in up to 20 percent of patients. Prior to the development of acyclovir, the mortality associated with varicella pneumonia in pregnancy approached 40 percent. ^[228], ^[229]

Diagnosis

The diagnosis of varicella is usually made by clinical examination alone. In problematic cases, the virus can be isolated in tissue culture and cytologic preparations may show multinucleated giant cells and eosinophilic intranuclear inclusions. Serologic assays are of primary value in assessing a patient's susceptibility to varicella immediately following exposure. The two most useful antibody assays are the fluorescent antimembrane antibody test (FAMA) and ELISA. Both assays show sustained elevations, usually lifelong, following natural infection. ^[228], ^[230]

Management of Maternal Infection

The optimal approach to maternal varicella infection is *prevention*. All women of reproductive age should be assessed for immunity to varicella, ideally before they attempt pregnancy. Susceptible patients, particularly those who are likely to be exposed to varicella either at home or in the workplace, should be offered the new varicella vaccine. Varivax (Merck) is a live attenuated vaccine that is highly immunogenic and approximately 70 to 80 percent effective in protecting the patient against natural infection. Individuals greater than 12 years of age should receive two subcutaneous doses of the vaccine, 4 to 8 weeks apart. Vaccine recipients should use effective contraception for 3 months after immunization. The vaccine can be administered simultaneously with the MMR immunization, but it should not be given in conjunction with blood or blood products. In addition, the vaccine is contraindicated in patients who are pregnant, who have immunodeficiency disorders, or who have received high-dose systemic steroids within 30 days of vaccination. ^[231]

If the patient first presents for medical care when she is pregnant, she should be questioned about varicella immunity at the time of her first prenatal appointment. If she is uncertain about prior infection, an IgG varicella serology should be performed. If the serology is positive, the patient can be reassured that she is immune and that she and her fetus are not at risk should subsequent exposure occur. If the serology is negative, the patient should be counseled to avoid exposure to individuals who may have varicella or herpes zoster.

Unfortunately, however, the more common situation that the obstetrician encounters is a pregnant patient who has been exposed acutely to an individual who "may have had chickenpox." The clinician's first step in the approach to this situation is to verify that the index patient actually has varicella. If infection is confirmed, the pregnant woman should then be questioned about immunity to varicella. If immunity cannot be documented by history, an IgG varicella serology should be obtained, and the result should be reviewed within 24 to 48 hours of exposure. If the serology is positive, the patient can be reassured that her fetus is not at risk. If the serology is negative, the patient should receive varicella-zoster immune globulin (VZIG). This preparation is 60 to 80 percent effective in preventing infection if given within 72 to 96 hours of exposure. The dose of VZIG is one vial (125 units) per 10 kg of actual body weight, up to a maximum of 5 vials. In problematic cases, if waiting for the varicella serology will delay administration of VZIG for more than 96 hours after exposure, the immunization should be given without confirmatory serology. ^[228], ^[232], ^[233] Acyclovir also is effective in preventing varicella when given prophylactically. The appropriate dose is 800 mg PO five times daily for 5 to 7 days. ^[234]

Patients who receive VZIG, as well as those who present for care too late for passive immunoprophylaxis, should be counseled about the clinical signs and symptoms of varicella. In particular, they must be advised to report immediately if early manifestations of varicella encephalitis or pneumonia develop. If serious sequelae occur, the patient should be admitted to the hospital for intravenous therapy with acyclovir. The recommended dose of acyclovir is 500 mg/m² every 8 hours, and treatment should be continued until the patient's systemic symptoms have resolved and the cutaneous lesions have begun to crust. Immunocompromised patients should be treated with intravenous acyclovir immediately at the onset of clinical illness because they are at such increased risk for serious complications. ^[228], ^[229] Otherwise, healthy patients also may be treated with oral acyclovir if they have moderate to severe systemic symptoms. The appropriate dose of acyclovir is 800 mg five times daily for 7 to 10 days. ^[228], ^[229]

Congenital Infection

Congenital varicella results primarily from hematogenous dissemination of virus across the placenta. Ascending infection following rupture of membranes is possible but extremely unlikely. Congenital infection may lead to spontaneous abortion, intrauterine fetal demise, and varicella embryopathy. The latter disorder is manifested by multiple abnormalities such as cutaneous scars, limb hypoplasia, muscle atrophy, malformed digits, psychomotor retardation, microcephaly, cortical atrophy, cataracts, chorioretinitis, and microphthalmia. ^[228]

Fortunately, two recent investigations have demonstrated a relatively low frequency of anomalies even following exposure in the first half of pregnancy. Pastuszak et al.^[235] reported a study of 106 women with varicella in the first 20 weeks of gestation. The frequency of varicella embryopathy was 1.2 percent, and the prevalence of preterm birth was 14 percent. Subsequently, Enders and co-workers^[236] published the largest prospective study of varicella in pregnancy. They observed a 2 percent incidence of congenital infection when maternal varicella occurred at 13 to 20 weeks' gestation. The frequency of congenital infection was only 0.4 percent when maternal infection occurred before 13 weeks' gestation.

The presence of varicella virus in the fetal compartment can be identified by detection of virus-specific IgM antibody and elevated total IgM antibody in cord blood. Virus also can be cultured in amniotic fluid and identified by PCR in placental tissue. Unfortunately, identification of viral DNA, virus-specific antibody, or even the virus itself does not accurately predict the degree of fetal injury. For this purpose, ultrasonography is the preferred diagnostic modality. Sonographic

findings suggestive of fetal varicella include polyhydramnios, hydrops, hyperechogenic foci in the abdominal organs (particularly the liver), cardiac malformations, limb deformities, microcephaly, and intrauterine growth restriction.^[229]

Neonatal Infection

The final major complication of varicella infection in pregnancy is *neonatal varicella*. Infection of the neonate occurs in 10 to 20 percent of infants whose mothers have acute varicella within the period from 5 days before to 2 days after delivery.^[228] Infection usually results from hematogenous dissemination of virus across the placenta at a time when no maternal antibody is present to provide passive immunity to the fetus. Less commonly, neonatal varicella results from postnatal exposure to the mother or another infected person.

The clinical course of neonatal varicella can be variable in progression and severity. The infant usually becomes symptomatic within 5 to 10 days of delivery. Some neonates have only scattered skin lesions and no systemic signs of illness. Others have a biphasic course, initially presenting with a cluster of skin lesions, followed by more widespread dissemination. Still others have a more severe acute illness associated with extensive cutaneous lesions and visceral infection. The most common life-threatening complication is pneumonia. In reports published before the widespread availability of acyclovir, the mortality associated with neonatal varicella was 20 to 30 percent.^[229]

To prevent neonatal varicella, an effort should be made to delay delivery until 5 to 7 days after the onset of maternal illness. If delay is not possible, the neonate should receive VZIG (one vial, 125 units) immediately after birth. An important additional preventive measure is isolation of the infant from the mother until all vesicular lesions likely to come in contact with the infant have crusted over.^[228], ^[233]

Occasionally, herpes zoster is present in the newborn. This condition is usually a manifestation of intrauterine varicella that occurs in the second half of pregnancy. The clinical course is typically benign, but in rare instances, encephalitis has been documented.

Key Points

Vaginal infections occur commonly in pregnancy. Moniliasis is best treated with topical antifungal compounds such as miconazole, terconazole, or chlortrimazole. Metronidazole is the only antibiotic with uniform efficacy against trichomonas. Clindamycin and metronidazole, administered either orally or topically, are effective for treatment of bacterial vaginosis.

Urinary tract infections in pregnancy are caused primarily by *E. coli*, *Klebsiella pneumoniae*, and *Proteus* species. Pyelonephritis is a particularly serious infection in pregnancy because it may be complicated by preterm labor, bacteremia, and ARDS.

Chorioamnionitis and puerperal endometritis are caused by multiple aerobic and anaerobic organisms. Antibiotic therapy should be directed against group B streptococci, aerobic gram-negative bacilli, and *Bacteroides* and *Prevotella* species.

Primary maternal CMV infection during pregnancy is associated with a 40 percent risk of fetal infection. Ten to 15 percent of infected infants are severely affected at birth. Ultrasonography and amniotic fluid viral culture are the best methods for diagnosing fetal infection.

All pregnant women should be screened for hepatitis B infections. Infants delivered to seropositive mothers should receive both hepatitis B immune globulin (HBIG) and hepatitis B vaccine shortly after birth.

HSV infection may be classified as *primary*, *initial*, *nonprimary*, and *recurrent*. *Primary infection* poses the major risk of perinatal transmission. Women with prodromal symptoms or visible lesions should be delivered by cesarean section; asymptomatic women may deliver vaginally.

All pregnant women should be screened for HIV infection. Prophylactic treatment of seropositive women with combination chemotherapy significantly reduces the risk of perinatal transmission of infection and prolongs maternal survival.

Maternal parvovirus infection may result in fetal hydrops. Intrauterine transfusion may be a lifesaving intervention for the hydropic fetus.

Primary maternal toxoplasmosis poses a serious risk of fetal infection. Fetal infection is best diagnosed by DNA analysis of amniotic fluid. Spiramycin is effective in treating both maternal and fetal infection.

Varicella in pregnancy presents serious risk to both the mother and her infant. Susceptible women exposed to varicella should be treated with VZIG. Neonates delivered to mothers with acute varicella also should receive immunoprophylaxis

with VZIG. Following delivery, susceptible women should be vaccinated with the new live virus vaccine, provided they are willing to use effective contraception for 3 months.

1349

Chapter 41 - Legal and Ethical Issues in Obstetric Practice

George J. Annas
Sherman Elias

Society has great expectations that modern medical technologies will improve longevity and quality of human life, and nowhere are these expectations higher than in the practice of obstetrics and the desire and expectation of having a healthy child. Along with the rapidly expanding capabilities in diagnosis and treatment, physicians find themselves facing numerous ethical dilemmas while practicing in a medicolegal climate in which malpractice suits can threaten even the most competent and conscientious practitioner.

We cannot address in a single chapter the seemingly infinite ethical and legal controversies facing contemporary obstetric practice and research. Instead, we focus on several topics of particular relevance to the practicing obstetrician.

ABORTION¹

The political debate over abortion during the past three decades has shifted among various dichotomous views of the world life: life versus choice, fetus versus woman, fetus versus baby, constitutional right versus states' rights, government versus physician, physician and patient versus state legislature. Hundreds of statutes and almost two dozen Supreme Court decisions on abortion later, the core aspects of *Roe v. Wade*,² the most controversial health-related decision by the Court ever, remain substantially the same as they were in 1973. Attempts to overturn *Roe* in both the courtroom and the legislature have failed. Pregnant women still have a constitutional right to abortion. The fetus is still not a person under the Constitution. States still cannot make abortion a crime (either for the woman or the physician) before the fetus becomes viable. States still can outlaw abortion after the fetus becomes viable only if there is an exception that permits abortion to protect the life or health of the pregnant woman. And states still can impose restrictions on abortion before fetal viability only if those restrictions do not actually create a substantial obstacle to a pregnant woman's obtaining an abortion.

Political tactics have shifted from the use of antiabortion rhetoric to change the law concerning abortion to the use of legislative and judicial forums to change the rhetoric of abortion. The hope seems to be that more heated rhetoric will help turn the public and physicians against abortion itself, regardless of its constitutionally protected status.

Roe and Casey

More than 25 years ago, in *Roe v. Wade*, the Supreme Court held that women have a constitutional right of privacy that is "fundamental" and "broad enough to encompass a woman's decision ... to terminate her pregnancy."³ If a right is fundamental, the state must demonstrate a "compelling state interest" to restrict it. The Court determined that the state's interest in the life of the fetus becomes compelling only at the point of "viability," defined as the point at which the fetus can survive independent of its mother. Even after viability, the state cannot favor the life of the fetus over the life or health of the pregnant woman: physicians must be able to use their "medical judgment for the preservation of the life or health of the mother." *Roe's* companion case, *Doe v. Bolton*, specifically included mental health in this determination, saying, "The medical judgment may be exercised in the light of all factors—physical, emotional, psychological, familial, and the

* This section is adapted from Annas,⁴ with permission.

woman's age relevant to the well-being of the patient. All these factors may relate to health. This allows the attending physician the room he needs to make his best medical judgment."

When the Court heard *Planned Parenthood v. Casey*⁵ in 1992, most commentators assumed that there were more than enough votes to overturn *Roe*. Instead, three seemingly anti-*Roe* Justices together wrote a joint opinion that while describing the abortion right as a liberty right (instead of a privacy right) and prohibiting the state from unduly burdening it prior to viability (instead of requiring the state to demonstrate a "compelling interest" in regulating abortion) nonetheless confirmed the "core holding" of *Roe*: that states could not outlaw abortion before the fetus becomes viable and could do so thereafter only when the life or health of the woman was not threatened by continuing the pregnancy.⁶ Twenty-four-hour waiting periods were approved; spousal notification was ruled unconstitutional. With the loss of all hope that the Court would ever overturn *Roe*, antiabortion advocates needed a new approach to keep the abortion debate alive. They found it in so-called partial-birth abortions.

Partial-Birth Abortion in Congress

In June 1995, the first Partial-Birth Abortion Ban Bill was introduced in Congress to make it a federal crime to perform "an abortion in which the person performing the abortion partially vaginally delivers a living fetus before killing the fetus and completing the delivery." In March 1996, the House passed a revised Senate version, which provided in part:

- a. Whoever, in or affecting interstate or foreign commerce, knowingly performs a partial-birth abortion and thereby kills a human fetus shall be fined under this title or imprisoned not more than two years or both.
- b. ... the term partial-birth abortion means an abortion in which the person performing the abortion partially vaginally delivers a living fetus before killing the fetus and completing the delivery ... it is an affirmative defense ... that the partial-birth abortion was performed by a physician who reasonably believed (1) the partial-birth abortion was necessary to save the life of the mother; and (2) no other procedure would suffice for that purpose.⁷

In April 1996, President Bill Clinton vetoed the bill at a White House press conference at which five women described how they made the decision to terminate their pregnancies with what could be considered a partial-birth abortion under the proposed law. He said that the debate was "not about the prochoice/prolife debate" but about the tragic circumstances of "a few hundred Americans every year who desperately want their children." The President said that he would sign a bill that was consistent with *Roe v. Wade*. In the President's words, "I will accept language that says serious, adverse health consequences to the mother. Those three words."⁸

When the Senate voted in September 1996 to sustain the President's veto, the leader of the fight to override it was Senator Rick Santorum (R-Pa.), who was challenged as having no personal experience or expertise in this area. A week after the vote, Santorum had his own story to tell.⁹ The senator's wife had been pregnant with their fourth child when they were informed that ultrasonography showed that their child had a "fatal defect," which turned out to be complete urinary tract obstruction. They were given three options: have an abortion, do nothing, or choose in utero surgery to insert a shunt. They chose the shunt procedure, which was successfully performed at 20 weeks' gestation. The procedure resulted in infection that put Karen Santorum in serious danger. An abortion would have removed the source of her infection, but she refused. Instead, she went into labor and gave birth to an extremely premature infant, Gabriel. Two hours later he died in his parents' arms.

This seemed to give Santorum the personal expertise to make him a more credible antiabortion advocate. But his experience also illustrates at least two major problems with the legislation he supports. First, his wife's actions can be considered praiseworthy only because she had a choice that is protected by current law. Second, the distinction between premature delivery and abortion on the edges of viability has always been problematic. Santorum, for example, has been quoted as having said, in relation to this experience, that even when the life of the mother is at stake, and "you have to end a pregnancy early ... that does not necessarily mean having an abortion. You can induce labor, using a drug like Pitocin [oxytocin]."¹⁰ If one accepts the standard medical definition of abortion (termination of a pregnancy when the fetus is not viable), this is a distinction without a difference. Whether a planned abortion is performed or labor is induced, both are intended to terminate a nonviable pregnancy. The real issue is not the method used to terminate the pregnancy, but the justification for terminating it. It is also reasonable to argue that after a fetus is viable, abortion is simply no longer possible by definition; the only option is premature delivery.

What makes the term "partial-birth abortion" so politically powerful is its inaccurate conflation of two polar-opposite results of pregnancy, birth and abortion. Senator Daniel Patrick Moynihan (D-N.Y.) has, for example, described it as "as close to infanticide as anything I have ever come upon."^[9] But close is not identical. When Virginia attorney general Mark Earley describes the procedure as a "disturbing form of infanticide,"^[10] he is making a legally inaccurate political statement. An almost born child is not yet born, and this is not a person under the Constitution. And, as the

Supreme Court has repeatedly held, if the viable fetus is killed for the sake of the woman's life or health, the act is not infanticide by definition.

Medical Practice and Medical Politics

In January 1997, Santorum reintroduced the Partial-Birth Abortion Ban Act in the Senate. Approximately 1 month later, the executive director of the National Coalition of Abortion Providers told reporters that he had lied in 1995 when he claimed that partial-birth abortions were rare and were performed only in extreme situations; instead, he said that "thousands" were performed annually, and most "on healthy fetuses and healthy mothers."^[11] The total number of abortions performed in the United States has been steadily declining, although there are no accurate statistics on the frequency of partial-birth abortions. There were two important differences in Congress this time around: medical organizations took conflicting positions, and substantial compromises were attempted in the Senate. The first time around, the American Medical Association (AMA) had taken no position, and the American College of Obstetricians and Gynecologists (ACOG) had urged the President to veto the bill.

In January 1997, ACOG's executive board issued its first and only statement on "intact dilatation and extraction." The board wrote that it understood that the bill attempted to outlaw a procedure containing all of the following elements:

1. deliberated dilatation of the cervix, usually over a sequence of days;
2. instrumental conversion of the fetus to a footling breech;
3. breech extraction of the body excepting the head; and
4. partial evacuation of the intracranial contents of the living fetus to effect vaginal delivery of a dead but otherwise intact fetus.^[12]

The board described this as "one method of terminating a pregnancy" after 16 weeks. The board noted that it was sometimes used to save the life or health of the mother, but that its "select panel ... could identify no circumstances under which this procedure ... would be the only option to save the life or preserve the health of the woman ... [although it] may be the best or most appropriate procedure." The board's primary point was that only the woman's physician should make the decision about what particular procedure to use in individual circumstances, and that therefore "the intervention of legislative bodies into medical decision making is inappropriate, ill advised, and dangerous."

The AMA took a different position. On the eve of the Senate vote in May 1997, the AMA's board of trustees agreed to support the legislation if Santorum would add two physician-friendly procedural amendments.^[13] These were a requirement that the physician's action be "deliberate and intentional," and a procedure to involve the state medical board in the trial of an accused physician. State bans on partial-birth abortion are based on the inherent police power that states have to protect the health and safety of the public. The federal government has no such power; the federal bill is instead based on the power of Congress to regulate interstate commerce. Because the AMA endorsed the federal bill, it implicitly agreed that what physicians do with individual patients in their offices is a matter of interstate commerce, and therefore subject to regulation by the federal government. This is a stunning concession.

Attempts to reach a real compromise that could have resulted in a bill that President Clinton could sign, and that would probably have been upheld by the courts as constitutional, were made primarily by Senator Dianne Feinstein (D-Calif.), Senator Barbara Boxer (D-Calif.), and Senator Thomas Daschle (D-S.D.). The Feinstein-Boxer amendment would have dealt specifically with the problem the President had with the original bill by adding "serious adverse health consequences to the woman" as an additional exception to the prohibition. Daschle offered to ban all abortions, by any technique, after viability. The only exception would be to save the life of the pregnant woman or to protect her from "grievous injury" to her physical health, defined as "a severely debilitating disease or impairment specifically caused by the pregnancy, or an inability to provide necessary treatment for a life-threatening condition."^[14]

Daschle's bill defined the realm of the debate as the period after viability (roughly the third trimester) but nonetheless attempted to limit the reach of *Roe v. Wade* by restricting the exception regarding the health of the pregnant woman to physical (not mental) health and to the risk of "grievous" harm, at that. ACOG endorsed the Daschle compromise, but in doing so seemed to put politics over loyalty to patients, since the Daschle proposal limited the ability of a physician to act to protect the health of a patient after the fetus becomes viable.

In May 1997, the Senate adopted the Santorum bill by a vote of 64 to 36, and in October 1997, it was passed by the House and sent to the President. Two days later, President Clinton again vetoed the bill. He issued a three-paragraph message to the House of Representatives, in which he said he was vetoing the bill "for exactly the same reasons I returned an earlier substantially identical version ... last year" that is, because of its failure to include an exception for abortion to prevent "serious harm" to a woman's health.

In 2000, in *Stenberg v. Carhart*, the U.S. Supreme

Court ruled, 5 to 4, that state laws outlawing "partial birth abortions," that were worded substantially identical to the laws passed by Congress and vetoed by President Clinton, are unconstitutional.^[15] The reasons are twofold. The first is that the law is unconstitutionally vague because the procedure it purports to outlaw is described in words that could be read to outlaw other abortion procedures that everyone agrees are constitutional. This places physicians in fear of prosecution, and may thus cause them not to perform abortions they otherwise would, putting an "undue burden" on pregnant women wishing to terminate their pregnancies. Secondly, the act makes no exception for the "health of the woman," and *Roe v. Wade* requires that this exception exist throughout the pregnancy. Ultimately, the central question regarding abortion remains who should make the decision: the state or women and their physicians together. The answer of the Supreme Court, as articulated in *Roe v. Wade*, and reinforced in *Stenberg*, is that the decision belongs to the woman and her physician together.^[16]

Government Regulation of Medical Procedures

Both sides admit that even if the technique of intact dilatation and extraction is outlawed, it is unlikely that even one abortion will be prevented. Thus, perhaps the primary lesson of the past 25 years is that the controversy over abortion in America is not susceptible to political solution. Moreover, since neither Congress nor the states can alter the constitutional law of abortion as set forth in *Roe v. Wade* and *Casey*, if the debate about partial-birth abortion were only a debate about abortion itself, it would be of little practical consequence. The debate, however, exposes other important issues.

The chief issue is the proper role of the government in regulating medical care. Historically, prochoice forces have favored this framing of the abortion debate. When the debate about abortion is argued as a choice between having a woman and her physician make the decision and having the state legislature or Congress make it, the woman and her physician are the overwhelming choice of Americans. The government-versus-physician framework is also uncomfortable for Republicans, who tend to argue against government interference with private decision making. And even when government regulation seems appropriate, most Republicans prefer regulation by the individual states to regulation by the federal government.

A more focused way to frame the debate is to ask whether decisions about specific medical procedures should be made by physicians or legislators. The AMA's support of the ban on partial-birth abortion seems to be a repudiation of its historic position against government interference in this realm. If the AMA believes that the federal government can outlaw a constitutionally protected procedure performed in the privacy of a physician's office on the basis of the federal government's power to regulate interstate commerce, then the AMA has conceded that the federal government can regulate all medical procedures. On the other hand, the AMA has never

had a consistent position on abortion. ^[17]

The issue of who (the medical profession or the state or health plans, for that matter) has the authority to determine what is and what is not a legitimate medical procedure has implications for everything done by physicians, not just for abortions. ^[18] *Roe v. Wade* and *Casey* both teach that government restrictions on legitimate medical procedures that are used to perform abortions before the fetus is viable are unconstitutional (at least if the use of such procedures does not increase the risks to the woman's health). These cases also teach that the failure to make exceptions to outlawed procedures (so that they can be used to protect the life and health of the pregnant woman) also makes the bills regulating partial-birth abortion unconstitutional as passed.

It has been primarily because of the failure to allow physicians to protect the woman's health after the fetus becomes viable, the vagueness of the definition of partial-birth abortion, and the application of the ban before fetal viability that courts have found that some of the similar laws regulating partial-birth abortion that have been passed in more than two dozen states are unconstitutional. ^[19] ^[20] ^[21] ^[22] ^[23] ^[24] One U.S. Circuit court, however, did approve the law if it was very narrowly interpreted, although the reasoning of the majority in this 5 to 4 opinion is deeply flawed. ^[25]

In the only case to reach the Supreme Court before the President's veto, in March 1998, the Court refused to hear an appeal of a lower-court decision that the Ohio ban on partial-birth abortion was unconstitutional. Three Justices (Clarence Thomas, Antonin Scalia, and William Rehnquist), however, voted to hear the appeal so that the Court could reopen what has become the central issue in the debate: whether the Constitution requires an exception to a ban on abortion after viability that includes the pregnant woman's mental health. ^[26] Although we can only guess at why none of the other six Justices voted to hear this case (it takes four Justices to agree to hear an appeal to the Court), it would appear that all of them think that a woman's mental health is as protected under the Constitution as her physical health.

President Clinton was thus on strong constitutional grounds when he based his vetoes on the failure of these bills to allow for a physician's action to preserve a pregnant woman's health. He was also on strong grounds in insisting, like ACOG, that the proper person

to make a judgment about the health of the woman is the physician (acting, of course, in partnership with the woman). As the Court put it in *Roe v. Wade*, this "decision vindicates the right of the physician to administer medical treatment according to his professional judgment." This means that if intact dilatation and extraction is a legitimate medical procedure, it is constitutionally protected under *Roe v. Wade*. If, however, it is not such a procedure, but rather in the category of nonmedical interventions, like female genital mutilation ^[27] and execution by lethal injection, it has (and deserves) no such protection. Therefore, another way to frame the debate about abortion is to ask who should have the authority to determine which procedures are legitimate medical procedures.

Efforts to reframe the abortion debate have always involved a dichotomy that allows us to ignore or marginalize either women or fetuses by asking us to avert our attention from abortion itself and concentrate on something else. Often, this something else is the physician and the relation of medicine to government. At other times, it is (appropriately, we think) the pregnant woman and her life and health. Pregnancy is a unique human condition; there is nothing else like it in medicine or life, and we must therefore deal with it on its own terms, and not by analogy. To do so is simply impossible in the political arena. Because abortion foes have never seemed to care whether or not the laws they propose are unconstitutional, they have promised to continue to try to pass such laws.

Professional organizations should set and follow the terms of their own specialties, and in this area ACOG is the proper body to make this determination. But when professional organizations determine the content and scope of reasonable medical practice not on the basis of their professional skills and the health interests of their patients, but rather on the basis of their reading of the prevailing political winds, they undermine their own credibility and explicitly agree that standards for medical practice should be set by politicians rather than by the medical profession.

GENETIC COUNSELING, SCREENING, AND PRENATAL DIAGNOSIS

Any woman who employs a physician for prenatal care should have the right to have the physician fully inform her of any reason the physician has to believe that her fetus might be handicapped and to inform her further of the existence of diagnostic tests that might identify the precise genetic condition. The physician incurs this duty to disclose because it is this type of information that the pregnant woman seeks prenatal care to discover (i.e., to learn all she can to help her have a healthy child). It is therefore entirely reasonable for the pregnant woman to expect her physician to apprise her of any relevant information regarding her fetus and options she might have so that she and the child's father can determine what action to take. ^[28]

A wrongful birth suit must allege and prove not only that the physician was negligent in the care of the pregnant woman, but also that had the negligent act not been done the child would not have been born (e.g., had the woman been properly informed that she was at risk to have a child with Down syndrome, she could have sought amniocentesis or chorionic villus sampling and had an abortion if her fetus were so affected). A related but far more controversial lawsuit is brought by the child (through its parents or guardian) against the physician because it was born, a so-called wrongful life suit. Until recently, most courts rejected lawsuits by the child because they thought it was impossible to put a monetary value on life in an impaired condition compared with nonexistence. The choice for these children is *never* to be born healthy, but only to be born with a handicap (such as Down syndrome or Tay-Sachs disease) or not to be born at all. We think that future courts are likely to limit such actions to *serious* handicaps, those in which fetuses, if they could speak to us (which, of course, they can only do through their parents), would agree with an "objective societal consensus" that their own best interest would be served if they were aborted. Put another way, they would be better off *from their own perspective* if they never existed. Conditions like deafness and Down syndrome would not qualify, whereas conditions like Tay-Sachs would. Measuring damages is problematic, but courts are likely to award at least the added medical costs caused by the handicap itself. However, because medical costs can be recovered in a wrongful birth case directly, wrongful life cases are only likely to be brought in those rare instances in which for some reason (e.g., the child has been given up for adoption) the parents have lost the right to sue on their own behalf. ^[29]

Genetic Counseling and Prenatal Diagnosis

The following conclusions may be drawn regarding the legal and ethical obligations of the obstetrician in relationship to genetic counseling and prenatal diagnosis.

First, the law requires physicians to give accurate information to the parents and forbids the withholding of vital information from them. These principles are consistent with the doctrine of informed consent and the reasonable expectations of pregnant women under a physician's care. The physician does not guarantee a healthy child, but the reasonable expectation of the

1354

patient is that she will be apprised of any information the physician has that the child might be handicapped and of the alternative ways to proceed so that the patient can determine what action to take. ^[30]

Second, no obstetrician can be required to perform chorionic villus sampling or genetic amniocentesis. Indeed, many are not qualified to perform these procedures and for them to do so may itself be malpractice. As stated in an opinion of the Judicial Council of the American Medical Association ^[31]

Physicians who consider the legal and ethical requirements applicable to genetic counseling to be in conflict with their moral values and conscience may choose to limit such services to preconception diagnosis and advice or not provide any genetic services. However, there are circumstances in which the physician who is so disposed is nevertheless obligated to alert prospective parents that a potential genetic problem does exist, that the physician does not offer genetic services, and that the patient should seek medical genetic counseling from another qualified specialist.

Third, genetic counseling should be morally nondirective, that is, the counselor should remain impartial and objective in providing information that will allow competent counselees to make their own informed decision. The Judicial Council of the American Medical Association ^[31] has given the following opinion:

Physicians, whether they oppose or do not oppose contraception, sterilization, or abortion, may decide that they can engage in genetic counseling and screening, but should avoid the imposition of their personal moral values and the substitution of their own moral judgment for that of the prospective parents. The ethical and moral decisions have to be made by the family and should not be imposed by the physician.

Fourth, to ensure the patient's interest in both autonomy and privacy, no information obtained in genetic counseling or screening should be disclosed to any third party, including insurers and employers, without the patient's informed consent. ^[32], ^[33] Such strict nondisclosure policies should be maintained unless and until specific legislation is enacted that would clearly delineate the circumstance in which confidentiality must be breached, analogous to certain contagious diseases, gunshot wounds, and child abuse. On the other hand, counselors should be permitted to attempt to persuade patients to make disclosures of important information to potentially affected relatives if there is a high probability of serious harm and if the disclosure is limited to pertinent genetic information. We recommend that the genetic counselor make clear, both verbally and in writing, the policy that he or she follows so that the patient can refuse to be screened or counseled if he or she is not in agreement with the disclosure policy. Such agreements will serve to heighten the public's confidence in genetic counseling and will encourage people to participate voluntarily in both screening and counseling.

Genetic Screening

Our ability to translate our expanding genetic knowledge into usable information for individual patients is at best uncertain. Taking a family history and, when indicated, recommending certain tests to identify carriers of genetic diseases are standard in obstetric care. Today's screening tests usually focus on conditions that occur either in the family or in the racial or ethnic group of one or both prospective parents. As our ability to identify genes associated with particular diseases increases, a panel of screening tests to identify carriers of numerous genes will be offered more routinely. It will then become increasingly difficult if not impossible to inform those offered screening or testing for reproductive purposes about all the genetic information that can be obtained and the implications of that information.

Consent for Screening

Our current model for screening and testing requires pretest counseling. ^[35] Such counseling is a method of obtaining informed consent, and the obligation to counsel can be seen as inherent in the fiduciary nature of the doctor-patient relationship. ^[36], ^[37] For ordinary medical procedures, the physical risks and treatment alternatives are the chief items of information that must be disclosed. There are few physical risks in genetic screening. What must be conveyed in counseling regarding genetic

screening is that the tests may yield new information that may ultimately force some unwelcome choices (such as whether to marry, abort, or adopt). Self-determination and rational decision making are the central values protected by informed consent. ^[36], ^[37] In the setting of reproductive genetics, what is at stake is the right to decide whether or not to have a genetic test, with emphasis on the right to refuse if the potential harm (in terms of stigma or unacceptable choices) outweighs, for the individual person or family, the potential benefit.

Generic Consent for Genetic Screening

As the Human Genome Project nears conclusion, tens if not hundreds of new genetic screening tests will compete for introduction into routine clinical practice. Already some researchers have suggested population-based screening to identify carriers of the genes for such conditions as the fragile X syndrome and myotonic

This section has been adapted from Elias and Annas,^[34] with permission.

1355

dystrophy. Each new screening test presents the same questions: What information should be given to which patients, when should it be presented, who should present it, and how and by whom should the results be conveyed? It will soon be impossible to do meaningful prescreening counseling about all available carrier tests. Giving too much information ("information overload") can amount to misinformation and make the entire counseling process either misleading or meaningless. ^[38] To prevent disclosure from being pointless or counterproductive, we believe that strategies based on general or "generic" consent should be developed for genetic screening. Their aim would be to provide sufficient information to permit patients to make informed decisions about carrier screening, yet avoid the information overload that could lead to "misinformed" consent. ^[39]

Traditionally, goals of reproductive genetic counseling, including counseling about screening carrier status, involve helping the person or family to

- (1) comprehend the medical fact, including the diagnosis, the probable course of the disorder, and the available management;
- (2) appreciate the way heredity contributes to the disorder, and the risk of recurrence in specified relatives;
- (3) understand the options for dealing with the risk of recurrence;
- (4) choose the course of action which seems appropriate to them in view of their risk and their family goals and act in accordance with that decision; and
- (5) make the best possible adjustment to the disorder in an affected family member and/or to the risk of recurrence of that disorder. ^[40]

For example, in the current context of counseling a couple at least one of whom is of Italian ancestry, each of these issues would be discussed as it relates specifically to -thalassemia, with explanation of the use of hemoglobin electrophoresis as a screening test to determine carrier status. If consideration of another prenatal test were appropriate as in the case of screening of maternal serum for -fetoprotein, human chorionic gonadotropin, and unconjugated estriol to detect fetal aneuploidy, open neural tube defects, and other abnormalities a separate discussion about these tests, including information on their sensitivity and specificity, and of each of the possible associated fetal disorders would also be required. Even knowledgeable couples could become confused, frustrated, and anxious if faced with scores of such options for genetic screening.

By contrast, an approach based on generic consent would emphasize broader concepts and common-denominator issues in genetic screening. We envision a situation in which patients would be told of the availability of a panel of screening tests that can be performed on a single blood sample. They would be told that these tests could determine whether they carry genes that put them at increased risk of having a child with a birth defect that could involve serious physical abnormalities, mental disabilities, or both. Several common examples could be given to indicate the frequency and spectrum of severity of each type or category of condition for which screening was being offered. For example, prenatal screening could include tests for fetal conditions such as neural tube defects and chromosome abnormalities such as cystic fibrosis and fragile X syndrome. In the future, a sample of fetal blood cells may be retrievable from maternal blood to be used not only for estimation of risks but also perhaps for definitive diagnosis. ^[41]

In the course of such counseling, important factors common to all genetic screening tests would be highlighted. Among these are the limitations of screening tests, especially the fact that negative results cannot guarantee a healthy infant; the possible need for additional, invasive tests, such as chorionic villus sampling or amniocentesis, to establish a definitive diagnosis; the reproductive options that might have to be considered, such as prenatal diagnosis, adoption, gamete donation, abortion, or acceptance of risks; the costs of screening; issues of confidentiality, including potential disclosure to other family members; and the possibility of social stigmatization, including discrimination in health insurance and employment. If carrier status is detected in the woman, it must be emphasized that the partner should also be screened. Before prenatal testing was agreed to in such cases, the woman would need to be told that she would be advised to consider abortion if the fetus was found to be affected with a nontreatable condition. ^[37]

This type of generic consent to genetic screening can be compared with obtaining consent to perform a physical examination. Patients know that the purpose of the examination is to locate potential problems that are likely to require additional follow-up and that could present them with choices they would rather not have to make. The patient is not generally told, however, about all the possible abnormalities that can be detected by a routine physical examination or routine blood work, but only the general purpose of each. On the other hand, tests that may produce especially sensitive and stigmatizing information, such as screening of blood for the human immunodeficiency virus, should not be performed without specific consent. Similarly, because of its reproductive implications, genetic testing has not traditionally been carried out without specific consent. Even in a generic model, tests for untreatable fatal diseases such as Huntington's disease should not be combined with other tests or performed without specific consent. ^[37]

What is central in the concept of generic consent for genetic screening is not a waiver of the individual patient's right to information. Rather, it would reflect a decision by the genetics community that the most reasonable way to conduct a panel of screening tests to

1356

identify carriers of serious conditions is to provide basic, general information to obtain consent for the screening and much more detailed information on specific conditions only after they have been detected. Since, in the vast majority of cases, no such conditions will in fact be found, this method is also the most efficient and cost effective.

Limits to Generic Consent

Some people require more specific and in-depth information on which to base their decision regarding screening. It is therefore essential to build into the screening program ample opportunity for patients to obtain all the additional information they need to help them make decisions. Clinicians, of course, must be open and responsive to the concerns and questions of patients. Counseling could be provided in person by a physician or other health professional. Alternatively, audiovisual aids could be used, which would help ensure consistency in the information provided, be more efficient, and respond to the shortage of genetic counselors.

Generic consent for genetic screening should help prevent information overload and wasting time on useless information. It would not, however, solve what is likely to be an even more central problem in genetic screening: are there genetic conditions for which screening should not be offered to prospective parents? Examples might include genes that predispose a person to a particular disease late in life (such as Alzheimer's disease, Parkinson's disease, or breast cancer). ^[37], ^[42] From the perspective of the fetus, life with the possibility or even the high probability of developing these diseases in late adulthood is much to be preferred to no life at all. Thus, in this case, unlike that of the fetus with anencephaly, for example, no reasonable argument could be made that precluding abortion by denying this information could amount to forcing a "wrongful life" on the child. ^[38] Because of a personal experience with a friend or family member who suffered from one of these diseases, however, the couple might see abortion as a reasonable choice under such circumstances.

We must address this question directly and publicly. Are there genetic diseases and predispositions for which screening of prospective parents and testing of fetuses should not be offered as a matter of good medical practice and public policy, regardless of the technical ability to screen and the wishes of the couple? Offering carrier screening to assist couples in making reproductive decisions is not a neutral activity but, rather, implies that some action should be taken on the basis of the results of the test. Thus, for example, merely offering screening for a breast cancer or colon cancer gene suggests to couples that artificial insemination, adoption, and abortion are all reasonable choices if they are found to be carriers of such a gene. We do not believe that pregnancies in women who want to have a child should be terminated for this reason, and thus we believe carrier screening for the breast cancer gene should not be offered in the context of reproductive planning. In the

absence of an effective way to set the standard of care for carrier screening, however, prenatal screening tests for these and similar genes will inevitably be offered by at least some commercial companies and private physicians.

A standard of care for genetic screening and consent in the face of hundreds of available genetic tests will inevitably be set. We believe the medical profession should take the lead in setting such standards and that, with public input, the model of generic consent for genetic screening will ultimately be accepted.

FORCED CESAREAN DELIVERY

In 1979, a group of Israeli obstetricians published a controversial article entitled "The fetal right to live," suggesting that when women in labor refuse cesarean delivery "It is probably that the patient hopes to be freed in this way of an undesired pregnancy . . . because it is an unplanned pregnancy, the woman is divorced or widowed, the pregnancy is an extramarital one, there are inheritance problems, etc."^[43] The view that women who refuse cesarean delivery are in some way willfully abusing their fetuses seems prevalent and deeply held, at least by some male obstetricians and judges. This opinion is reflected in several cases in which judges have ordered women who were refusing cesarean delivery during labor to undergo the procedure "for the welfare of the unborn child."

In 1987, Kolder et al.^[44] reported a U.S. national survey revealing that court orders have been obtained for cesarean deliveries in 11 states, for hospital detentions in 2 states, and for intrauterine transfusions in 1 state. Among 21 cases in which court orders were sought, the orders were obtained in 86 percent; in 88 percent of those cases, the orders were received within 6 hours. The majority of the women involved were black, Asian, or Hispanic, and all were poor. Nearly one half were unmarried and one fourth did not speak English as their primary language. In the survey, they also found that 46 percent of the heads of fellowship programs in fetomaternal medicine thought that women who refused medical advice and thereby endangered the life of the fetus should be detained. Forty-seven percent supported court orders for procedures such as intrauterine transfusions. Until 1990, with the exception of one case in the Georgia State Supreme Court, all cases had been decided by lower courts and therefore had little precedential

1357

importance.^[45] In the vast majority of cases, judges were called on an emergency basis and ordered interventions within hours. The judge usually went to the hospital. Physicians should know what most lawyers and almost all judges know: when a judge arrives at the hospital in response to an emergency call, he or she is acting much more like a lay person than a jurist. Without time to analyze the issues, without representation for the pregnant woman, without briefing or thoughtful reflection on the situation, in almost total ignorance of the relevant law, and in an unfamiliar setting faced by a relatively calm physician and a woman who can easily be labeled "hysterical," the judge will almost always order whatever the doctor advises. There is nothing in *Roe v. Wade*^[2] or any other appellate decision that gives either physicians or judges the right to favor the life or well-being of the fetus over that of the pregnant woman. Nor is there legal precedent for a mother being ordered to undergo surgery (e.g., kidney or partial liver transplant) to save the life of her dying child. It would be ironic and inconsistent if a woman could be forced to submit to more invasive surgical procedures for the sake of a fetus than a child. Forcing pregnant women to follow medical advice also places unwarranted faith in that advice. Physicians often disagree about the appropriateness of obstetric interventions, and they can be mistaken.^[46] In three of the first five cases in which court-ordered cesarean delivery were sought, the women ultimately delivered vaginally and uneventfully. In the face of such uncertainty compounded by decades of changing and conflicting expert opinion on the management of pregnancy and childbirth the moral and legal primacy of the competent, informed pregnant woman in decision making is overwhelming.^[47]

Physicians may feel better after being "blessed" by the judge, but they should not. First, the appearance of legitimacy is deceptive; the judge has acted injudiciously, and there is no opportunity for meaningful appeal. Second, the medical situation has not changed, except that more time has been lost that should have been used to continue discussion with the woman directly. And, finally, the physician has now helped to transform himself or herself into an agent of the state's authority.^[47]

The question of how to help a woman who continues to refuse intervention in the face of a court order remains. Do we really want to attempt to restrain and forcibly medicate and operate on a competent, refusing adult? Although such a procedure may be "legal," it is hardly humane. It is not what one generally associates with modern obstetric care and may cause harm. It also encourages an adversarial relationship between the obstetrician and the patient. Moreover, even from a strictly utilitarian perspective, this marriage of the state and medicine is likely to harm more fetuses than it helps, because many women will quite reasonably avoid physicians altogether during pregnancy if failure to follow medical advice can result in forced treatment, involuntary confinement, or criminal charges.

Extending notions of child abuse to "fetal abuse" simply brings government into pregnancy with few, if any, benefits and with great potential for invasions of privacy and deprivations of liberty. It is not helpful to use the law to convert a woman's and society's moral responsibility to her fetus into the woman's legal responsibility alone.^[48] After birth, the fetus becomes a child and can and should thereafter be treated in its own right. Before birth, however, we can obtain access to the fetus only through its mother and, in the absence of her informed consent, can do so only by treating her as a fetal container, a nonperson without rights to bodily integrity.

The American College of Obstetricians and Gynecologists has issued an opinion from its Committee on Ethics entitled "Patient Choice: Maternal Fetal Conflict"^[48] that we believe provides thoughtful and useful guidance for the medical practitioner. The conclusions of this statement are as follows:

1. With advances in medical technology, the fetus has become more accessible to diagnostic and treatment modalities. The fetomaternal relationship remains a unique one, requiring a balance of maternal health, autonomy, and fetal needs. Every reasonable effort should be made to protect the fetus, but the pregnant woman's autonomy should be respected.
2. The vast majority of pregnant women are willing to assume significant risk for the welfare of the fetus. Problems arise only when this potentially beneficial advice is rejected. The role of the obstetrician should be one of an informed educator and counselor, weighing the risks and benefits to both patients as well as realizing that tests, judgments, and decisions are fallible. Consultation with others, including an institutional ethics committee, should be sought when appropriate to aid the pregnant woman and obstetrician in making decisions. The use of the courts to resolve these conflicts is almost never warranted.
3. Obstetricians should refrain from performing procedures that are unwanted by a pregnant woman. The use of judicial authority to implement treatment regimens in order to protect the fetus violates the pregnant woman's autonomy. Furthermore, inappropriate reliance on judicial authority may lead to undesirable societal consequences, such as the criminalization of noncompliance with medical recommendations.

In 1990, the District of Columbia Court of Appeals, in a strongly worded opinion, essentially adopted the

1358

American College of Obstetricians and Gynecologists statement as law, holding that the decision of the pregnant woman must be honored in all but "extremely rare and truly exceptional" cases.^[50]

FETAL RESEARCH

Federal Regulations

Society has a critical stake in both the treatment of fetal disorders and the maintenance of respect for the human dignity of the fetus. Fetal research and its regulation is one of the most controversial and complex areas in the entire field of human experimentation. The National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research, for example, spent the first year of its existence working on the subject of fetal experimentation under a congressional mandate to make recommendations regarding fetal research before working on any other topic. This mandate itself was most influenced by the 1973 *Roe* decision discussed above. The consequence of this decision was an increase in the number of fetuses aborted; hence the amount of fetal material available for research also increased.

Before experimentation involving human fetuses begins, current U.S. Department of Health and Human Services (HHS) regulations require that appropriate animal studies be performed and that investigators play no role in any decision to terminate a pregnancy. The purpose of any in utero experiment must be to meet the health needs of the particular fetus, and the fetus must be placed at risk only to the minimum extent necessary to meet such needs. In the case of nontherapeutic research, the risk to the fetus must be "minimal" and the knowledge must be "important" and not obtainable by other means. The consent of both the mother and father is required, unless the father's identity is not known, he is not reasonably available, or the pregnancy resulted from rape. Fetal research protocols must be approved by an institutional review board (IRB), taking special care to review the subject selection process and the method of obtaining informed consent.

Technically, these federal regulations apply only to investigators who receive federal research funds or who are affiliated with institutions that have signed an agreement with HHS that all research performed in their institution and by their staff will be approved by an IRB under these regulations. We believe, however, the principles set forth by these regulations to be so fundamentally important to the protection of the integrity of the fetus, the potential parents, and the research enterprise itself that they provide the minimum guidelines that should be adhered to voluntarily in all institutions undertaking fetal research projects.

State Statutes

More state legislation has been enacted regarding fetal research than any other type of research, and the poor quality of the legislation has added to the complicated nature of this issue. About one half of the states currently have statutes regulating fetal research; 15 were passed soon after the *Roe* decision and in direct response to it. Most state statutes restrict both in utero and ex utero research, and the restrictions are generally more stringent than the federal regulations with the exception of New Mexico's statute, which is modeled after federal regulations. In Massachusetts, for example, it is a crime to study the fetus in utero unless the research does not "substantially jeopardize" the life or health of the fetus and the fetus is not the subject of an elected abortion. Because the law includes the embryo in its definition of a fetus, it could also inhibit stem cell research that involves the destruction of a human embryo.^[52] Thus, therapeutic research, such as shunting procedures to treat fetal urinary tract obstruction, is permissible even in this restrictive state. Utah, the only state to deal exclusively with in utero fetuses, prohibits all research on "live unborn children." Some states limit their prohibition to the living abortus and thus do not apply to fetal surgery. California restricts experimentation only on ex utero fetuses, outlawing "any type of scientific or laboratory research or any other kind of experimentation or study, except to protect or preserve the life and health of the fetus." Thus there is little consistency or rationale among jurisdictions regarding regulations directly pertaining to fetal research. Nonetheless, one is bound by the laws of the state in which one performs fetal research, and knowledge of its provisions is obviously necessary in states that have such statutes.^{[52] [53] [54]}

Consent

A fundamental premise of Anglo-American law is that no one can touch or treat a competent adult without the adult's informed consent. This doctrine is based primarily on the value we place on autonomy, or self-determination, and secondarily on rational decision-making. The first requires that individuals have the ultimate say concerning whether their bodies will be "invaded"; the latter requires disclosure of certain material information, including a description of the proposed procedure, risks of death and serious disability, alternatives, success rates, and problems of recuperation before one is asked to consent to an "invasion."^[55]

These issues are relatively straightforward when dealing with an adult, but how do they apply when experimentation or therapy is directed toward a fetus? Unfortunately, the distinction between experimentation and therapy is often unclear. In general, therapy involves procedures performed primarily for the benefit of the

patient that are considered "good and accepted practice," whereas experimentation involves new or innovative procedures not yet considered standard practice performed for the primary purpose of testing a hypothesis or gaining new knowledge.^[56]

In the therapeutic setting, the consent of either one of the parents is usually sufficient for beneficial procedures to be performed on children. In the case of the fetus, however, if the proposed investigative therapeutic procedure will place the mother at any risk of death or serious disability, she alone has the right to consent and the corresponding right to withhold consent. Even after fetal viability, *Roe* and *Casey* give the woman and her physician the right to terminate the pregnancy if her life or health is endangered. This is consistent with the Court's ruling that where conflict exists between a potential father and the pregnant woman over the issue of an abortion, the woman's position should prevail because she has more at stake (e.g., her body, health risks) than the potential father.^[57] The same logic applies here. Consent of the pregnant woman is a mandatory prerequisite for both investigative procedures and therapy. Her consent must be informed, and she should be told as clearly as possible about the proposed experimental procedure or therapy and its risks to herself and her fetus, as well as alternatives, success rates, and the likely problems of recuperation.^{[58] , [59]}

Key Points

So-called partial-birth abortion bans are unconstitutional unless they provide an exception for the pregnant woman's life and health.

In *Roe v. Wade* (1973), the United States Supreme Court determined that a fundamental "right to privacy existed in the Fourteenth Amendment's concept of personal liberty" that is "broad enough to encompass a woman's decision whether or not to terminate a pregnancy" prior to fetal viability without state interference. In *Planned Parenthood of Southeastern Pennsylvania v. Casey* (1992) the United States Supreme Court reaffirmed the "core" of *Roe v. Wade* and ruled that prior to fetal viability states cannot "unduly burden" a woman's decision to terminate a pregnancy (i.e., although consent and waiting periods may be constitutionally acceptable, states cannot regulate abortion in ways that will prevent a significant number of women from obtaining them.)

Roe and *Casey* are critical to understanding the rights of obstetricians (which are derived from the rights of their patients) because they are the major sources of law regarding how far states can go to regulate decisions made in the obstetrician-patient relationship.

The legal and ethical obligations of an obstetrician in relationship to genetic counseling and prenatal diagnosis can be summarized as follows: (1) the physician must give accurate information to the parents and cannot withhold vital information from them; (2) no obstetrician can be required to perform prenatal diagnostic procedures; (3) prenatal genetic counseling should be morally nondirective; and (4) to protect patient privacy and autonomy, no information obtained in genetic counseling or screening should be disclosed to any third party without patient's authorization.

"Generic" consent for genetic *screening* that emphasizes broad concepts and common-denominator issues should help maximize rational decision making by preventing information overload and wasting time on useless information.

Fetal research protocols must be approved by an institutional review board, which must review the scientific protocol, the subject selection process, the consent form, and the method of obtaining informed consent from both the recipient and donor.

Self-determination and rational decision making are the central purposes of informed consent, and information on recommended procedures, risks, benefits, and alternatives should be presented in a way that furthers these purposes.

Consent of the pregnant woman is a mandatory prerequisite for both investigative procedures and therapy. Her consent must be informed, and she should be told as clearly as possible about the proposed experimental procedures or therapy, its risks to herself and her fetus, as well as alternatives, success rates, and the likely problems of recuperation.

The fetomaternal relationship is a unique one that requires physicians to promote a balance of maternal health and fetal welfare while respecting maternal autonomy. Obstetricians should refrain from performing procedures that are refused by pregnant women: the decision of the competent pregnant woman must be honored in all but "extremely rare and truly exceptional" cases, although reasonable steps to persuade a woman to change her mind are appropriate.

APPENDIX: Anatomy of the Pelvis

Figure 1 Major components of the bony pelvis shown in a frontal superior view of the female pelvis. The plane of the pelvic brim faces forward and forms an angle of about 60 degrees to the horizontal. Features that most clearly distinguish the female from the male pelvis include a wider subpubic angle, wider sciatic notch, and greater distance from public symphysis and anterior edge of the acetabulum.

1362

Figure 2 Major ligaments and notches of the female pelvis, posterior view. During pregnancy, temporary changes take place in the ligaments that permit both movement of the joints and enlargement of the pelvic cavity. This becomes important during parturition.

Figure 3 Muscles of the pelvic diaphragm, oblique view. The pelvic diaphragm forms a muscular floor for the support of the pelvic organs. Note the location of the urethra, uterus, and rectum as they pierce the floor of the pelvic diaphragm.

1363

Figure 4 Muscles of the pelvic diaphragm, superior view. As seen from above, the pelvic diaphragm consists of a number of different muscles and ligaments. The spaces between these muscles transmit a number of vessels and nerves as they leave the pelvis. Note the relationship of the central tendon of the perineum to the rectum and uterus.

Figure 5 Inferior view of muscles of the pelvic diaphragm. The pelvic diaphragm is bilaterally symmetric, with the perineal body (central tendon) and the anococcygeal ligament forming a strong median raphe. lig., ligament.

1364

Figure 6 Fascial and peritoneal relationships of the pelvic diaphragm. In this frontal view of the pelvis, the levator ani can be seen to slope downward and medially, surrounding the vagina. The loose connective tissue beneath the pelvic peritoneum is variable in thickness, depending on the general adiposity of the individual. Note also the continuity of the different fascias as they merge to form the neurovascular sheaths.

Figure 7 Muscles of the deep perineal space, inferior view. As viewed with the patient in dorsal lithotomy position, the deep perineal space consists of smaller muscles than the superficial perineal space. Note that the vestibular bulb lies within the superficial perineal space. *Inset:* Division of the perineum into a urogenital (anterior) triangle and an anal (posterior) triangle.

1365

Figure 8 Muscles of the superficial perineal space, from below. As viewed with the patient in dorsal lithotomy position, the muscles of the superficial perineal space of the urogenital triangle and the muscles of the anal triangle all converge in the midline. m., muscle.

1366

Figure 9 Ischiorectal fossa, frontal section. The ischiorectal fossa surrounds the rectum and vagina and forms most of the potential space within the posterior triangle of the perineum. The fascia of the levator ani merges with the visceral sheath of the rectum and vagina to lend support.

Figure 10 Ischiorectal fossa and urogenital diaphragm, sagittal section. The ischiorectal fossa extends both forward and backward from the anal triangle. The urogenital diaphragm subdivides the urogenital triangle, with the anterior recess of the ischiorectal fossa superior to it. The subcutaneous fat between the inferior aspect of the superficial perineal space and the skin varies among individuals.

1367

Figure 11 External anal sphincter as viewed in dorsal lithotomy position. The external anal sphincter is composed of three muscles that arise from the coccyx and converge into the central tendon of the perineum. Midline or mediolateral episiotomy may damage this sphincter; proper reapproximation is essential for fecal continence.

Figure 12 Cutaneous nerve supply to the perineum. Most cutaneous innervation to the perineum comes from the pudendal nerve, but important regions are supplied by other sources. Pudendal block thus only anesthetizes a portion of the perineal surface. The exact limits of each specific nerve supply are variable. N., nerve; nn., nerves.

1368

Figure 13 Superficial perineal blood supply and nerves, as viewed with the patient in dorsal lithotomy position. The vessels and nerves to the superficial perineal space follow each other. The vasculature is markedly engorged during pregnancy, and there may be significant bleeding from these vessels because of laceration, trauma, or episiotomy. Note the transverse branch of the perineal artery, a vessel often encountered during routine midline or mediolateral episiotomy. br., branch; a., artery; n., nerve.

Figure 14 Vessels and nerves of the deep perineal space. The vasculature and innervation to the deep perineal space enters the anterior triangle from superior to inferior, in contrast to the superficial perineal space vessels and nerves. Note that the blood supply and innervation to the vestibular bulb and greater vestibular gland (Bartholin's gland) are derived from the deep perineal vessels and nerves. a., artery; n., nerve.

1369

Figure 15 Major organs of the pelvis, sagittal section. The internal organs of the pelvis are supported by the levator ani. Note how the anteverted, anteflexed uterus gains further support from both the urinary bladder and rectum. The ureter crosses the lateral aspect of the uterus at the level of the internal os on its way to the bladder. The actual position of the ovary and fimbriated end of the tube is quite variable.

Figure 16 Anatomy of the fallopian tube and ovary, posterior view. The ovary and tube are suspended by mesenteries derived as specialized portions of the broad ligament. The vasculature and nerves enter through the mesovarium and mesosalpinx.

1370

Figure 17 Anatomic regions of the uterus, lateral view. The uterus is composed of cervix, isthmus, corpus, and fundus. Because the regions of the uterus grow at different rates during pregnancy, the distance between cornual fallopian tube and fundus increases markedly with increasing gestation. Note that the peritoneal reflection of the bladder occurs at the level of the uterine isthmus.

Figure 18 Anatomic relationships of the uterus, lateral view. The broad ligament contains the uterus and forms an anterior and posterior covering. The triangular space along the lateral uterine wall lies between the leaves of the broad ligament. Note the relationship of the ureter to the uterine artery. lig., ligament.

1371

Figure 19 Broad ligament and contained organs, frontal view. The round ligament runs within the anterior leaf of the broad ligament and inserts through the inguinal canal to the labium majus. *Inset:* The relationships as seen from an anterosuperior perspective. Note the rectovaginal pouch as seen from above and anteriorly. lig., ligament.

Figure 20 Organs of the pelvis, posterior view. The rectouterine pouch is demarcated by the uterosacral ligaments. This pouch is often termed the *posterior cul-de-sac*. In this diagram, a section of the posterior leaf of the broad ligament has been removed to show the relationship of the uterine artery to the ureter. Intraligamentous tumors, infection, endometriosis, or previous surgery can often alter this relationship. lig., ligament.

1372

Figure 21 Major vessels of the pelvis, frontal view. The major vasculature of the pelvis is shown in relationship to the pelvic diaphragm. The proximity of the ureter to the internal iliac (hypogastric) artery is noteworthy. Ligation of the hypogastric artery may thus jeopardize the ureter unless care is taken. Note the anterior and posterior trunks of the internal iliac artery. a., artery; v., vein.

1373

Figure 22 Major vessels of the pelvis, lateral view. The major subdivisions of the anterior and posterior trunks are highly variable, and no singular branching pattern accounts for most patients. Note the relationship of the vessels to the sacral plexus. The uterus has been amputated at the level of the isthmus to permit a better view of the branching patterns of the anterior trunk. a., artery; aa., arteries.

Figure 23 Blood supply to the uterus, tube, and ovary. The vasculature supply to the major pelvic organs is derived from the internal iliac (uterine) artery and the ovarian artery. Note the anastomotic plexuses of vessels along the lateral aspect of the uterus at the region of the cornu. Descending branches from the uterine artery supply the cervix and vagina. a., artery; br., branch.

Figure 24 Blood supply to the vagina. Like the uterus, the vagina derives its blood supply from two major sources: the uterine and pudendal arteries. The internal pudendal artery supplies the vagina from inferior to superior. The vaginal artery, often a branch from the uterine artery, and the uterine artery itself supply the superior position of the vagina. a., artery; U-G, urogenital; br., branch.

Figure 25 Major lymphatics of the pelvis. The major lymph nodes of the pelvis follow the major vessels. Each group of nodes receives contributions from multiple organs. The groupings are somewhat arbitrary, for no distinct separation of individual node groups exists.

Figure 26 Major nerves of the pelvis, lateral view. Few branches of the sacral plexus are evident, as these nerves leave the pelvis even as the branches are forming. Most of the pelvic plexus lies medial to the vasculature. n., nerve.

Figure 27 Afferent innervation of the female genital tract. The left side of this diagram demonstrates the sympathetic nervous system. Fibers entering the spinal cord are illustrated on the right. The major afferent pain fibers for the uterus, tubes, and ovaries enter the cord at T10, T11, and T12. The afferent innervation of the vagina and external genitalia enter at S2, S3, and S4. sup., superior; n., nerve; nn., nerves.

Figure 28 Changes in the uterus with age and parity. At puberty, growth occurs primarily in the corpus and the fundus, although the cervix continues to grow as well. After menopause, the uterus regresses to a state more closely allied to that of the premenarcheal anatomy. During pregnancy, the cervical portion is relatively greater than in the nonpregnant state.

Figure 29 Changes in the uterus caused by pregnancy and parturition. The hormonal changes of pregnancy as well as dynamic forces of labor cause the development of the lower uterine segment from the vestigial uterine isthmus. After parturition, these changes regress dramatically. Low transverse cesarean delivery incisions are performed through this thinned isthmic region, known as the *lower uterine segment*.

Key Points

To facilitate childbearing, the female pelvis is opposed to the male pelvis characterized by a wider subpubic angle, increased width of the sciatic notch, and greater distance from the symphysis pubis to the anterior edge of the acetabulum.

The levator ani, the major supporting structure for the pelvic viscera, is a tripartite muscle mass composed of the iliococcygeus, pubococcygeus, and puborectalis; the iliococcygeus is the broadest and most posterior portion.

Innervation of the levator ani is through the third and fourth sacral nerves.

The major nerve supply of the perineum is derived from the pudendal. However, the ilioinguinal, genitofemoral, perineal branch of the posterior femoral cutaneous, coccygeal, and last sacral nerve also contribute; thus, a pudendal nerve block anesthetizes only a portion of the perineum.

The internal iliac (hypogastric) artery arises at the level of lumbosacral articulation. It can be distinguished from the external iliac by its smaller size and by its more medial and more posterior position.

The ureter lies more superficially and is either medial or slightly anterior to the internal iliac artery.

The cardinal ligaments are located at the base of the broad ligament, are continuous with the connective tissue of the parametrium, and are attached to the pelvic diaphragm through continuity with the superficial superior fascia of the levator ani.

Since the origin of the uterine artery is quite variable, its isolation and ligation for control of postpartum bleeding are often fruitless. The uterine artery usually arises as an independent vessel from the internal iliac artery, but it may also arise from the inferior gluteal, internal pudendal, umbilical, or obturator arteries.

Afferent pain fibers for the uterus, tubes, and ovary enter the cord at T10, T11, T12; thus, spinal or epidural anesthesia must extend to these levels. Fortunately, efferent fibers to the uterus enter above these levels, thus not interfering with contractions.

The body of the nonpregnant uterus weighs approximately 70 g, whereas at term it weighs approximately 1,100 g.
